- The personal context includes the user profile that is made of static as well as dynamic properties (gender, age, interests, physical capabilities, access privileges, etc.). This information can be acquired by different means, either explicitly or implicitly. For instance, an overview of the sensors embedded in mobile phones and their potential as a computing platform to acquire user parameters is reviewed in Lane et al. (2010). Dynamic properties can be also considered on the fly to take into account real-time user’s behaviors, which, in turn, can be broadcast to other users when necessary and possible. In fact, user-derived contexts are of valuable importance for the development of recommender systems in indoor spaces.

Ideally, a contextual system can infer some predominant user interests and provide him/her with relevant recommendations. But users’ activities and interactions between them are still to be considered; this leads to a research challenge, as tracking these behaviors is far from straightforward. Interaction between users stresses the need for a better consideration of effective models of collaborative usage. A collaborative usage model should classify users into groups or communities, within which they share a common characteristic or interest. A user can belong to a community either explicitly by a subscription-based mechanism or implicitly if he/she has a common characteristic or property. On the one hand, subscription-based communities encompass users that share a given interest or are involved in a similar practice (i.e., group of people working together and constantly conducting solutions in a given shared field). On the other hand, implicitly generated communities depend either on the current location of users or on their trajectories (i.e., if they have similar spatiotemporal patterns) or on their behaviors in a similar context. This collaborative usage model derives similar behaviors and interests, so that the system can act proactively by notifying users of certain events or adapting certain query answers. Push-based services can thereafter be designed based on such communities.

One of the peculiarities of indoor spatial data models relies in its large scale, closely related to real-time activities as humans acting in such environments behave in a fast mode. The availability of data at the right time is then a crucial issue. Based on data gathered from fixed and/or mobile sensors and on user-generated content (i.e., information shared by users to the system or within communities to notify certain events), an indoor system should be able to manage events in real-time and even filter the ones that are relevant for a given user. Some examples of real-time services to deliver are that people who share a common interest or common context should be notified. Depending on the relevance of such events, an indoor-based system might either let the user decide whether to integrate this event into his/her relevant queries, or simply ignore it. Some types of events should be directly handled by the system itself (in case of emergency or other important events). Overall, these contextual dimensions represent the user-centric context and should be taken into account by an indoor system in real time in order to completely incorporate context-awareness into intelligent navigation services.

Towards a unified indoor/outdoor data model

Another crucial research challenge is to investigate how a contextually-enriched semantic location and semantic trajectory of moving objects can improve the quality and adaptability
Figure 2  Taxonomy of contextual dimensions.
of navigation services and LBSs in mixed outdoor/indoor environments. As already suggested in Worboys (2011), designing a generic and unified data model for a mixed indoor/outdoor environment is a mandatory development for the delivery of intelligent-based context-aware systems. Bringing these two spaces together into one generic model provides users with a consistent and seamless navigation between built and natural environments. Different issues need to be addressed at the conceptual, functional, technical, and application levels. Particularly, differences and similarities between both spaces should be clearly identified. For instance, in contrast with outdoor environments, a hierarchical structure is typical in an indoor environment. Furthermore, small-scale indoor spaces encompass some specific properties and different levels of granularity, when compared with large-scale open spaces. Also, interactions among humans and/or other objects in a small-scale space are much more frequent than in a large-scale one, which is usually beyond the range of humans’ physical interactions. Although research on unified indoor/outdoor models is still at an early stage, some researchers have already started to address this challenge (Xu and Giiting 2011). A generic data model for representing the movement of a moving object (i.e., indoor and outdoor movements), where the roads, streets, and rooms are considered as constituting entities, has been developed (Xu and Giiting 2011). An indoor graph has been designed based on specific data types to support indoor trip planning at the room level, while additional data types have been provided for representing moving points in a public transportation network (i.e., buses, trains, and underground trains). However, this model does not represent objects’ movements at a fine-grained level and does not support context-awareness.

Data management techniques for indoor moving objects

Many mobile applications need to incorporate a mechanism for the continuous processing of location-dependent queries over moving objects on top of indoor space models. Examples of such services include continuous crowd monitoring within a given area, location-based alerts (e.g., continuously send E-coupons to all customers within 200 meters of my store), crowd notification in an emergency situation, and location-based friend finder (e.g., 1 – “let me know if I am near a restaurant while any of my friends are there;” and 2 – “if I continue moving towards this direction, which will be my closest restaurants in the next 10 minutes?”).

A continuous query remains active over a period of time and has to be continuously evaluated during that period as the objects of interest are moving. Efficient processing of such queries is a complex task in location-based services due to its expensive consumption of memory and computational resources. A straightforward approach to deal with this kind of query would be to periodically re-compute the best answer from scratch for all queries upon arrival of every delay update. However, such a naive approach performs poorly in highly dynamic environments, where the locations of both the query point and the target objects change over time.

Different architectures, indexing strategies, and update methods have been proposed to deal with location-dependent queries over moving objects (Prabhakar et al. 2002). These approaches can be mainly classified into two categories: (i) approaches for continuous query processing in moving object databases; (ii) approaches for continuous processing of spatiotemporal data streams. It should be noted that most of those strategies have been developed for outdoor
environments. A few works regarding architectures for mobile data management in indoor environments are presented in Jeng (2009) and Afyouni et al. (2013a). There is also a lack of approaches that incorporate user preferences and other contextual dimensions in continuous location-dependent query processing. Consequently, there is a growing need for approaches that provide adaptive and incremental query processing techniques to enhance efficiency of location-dependent queries over moving objects (Mokbel et al. 2005). On the one hand, adaptive query processing addresses the problems of unpredictable costs and dynamic data by using runtime feedback in order to tune query execution in a way that provides appropriate answers with better response time or memory utilization. On the other hand, an incremental execution paradigm deals with continuous query processing by reusing information from previous searches to speed up current searches. Therefore, new answers for series of similar search problems can be computed faster than by re-evaluating each query independently from scratch (Sun, Yeoh, and Koenig 2009). Both adaptive and incremental execution paradigms are required in order to achieve sufficiently flexible and more efficient continuous query processing.

A few research studies have addressed the specific requirements necessary to manage and query indoor moving objects (Jensen, Lu, and Yang 2009). For instance, a framework for managing and querying indoor moving objects has been proposed in Xie, Lu, and Pedersen (2013). This approach suggests one manage indoor geometries (i.e., spatial entities), indoor topologies (i.e., relationships among spatial entities and between space and moving objects), as

Figure 3  Context-aware navigation system architecture.
well as indoor moving objects (modeled with uncertainty regions around), with a composite index scheme in order to support efficient distance-aware queries. However, only static query points are considered and this approach did not discuss how to incrementally re-evaluate those queries.

Over the past few years, several research studies have also discussed the integration of some contextual dimensions in query processing (Mokbel and Levandoski 2009). Users’ preferences have traditionally been exploited in query personalization to better anticipate their needs and customize their experience. In order to deliver personalized query answering in mobile environments, context- and preference-aware query processing techniques are increasingly required. A query processing strategy should provide sufficient flexibility to location-based services. However, there is a lack of approaches addressing context-awareness in continuous location-dependent query processing.

Towards context-aware query processing

A continuous query processing framework should take several contextual dimensions into account. A comprehensive approach should be designed to support the extended context model previously described. Such a system should deal with a highly dynamic environment in which objects are moving continuously and their environment is dynamically changing. One important direction to consider in future work is the complete integration of the context model into the query processing engine. A generic context-aware system architecture is presented in Figure 3. A spatiotemporal continuous query execution framework should first be used, such as the one proposed in (Afyouni et al. 2013a). This framework manages indoor moving objects and suggests continuous path and range queries over a hierarchical indoor spatial data model. This framework can then be linked to a user context manager that should take into account live context from mobile sensors, as well as from social and personal data, and also historical context in order to help enrich the user navigation experience.

This implies the development of a “cost model for evaluating context-aware queries” that provides not only a quantitative value as a result of a cost function but also a semantic indicator that evaluates the quality, usefulness, and uncertainty of query results. The main challenge in developing a performing cost model is to take into account the different parameters of the context while associating different quantitative scores and semantic indications to each parameter according to the corresponding user. This means that, for instance, a user with special needs has different constraints with different impedances than a user with complete physical capabilities. Taking all these factors into account when designing a cost model for context-aware queries is challenging. The main goal is to provide a context-aware query processor that avoids modifying the database engine with the addition of each new context parameter. Instead, an extensible query engine that is general enough to support any kind of context should be designed.

When considering context-aware query representation, a taxonomy of spatiotemporal operators that can be combined with conventional query operators has been proposed in a related work (Afyouni et al. 2013b). Several spatiotemporal operators that can execute standard as well as navigation-related queries have been introduced. To fully integrate the proposed context model, additional “preference-and context-aware query operators” are still to be developed in order to take into account explicit preferences and other users’ constraints and
Representation: Indoor Spaces

wishes. At the performance level, this will help to compute cost functions for the continuous processing of location-dependent queries.

Semantic annotation of heterogeneous trajectories

As another possible direction for further research, semantic and location-based services that combine users’ trajectories with contextual data can favor the development of advanced intelligent services. Not only will current movements be taken into account but so, too, will other user trajectories as well as additional semantic information that will help to deliver user-oriented services. In such a collaborative environment, active objects in the environment, which can be classified as repellent, attractive or neutral, as well as events will also be part of the system environment. Users should be given the opportunity to annotate these points of interest (POIs) and then contribute to a sort of volunteer indoor system (Mata, Claramunt, and Juarez 2011). Such a system should classify those POIs as either attractive, repellent or neutral regarding other users depending on their context. Users might also share some common interests and might follow some similar patterns from either semantic (e.g., shop recommendations, etc.) or spatiotemporal points of view. Overall, semantic annotations of locations, trajectories, and objects of interest in the environment together with typical movement patterns open new research directions for intelligent and collaborative location-based services in indoor spaces.

These research directions also require the development of benchmarks and evaluation methodologies for the assessment of scalable and distributed techniques for real-time processing of contextual data in mobile and indoor environments. Furthermore, the search for a unified indoor/outdoor design (discussed in the section “Towards context-aware indoor spatial data models”) would require the study and development of efficient algorithms and systems that will support scalable data management and information integration for spatial, temporal, and semantic big data at the city scale. A new paradigm for such large scale management is emerging and new techniques to store, share, query, and analyze these big datasets is surely required.

Application perspectives

Application perspectives are very large, from the development of interactive systems for built environments, to additional professional- and user-oriented services. The numerous application types range from mobile location-aware services to context-aware recommender systems. New classes of applications, which can take advantage of both low-level sensor data and high-level events, context, and activities inferred from mobile phone sensor data, are being explored not only in academic and industrial research laboratories but also within large corporations such as Google and Apple as well as start-up companies.

Not only are the application perspectives promising, but also in terms of business as the range of possibilities will surely open many opportunities. In a report published by ABI Research (http://www.abiresearch.com) on “indoor location smartphone applications,” it has been noted that the indoor location market broke one billion application downloads by 2016. It has been also emphasized that the future adoption of a variety of indoor location technologies will be considered across a range of different application categories, such as retail, navigation, environmental monitoring, location-aware social networking, health
and wellbeing, personal tracking, while also enhancing services such as advertising, ambient intelligence, augmented reality, and local search.

Conclusions

This entry has introduced recent advances and research challenges closely related to the development of indoor space applications and context-aware indoor navigation systems. Current spatial data models, data management, and query processing techniques developed for indoor spaces have been surveyed. It has been shown that the representation of indoor spaces implies different modeling abstractions, from static to dynamic features. A series of recommendations has been given for designing and developing indoor space applications. Amongst many research issues still opened, current challenges on modeling, querying, and indexing moving objects, as well as location-dependent queries have been discussed. In particular, this entry has shown the close connection between indoor spaces and the contextual dimension. It is believed that a close consideration of indoor spaces and context-aware systems should open a series of application avenues worth exploring by the GIScience research community.

**Further reading**

The world is a dynamic place. Processes affecting our natural and human environments are highly complex and interrelated, operating at multiple temporal and spatial scales. Gaining understanding of these processes, and thus also of past and potential change, requires study of how properties of entities and their locations vary through time and how entities interact in cause-and-effect relationships.

It is only by the inclusion of the temporal component in the observed data or model that change can be represented, cause and effect relationships derived from the world model, and ultimately an understanding arrived at of the true nature and structure of the process involved. Change is normally described as an event or collection of events – something of significance that happens. For the purpose of spatiotemporal data representation, this is most frequently conceptualized as a change in state of one or more locations, entities, or both. Change relating to entities or locations can be sudden or gradual. Depending on the temporal resolution, events can be represented as having duration – extending over a temporal interval – or as having only a single temporal location. This is analogous to spatial representations where, depending on the resolution of the representation, an entity or spatial attribute can be represented as occurring either at a single point location or extending over an area. Change can also be a continual and gradual process, such as the income level associated with a particular county or groundwater level in a particular aquifer. For such instances of gradual and continual change, a change event is recorded at the time when the amount of accumulated change since the last recorded change is considered to be significant or by some other domain-specific rule. Events relating to entities have additional considerations. Entities can appear, move, expand, shrink, change shape, split, merge with another entity, and potentially disappear.

The study of temporal, as well as spatial, representation has a long history dating back at least to the ancient Greeks. Within geography, an early example of the explicit inclusion of time in the representation and analysis of space–time dynamics is Clark’s work on changing agricultural patterns in Nova Scotia (1959, 1962), Berry proposed a “geographic matrix” (1964) in which he integrated the temporal dimension within a general framework for classifying the multiple approaches for geographic analysis. Hägerstrand’s “time geography” (1967) and his well-known models of diffusion and spatial processes emphasized the temporal dimension. Going forward, other geographers, including Getis and Boots (1978) as well as Bennet (1979), incorporated time in their models.

Temporal and space–time representation from philosophical, cognitive, and formal perspectives has been a research focus in GIScience since the late 1980s (Armstrong 1988; Langran and Chrisman 1988). Interest in temporal, as well as spatial, analysis in geographic information science was spurred by the availability of remotely sensed satellite data as well as the exponential accumulation of other geographic observations over successive points in time. These data, along with advancing computer hardware and software...
Representational considerations relating to intrinsic properties of time versus space

Everything everywhere is inexorably progressing forward in time. Nothing can stop traveling through time in the experiential world. This is only possible in the sense of a historical retrospective. Because of this, we also usually think of time as being unidirectional, although we can usually go backwards in space. Things can also move through space at varying velocities, whereas everything progresses through time at the same rate (the theory of relativity aside, since it does not apply to the perceived everyday world). This can have obvious implications with respect to the varying measurement scales used.

From the standpoint of data collection and storage, we also normally look at space as being finite. We speak in terms of “the study area,” for example. Time, on the other hand, is open-ended and the temporal scope of observational data is continually expanding if one attempts to represent the ever-new “present” as well as past reality. One of the great potentials in the reality of spatiotemporal representations is the ability to search backward from an event or world state to its origins, thus using this technique as a tool to develop models of observed world phenomena.

For purposes of measurement, both space and time are normally broken down into discrete units. Space and time can both be divided into units of uniform or variable length, although the temporal units are necessarily different from those for space. For example, feet or meters cannot normally be used to measure temporal duration. Variable intervals of time normally separate events. Besides the events, the intervening intervals also have significance. Length of time, or duration, is divided into units of seconds, minutes, and days, moons, reigns, or other units suitable for the given data.

The segmentation of time into discrete units of measurement brings up the question of how small these units should be, particularly in measuring evolutionary change. This is directly analogous to spatial resolution and the modifiable areal unit problem (MAUP). And as is the case for...
spatial resolution, temporal resolution (or hierarchy of resolutions) must always be related to the scale of the phenomenon represented and to the intended problems or questions being addressed.

Extensions of traditional entity-based and location-based representations

Initially, representation of dynamics in observational data in GIS was accomplished by extending the familiar location-based and entity-based representations already used in GIS. This solution was pragmatic in that it employed familiar approaches, and it also fits with the dual philosophical views of space and time. Location-based representations, usually in grid or raster form, correspond to the Newtonian perspective of space. In this view, space is the container of objects and exists independent of those objects. In this view, time also exists independent of objects. Space and time are continuous; they are the backdrop upon which the dynamics of physical objects can be measured. In contrast, entity-based representations, most commonly in vector form, correspond to the Aristotelian view of space, where place is a property of objects. In this view, time is also a property of objects. Space and time are a system of relations between material objects. As such they are also viewed as discrete in nature.

The first space–time representation used in GIS is known as the snapshot approach. This representation utilizes sequential images, or “sequent snapshots,” of values for a given variable over a given area for a known point in time. These snapshots are conceptually equivalent to slices extracted from Hägerstrand’s continuous space–time cube. Snapshots also do not need to be evenly spaced in time.

Sequent snapshots are easy to implement utilizing the standard raster and vector data models available in nontemporal GIS by tricking the software. Instead of representing a set of thematic layers (elevation, vegetation, soil type, etc.) (Peuquet 2006), each spatially registered “layer” represents the state at a given moment in time for one of these themes. This approach is conceptually straightforward, and the state for any recorded spatiotemporal location can be easily retrieved. This approach can also utilize the standard map operations available in GIS for static data. Temporal change is easily calculated as the difference between two snapshots.

Recognizing the importance of inferring spatiotemporal change when the data are captured in snapshot form, as in satellite and other geosensor data, Worboys and Duckham (2006) derived a set of local transition rules used to constrain temporal inference for continually evolving regions and to detect higher-level events. McIntosh and Yuan (2005) provided a dynamic time warping (DTW) method to assess similarity of events and derive common characteristics of higher-level events using the example of precipitation data to derive similarity of storms.

There are, however, inherent drawbacks to the sequent snapshot approach, as detailed by Chrisman (1998). Since the actual changes that occurred between recorded snapshots are not explicitly stored and must be interpolated, it is possible that a critical change occurred between the two times. In this case, the stored observational data provide a misleading portrayal of the process or processes taking place. Another drawback is that values for the entire area (the state of all locations or entities at the time represented by the snapshot) are recorded, whether or not a particular location or entity had changed. This redundancy greatly inflates the total volume of stored data.

An alternative approach, to overcome the redundancy problem of the snapshot approach, was introduced by Langran (1992). In this
“base-state-with-amendments” representation, only the changes known as specific times are recorded. A third conceptual scheme is the space–time composite, originally described in Langran and Chrisman (1988). This can be thought of as the result of stacking all successive changes on top of one another as virtual transparencies, flattening the space–time cube into a single, cumulative depiction.

Implementing the base-state-with-amendments can be accomplished in either grid or vector form, as is the case with the snapshot approach. A grid-based implementation records a complete snapshot as the first in the sequence, and then grids representing subsequent times only record changes, noting the new values in the appropriate coordinate (row, column) location. A grid version of the space–time composite scheme was mentioned by Langran (1992) and also documented for use in electronic circuitry design analysis (Fujimoto 1990). Each location in the grid contains a list of timestamped changes. Each change list has a variable length, with each successive change added to the top of the list for that location. The “present” world state for the entire area is easily retrieved by referencing the top of the list for all locations.

The vector implementation is similar, only it is the changes to entities instead of locations that are stored in each successive time “layer.” The base state consists of all objects, or entities, as they are configured at the starting time (i.e., the original state) as points, lines, and polygons. Changes to point entities are noted as single $xy$ coordinates, and to line and polygon entities as strings of $xy$ coordinates representing “change vectors.” At each time “layer,” new and obsolete locations are noted for specific entities as they appear, disappear, grow, shrink, and move. These successive increments are stored in this model by noting only the timestamped “change vectors.” Similar to the grid representation, the “present” world state for any or all entities can be easily retrieved by referencing the most recent change vectors. Although the temporal integrity of individual spatial objects is maintained, the resulting representation for any real-world data quickly becomes unwieldy as individual map elements evolve through successive changes at various points in time. This is particularly true for situations where the typology of connected map vectors also changes as features come into and go out of existence as well as changing size and shape.

Following on this work, Worboys (1994) proposed an extension of the vector model where each object in space has a collection of boundary states through time. This work included specification of relationships from which a set of query operations could be defined. Raza and Kainz (1999) proposed an extension to Worboy’s model, but separated out space, time, and attributes as distinct elements. A different approach was proposed by Yick and colleagues (2002) that utilized the Voronoi spatial model to record topological relationships in an initial state and a set of operations to express changes, keeping only the changes in a log file.

Time-based representations

All the extended and vector models described above incorporate the temporal dimension in some way while retaining their functional organizational basis. They thereby also retain their relative functional advantages and disadvantages. All vector models are entity-based in the sense that all locational and temporal information, as well as other types of attribute information, is stored relative to specific geographic/cartographic entities, and their topologically defined components (lines and nodes). In other words, geographic/cartographic entities serve as the basic conceptual element
and organizational basis of the representation. Conversely, the grid model, or more generally any tessellation model, can be said to be location-based, since all other information is stored relative to specific locations. These two models correspond to the dual entity-based and field-based conceptual approaches, respectively, as discussed by Couclelis (1992).

Because of these two fundamentally different orderings of stored information, the vector model can be used most effectively to store information and perform tasks and queries relative to spatial entities, including determining topological relationships between them over space, but not nearly as effectively to store information and perform tasks relating to a specific location or set of locations. Conversely, a grid or tessellation model can much more effectively perform tasks relative to specific locations and sets of locations (Peuquet 1988).

In the time-based approach, location in time becomes the primary organizational basis for recording change. The sequence of events through time, representing the spatiotemporal manifestation of some process, is noted via a timeline, that is, a line through the single dimension of time instead of the two-dimensional (2-D) surface over space. Such a timeline, then, represents an ordered progression through time of known changes from some known starting time to some other known, later, point in time. An early example of this, proposed by Peuquet and Duan (1995), was the event-based spatiotemporal data model (ESTDM).

Each location in time along the timeline (with its temporal location noted as \( t_0, t_1, \ldots, t_n \)) can have associated with it a particular set of locations and entities in space–time that changed (or were observed as having changed) at that particular time and the new value to which they changed. Recording only times when change occurs, as opposed to a complete timeline that contains an entry for every “tick of the clock” at a given temporal resolution, avoids storing redundant data. In other words, the changes relating to times are explicitly stored, and only the changes. This top level of information where a time of change is recorded is called the “event list.” (An event is defined as an instant in time when a change occurs, that is, change in some property or attribute that can be denoted as such for some entity, location, or set of entities or locations.)

In the time-based approach, the time associated with each change (i.e., each event) is stored in increasing order from the initial “world state” at time \( t_0 \) (e.g., January 21, 1952) to the latest recorded change at time \( t_n \). These may be recorded at any desired temporal resolution. For most phenomena, the length of any temporal interval (i.e., temporal distance between \( t_{i-1} \) and \( t_i \)) and any other such interval will typically be unequal. Associated with each \( t_i \) are the changes that occurred between \( t_{i-1} \) and \( t_i \). The only exception to this is that the entire base map or starting world state must be stored with the first recorded time, \( t_0 \). The changes associated with any \( t_i \) may also be extensive, affecting a large geographic area and many entities within it, or perhaps may be only a single location or entity. The timeline is compacted in that temporal locations where no change occurs are not recorded. It is assumed that each event list and associated changes relate to a single thematic domain (e.g., land use or population). Each stored event can relate to a location or set of locations, or to a set of entities or set of entities.

This type of representation has the unique advantage of facilitating time-based queries (e.g., retrieve all events that occurred between May 1, 2016, and September 15, 2016). Adding new events as time progresses is also straightforward; they are simply added to the end of the timeline. A similar timeline approach, with associated temporal topology and query operators, was
described by Claramunt and Thériault (1995). An alternative approach was suggested by Frank (1994). In Frank’s approach, the timeline is strictly ordinal where the precise dates of events are not known. Such a limitation is encountered in various application domains such as archaeology and ecology. Nevertheless, a strictly ordinal timeline facilitates the comparison of entity histories and parallel sequences of events.

Recognizing that events can be viewed hierarchically at differing levels of detail, Yuan (2001) proposed a hierarchical conceptual structure where an event has duration, with a starting and ending time. Within this time span, an event is composed of multiple changes in space and time. Mountrakis and colleagues (2002) instead proposed dealing with differing levels of detail in event data through the use of aggregation operators.

In parallel with these efforts on general spatiotemporal representation schemes, work began to appear to provide structured methodologies for deriving models tailored to specific applications. Raper and Livingstone (1995) proposed OOgeomorph—an object-oriented technique for spatiotemporal representation of geomorphologic processes. Wachowicz (1999) demonstrated how object-oriented design methods can be used for modeling spatiotemporal data in a wide range of applications including boundary record maintenance and analyzing the spread of disease and the environmental impacts of climate change. There was also a significant amount of work on structured methodologies for spatiotemporal representation within the database management systems (DBMS) community. These included work by Parent and her colleagues (1999), who proposed a spatiotemporal modeling technique called MADS (modeling of application data with spatiotemporal features) for bridging the application-view/implementation-view gap. Tryfona and colleagues (1999, 2003) described an extension of the entity-relationship (ER) database design technique, which they called STER (spatiotemporal ER), and an extension of UML (Unified Modeling Language) elements to directly support design of spatiotemporal data models. Their STER technique utilizes a set of very basic ontological principles dealing with the unique aspects of the space–time domain— that properties and interrelationships of entities can be defined on the basis of either discrete or continuous change with respect to spatial change (i.e., movement, change of size, change of shape) and/or nonspatial change (e.g., change in temperature). Chomicki and Revesz (1999) proposed constraint databases as a common language for facilitating interoperability of spatiotemporal data models.

The space–time cube

The space–time cube was first employed as a spatiotemporal representation for geographic data in the early 1970s by Hägerstrand (1970) in his work on what became known as time geography. He used it as a convenient graphic device for showing movement of individuals in a “space–time path” and how people interact in space–time. A related concept was the “space–time prism,” which encompasses the extent of potential movement within given space–time constraints. The base of this three-dimensional (3-D) diagram represents continuous, planar space, and the vertical dimension of the cube represents continuous time. Advancement of time geography, however, was hampered by the very limited capacity of computers of the day as well as difficulties in collecting data. Both rendering of the space–time cube representation and data collection/processing were predominantly manual processes, and therefore also tedious and time-consuming.
As mentioned earlier, the renewal of interest in spatiotemporal analysis and representation in the late 1980s was coincident with the development of advanced storage and processing capabilities of modern hardware and advanced networking and software technology, as well as with large amounts of continuous spatiotemporal data becoming available. This spurred renewed interest in Hägerstrand’s work and what has been called the “new” time geography (Miller 2004). The space–time cube has been employed recently in transportation research as an analytical modeling tool, extending and refining the space–time path and prism concepts (Shaw and Yu 2009; Ellegård and Svedin 2012; Song et al. 2015).

Stefanidis and colleagues (2004) developed an extension of the space–time cube they called the ST Helix for the analysis and management of large motion imagery datasets. This model incorporates both movement and entity deformation within the same representation. A central “spine” models the spatiotemporal trajectory and protruding prongs express expansion/contraction and deformation of the entity’s outline at specific time instances.

Kwan’s work on the analysis of disaggregate activity-travel behavior (2000) focused on the use of the space–time cube as a 3-D visualization to facilitate exploratory analysis of space–time interrelationships of human activity and travel patterns. While modern computing capabilities allow interactive pan, zoom, rotation, walk-throughs, and fly-bys, the use of the space–time cube as a visualization tool is inherently limited in its capability to display more than very modest amounts of data since individual movement traces quickly become obscured in a visual tangle of lines.

Manipulations such as 3-D rotation and fly-bys can help overcome the scaling problem to some extent, but these can also be perceptually disorienting. The space–time cube also assumes data are continuous over both space and time. This can be particularly problematic with historical reconstructions. In Nakaya’s recent work (2013) focusing on three example uses of the space–time cube, he argued that its support as a visual representation should be supported in the next generation of geographic information systems. While acknowledging the problems with this representation as a visual tool, he suggested some possible strategies.

A number of visualization researchers have explored ways to overcome the problems associated with scalability, disorientation, and missing data. Kraak developed a multiview environment, with dynamic linking, that includes 2-D and attribute views as well as a close-up view of the space–time cube that assist the user in orientation and navigation (2003). Another notable effort investigated use of the space–time cube to explore events represented as dots or circles (Gatalsky, Andrienko and Andrienko 2004). Here, interactive temporal filtering and zooming were employed with the 3-D display linked to a (2-D) map.

Combined approaches for spatiotemporal representation

Associating temporal information with individual entities provides a means of recording entity histories, and thereby allows histories of entities and types of entities to be easily traced and compared. Similarly, associating temporal information with locations allows the history of individual locations and sets of locations to be traced and compared. Since these different types of representation provide differing perspectives on the data, each facilitates a different type of query.

Worboys and Hornsby (2004) showed how the entity–based paradigm could be extended
to incorporate event information and proposed a unified modeling approach for both events and entities. Earlier work recognized that location-based and entity-based representations should be considered complementary in a unified, dual field-based and entity-based conceptual framework (Peuquet 1988; Couclelis 1992). Based on this, Peuquet (1994) proposed that all three – time-based, location-based, and entity-based representations – need to be considered complementary and interdependent in a triad representational framework. A similar framework was proposed in an application context in Yuan (1994). This triad framework corresponds to human cognition in that people store and use knowledge about the world via interdependent location-based, entity-based, and time-based perspectives (Mennis, Peuquet, and Qian 2000; Peuquet 2002). Yang and Claramunt (2003) extended a combined representation based on locational, temporal, and thematic domains to allow for the representation of continuous change.

Van de Weghe and colleagues (2014) introduce a continuous spatiotemporal model (CSTM) in order to address the need for representations that can support multiscale analysis, since spatiotemporal processes commonly occur at multiple, interrelated scales. This has been a significant and long-standing issue, since analysis at a single scale can miss important patterns and relationships and thus present an incomplete, and perhaps misleading, portrayal of a phenomenon. While multiscale spatial and temporal representations are not new – as an example, Hornsby and Egenhofer (2002) presented a method to describe moving entities over multiple spatial and temporal resolutions utilizing lifelines within the space–time cube – the CSTM model provides a solution for multiscale representation of more complex and much larger volumes of data. The spatiotemporal hierarchy in the CSTM representation utilizes a tree structure based on the spatiotemporal evolution element (stevel). The stevel is composed of four variables: pixel location, spatial resolution, temporal interval, and temporal resolution.

Temporal and spatiotemporal query operations

If we loosely regard the location-based and entity-based views in the dual framework as storage of information relating to where and what, respectively, the time-based view in the triad representational framework provides storage of information relating to when. In the dual framework, the two complimentary representations together are able to answer the two basic types of static spatial questions. These questions in their most general form can be stated as follows.

1. Using the location-based view – given a location or set of locations, describe what things are there (where → what).
2. Using the entity-based view – given an entity or set of entities, describe their location (what → where).

For each of these, the given information represents the search keys, or elements that must be retrieved in order to provide the desired associated information. Extending this to include a temporally based view, there are then three basic types of questions, as follows:

1. when + where → what: describe what entities are present in a given location or set of locations at a given time or set of times;
2. when + what → where: describe the location or set of locations occupied at a given entity or set of entities at a given time or set of times;
where + what → when: describe which times a given entity or set of entities occupied a given location or set of locations.

Relationships, whether temporal, locational, or entity-oriented, are viewed as operators on stored observational values. As operators, they enable the user to combine data in an ad hoc manner and to combine relationships in order to express, and thereby search for, more complex patterns. In a manner similar to the way that a spatial distribution pattern can be random, uniform, or clustered, a temporal distribution can be chaotic, steady-state, or cyclic.

Utilizing a time-based representation, all temporal relationships can be divided into three distinct classes: (i) linear metrics and topology, (ii) Boolean operators, and (iii) generalization. Temporal relationships between and among entities specifically allow the examination of cause-and-effect as well as overall patterns (i.e., temporal rhythms). In other words, they are the key element that allows hypotheses regarding process to be derived and/or verified from stored observational data.

The first class of temporal relationships comprises those that operate along a single, continuous, linear timeline, or event vector, at a given temporal scale. These include metric and topological relations. Given that time is one-dimensional, there is only a single temporal metric: temporal distance. Temporal distance is the measure of the length of the interval between any two given points in time. This metric can represent the length of a single event (i.e., its duration), the length of time between two events, or the duration of some continuous “world state.”

Since intervals between events are subject to variability in the recording and fineness of measurement, it is also useful to be able to express relationships between events strictly in an ordering sense. In terms of real-world analysis, this allows for examination at different temporal rates or timescales that may have influenced different processes. The study of temporal topology has a long history in a number of fields, including philosophy, mathematics, linguistics, and artificial intelligence (Allen 1984; Shoham 1988; Davis 1990). These temporal topology relationships are: before/after, equals (coincident), meets, overlaps, during, starts, and ends. Note that each of these seven basic relative interval relationships has an inverse. Since $X = Y$ and $Y = X$ is an identity, there are 13 possible temporal topological relationships in all.

The second class of temporal relationships comprises those that operate specifically to combine separate event vectors (e.g., fire history and weather history). These are the temporal overlay relationships that act as Boolean set operators (intersection, union, negation) to associate the overall concurrence of different event types over the entire length of a given time interval.

The third class of temporal relationships is temporal generalization. Operators in this class associate specific events at various levels in the temporal scale hierarchy and are thus derived from the fourth characteristic. The method of generalization is dependent on the metric used (e.g., four seasons, 12 months, or 365 days (usually) each equal one year). It may also vary from scale to scale. It is temporal generalization that allows the rhythms of biological, cultural, or other types of phenomena that operate at different temporal scales to be compared.

In addition to temporal relations that operate on the time-based view, there are also temporal relations that operate on the locational-based view, and still others that operate on the entity-based view. The most apparent location-based temporal relationship is a location-based temporal overlay, utilizing Boolean functions to compare changes (or similarities) at the same set of locations over a series of different times in
a snapshot representation. This corresponds to how overlay is defined for a series of different conceptual layers.

A typology of entity-based temporal relations was presented in the work by Claramunt and Thériault (1995). These were further explored in an application analyzing dynamics of precipitation patterns in a projected climate change scenario (Bothwell and Yuan 2011). Claramunt and Thériault enumerate separate sets of temporal relationships for the evolution of a single entity, relationships between entities, and evolution of spatial structures involving two or more entities, as follows.

1. Evolution of a single entity: (a) existential changes: appearance, disappearance; (b) transformation: expansion, contraction, deformation; (c) movement: displacement, rotation.

2. Relationships between entities: (a) replacement processes: succession, permutation; (b) diffusion processes: production, reproduction, transmission.

3. Evolution of spatial structures involving two or more entities: (a) restructuring: split, join, reallocation.

Diffusion processes involve a transfer of characteristics between spatial entities. Production involves the creation of new entities by the behavior of one or more entities of differing types. Reproduction is the creation of new entities of the same type, and transmission is the modification of the characteristics of one or more entities due to the influence of one or more other entities. These diffusion relationships are truly important in space–time analysis as cause–and–effect relationships. Renolen (2000) defined seven entity-based temporal relations: creation, alteration, destruction, reincarnation, split, merge, and reallocation. These are similar to those given by Claramunt and Thériault but without the diffusion process relations. Hornsby and Egenhofer (2000) derived a set of 18 identity-based change operations in what they termed the identity-based change (IBC) model. Their approach highlighted the minimum elements necessary for reasoning about identity, as well as the ordering and co–occurrence of identity states. This work was recently expanded by Yi and colleagues (2014) to account for identity states of entities that are components of a composite structure. Worboys (2005) explored entity-based temporal relationships using algebraic approaches. This work was later extended to represent reasoning about complex entity changes using trees and structure-preserving mappings between them (Jiang and Worboys 2009).

From world models to process models

The location-, entity-, and time-based models discussed above are all designed to represent observational data in a world model. This conforms to the fact that many spatial and spatiotemporal analysis techniques used in GIScience, and geography more broadly, are observation-driven methods. The development of understanding of a phenomenon, however, involves a significant amount of theory-driven investigation. This is true for both science and everyday cognition. Theory–driven investigation in science is the domain of modeling and simulation. Well-known examples for modeling geographic processes include UrbanSim for simulating urban systems (Borning, Waddell, and Förster 2008) and IBIS (Integrated Biosphere Simulator) for vegetation dynamics (Foley, Kucharik, and Polzlin 2005). These tend to be stand-alone and focused on a highly specific context because of the complexity of the process being modeled.
Goodchild has stated that GIScience, however, has been focused on the study of form rather than process – of how the world looks rather than how the world works (2004). Thus, while vast amounts of spatiotemporal data can currently be stored, accessed, manipulated, and analyzed, what can actually be learned from observational data in terms of deeper understanding of the phenomenon under study relies completely upon, and is therefore also limited by, the expertise, experience, and memories of the specific people studying the data at a given time. This can be problematic, particularly in an emergency situation when insight and an actionable response are quickly needed. Process models, on the other hand, are designed to represent how a particular phenomenon works – the mechanisms involved that effect change. As such, this is higher-level, derived information involving the interactions among entities that are interlinked, with complex chains of interactions.

Raper and Livingstone (1995), as part of their argument for object-oriented data representation within the context of environmental phenomena, argued that process models and data models should be linked, thereby extending the triad approach described above for multirepresentation of data of the what/where/when scheme into a what/where/when + how framework. While direct linkages of current, complex simulation models with spatiotemporal data models as known in GIScience would be over-reach as a first step, linkage to a simpler structure for stored, higher-level rules of association and known cause-and-effect would allow two significant enhancements to current capabilities (Peuquet 2009). First, it would provide a common and perhaps negotiated set of derived views on which collaborative analysis could be based. Second, it would allow information or insights captured as the results of analyses to be explicitly stored and potentially used to inform subsequent analyses.

Yi and colleagues (2014) recently proposed such a composite structure. Their framework consists of a hierarchy of representations. The bottom of the hierarchy consists of what they call static structures: the shapes, locations, and characteristics of entities derived from a series of remote sensing images viewed as observational snapshots. At the mid-level of the framework are stored sequences of footprints for individual entities during the entire time span of the observational data assembled from the static structures. The top level contains what they call scenarios, which are composite structures representing interactions among the entities and groups of entities. They expand on Hornsby and Egenhofer’s IBC model (2000) to describe the changes and interactions of individual entities and composite structures.

While Yi and colleagues were able to build a composite structure, deriving the higher-level information required a significant amount of human input to interpret algorithmic results. Deriving higher-level information needed to build a process model from the large and complex data currently available requires a more automated approach. This brings up two well-known problems related to temporal reasoning, which have become known as the frame problem and the ramification problem (Shanahan 1997; Papadakis, Antoniou and Plexousakis 2006). Both of these are a direct result of the necessary incompleteness of stored world observational information. The frame problem is the problem of knowing what world states and other events are not changed by a given event or action. For example, migration of workers does not change their gender. The complementary problem is the ramification problem. This is the problem of predicting how one entity or location state will automatically change when another does due to some relationship connecting them.
REPRESENTATION: TIME

One solution to both of these problems is to explicitly enumerate the specific entity/location states that are or are not affected, but such exhaustive enumeration can have obvious drawbacks. The other solution is to incorporate generalized rules regarding what types of entity/location states may or may not be affected by a given event type. In either case, it is necessary to be able to separately and independently reference events, locations, and entities in order to reference these relationships and store this higher-level information within the specific type of element to which the information pertains. Brown and colleagues (2005) proposed the use of agent-based models for storing rules of how locations, entities, and events interact within a tightly coupled process—a multirepresentation data model environment. As part of this, they also discussed four key relationships that affect how the world model and process model interact: identity, causal, temporal, and topological. Torrens and Benenson (2005) proposed a similar approach that combined agent-based models with cellular automata. That same year, Reitsma and Albrecht (2005) proposed an alternative approach for representing process that tries to take the integration of behavioral rules a step further. Based on their critique that the rules in agent-based and cellular automata approaches typically represent the relationships only between the current and future states of cells or agents, they extend process representation to include the set of rules that govern interactions with other processes.

The problem remains of how to derive these rules and relationships. But also the question arises as to whether these are among the various types of associations that describe the process model that we are trying to uncover to begin with. This gets down to the ultimate goal of extending a world model, represented as locations, entities, and events, to a process model that can be represented as sets of quantified relationships and constraints.

Certainly, one way to get around the issue of needing a priori rules is spatiotemporal analysis in the form of exploration, or what Tukey (1977) called exploratory data analysis (EDA). This entails simply looking at the data in various ways visually and statistically to see what patterns and associations the human analyst can perceive. The visual aspects of this have been termed “geovisual analytics” within the GIScience community (Andrienko et al. 2007), and has gained significant attention for exploring and gaining insight relating to spatiotemporal processes (Beard 2008; Andrienko and Andrienko 2006; Chen, MacEachren, and Guo 2008; Kraak 2014). Both visual and statistical approaches, and their combination, as approaches to EDA are becoming a set of increasingly valuable tools, particularly in the current era of big data, where the volume of observational data about the Earth, once in short supply, now exceeds the human capacity to absorb all information contained within it without help from computers.

Cognitive science holds some insights into a method that would also allow computers to assist in deriving these relationships from complex observational data based on how humans learn such relationships in everyday life so that they can subsequently be verified and formalized in process models. Pazzani (1991) described a process that uses a theory of causality as background knowledge. The process, which he called theory-driven learning (TDL), hypothesizes causal relationships consistent with observed data and a general theory of causality.

Theories of causality are able to assist the learning process and allow cause-and-effect associations to be made more quickly than by a simple process of repeated observation to yield a conclusion, as well as allowing the connection to be made between a specific type of event...
and a specific world state change with causal links. It is these theories of causality that are gradually accumulated and refined, thereby progressively achieving greater accuracy. They are inductively learned over a series of temporally based observations comparing before-after states. This inductive learning also is based on a few elemental causal constraints. The elemental causal constraints that influence the acquisition of causal relationships from the observed world as discussed by Pazzani include the following.

- **Regularity** – An effect must regularly and repeatedly occur with its cause.
- **Temporal order** – An effect must happen after the cause.
- **Temporal contiguity** – An effect normally happens very soon after the cause. The more temporal separation, the less likelihood that there is a cause–effect relationship.
- **Spatial contiguity** – An effect normally happens in contact with (or very near) the cause. The more spatial separation, the less likelihood that there is a cause–effect relationship.

It is important to note that regularity and temporal and spatial contiguity are not absolute requirements, but provide generalized guidelines. Spatial continuity applies as a causal constraint only two processes involving spatial interaction. There are many processes involving social interaction that may not have a direct spatial component, particularly in the current era of electronic communication. All such constraints, however defined for a particular context, function to focus attention on the potentially relevant features and to establish chains of cause–effect relationships. They also help to ascertain the true cause of an event, such as being able to distinguish whether a tree fell down because its trunk had been sawn through rather than as a result of some other independent event that may have happened at the same time (e.g., a bird landing in the tree).

The combination of a large amount of complex observational data with TDL allows explanations and predictions to be made on the basis of relatively few selected factors, but also for the greater amount of information to be tapped into when exceptional conditions arise. Specific known or presumed causal relationships can be stored with the entities as causes/caused-by links. Causal constraints and the other rules regarding how entities, locations, and times can (and cannot) interact can also be stored.

### Issues and challenges

Significant progress has been made since the early 1990s in the development of spatiotemporal representations that go beyond extensions of traditional, static spatial data models. Along with evolution of an underlying theory of space–time representation, semantically driven representations and operators are being developed that seem more “natural” to the human user, and at the same time take advantage of modern computing capabilities. Two issues, in particular, remain as relatively unaddressed that have unique aspects with respect to temporal data, as follows.

### Missing and erroneous data

While we are currently in an era of continuous and fairly exhaustive spatiotemporal data collection with the use of geosensor technology, many historical databases also are being developed from archival sources that provide a wealth of information on past world states and events not previously accessible in any variety or volume (Knowles 2000; Knowles and Hillier 2008). These historical archives often contain gaps of missing information from some long-past time.
that cannot be revisited, and the past states or events often cannot be interpolated with any degree of certainty.

There is, however, a significant body of literature on how to evaluate and/or correct error and uncertainty in data, mostly generated within the image processing community. Some of these methodologies have been utilized to improve the accuracy of transitions noted from one time to another using erroneous maps, in effect distinguishing actual change from noise (Pontius and Li 2010).

As pointed out by Bol (2013), place names provide an essential link between the historic and the geographic. Data including tax records, population, and economic activities are linked to a place, yet place names are dynamic. Many of the primary sources of geographic names do not include time as an attribute of place. This includes those provided by the US government, including the Geographic Names Information System for place names within the United States and the GEOnet Names Server (NGS) for place names outside of the United States. The largest nongovernmental gazetteer, Geonames, also does not include time as an attribute.

One strategy for addressing the problem of missing and erroneous data is information fusion. As related digital data are accumulated, related elements can be compared to help validate elements and “fill in the blanks.” Information fusion is the process of integrating information from diverse sources and is a fairly standard process for business databases. Duckham and Worboys (2005) provided one example where this approach has already been applied to spatial information data.

Multiple times and alternative histories

Spatiotemporal representations developed within GIScience are designed to handle time with respect to events as they are reported to have occurred. But representation of the temporal dimension is not always that simple. It has long been recognized in the database community that for temporal databases there needs to be two kinds of times—“valid time” and “database time” (Snodgrass 1986). These relate to the time the event happened in the real world, thus often called “world time,” and the time when information relating to that event was entered into the database, respectively. The distinction between the two, and the ability to record both, is important in business applications, particularly banking. How to effectively represent both types of times within spatiotemporal databases was discussed as an important issue for applications such as cadastral systems early on (Al-Taha 1992; Worboys 1994). And as these and other researchers have noted, these two times can be noted as attributes in an entity-based representation, with the world time and database time for each boundary change as an example.

This idea of multiple time attributes can be extended. In the case of a spatiotemporal database for an archaeological dig, there can be the need to store multiple kinds of times: the date an artifact was found, the date the artifact was entered into the database, the date attributed to the entity as the time of its fabrication, and the date attributed to the stratum in which the artifact was found. But there are other kinds of time where representation is not as simple. The representation of multiple times to represent alternative histories or alternative futures is still problematic. This is an important issue in that the capability for such representation is important for the study of process, looking both backward in what are potential explanations as precursor conditions for observed events, and forward from observed events in the realm of prediction. This represents a critical link between observations.
and abstract process models, either mathematical or rule-based, as simulations.

References

A trajectory is the spatiotemporal footprint that an object leaves behind when its movement is tracked. As tracking technologies get better and cheaper, trajectory data advance to an important type of geographic information representing the movement of people, animals, goods, or any object that moves in geographic space. Even though all trajectories capture the spatiotemporal footprint of mobile objects, they do so in various ways and, hence, come in many diverse forms. They often come as lists of time-stamped positions recorded by a GPS receiver, for instance, fitted to a collar attached to a deer or a migratory bird in an ecological study (Figure 1a). Another typical form of trajectory results when connecting the sequence of positions where a mobile phone user made a call or connected to the Internet (Figure 1b). Yet another type of trajectory emerges when lining up the locations of a commuter’s check-ins into the electronic ticketing system of an urban transit network (Figure 1c). The interest in movement is omnipresent in geography; hence trajectories of a most diverse and wide range of objects are recorded, with examples including migrants or commuters in human geography, cars, truck or taxi fleets, ships, airplanes, or containers in economic geography, or tornadoes, icebergs, or even individual rocks in a rock slide in physical geography.

Major dimensions of representing movement trajectories

For a better understanding of the dynamic processes producing the observed movement, the respective trajectories must be abstracted and conceptually modeled such that they can be represented and then analyzed in computer systems (such as GIS or spatial databases). The way in which a specific movement process can be represented as trajectories results from the interplay of four important dimensions:

- the characteristics of the underlying (geographic) space embedding the movement;
- the characteristics of the movement process itself;
- the perspective of observation;
- the semantic aggregation level that is of interest in a given study.

In the following, the above four angles are illuminated. For every angle important properties are discussed and respective categorizations are proposed.

The choice of trajectory representation matters because the representation used has implications on suitable techniques for analysis. The representation rules which techniques can be used, for example, for assessing the similarity or dissimilarity of trajectories, or the way in which collective movement patterns can be formalized and algorithmically detected. For example, geometry-based measures from computational geometry might be suitable for assessing the similarity of line-shaped GPS trajectories, whereas
the similarity of mobile phone call logs might be better studied using sequence rule mining borrowed from molecular genetics.

Properties of the movement space

It is widely acknowledged that the representation of movement involves both the spatial and temporal characteristics of the trajectories, but crucially also the structure and properties of the space embedding that movement (Andrienko et al. 2008). In the following paragraphs key characteristics of the most commonly used spaces embedding movement are investigated.

Continuous versus discrete movement spaces

A first important distinction can be made between continuous and discrete movement spaces. In some contexts, the underlying movement space is best represented as a continuous Euclidean space. For instance, the trajectories of birds flying across the sea or a deer roaming through the woods might be perceived as sequences of fixes that can express any \( x \)- and \( y \)-coordinate tuple in a Euclidean space (Figure 2a). By contrast, the space embedding phone call histories from GSM networks is typically modeled as discrete Voronoi cell-shaped neighborhoods around antenna tower locations. Such a trajectory will then consequently be modeled as a sequence of visited Voronoi cells (Figure 2b, sequence \( h-i-j-f-g \)). Similarly, when cars are tracked in between cordons located at the nodes of a street network, their trajectories take the form of a sequence of discrete nodes and edges (see the networks in Figures 2b and 2c).

Conceptual models and data structures

The common GIS field and entity conceptual space models offer a second useful categorization for movement spaces. Deer in the Yellowstone National Park might be represented as moving over a field-based digital elevation model (DEM) (Figure 2a a.2). When their movement is simulated using an agent-based model (ABM), the underlying movement space will most likely also be represented using a grid-based raster data structure. By contrast, the same deer can also be represented as moving across an entity-based land-use layer consisting of habitat polygons enclosed by street and water body networks (Figure 2a a.3). Clearly, an entity-based
Figure 2 Movement spaces, movement traces, from varying observation perspectives: (a) unconstrained and limited movement in a Euclidean space, also modeled using field versus entity conceptual data models, observed from the Lagrangian perspective; (b) network-based movement observed from the Eulerian perspective, where the moving object passes by static beacons, here GSM antenna locations; (c) again network-based movement observed from the Eulerian perspective, where the objects are located when they pass through ticket gates.

Movement space is also a discrete space. Whereas animals are seemingly free to roam around, most human movement activity adheres to transportation infrastructure that is best represented using network data structures consisting of edges and nodes. Hikers walk on trails, cars drive along streets, and even airplanes follow clearly defined air traffic networks (Figures 2b and 2c).

Irrespective of the use of field, entity, or network movement spaces, GIS offers a wide range of concepts for modeling the properties of movement spaces that influence or control the movement embedded in those spaces. For instance, using a network movement space allows for modeling one-way streets or speed limitations (Figure 2b). Alternatively, field-based movement spaces can come useful when movement across space must be allocated anisotropic costs.

**Dimensionality of movement spaces** In most cases movement is represented in 2-D spaces. A position fix is then given with the coordinate tuple \((x, y)\) or \((\text{latitude}, \text{longitude})\), typically time-stamped with a time \(t\). However, in some cases the movement space can be simplified to a 1-D linear space. When movement is modeled over a digital elevation model (DEM), the dimensionality of the space becomes 2.5-D, with the pseudo-third dimension being the unique elevation value per location. Whereas such a 2.5-D space does not allow for representing vertical movement, a true 3-D space would allow exactly this (Ware, Arsenault, and Plumlee 2006). Here, position fixes come as tuples of \((x, y, z, t)\); with multiple \(z\)-values for a unique \(x, y\) position). Also, time \(t\) can be perceived as the third dimension \((2D + T)\). Such a movement in a space–time cube goes back to Hägerstrand’s time geography (Hägerstrand 1970) and is still popular especially for visualizing movement (Andrienko et al. 2010). The temporal dimension is different since it is directed and permanently progressing, hence movement trajectories in space–time cubes take the form of upwards-directed lifelines.
Properties of the movement

The movement processes studied in geography are very diverse, and so are the properties of the respective trajectories. Just as with the embedding movement space, choosing the appropriate representation for the movement trajectory itself is a modeling process, and hence requires abstraction focusing only on certain aspects of the movement process whilst ignoring others. So, identifying the relevant characteristics of the studied movement is a pivotal task when choosing the suitable trajectory representation.

Unconstrained versus limited versus constrained/restricted

The most crucial fact is whether or not the objects are free to move wherever they want, or whether their movement is constrained in space. Again, a bird can fly wherever it wants. Its movement is unconstrained. Some moving objects are somewhat limited in their freedom to move by boundaries that cannot be crossed. Examples include sheep on their paddock, shoppers limited by the walls of a mall, or football players that at least during the game typically do not leave the pitch (Figure 2a a.1). Yet other moving objects are totally constrained by their movement spaces. Trains must follow their tracks and cars (mostly) use roads. A frequent combination of constrained movement is with network movement spaces, where the moving objects can only move along the edges of the transportation network (Figures 2b and 2c).

Whether or not movement is constrained by its embedding movement space critically influences the respective trajectory representation. Unconstrained moving objects are typically represented by lists of time-stamped positions \((x, y, t)\). By contrast, network-bound movement can be represented as a time-stamped sequence of the identifiers (ids) of visited edges and nodes (Richter, Schmid, and Laube 2012). Also continuous movement can exploit network structures: the position of a train on a leg of the transport network can be represented as a fraction of the already traversed portion of edge divided by the remaining portion \((v:w)\) in Figure 2c).

Uniform versus intermittent, periodic

Another characteristic of the studied movement that can be exploited for representing trajectories is the rhythm or “pulsing” of the movement. Some objects adhere to a rather uniform or permanent form of mobility. Examples could include migrating animals. By contrast, other objects express intermittent or periodic movement. Here, stationary phases are typically intermitted by bursts of movement. Commuters show such intermittent movement: most of the time they are at home or at work, with these stationary phases only being disrupted by regular or irregular movement bursts to the mall or the gym. This can become relevant when deciding how to track such different movement forms. It may not be feasible to record large volumes of redundant GPS fixes of an object that is most often stationary. Here, a trajectory representation could be chosen that models steps or moves between stationary points of interest. Clearly, uniform and intermittent movement can also characterize distinct phases or segments of the same moving object. A bird’s trajectories can express phases of uniform migration but also phases of intermitted movement bursts when, for example, feeding.

Active or passive

Finally, movement can also be categorized into active and passive forms. In active movement forms, the moving objects are typically self-propelled, and often express purposeful and goal-directed movement. Salmon returning to spawning grounds show very much active and goal-directed movement. By contrast, jellyfish could be carried away passively by an ocean stream. Other examples for passive movement include particles in an air stream or survey pegs...
on a downhill creeping landslide. This last distinction has perhaps little direct implication for the choice of a suitable trajectory representation, but it is closely related to the Eulerian and Lagrangian perspectives of observations that are discussed next.

**Perspective of observation**

Movement must be observed before it can be studied or analyzed. Just as conventional static spatial variables can be sampled in different ways, so can movement be observed adhering to rather different observation perspectives. Again, depending on the perspective of observation, the very same movement can be represented using rather different concepts. The perspective of observation is clearly very much related to the tracking technology that is used: GPS data are quintessentially different from mobile phone call data records and e-ticketing check-in histories. Many movement studies exploit third party data, where the choice of a tracking system with all its implications lies beyond the reach of the data analyst. However, when a movement study is designed from scratch, it is well worth considering the implications of the tracking system on the representation of the trajectories to be captured.

**Lagrangian versus Eulerian perspective** Movement can be perceived from two different perspectives, inspired by the Eulerian and Lagrangian representation of fluid dynamics in physics (Turchin 1998). The Lagrangian perspective considers changes in a moving object’s position. Here, the moving object produces a sequence of position fixes as it moves across space (Figure 2a). GPS tracking is the classic example for the Lagrangian perspective, where at a given sampling rate the GPS receiver measures the object’s position as a tuple of the form \((x, y, z, t)\). By contrast, the Eulerian perspective describes movement as changes in position of moving objects relative to known, fixed locations in space. Movement is perceived as a flux of objects passing by check-points or cordons. Eulerian trajectories are produced by groupe spécial mobile (GSM; a global system for mobile communication) antennas that monitor passing-by mobile phone users (Figure 2b), radio frequency identification (RFID) tag readers that monitor the movement of shopping trolleys, or checkpoints and traffic gantries that monitor the flow of passing cars (Figure 2c). The key difference to the Lagrangian perspective is that here the location of the checkpoints is known and fixed, and the movement is represented in the form of time-stamped sequences of IDs of passing objects. Recent developments in GSM and mobile information and communication technologies (ICT) promote the latter perspective, as more and more applications track moving objects in cordon-structured systems.

**Sampling regime** A conventional study of static geographic variables requires setting a sampling regime; for example, choosing between a systematic sampling raster and scattered focus areas. The very same holds for sampling positions of moving objects, just that here the temporal dimension takes the role of the frame of reference for the sampling. Some movement studies require that the positions of the moving objects be permanently monitored. A GPS tracking device with a preset sampling frequency can deliver just such continuous sampling. Even though a GPS receiver can deliver continuous tracking, where battery power and communication bandwidth are limited (as, for instance, with GPS collars attached to animals in costly capture-release procedures), noncontinuous sampling regimes are used. In movement ecology, where the study of animal behavior is key, fine-grained bursts are often interspersed with longer intervals with much sparser sampling. Another strategy for avoiding
unnecessary depletion of sensor resources is offered by *event-based* sampling. When it is known that the movement performed by the studied actor is of the periodic type, the sampling regime can exploit this knowledge and only record the moving object’s position in the event of a position or behavior change. Finally, in many Eulerian tracking systems, the sequence of position fixes is governed by the times when a moving object happens to pass a check-point. Hence, the samples will come in *irregularly*, depending not only on the movement behavior of the actor but also on the arrangement and density of check-points. Event-based sampling and irregular sampling are closely related to the question whether the observer can enforce a position fix to be taken or not. This distinction is discussed in the next paragraph.

*Active or passive tracking* The distinction between active and passive tracking systems has an influence on how movement is appropriately represented. In *active* tracking systems the control on when and how often position fixes are taken lies in the hands of the observer. For example, when tracking users of mobile phones, an active tracking system can trigger the localization by presetting a sampling frequency or by remotely “pinging” the phone. By contrast, in *passive* tracking systems, the observer has no control over when and how often positions are captured. Again when tracking mobile phone users, in a passive setting the mobile phone’s location will only be logged when the user makes a call or accesses the Internet (so-called call data records or CDR). Clearly, the latter tracking procedure results in trajectory data of much lower quality. However, whereas active tracking is typically limited to rather small numbers of tracked individuals in the low hundreds, the sample sizes possible with passive tracking are almost limitless (Ahas et al. 2009).

*Off-line or real-time* The perspective on movement and how it is represented is furthermore depending on whether the objects must be followed in *real-time* or in an *off-line* mode when the movement is over. For example, air traffic control or a taxi fleet management requires real-time tracking, whereas sports scene analysis can easily wait until the game is over and done with. With respect to choosing a suitable trajectory representation, the key difference lies in the fact that for off-line tracking the movement is over and known in its entirety, whereas representation for real-time tracking must accommodate for an incoming stream of location information packages that immediately after their arrival are already outdated as the object has moved on in the meantime. The database community has addressed such issues and put forward concepts explicitly tailored for storing, managing, and querying moving object data in databases.

Most prominently, Güting and Schneider (2005) introduce the moving object spatiotemporal (MOST) data model for moving object databases (MOD). MOST explicitly aims at representing the current and even future movement of mobile objects in motion *right now*. The key ingredients of the MOST model are so-called dynamic attributes. A dynamic attribute, $A$, changes its value with time automatically, and consists of $A.value$, $A.updatetime$, and $A.function$. For instance, the permanently changing position of a moving car can then be described as pos: $(x: \text{dynamic real}, \ y: \text{dynamic real})$, whereas other car attributes are represented using conventional data types (licence_plate: string). The current position of the car is then represented as an extrapolation from the last known location $A.value$ based on $A.function$ and the progressed time. The challenge lies in finding a good balance between updating costs and acceptable imprecision of the estimated positions. MOST is closely linked to a query language called
future temporal logic (FTL), which allows for expressing queries about future developments. Clearly, extrapolating the position of a moving object into the near future requires a notion of uncertainty. Güting and Schneider therefore argue that a trajectory can also be viewed as a motion plan for the future, introducing uncertain trajectories with an associated bound on the uncertainty of the time-dependent position. When compared against a polygonal query region, uncertain trajectories then allow for uncertainty-based spatio-temporal predicates, such as, for example, “SometimesPossiblyInside” or “DefinitelyAlwaysInside.”

**Obfuscation for safeguarding privacy** Fine-grained individual trajectories are inherently sensitive information. Tracking data may reveal where a person lives, where the person works, and places that person frequently visits. Even though more and more users of mobile ICT devices want to benefit from the various location-based services available, most users do it with severe reservations and acknowledging that these services compromise their personal privacy. The crux with tracking data is that conventional anonymization techniques fail, because personal points of interest such as the home and work address serve as accessible quasi-identifiers allowing for a re-identification of beforehand anonymized records. It is here that GIScience offers a perspective on movement that explicitly aims at safeguarding the user’s privacy. The key idea is to blur the focus of observation when following a moving individual. By definition, obfuscation is the process of deliberately degrading the quality of personal location information (Duckham and Kulik 2005). For many location-based services it may be sufficient to reveal only the current street block a user is in; the precise position of the user is hidden away from the service provider. For example, Figure 2b reveals only that the object is in cell $i$, but obfuscates its precise location. An obfuscated trajectory representation can be based on any combination of the familiar spatial data quality measures – inaccuracy, imprecision, or vagueness. An app searching for the closest petroleum station could hence reveal the user’s position as 250 m off the actual position (inaccuracy), within a neighborhood of radius 500 m around the actual position (imprecision), or as somewhere in between intersections $M$ and $N$ (vagueness).

**Semantic level of interest**

The semantic level of interest constitutes the final dimension having a profound influence on how movement trajectories are represented. Just as static geographic variables are often aggregated for analysis (e.g., household socioeconomic data is aggregated to neighborhood or district level), so movement data are often studied at a wide range of spatiotemporal aggregation levels (Laube et al. 2007). The spectrum ranges from the instantaneous level (fix, vector) through to interval aggregations (move, segment) up to global aggregations (convex polygon and field-based aggregations (Figure 3)).

**Fix** The most primitive spatial expression of movement comes in the form of a time-stamped position, a $\text{fix} \ (x, y, (z), t)$. A fix captures where a moving object was at a given time. This level of aggregation offers itself to studies where the fixes are attributed by some spatial variable, for example, the land-use type the map pins are sitting on. The resulting distributions are then fed into descriptive statistics.

**Vector** Strictly speaking, the above fix is not really a representation of movement, but rather only of static presence. The dynamic notion of the instantaneous level comes in the form of a vector, where the punctual measurement not
only features the position but crucially also has a movement direction (azimuth) and a speed. Note, even though from a conceptual point of view, a vector can indeed be sampled at an infinitesimal short interval, the actual computation of direction and speed typically requires at least two consecutive fixes or even longer intervals.

**Move** Neither the fix nor the vector has a spatial extent. By contrast, a move is defined as the displacement between two consecutive stopping points (Turchin 1998), hence having a spatial and temporal extent. A move can then be represented as a straight-line connector between two consecutive fixes or vectors. A move also has a direction, which can be different from the directions of its constituting vectors. Moves can span very different spatial extents and temporal intervals; they can, for example, represent the displacement of a butterfly moving from one flower to another or residential displacement in geospatial lifelines spanning decades.

**Segment** A segment represents the movement of an object over more than two consecutive fixes. As a geometric primitive it is a polyline, which can self-intersect. Most often segments emerge from a segmentation process, where a list of fixes is divided into meaningful segments according to some quantitative rules. A first natural notion of a segment emerges when tracking data are split into stops and connecting movement segments. Stops can formally be defined in many different ways, for instance, using a lower speed threshold. Further natural segmentation criteria are time of day (morning, noon, afternoon, evening) or the four seasons. Segmentation aims for aggregating several consecutive fixes, vectors, or moves into segments, which are homogeneous with respect to their geometric characteristics (e.g., sinuosity), semantics (e.g., travel mode walk or drive), or even in terms of some properties of contextual information (e.g., on highway or minor road). In some contexts such segmentation is called “semantic enrichment” of trajectories and can be considered a first analysis step (Baglioni et al. 2009). Others explicitly require trajectories to be semantically structured (i.e., segmented) in the first place, and hence to be explicitly separated from raw tracking data (Bogorny et al. 2014).

**Areal aggregations** Finally, in some application contexts the individual moves are less important, but what matters is the global movement footprint, summarized, say, for an entire day, a migration cycle, or even a lifetime. To achieve such a global level of aggregation, all relevant fixes can be aggregated to form an areal representation of the trajectory. GIScience offers a range of concepts for representing the spatial extent of a point set. The minimum bounding rectangle (MBR, also minimum bounding box) is simple and very easy to compute. A little more effort is required for computing the convex hull, or the minimum convex polygon (MCP). Both approaches share the simplicity of resulting in a vector structure that can conveniently be used for subsequent spatial analysis. Given their easy accessibility in many computing environments, field-based density...
Maps or heatmaps are popular representations for the global aggregation level. These typically come as some form of kernel density estimation (KDE), where for every location in a field the fix density is interpolated. “Hotspots” of space-use can then be interpreted as important places for the behavior of the observed individual (e.g., the home and office locations for people, or nest sites or feeding grounds for animals).

It is important to note that MBR, MCP, and KDE all ignore the temporal sequence with which a location was visited in space. It could also be said that they are strictly “spatial” representations of movement, as they only consider spatial proximity of the fixes but not their temporal proximity. However, when studying movement it may very well matter if visits to the same location are temporally clustered or, by contrast, temporally scattered, separated by long temporal gaps. Addressing this issue, density representations were developed that respect the sequence and timing of fixes. For example, the concept of “time-geographic density estimation” extends on traditional KDE taking into account a maximal speed value for modeling the potential path area (Downs 2010). The Brownian bridge movement model (BBMM) goes one step further and has become very popular in animal movement ecology. The BBMM is a stochastic model of movement, where the probability of occurrence in an area is conditioned on the position, sequence, and elapsed time between fixes (Horne et al. 2007). When comparing KDE density surfaces with Brownian bridge based ones, it becomes evident that the latter are much better at representing the pathways traveled in between hotspots.

The road ahead

The arrival of inherently spatiotemporal movement trajectories has challenged GIScience and the spatial database community, both adhering to a rather static view of the world. Initially, using the available concepts for representing movement was logical, but somewhat limited. Polylines trajectories, convex hulls or kernel density maps helped in acknowledging the issues but their static nature remains a mismatch to inherently spatiotemporal movement. A movement trajectory is just simply more than just its static footprint polylines – it involves sequence and rhythm. Clearly, there is progress. Examples include the Brownian bridge movement model (BBMM) explicitly focusing on sequence and timing of the fixes. Or then there is the moving object spatiotemporal (MOST) data model for moving object databases allowing for handling current and near-future positions for real-time trajectory management. The rather sophisticated nature of these two successful examples underlines that there is more complexity to movement data that could be presumed from seemingly simple stringing up of some position fixes. Further challenges arise from the fact that the characteristics and the sheer volume of available movement data undergo dramatic changes. Whereas initial movement analysis studies investigated relatively small datasets of, say, dozens of collared animals, passive mobile phone tracking can easily result in millions of tracked commuters, producing an endless stream of fine-grained tracking data. Up-lifting movement analysis into the era of big and open data requires the theory of trajectory representation to address the following challenges.

- Privacy. Safeguarding individual privacy remains a pivotal issue when tracking people. Even though the increasing pervasion of information and communication technologies is likely to change people’s attitudes towards privacy, it is neither to be expected nor to be wished for that the users’ fundamental disapproval of service providers...
monitoring their activities will go away. Trajectory representations are required that at the same time allow for providing location-based services, but put the control over sensitive movement data back into the hands of the users.

- *Multisensor data.* More and more researchers agree that the behaviors producing movement data cannot be fully understood from only studying the spatiotemporal movement trajectories alone. For that reason, many studies aim for semantically enriching position data with additional concurrent sensory data. This starts with obvious accelerometer and gyrometer data that are easily available from mobile ICT devices, but can also include more specific sensors, tracking, for example, physiological variables of tracked animals (e.g., body temperature, heart rate).

- *Dealing with notorious uncertainty.* Most trajectory representations are based in one way or another on simplifying assumptions that are knowingly incorrect. For instance, many movement analysis techniques are based on representations of linear moves between crisp and precise fixes. This is in stark contrast to our actual knowledge about an object’s location that is most often inaccurate, imprecise, and also vague. Another known aspect of uncertainty lies in what happens in between observed fixes. It is clear that a straight-line connector between two consecutive fixes is a massive simplification and rarely represents where the moving object actually was. BBMM go into a right direction accounting for a stochastic probability of presence. However, when comparing to the simplistic straight-line link, BBMM are computation intensive and laborious in handling. New trajectory representations seek approaches to handle a detailed notion of uncertainty, and also allow this uncertainty information to be carried along into the subsequent analysis process.

- *Conflicting information.* Further representations are required to accommodate for conflicting information about the positions of tracked individuals. In many cases it is clear that a tracked object was moving along a street, but its positions were recorded next to the street due to the tracking system’s measurement inaccuracy. Although there are sophisticated map-matching algorithms that help in relocating obviously incorrect fixes onto the street, such alteration of the raw signal inevitably distorts the geometric properties of the resulting trajectory, and analyzing geometry-based, derived trajectory parameters such as speed or turning angle from the altered geometry can become inappropriate. Novel trajectory representations should be envisaged to handle uncertainty and conflicting information depending on the analysis task at hand.

Further reading

In its broadest sense, representation refers to both a process and a product. The process of representation involves describing, depicting, or portraying something. The product may take a variety of forms, including written, visual, aural, or oral forms, and also products that may be material, symbolic, or both. While representation has a variety of meanings, recent academic work in geography has argued that the term is used in a limited way within the discipline, leading to claims of a “crisis of representation,” and resulting shifts in the theoretical understanding of representation. However, a lasting effect of the recent focus on representation has been a more nuanced understanding of its relationship with power and politics, which continues to be influential within contemporary academic geography.

Representation in geography

Representation has long been at the center of geography as a body of knowledge and as an academic discipline. The origins of the word “geography” – geo, meaning Earth, and graphia, meaning writing – suggest this centrality of representation. “Earth writing” involves the processes of description, depiction, and portrayal. For early geographers, this process happened through oral and written accounts and through images, particularly maps. These maps were visual representations that described and portrayed known, lesser-known, and unknown places and peoples. They served to disseminate knowledge, to assert control and ownership over territory, and to signify civilization and advancement. Maps were not the only way in which early Earth writing occurred, but they are one of the most lasting forms. They clearly show representation both as a product and as a process. The product is the tangible map, while the process is the art and science of translating three dimensions into two and of claiming knowledge and ownership of the territory represented by the map. As geography developed as an academic discipline, geographers began to prioritize a more scientific form of Earth writing. This empiricist emphasis allowed geographers to identify as objective observers and documenters of reality. Representation as process was subjugated to representation as product, where the product served a very particular role. In this more scientific approach to geography, representations were valued for their mimetic quality – in other words, they were believed to accurately resemble “reality.”

While representation has been an important part of geography since its early beginnings, in the late twentieth century it began to take a more prominent position in the discipline. This emphasis emerged in particular from the work of humanistic geographers and cultural geographers. Humanistic geographers were concerned with the ways in which the quantitative revolution in geography had resulted in particular and narrow representations of human undertakings. They argued for a more expansive set of ways of depicting and understanding human activities, motivations, and beliefs. In this way, their critique focused on the limited representations of
human geographies within academic geography in the 1960s and 1970s. These critiques were developed and expanded by “new” cultural geographers such as Denis Cosgrove and Peter Jackson. Cultural geography, one of the longest-established branches of academic human geography, had traditionally placed an emphasis on landscape as its central object of study. New cultural geographers argued that the way in which landscape was understood was too limited. They noted that traditional studies of landscape focused on physical artifacts – for example, cabins, fences, and boundaries (Cosgrove and Jackson 1987). This emphasis on landscape as the tangible, material product of a particular cultural group at a particular point in time ignored or marginalized the broader processes through which landscapes were created, maintained, and altered. Cosgrove and Jackson argued that landscapes needed to be understood as both product and process. In order to develop this perspective, they described the landscape as a text, and sought to interpret this text using methods of literary critique and analysis. They noted the role of humanistic geography in suggesting this potential approach, but wanted to extend the work of humanistic geographers in order to consider landscapes as “configurations of symbols and signs” (Cosgrove and Jackson 1987, 96). Kong suggested that this approach saw the “landscape as a text to be read as a social document” using interpretive rather than morphological methods (Kong 1997, 178). The description of landscape as text brought questions of representation to the heart of cultural geography from the 1980s onward. This approach transformed the study of landscape, but it also extended beyond cultural geography in a significant way. The “cultural turn” compelled other subdisciplines in geography, such as cartography, social geography, political geography, historical geography, and economic geography, to ask important questions about representation. In many cases, such questions involved significant challenges to dominant epistemologies and methodologies within these subdisciplines, such as recent efforts to develop a postcolonial economic geography. In some instances, the meaning of representation has remained stubbornly resistant to challenge. Within electoral geography, for example, the term “representation” continues to be associated with the practice of democracy and with measuring the extent to which elections may be described as fair and proportional.

Earlier work on representation, particularly within humanistic and cultural geography, tended to focus on landscape and place. As interest in representation gathered momentum, the relationship between representation and space came under scrutiny. One approach suggested that space could be understood in the manner of a text within literary theory, positing space, particularly social space, as a text that has authors and is interpreted by readers. This approach was similar to the treatment of landscape as text in new cultural geography. An alternative approach argues that space and representations are mutually constitutive, that representations help to construct space, and that space in turn shapes and challenges representations. The second approach was influenced by the work of French theorist Henri Lefebvre. In his discussion of how space is produced, he distinguished three different components, which include “representations of space,” “representational spaces,” and “spatial practice” (Lefebvre 1991). Lefebvre described representations of space as verbal signs to represent the dominant forms of space in a society. In contrast, he described representational spaces as the nonverbal signs and symbols of the inhabitants who lived in, rather than designed, planned, and managed, a particular space. Lefebvre’s conceptual triad, which linked
representation and space together, has been used by geographers to discuss a wide range of topics, from cartography to urban unrest.

The crisis of representation

The “crisis of representation,” in geography and in the academy more generally, is a challenge to the belief that representations as products are accurate portrayals of that which they purport to depict. It draws from the work of theorists such as Michel Foucault, Roland Barthes, and Jacques Derrida who, in a variety of ways, showed how the representations we create and use are incomplete and contested and always subject to challenge and change. These theorists focused primarily on language, showing how the meanings of words are unstable, uncertain, and contestable, despite a widespread belief that words accurately portray both tangible and intangible things in a way that permits a shared understanding. Foucault introduced the concept of discourse, which he defined as a system of representation or as groups of statements about a particular topic at a particular time. Barthes drew on semiotics to highlight the rupture between the signifier (e.g., a word) and the signified (that which the word purports to represent). From Derrida, geographers imported the practice of deconstruction, which involves challenging specific positions, particularly by looking for what got displaced in the process of securing those positions (Doel 2005). While different in focus and emphasis, the work of these and other theorists has served to challenge the focus on representation as a product, and instead to direct attention to representation as a (partial) process. Geographers have drawn inspiration from this work in a variety of ways.

The crisis of representation emerged in studies of cartography from the 1980s onward. In his plea for an “epistemological shift” in the nature of cartography, J.B. Harley drew inspiration from Foucault and Derrida to challenge the idea of maps as “objective” or “scientific” (Harley 1989). Instead, Harley argued for the use of deconstruction in order to better understand the power of maps. His argument was further developed by Denis Wood and John Fels, whose deconstruction of the power of maps showed the ways in which maps use systems of signification to serve interests and to mask those interests. As Wood later commented, he began to see maps as (partial) texts and narratives. “Only cartography’s general reference map pretends otherwise, has the hubris to present the world, you know … as it really is, as if to say Europe, … the real deal, now and forever” (Wood 2013, 29). This led to a recognition of maps as social constructions and as practices (Kitchin and Dodge 2007).

The work of feminist geographers also contributed to a critique of representation in geography. Early work challenged the belief that the “human” in human geography was inclusive, pointing out the various ways in which women’s lives and experiences were not considered or included in geographical research. Later, Gillian Rose went further, arguing that geography was masculinist because it claimed to be universal while ignoring women’s experiences. She suggested that masculinism had shaped what kinds of research and knowledge were validated, how research was carried out, and how research findings were presented within geography (Rose 1993). Rose included new cultural geographers in her critique, claiming that attempts to construct landscape as text employed masculinist ways of seeing and knowing and served to support the idea of an all-seeing and all-knowing authority. As feminist geographies developed, they placed considerable emphasis on both representations and representational processes. In particular, the work of feminist geographers
showed the silences and absences at the heart of the construction of geographic knowledge. This broader approach has been used to highlight other exclusions, for example in relation to issues such as race, sexuality, and disability. Feminist geographers also directed attention to the power relations involved in processes of representation, and instigated a more reflexive, self-consciously subjective approach to knowledge generation and knowledge dissemination.

The identification of a crisis of representation in geography also resulted in attempts to broaden the methods and means of representation. Geographers have engaged with and experimented with alternative forms of representation, including art, photographs, literature, music, film, documentary, and dance. In some instances, this has resulted in the recognition of different forms of representation, such as fiction or comic books, as sources of geographic knowledge. In other instances, it has involved alternative approaches to research, for example using visual methodologies. It has also involved experiments with different forms of representation, for example using dance, although this has more recently been described as “more than” or “non”-representational geography.

The crisis of representation was initially associated with postmodern or poststructural perspectives within geography. Critics of postmodern and poststructural approaches often claimed that these approaches resulted in a relativism that made it difficult to make judgments or identify different levels of significance or importance. This critique persists. In recent years, non-representational geographers have developed alternative critiques of representation as understood in geography. In particular, they associate representation with social constructivism, and argue for a broader understanding of the term that focuses on practices and on relational analyses (Anderson and Harrison 2010). In these ways, a crisis of representation continues, although the reasons for this crisis vary. The scrutiny of representation, and the insistence on representation as a process as well as a product, have had an important impact on geography.

**Representation, power, and politics**

The renewed interest in representation that began in the late twentieth century has had a lasting impact on the discipline of geography. In particular, the focus on the process of representation – on who speaks for whom, and in what form – has resulted in a re-examination of the history of the discipline, and an interrogation of its means of knowledge construction and its methods of research.

The history of geography came under particular scrutiny from the 1970s onward, from geographers concerned with the ways in which representations of the discipline’s history obscured its links to broader questions of power and politics. Brian Hudson (1977) highlighted the intimate link between the growing institutionalization of geography as a subject in European universities, and European imperial and colonial practices. Hudson’s was an early intervention, but later interventions made more use of the work of Edward Said, particularly *Orientalism* (1978). *Orientalism* uses an approach known as colonial discourse analysis, which involves analyzing discourses produced by and about the colonial period as a means of examining how colonial power operated. Said examined the discourses (particularly texts and images) that the West (or Occident) produced of the East (or Orient) in the imperial and colonial periods. He showed how the Orient was effectively a European invention, albeit an invention with material consequences. The invented Orient served as the other for Western European powers, and also
provided a justification for the ongoing practices of imperialism and colonialism. Inspired by Said, geographers have since examined the ways in which colonized or marginalized peoples and places were and continue to be portrayed, drawing attention to the assumptions that underpinned geographic discourses during the colonial period and to the absences in these discourses, such as the accounts of local people or women. In these ways, geographers interested in the history of the discipline have interrogated the relationship between colonial geographies as particular forms of representation and broader structures of power. This is sometimes described as a postcolonial approach. Postcolonial approaches are concerned with representation as both process and product, seeking to show the colonial power relations at work in the processes of producing and interpreting particular representations.

Postcolonial approaches have also been influential – together with feminist and poststructuralist approaches – in raising questions about the power relations that influence the construction of geographic knowledge as a form of representation. Each body of work has a slightly different focus. Feminist theory highlights the masculinist nature of knowledge construction in geography. Postcolonial theory shows the extent to which geographic representations were (and still sometimes are) Eurocentric and excluded the perspectives of those who were colonized. Poststructuralism challenges metanarratives, which claim to explain the world in singular ways, such as Marxist geographies, and also challenges concepts of objectivity, rationality, and truth. Despite these different emphases, these approaches share a concern with the processes through which geographic representations are constructed and validated. The concerns raised created the possibility for constructing geographic knowledge in new ways, for example, indigenous geography, which has emerged since the 1990s. It is influenced by postcolonial and poststructural thought in particular, and has a number of priorities. Indigenous geography aims to create a space for research that engages with indigenous issues, some of which are distinct to indigenous communities and some of which are shared with a wider population. It seeks the “decolonization” of geography as an academic discipline, which includes recognizing the very different forms of geographic knowledge produced by indigenous peoples. It also demands research by and with, rather than on, indigenous peoples (Shaw, Herman, and Dobbs 2007).

The focus on questions of power and politics in relation to representation has also influenced how research is conducted within geography. In particular, it has challenged the idea of researchers as objective, and it has shown the need for the process of research to be more participatory and engaged. Feminist geographers have been to the forefront of these developments, and their work has directed attention to the politics and power relations present in research with marginalized, minority, or less powerful groups of people. This careful scrutiny of how representations are constructed, portrayed, and received is now a feature of much qualitative, and some quantitative, research within human geography.

Conclusion

At the start of the twenty-first century, questions of representation no longer receive as much attention within the discipline of geography as they previously did. In many ways, the critiques of representation that developed as a result of the crisis of representation have become mainstream within the discipline. As a consequence, representations are now generally understood as processes as well as products, and both process
and product are interrogated when representations are researched and analyzed. Instead, attention has turned to the limits of representation, particularly in relation to embodied or affective experiences that are preverbal. However, these nonrepresentational or more than representational geographies continue to rely heavily on text and images in order to make their arguments, albeit from a perspective that is cognizant of the power relations, politics, and incompleteness that mark any representation.

Marxist feminists in the 1970s discussed the role of reproduction and the contribution of women’s unpaid work to capitalist accumulation. In doing so they challenged the idea, commonly held by Marxists, that unpaid labor was unproductive labor as if value was only generated through waged labor in the public domain. Although there were various formulations, intense debates took place around domestic labor and wages for housework. The emphasis was very much on labor benefiting the male breadwinner with no attention paid to childcare and rearing or to the use of paid labor in the household itself, issues that would subsequently become significant in studies of reproduction. By the end of the decade, many feminists concluded that the discussion was too simplistic and narrowly focused on the role of women's domestic work in relation to the needs of capitalism and that it did not adequately explain women’s subordination in industrial capitalist, socialist, or “third world” societies.

In gaining a more complex understanding of women’s subordination in society, three different categories of reproduction were outlined (Mackintosh 1981, 11–12). The first concerned the reproduction of labor, which includes the production of people, involving their biological production, care, and socialization of children, as well as maintenance of adults throughout their lives and over generations. A second, narrower meaning covered human reproduction centering on marriage and kinship and thus issues of the social organization of fertility and sexuality, leading to the argument that it was women’s domestic responsibilities and the sexual division of labor in the household that weakened their participation in the wage economy. The third meaning of social reproduction referred very broadly to the ways in which the relations of production are recreated and perpetuated.

Historically, dimensions of social reproduction, such as childcare and responsibility for dependents, including the ill and the old, were understood as being played out differently in middle- and working-class families, as well as with changing gender relations and greater public and state responsibility for social reproduction in the twentieth century. Racial differences in studies of social reproduction, on the other hand, were not considered (Glenn 1992). In the United States, racialized and ethnic minority women, such as Mexican, Chinese, and black Americans, had historically been assigned distinct responsibilities for reproductive labor and performed the most menial tasks, whether in the household or outside of it. In the course of the twentieth century, there was a shift for these women from working in households to performing low-paid reproductive work in institutional sites, for example, as nursing aides (Glenn 1992).

By the 1990s, as migrant women increasingly came to fill the growing demand for reproductive labor in North America, Europe, and Southeast and East Asia, global analyses of an international division of reproductive labor were developed (Truong 1996). Recourse to paid domestic work was seen to be due to the inadequacy or withdrawal of welfare services, the increasing participation of women in paid work, and the inflexibility of the sexual division of labor in the household.
Although the use of the concept of social reproduction had declined since the 1980s, often displaced by other terms such as “care” (Kofman 2012), the assault on public provision and declining support for social reproduction and work security has led to a renewed interest in the concept and fresh directions of study. Feminist geographers have focused on the new forms of governance or social contract (new constitutionalism) and how local-global relations have impacted on the struggle over reproduction and distribution of risk, characteristic of neoliberalism (Bakker and Silvey 2008). Unlike previous analyses, where production and reproduction were treated largely as separate spheres, the two are conceptualized as structured practices that unfold in dialectical relation with each other, mutually constitutive and in tension. Yet while some have sought to dissolve the boundaries between work and home and leisure or life’s work as the new “contemporary habitus ... of permanently mobilized bodies in new kinds of technologies of power” (Mitchell, Marston, and Katz 2003, 429), others have questioned to what extent this nexus applies beyond the world of the professional middle classes and to the working class and immigrants with precarious lives.

Social reproduction involves a range of activities for its maintenance and reworking. Two key sites, where the needs of capital accumulation and social reproduction come together, are the family and the state (Bakker and Silvey 2008). While marketization, privatization, and informalization have strongly characterized trends in contemporary social reproduction, the state sets the parameters within which it occurs and may support or offload the burdens and costs of reproduction onto the family. Through its family and social policies, the state may sustain the social reproduction of the middle classes and the deserving working poor while withdrawing support from the increasingly demonized undeserving poor (unemployed, disabled, homeless, migrants), who are forced to turn to charitable provision such as food banks. Thus the crisis of social reproduction, although more acute in the Global South, is also affecting large numbers in the Global North who face inadequate access to basic necessities such as food, heating, and shelter. In many African countries the crisis is further exacerbated by the prevalence of HIV/AIDS (human immunodeficiency virus/acquired immune deficiency syndrome), high rates of mortality among younger populations, and orphaned children, which place even more demands on women’s time and care-giving. The crisis in reproduction has been defined as a critical gap between outflows – domestic, affective and reproductive – and the inflows that sustain health and wellbeing. It is suggested that resources required and their absence could be measured using qualitative and quantitative methods, such as time-use surveys, which would provide the tools for recognizing the value and costs of domestic work, as has been recognized recently in Venezuela, where mothers are now eligible for pensions.

Of course, individuals and households deploy different means to counter depletion. In order to ensure the social reproduction of their households, women are working longer hours and individuals and families are migrating, both within countries and internationally. Hence, social reproduction is also undertaken across borders, resulting in the international transfer of physical and emotional labor. Social reproduction offers us a lens through which to examine the ways in which inequalities between women and men, classes, and racialized populations, are reproduced, intensified, and transformed. To these social divisions we need to add legal status, which stratifies the rights between citizens and noncitizens to social reproduction through
conditionalities regulating transfer payments and access to provision, such as childcare, education, and health.

Over the past 15 years, studies of social reproduction have sought to bring together the variety of everyday activities and resources required to sustain individuals, households, and communities and policies promoted by states and international organizations. However, this endeavor also demonstrates the difficulty of holding the tension between an emphasis on governance and structural processes, on the one hand, and on the other an engagement with struggles over social reproduction in terms of class, gender, race, and citizenship at the everyday level in communities, within states, and across borders.

Resampling, raster

A-Xing Zhu
University of Wisconsin, USA

Resampling is a process of transferring an existing raster dataset to a new raster dataset of the same data type by computing a new pixel value from the values of the corresponding pixels in the original dataset. There are two typical scenarios for which resampling of a raster is required (Tobler 1988). The first one is the mismatch of pixel resolution between two raster datasets that are to be overlaid (map algebra) for geographic analysis (Figure 1). In Figure 1, raster A has a higher spatial resolution than raster B. Direct overlay of these two raster datasets is not possible because each pixel in raster B corresponds to many pixels in raster A. Raster A must be first resampled to the same resolution as that of raster B. Furthermore, resolution mismatch often results in scale incompatibility, which leads to modeling bias. Thus, incompatible datasets need to be made compatible, and one of the techniques to do so is resampling (Zhu 2008).

The second scenario is when a raster dataset is converted into a different coordinate system (Figure 2), which often occurs in remote sensing image processing (Lillesand, Kiefer, and Chipman 2007; Richards 2012). Under this scenario, after coordinate transformation (registration) the pixels in the transformed raster no longer have the “squared” shape of the regular raster (Figure 2b). This is problematic for the raster data model because under this model the shape of a pixel is implicit, which means that the coordinates of the pixel shape are not explicitly stored and the shape is assumed around the center of the pixel for a given resolution. If we simply assume the pixel shape from the center, then the area represented by this pixel is no longer the same as it was before (see the insert in Figure 2). In addition, the center of the pixel in the new raster may not exactly match the center of the pixel in the original raster for a number of reasons, including different pixel size and different starting coordinates of the new raster (Tobler 1988). As a result, the grid of the new raster and the grid of the transformed raster may line up in the way shown in Figure 2c. So, to populate the new raster dataset, one needs to perform resampling.

There are several methods for determining the pixel values in the new raster from those in the original raster, including the nearest neighbor, majority, and averaging methods, and bilinear and cubic convolution interpolation. Nearest neighbor method selects the value of the pixel in the original raster whose center is nearest to the center of the pixel in the new raster (Figure 3). The nearest neighbor approach does not change the values of pixels from the original raster, thus the pixels in the new raster always have the same values in the original raster. For example, the value of 10 in the original raster will always be the value of 10 in the new raster. It will never be 10.5 or 11. Due to the fact that the values of the pixels in the
RESAMPLING, RASTER

Figure 1  Resampling to correct the resolution mismatch between two raster datasets for overlay.

new raster remain the same, the nearest neighbor approach is a good choice in resampling for nominal or ordinal data, where each value represents a class, member, or classification (categorical data such as a land-use, soil, or forest type).

The majority method takes the modal value (the most frequently occurring value) from the original raster within the neighborhood defined by the center of the pixel in the new raster. This method is used for resampling of categorical data (such as land-use, soil, or forest type). It is often used when resampling a fine resolution raster to a coarser raster, in which the neighborhood is often defined to be the pixel size of the coarser raster (Figure 4). The averaging method is very similar to the majority method except that it takes an average of the pixel values from the original raster in the neighborhood and it is used for resampling of interval or ratio data types (such as temperature, rainfall). The values in the new raster will be different from those in the original raster due to averaging.

Bilinear interpolation uses the values of the four pixels from the original raster whose centers are nearest to the center of the pixel in the new raster to determine the value of the pixel in the new raster (Figure 5). The new value for the pixel in the new raster is a weighted average of these four values, adjusted to account for their distance from the center of the pixel in the new raster. Due to the fact that the value for the pixel in the new raster is a weighted average of the original values, bilinear interpolation produces a value which does not necessarily
exist in the original raster. For example, the original raster may just contain all integers, but with bilinear interpolation the new raster could contain values with decimal points such as 10.2. Since the values for the pixels in the new raster are calculated based on the relative position and the values of the pixels in the original raster, bilinear interpolation is preferred for data that are continuous in nature, such as elevation, slope gradient, pollution level, and soil organic matter content. *Cubic convolution interpolation* is similar to bilinear interpolation except that the weighted average is calculated from the 16 nearest pixel centers and their values (Figure 6).

In summary, the values produced from resampling are an approximation, even if the values in the original raster are observations, because resampling is essentially a spatial interpolation process, which estimates the new values from the values in the original raster. In this sense, raster resampling often results in loss of accuracy.

Residential mobility

Si-ming Li
Hong Kong Baptist University, China

Residential mobility encompasses residential moves of all kinds; however, given that longer distance moves are usually referred to as migration, the study of residential mobility is often restricted to moves within a metropolitan area. Ever since the publication of Peter Rossi’s landmark text *Why Families Move*, the proposition that residential mobility is a spatial process through which households adjust housing consumption to changing needs and circumstances has caught the attention of generations of geographers, sociologists, and economists alike (Clark and Dieleman 1996). The main hypothesis is that moving is costly in both monetary and psychological terms, and a move to restore the equation between housing needs and consumption will be considered only if the stress that the household has to endure by remaining in the same residence is beyond a certain triggering point. But whether a move will actually be conducted depends on whether an appropriate vacancy is located after a more or less exhaustive search. The notion of family life cycle, which is closely related to the housing needs and aspirations of a household and which correlates with the householder’s position in the job ladder, assumes particular importance. In the United States and other developed countries, it has often been argued that households move from renting an apartment in the central city to owning a suburban home in anticipation of the arrival of offspring to the family. From then onwards, the propensity to undertake further moves declines significantly. However, with children moving out to form their own households and with declining physical strength of both spouses, a move back to apartment living is not unusual for older families (Clark and Dieleman 1996).

Over the past several decades, in Western societies in particular, the family institution has been subject to major challenges. Unregistered and shorter term partnership is now an accepted part of life, and divorces and remarriages are becoming frequent. Such major life events are almost invariably accompanied by residential moves. Correspondingly, recent studies on residential mobility focus on the life course of individuals rather than households and analyze moves in association with complex partnership trajectories as well as the timing and sequencing of careers, such as education and jobs that parallel household and housing careers. The analysis of parallel careers often incorporates interregional and international moves and blurs the distinction between intra-urban and longer distance migration (Michielin and Mulder 2008). Perhaps paradoxically, relatively fluid partnership could have resulted in greater reliance on the extended family for personal support, be it financial, psychological, or social, especially at time of crisis. This in turn has major implications for residential decisions and change. Indeed, residential decisions are highly contextual, contingent upon the myriad of events that bear on an individual’s life course, including developments external to the individual and the family. For instance, in the United Kingdom, World War II delayed new family formation and hence home purchase. On the other hand, the postwar baby boom fueled the demand for suburban homes, resulting
RESIDENTIAL MOBILITY

in accelerated suburbanization (Michielin and Mulder 2008).

From an economic perspective, barriers to residential mobility are tantamount to barriers to attaining Pareto optimality, or the state that the utility of an individual cannot be improved without causing at least one other individual to be worse off. The obvious policy implication then is to find ways to reduce the costs involved in the housing transaction, including the cost of house search. Of particular importance is the reduction of the information asymmetry between sellers and buyers by providing more adequate and readily available and accurate information. In the United States, where housing access is largely market based, residential moves take place quite frequently. An oft-quoted figure is that one fifth of households move every year, although the residential mobility rate appears to be declining. The high mobility rate is often seen by economists as an indicator of market efficiency, although this does not mean that constant mobility is desirable for individuals, families, or the communities to which they contribute.

Until recently, in many European countries a high proportion of households have resided in social housing (Clark and Dieleman 1996). For such households, policies and regulations governing access to and management of social housing to a significant extent delineate the housing opportunity set. Gatekeepers also play a key role in structuring residential moves. In Britain in the 1980s, under the “right-to-buy” policy of Margaret Thatcher local governments sold the bulk of council housing to sitting tenants at heavy discounts, a major purpose of which was to free up mobility constraints. Yet, homeownership inhibits mobility. Also, because of the concentration of young, unemployed, and single-parent households, the mobility rate in the residual social rental sector is likely to be higher than in privatized council housing.

Massive transfers of ownership of public-sector housing to sitting tenants have also taken place in China and other former centrally planned economies. In the Chinese case this has been accompanied by unprecedented urban expansion and proliferation of sprawling suburban housing estates. Simultaneously, there have been wholesale redevelopments of inner-city neighborhoods, resulting in forced relocation particularly of older families to remote and unfamiliar suburban locations. A switch to market-based housing provision led to an increase in the residential mobility rate in Chinese cities in the late 1990s and early 2000s (Li 2005). However, the attainment of homeownership by large proportions of urban dwellers would have dampened further mobility. Residential decisions depend on prior migration experiences. Over the past two to three decades in China hundreds of millions of rural migrants have flocked to the major metropolises. Yet, the hukou or household registration system denies migrants permanent residential status in the city of current domicile; in many respects they are forever transients and subject to discrimination of all kinds, particularly in the job and housing markets. Split families are common – children are often left behind in the home village to be taken care of by the grandparents while the parents are in constant search for job and shelter in the host city. The residential mobility rate among the migrant population is high. However, this high mobility is unlikely to signify their capability to respond proactively to changing spatial opportunities over the urban area.

Clearly, high residential mobility might have nothing to do with economic efficiency. Furthermore, recent developments, more specifically the global financial crisis triggered by the collapse of the subprime mortgage market in the United States in 2007 – 2008, call into question
the unfettered faith in the market underscoring neoliberal reforms. Deregulation of the financial sector and the consequential financialization of the global economy have substantially amplified economic and housing market cycles. In what has been called the Great Recession, banking giants such as Citi were saved only with the heavy injection of taxpayer money. Individual households whose wealth evaporated overnight were not so fortunate, however. Millions of American households had their homes foreclosed and were forced to relocate. Others who would like to move to a more affordable residence because of unemployment or declining incomes were spatially trapped because the proceeds from selling the existing home could not cover the outstanding mortgage.

Within an urban area, residential location and relocation reflect differential spatial growth, especially between the central city and suburbs and sociospatial differentiation over the metropolitan area. In the United States and other countries characterized by fragmented metropolitan governance and local governments’ dependence on the property tax as the major source of income, the out-migration of high-income families to the suburbs and the consequential filtering down of central city homes and neighborhoods was a major cause of the fiscal crisis of the state, particularly the local state, in the 1970s. The central city–suburb schism is closely related to the notion of spatial mismatch between housing and labor market outcomes. The extent of spatial mismatch is particularly acute in US cities where African Americans are trapped in deteriorating inner-city neighborhoods amidst rapid suburbanization of employment. Ironically, the “flight to the suburb” by whites also provides opportunities for expropriations of rent gap, that is, the difference in rent under the current dilapidated conditions and potential rent upon refurbishment, by real estate developers through the gentrification of selected inner-city neighborhoods into citadels of high-income professionals, who are attracted to the city’s entertainment and cultural amenities.

Residential mobility is also related to neighborhood stability and change in some other ways. For instance, within a given neighborhood a high mobility rate is indicative of the lack of neighborhood satisfaction as well as community cohesiveness and attachment (Clark and Ledwith 2006). Lively engagement among long-time residents is often praised as a way of life that policymakers should try to preserve. Urban renewal projects in the United States in the 1960s and 1970s and more recently in China displaced hundreds of thousands of households from inner-city neighborhoods; invariably, this resulted in the severance of long-established ties and instantaneous evaporation of valuable social capital and aggravated the plight of the socially deprived. However, the absence of residential mobility does not necessarily imply health for the community. Instead, it could as well mean neighborhood aging and declining vitality. The decline and even absence of young families in a neighborhood means that schools and playgrounds are rendered redundant. At the same time, the migration of young families to outlying districts where good schools are lacking might necessitate unpleasant long-distance commutes for young pupils. Moreover, the inability to move out of crime-stricken poor inner-city neighborhoods contributes to the development of a culture of poverty and hence the persistence of inequality across generations. Experiments have been carried out in the United States to provide opportunities to low-income black families to move to higher status suburbs in order to generate gains in social integration, employment, and earnings for more marginalized populations (Rosenbaum, Reynolds, and Deluca 2002).
RESIDENTIAL MOBILITY

Echoing the experimental findings is evidence of increasing fluidity in residential patterning among minorities in American cities. Of course, these social engineering programs carry risks and ethical questions about the choices and agency of participants; those involved could also confront immense challenges, not least the continuing prejudice against ethnic minorities in new neighborhoods.

The study of residential mobility has occupied an important place in urban geography and cognate social science disciplines. Much of the literature is related to the matching of households with divergent needs and wants to housing of various kinds and in different locations within a metropolitan area. The recent adoption of the life-course approach has opened up a whole new front on residential mobility research, which contextualizes residential moves to events not only pertaining specifically to the individual and his or her family but also to developments that have taken place in the broader geographical and historical setting. The life-course approach to some extent has blurred the distinction between the study of intra-urban and longer distance migration.

Residential segregation

Steven R. Holloway
University of Georgia, USA

Residential segregation occurs when people who identify, or are identified, with different social groups live in different sections of cities. Segregation characterizes contemporary cities and has a long historical precedent. Ancient Sumerian city-states were structured by a rigid social hierarchy reflected in distinct social orderings of urban space. The hierarchy's highest tiers occupied the city's central districts, often associated with the seat of military-religious power. Cities in Medieval Europe were socially organized on the basis of craft – producers of similar goods lived in the same areas of the city. Cities of early modern Europe pioneered another innovation in residential segregation – the ethno-religious ghetto. Jews were needed in Venice, Italy, by Christian merchants to handle financing (i.e., money-lending) prohibited by the Catholic Church, and in 1516 were forced to live in a city district, surrounded by canals, that had formerly been a foundry. The practice of forcing Jews to live in their own districts, often surrounded by walls with gates locked at night, spread throughout many other European cities where Jews lived in significant numbers, and persisted well into the middle of the twentieth century.

Urban residential segregation should be understood as a verb – a set of actions perpetrated on one identified group of people by others who possess more power (e.g., Christian Venetians segregated Jews into the ghetto; African Americans were segregated into racial ghettos of industrial cities; South Africans were segregated into apartheid settlements). The sociospatial patterning of the city that resulted highlights segregation as a noun. Throughout urban history, segregation has existed as both verb and noun – as a power-laden process and as a map-able pattern.

Global perspectives on residential segregation

Carl Nightingale (2012, 4–5) powerfully examines the techniques of segregation that were developed across time and space to support colonial European efforts in which he includes the United States and Canada. He “asks us … to consider not only the idea that residential color lines have proliferated across the world but also … that such movements to segregate cities spread because they were interconnected.” Those responsible for creating and maintaining urban racial residential segregation were successful because they developed savvy institutional connections in a wide range of governments and in the modern capitalist real estate industry. Critically, they were able to spread ideas and tactics through global networks of intellectual exchange that included books, lecture circuits, international conferences, and a suite of professional journals, newspapers, and popular magazines. The key insight is that racial residential segregation over the last several centuries is global in scope and yet reflects the specificities of each colonial society in which it became embedded.

We have seen over the last several decades a renewed period of economic globalization that affects residential segregation. General trends that characterize globalization include
interconnected financial markets that circulate at ever-increasing speeds, downscaled governance necessitated by federal devolution, deepening social polarization marked by increasing economic inequality, and increased competitiveness efforts between cities as they struggle to survive. The spatial imprint of globalization on cities is seen in the emergence of new citadels that cater to global financial elites and the development of exclusionary enclaves, often associated with invigorated gentrification. These features are offset by growing immigrant enclaves, old and new (often now found in the suburbs), transformed working-class neighborhoods devastated by the global financial crises, and new concentrations of poverty in older suburbs. Many of these spaces are segregated in new ways, including most prominently by class. Ironically, competitiveness rhetoric fetishizes diversity in urban spaces, using terms like “social mix” and encouraging of alternative sexuality (visible gay and lesbian) presences. Creative city proponents have long argued that cities can improve their competitiveness in the global arena by remaking themselves to be more attractive to folks who work in knowledge- and ideas-based industries. There is now concern that such creative class populations are increasingly living in segregated neighborhoods. Concerns are also growing about increased levels of economic segregation, fueled by both the isolation of the poor and wealthy from other segments of society.

Racial segregation in the United States

US cities, especially those in the industrial heartland, became extremely segregated by race in the middle decades of the twentieth century. While the causes are complex and dependent on conditions in the specific city, several themes recur. First, the great migration of blacks from the South brought millions of migrants, in pre- and post-World War II phases, to northern and Midwestern cities, mostly in inner-city neighborhoods that became almost completely segregated by race.

Second, segregation was imposed upon African American migrants as they faced extreme and often violent forms of systemic discrimination, including their explicit exclusion from residential areas where whites lived. The means of discrimination were both direct and indirect and simultaneously personal and institutional. Private actions, discriminatory market processes, and explicit governmental policy produced segregation. The result was extreme: whites and blacks lived completely separate lives. Many cities where black migrants were most segregated had also housed innumerable European immigrants in the decades just before and just after the turn of twentieth century. While immigrants also faced discrimination and lived in segregated neighborhoods, the magnitude of segregation experienced by black migrants far exceeded that experienced by European immigrants.

Third, because of multilayered discrimination experienced in labor and housing markets, many black residents of segregated neighborhoods were also poor – African American neighborhoods like Chicago’s Bronzeville, Cleveland’s Fairfax, New York’s Harlem, and Atlanta’s Sweet Auburn housed great concentrations of poor migrants. Later, after the ravages of early post-World War II urban renewal and highway building programs, racial ghettos were often spatially anchored by isolated and dense public housing. Neighborhoods proximate to the older black ghettos transitioned amidst great interracial conflict and anti-black violence because the black population of the ghettos swelled during the second wave of the great migration. White flight describes the process whereby most or all white residents would move en masse
away from neighborhoods when black residents would move in. Whites seeking to leave were greatly assisted by energized suburbanization and the housing construction boom of the 1950s and 1960s. Newly developed areas used a wide array of tactics to stem the expansion of the ghettos and maintain white segregation of the suburbs.

Civil rights struggles in the 1950s and 1960s altered the nature of discrimination faced by African Americans in cities across the United States. Some of the most explicit tools used by financial institutions, city leaders, and governments at multiple levels were either ruled illegal or rendered so by new laws that purported to guarantee the housing and economic rights of African Americans. By the end of the 1970s, black Americans began moving out of institutionalized ghettos and into nearby and suburban communities. Racial panic followed and processes of white flight increased in intensity.

Causes of segregation in the United States

Vigorous debate swirls around the causes of residential segregation, especially after the enactment of civil rights laws in the 1960s and 1970s. To what degree does racial residential segregation remain a cause for substantial social concern? If people simply live where they feel most comfortable and can afford, then should it matter if different groups choose to live in different parts of the city? Is not this natural? It is useful to break this down into facets of the debate.

First, housing is very expensive and costs vary widely across neighborhoods. Groups whose members have fewer economic resources will, on the average, concentrate in less expensive neighborhoods. While income and wealth differentials account for some portion of observed patterns, racial segregation levels exceed what we would expect based on economic differentials alone.

Second, the question of choice partly depends on the myth that housing markets function like abstract economic models of efficiency and perfect information. If housing markets function as predicted by normative economic theory, then residential segregation simply reflects rational choices made by informed housing consumers. This notion avers that all groups, majority and minority, prefer to live in neighborhoods with other members of their group. A neighborhood’s population can shift rapidly from majority to minority once the minority share of the population exceeds a “tipping point,” somewhere between 10 and 20%. This shift represents only the preferences of current and potential residents for an acceptable neighborhood racial composition. If the minority share gets “too high” for the majority group, current residents will move out and potential residents will select different neighborhoods.

Research demonstrates that while most social groups show some own-group neighborhood preference, only the preferences of the majority matter. The Multi-City Study of Urban Inequality (MCSUI) demonstrates that blacks typically prefer racially integrated neighborhoods, whereas whites typically prefer neighborhoods with no more than a trivial share of minorities. Thus, racial residential segregation can result only from the preferences and choices of white residents, even when minority groups do not prefer segregated outcomes.

Third, questions about discrimination and racism remain central to causal debates. The historical literature clearly shows that a wide range of discriminatory actions produced deep racial residential segregation: explicit and implicit,
RESIDENTIAL SEGREGATION

private and public, individual and collective. While few scholars would argue that segregation was not produced and imposed, historically, by racism and discrimination, some argue discriminatory processes no longer characterize contemporary cities. To what extent does discrimination continue to exist and, if present, to what extent does it produce residential segregation? Several studies demonstrate that minorities more frequently experience disparate treatment in housing market transactions. These studies use a carefully matched set of potential renters and homebuyers who respond to advertised housing offerings. While the magnitude of disparate treatment has declined since the 1970s, black and Hispanic testers are treated less favorably than white testers.

Minority consumers accuse financial institutions of ongoing unfair treatment. Until the late 1960s, mortgage-lending institutions openly practiced the spatial discrimination known as redlining, where they would either refuse to issue loans to minority borrowers for homes in minority neighborhoods or they would do so with extremely harsh financial terms. Even after key civil rights legislation outlawed these practices in the late 1960s and 1970s, lenders systematically deprived minority borrowers and minority neighborhoods of capital. In an intensely ironic twist, lenders began to predatorily target minority borrowers and their neighborhoods with new, evermore complex loan products designed to be sold quickly on the secondary mortgage market. These loans were designed, in part, to circulate quickly in global financial markets without regard to the fate of borrowers and their neighborhoods. Such predatory lending ramped up through the late 1990s and middle 2000s. When the speculative housing price bubble of the early 2000s burst and the global economy stalled, housing values plummeted and borrowers saddled with unrealistic loans defaulted in large numbers. The effect was to strip equity and wealth from vulnerable communities. Mortgage defaults both contributed to and resulted from the globalized financial crisis. Predatory lending was both made possible and intensified by racial residential segregation. The mortgage default crisis was concentrated in and had its most pernicious effects in segregated minority neighborhoods.

Impacts of segregation

Residential segregation creates a variety of impacts. Groups that voluntarily segregate do so for perceived benefits. For example, wealthy whites segregate because exclusivity is perceived to maintain property values and social homogeneity. Immigrants who congregate in gateway neighborhoods might benefit from co-ethnic social institutions, cultural amenities, and economic opportunities.

When segregation is something imposed, however, impacts are more detrimental. During the time of Jim Crow laws, residential segregation was a key feature of the broad set of social exclusions imposed on African Americans that also included churches, schools, parks, swimming pools, public transit, and almost every other aspect of life. These exclusions were designed to preserve racial and class privileges enjoyed by the majority. Even after Jim Crow was challenged and partially dismantled in response to civil rights activism, exclusions proved to be deeply persistent and black residents of segregated neighborhoods understood residential segregation to be central to their experiences. In response to the riots experienced by several large US cities in the late 1960s, prominent commissions were established to explore the causes of the violence. President Johnson appointed the Kerner Commission
in 1967, and California Governor Pat Brown appointed the McConne Commission in 1965 after the Watts rebellion. Both commissions reported that residential segregation, enforced through widespread discrimination, was a key feature of the multifaceted social and economic disadvantages that produced deep anger and frustration among residents. Violence was often spurred by racist policing, which saw echoes in the Rodney King riots in 1992 and the Ferguson and Baltimore riots of 2015.

Economist Yinger (1997) computed the financial and economic cost to those who experience housing market discrimination – a discrimination tax. Because discriminatory behavior is found at every stage of the housing search process, and because it reduces information about potential housing relocation choices and diminishes choice, minority housing consumers endure higher transaction costs, higher housing prices, higher interest rates, and less favorable loan terms. He estimates that discrimination might cost an average minority consumer almost $8000 (in 2015 dollars) and might cost society more than $12 billion (in 2015 dollars).

Sociologists Massey and Denton (1989) argue that residential segregation remains the structural lynchpin of racial oppression, provocatively titling their 1993 book *American Apartheid*. They contend that desperate social conditions experienced in impoverished central-city neighborhoods are created and actively maintained by ongoing racial discrimination and residential segregation. Scholars examine what impact living in deeply disadvantaged and segregated neighborhoods has, especially for kids. These interests converged with concerns that high-density public housing was not working. Scholars argue that disadvantaged neighborhoods adversely affect residents: (i) by disrupting socialization and mechanisms of informal social control; (ii) by limiting the development of effective social networks; (iii) by stigmatizing residents, especially in the labor market; (iv) because institutional resources are severely limited; and (v) because they are spatially inaccessible.

Sampson (2012) capped several decades of intense Chicago-based empirical research with a book in which he demonstrates that Chicago’s disadvantaged neighborhoods themselves are persistent and that they impart a number of adverse impacts on residents. Sharkey (2013) capitalized on unique data that allowed him to track people over time and argued that the adverse impacts of growing up in disadvantaged neighborhoods last over the lifetime. A major policy experiment called moving to opportunity (MTO) initially provided disappointing results (Briggs, Popkin, and Goering 2010). The experiment allowed some residents of disadvantaged public housing projects to move into better neighborhoods. Even though the first major assessments of this experiment did not confirm the idea that changing neighborhoods improves life chances, a major recent reassessment of this project reaches a more optimistic conclusion (Chetty, Hendren, and Katz 2015). Considerable benefits accrued to the children who relocated out of the worst of the public housing projects into better neighborhoods, even though these benefits did not appear in the short term.

Measuring segregation

Quantitative measures of segregation were developed soon after World War II as racialized segregation increased dramatically. The index of dissimilarity (equation 1), the most commonly used index, measures the degree to which two groups’ members are unevenly distributed across a set of spatial units.
where $X$ and $Y$ are the total number in each group in the city in which there are $J$ spatial units, often census tracts. The number in each tract is given by $x_j$ and $y_j$. The index ranges from 0 to 1 and represents the share of one group that would have to relocate to different tracts to equalize the groups’ distribution across tracts. The index of dissimilarity remains the most widely used measure of residential segregation, despite deep critique, because of its computational simplicity and ease of interpretation.

The second most common measure of residential segregation is based on a suite of exposure/isolation measures, known as “$P$-star” indices (equation 2).

where $y_j$, and $X$ are defined as before and $t_j$ is the total number of residents in each tract. The indices range from 0 to 1 and have several useful characteristics. First, they convey the average neighborhood racial composition for a group, or, equivalently, the chance that a group $X$ member can encounter a member of group $Y$ in their neighborhood. Second, whereas the index of dissimilarity is symmetric (meaning that group $X$’s dissimilarity from group $Y$ is the same as group $Y$’s dissimilarity from group $X$), the exposure indices are asymmetric and reflect each group’s share of the overall population. We can thus observe the degree to which two groups share neighborhood space. For example, if the neighborhood residential exposure of group $X$ to group $Y$ is 0.67, we can say that two-thirds of the people encountered in the neighborhood of the average group $X$ member would be from group $Y$. This will reflect both the overall racial composition of the city’s population and the degree to which the groups are segregated among its constituent spatial units. Conversely, the neighborhood residential exposure of group $Y$ members to group $X$ will not be 0.67 – it will be much lower.

We can compute a suite of $P$-star exposure values that capture the entire range of groups present in the city, including the neighborhood residential exposure of a group to other members of the same group.

The result tells us, on average, what share of people encountered in the average neighborhood are from the same group – in other words, how residually isolated are members of the group. The isolation version of the index is most commonly used in comparison with the index of dissimilarity because each of these indices tells something a little different about the degree of segregation between two groups.

Residential segregation has five primary measurable dimensions. In addition to evenness (most commonly measured with the index of dissimilarity) and exposure/isolation (most commonly measured with the $P$-star indices), centralization captures the degree to which a group lives in a city’s inner-most neighborhoods. Clustering describes the degree to which members of a group live in neighborhoods that are proximate to one another as opposed to scattered around the city, and concentration describes the degree to which a group lives in a minimal amount of urban space. A group that simultaneously experiences high levels on most or all dimensions of segregation is hypersegregated. Only African Americans are subjected to hypersegregation in significant numbers even though Hispanic segregation recently increased to the level of hypersegregation in a few metropolitan areas.
Massey and Tannen (2015) found in the most recent update of this work that while the number of hypersegregated metropolitan areas declined by half from 40 to 21 since 1970, the areas that remain hypersegregated are among the nation’s largest and house more than one-third of all metropolitan blacks.

Recent trends in residential segregation

Economists Glaeser and Vigdor (2012) argued in their provocatively titled report “The End of the Segregated Century” that racial residential segregation levels have declined enough over recent decades that we should end our concern with segregation as a social problem and de-emphasize its presumed links with broader racial inequality. Figure 1 shows the basic trend that they reported. Black/non-black segregation levels have indeed declined since their peak in 1970 as measured by both dissimilarity and isolation indices. They interpret the decline as a result of the ending of government sanctioned discrimination, which allowed easier access to housing finance capital. Two migration patterns resulted. One, blacks followed broad regional migration patterns from older Rust Belt cities to newer Sun Belt cities where segregation is generally lower. Two, blacks moved from inner-city ghettos to suburbs. They also argue that gentrification and immigration contributed to declining segregation and note that racial economic inequality has not declined along with segregation.

Glaeser and Vigdor’s optimistic interpretation has been challenged by prominent segregation scholars. John Logan (2013; Logan and Stults 2011) also reports that black dissimilarity and isolation declined, though the decline was more modest in the metropolitan regions where blacks are more likely to live. Three reasons capture Logan’s less optimistic interpretation.

One, black—white segregation remains relatively high in absolute terms; it will take several more decades before it declines to a level comparable with other minority groups. Two, the old industrial cities of the manufacturing belt persistently have the highest levels of racial residential segregation for blacks. In these areas, whites rarely move into black neighborhoods and seem to be actively moving out of ethnically and racially diverse neighborhoods, which does not augur well for the future. Three, blacks and Hispanics still live in neighborhoods with much higher levels of social and economic disadvantage, even when controlling for household affluence; the most affluent black households live in neighborhoods more disadvantaged than the least affluent white households.

Table 1 shows average segregation levels using dissimilarity and isolation indices for blacks, Asians, and Hispanics for large metropolitan areas (over 1000000 in population by 2010). These data show declines in segregation as measured by both indices for blacks over the last two decades – even though the magnitude of decline seems to be a bit more modest than argued by Glaeser and Vigdor. Hispanic dissimilarity

increased during the 1990s and Asian dissimilarity remained constant. Isolation increased for both groups, especially Hispanics, as their share of the population increased due in part to immigration.

The categories “Hispanic” and “Asian” each include too many ethnic and national-origin backgrounds to be deeply meaningful. Logan and Turner (2013) examined Hispanic segregation by origin group. The US Census asks respondents to indicate their “Hispanic, Latino, or Spanish” origin separately from race, and requires them to report their specific origin using terms that are interpreted as the nation–state from which they or their ancestors originated (e.g., “Chinese,” “Filipino,” and “Vietnamese,” among others). The Asian population has grown rapidly over the last two decades and is now as large as the Hispanic population was in 1990. While Asians are overall less segregated from whites than are Hispanics or blacks, Vietnamese are the most segregated Asian group and their dissimilarity index values are higher than Hispanics as a group and almost as high as blacks in 2010. Japanese are the least segregated Asian group, in part reflecting the fact that most are US born. Importantly, Asian residential segregation is not associated with socioeconomic disadvantage in the same way that it is for blacks and Hispanic groups – in fact, all of the Asian groups live in neighborhoods where the typical household income is higher than it is for whites, with the magnitude of this neighborhood advantage greatest in suburban areas.

International studies of residential segregation highlight both different processes and different patterns. European cities did not experience the large waves of immigration in the late nineteenth and early twentieth centuries that so strongly shaped US cities. Thus, concepts of race, region, and ethnicity vary across national context, as do data collection and classification schemes. In
RESIDENTIAL SEGREGATION

the late twentieth century and early twenty-first century, however, guest workers, labor migrants, ex-colonials, and refugees increasingly moved to European cities. As a result, many major European cities, including London, Amsterdam, Frankfurt, Brussels, Paris, Lisbon, and Stockholm (among many others), have neighborhoods perceived as homogeneously “ethnic.” In London, for example, there are neighborhoods associated with Pakistani-, Bangladeshi-, or Indian-background residents. In Paris, ethnic neighborhoods are often populated by North-African immigrants. Scholars of segregation in European cities typically use the terminology of “ethnicity” rather than “race” and generally agree that residential segregation broadly characterizes European cities. Levels of ethnic segregation in European cities are lower than black–white segregation in US cities, although comparative research does not reflect the continued decline of black–white segregation during the 2000s. Several UK cities, including Birmingham, Bristol, London, and Oldham (Manchester), show very high levels of residential segregation, comparable to black–white segregation in US industrial cities, for Bangladeshi- and Pakistani-background populations. Catney (2016) shows, however, that residential segregation is declining in UK cities for most non-white groups, including Bangladeshis (outside of inner London) and Pakistanis.

Economic inequality has deepened dramatically over the last several decades. Buffeted by neoliberal globalization, and increasingly abandoned and/or disciplined by governments keen on rolling back the social safety net, the economic fortunes of the working and middle classes have deteriorated. At the same time, the fortunes of the wealthiest segments of society have improved dramatically. Economic residential segregation has increased accordingly. Scholars and policymakers increasingly express concern with increasing levels and new forms of residential segregation by class. Using census data, Bischoff and Reardon (2014) demonstrate a broad increase in segregation by income from 1990 to the present. They find that both the poor and the wealthy have experienced increased residential segregation. The global financial scandal and subsequent economic dislocation hit hard in many working-class and lower middle-class neighborhoods, while at the same time decades of building highly exclusive, often gated communities remained in place.

The space, scale, and geography of segregation

Wong (1997, 2002) and others (e.g., Reardon and O’Sullivan 2004) demonstrate that standard segregation measures inadequately reflect the spatial arrangement of neighborhoods within the city. They have developed an array of spatially sensitive alternatives to the index of dissimilarity and the P-star indices. Some scholars advocate the use of spatial statistics such as Morgan’s I or Geary’s C. These approaches generally require the use of GIS software and are more labor intensive to implement broadly than are the traditional measures.

Scale constitutes another strain of geographically relevant segregation research. Research shows that groups may be more or less segregated at different scales of aggregation within the city. For example, the US Census Bureau defines block groups as substantially smaller (≈1200 people) than census tracts (≈4000 people). Segregation indices measured using block group-level data will generally be higher than the same indices measured using census tracts. Historical research that attempts to measure residential segregation in the early twentieth century or late nineteenth century might use election ward data because the US Census Bureau had
not yet started defining and releasing data for census tracts. Since election wards are larger than census tracts, measured levels of segregation will generally be lower than if segregation had been measured using spatial units the size of census tracts. This issue can be generalized in the sense that our understanding of the magnitude of residential segregation depends on the scale at which we view it. While some groups are more segregated in smaller aggregates than they are in larger aggregates, other groups will show different levels of segregation across levels of aggregation. Scale constitutes an ongoing area of contemporary segregation research of interest not just to geographers, but also scholars in sociology, demography, political science, urban planning, and other disciplines. Lee et al. (2008) and Reardon et al. (2008), for example, develop a detailed methodology that uses very small census block data (there are more than 11,000,000 blocks in the United States and Puerto Rico and there are an average of 39 blocks per block group), sophisticated spatial analysis, and GIS, which demonstrates that residential segregation for any given city varies across scales in what they call a segregation profile.

Recent research recognizes the increasing complexity of urban residential landscapes in the face of growing income inequality and new patterns of ethnic and racial diversity. While several multi-group measures of residential segregation have been proposed, scholars have not yet settled on a single approach. As an alternative to the increasingly complex array of indices, several scholars are using categorical approaches, either alone or in combination with single-value indices. Johnston, Poulsen, and Forrest (2003) developed a classificatory scheme, which they argue is globally generalizable, that centers on the dominance of white settler populations. Other neighborhood types are then identified based on an array of racial composition thresholds. Holloway, Wright, and Ellis (2012) developed a categorization system to facilitate effective cartographic representation (mixedmetro.com) based on a summary index of racial and ethnic diversity augmented by easily interpreted thresholds of compositional dominance. They explored and depicted the ways in which increasing diversity and persistent residential segregation enfold one another in complex and city-specific ways.

Social media provide a large source of data that can be utilized for segregation research and cartographic representation. Shelton, Poorthuis, and Zook (2015) used geotagged Twitter data to critically examine and map Louisville, Kentucky’s racial divide. They caution, however, that “big data” present many technical and conceptual challenges to which researchers need to attend.

Resilience and human geography

Geoff A. Wilson
Plymouth University, UK

The notion of “resilience” has begun to influence research by human geographers, and human geographers, in turn, have begun to shape thinking about the meaning and significance of resilience. This entry outlines the scientific genesis of the concept, and then focuses specifically on contributions to resilience research by social scientists and human geographers. The entry demonstrates that resilience – much like “sustainability” – remains a relatively ill-defined and elusive term, and that different disciplines and subdisciplines use the word in often different and contradictory ways. The entry concludes by suggesting that human geographers are particularly well placed to contribute to both further clarification and improved practical application of the term.

The genesis of resilience research

The notion of “resilience” (from the Latin “resilire,” meaning to leap back, rebound, or recoil) has undergone profound changes in meaning, scientific relevance, and practical applicability over several decades. From the beginning of the twentieth century, the first scientific reference to resilience occurred in engineering, where resilience of materials or buildings was understood as an ability to withstand stress. In the early 1970s the notion of resilience was incorporated into ecology, where seminal work by ecologist Chris Holling (1973) suggested that the term could be used as a scientifically robust concept to highlight how able an ecosystem was to cope with stress and respond to disturbances (ecological resilience), whereby the vitality of a system was not seen to be defined as the ability to reach a “climax” but rather in terms of evolutionary change. Resilience in this sense was seen as an emergent property – a relative attribute characterized by responses to disturbances which can only be assessed by looking at changes in a system over time. Ecologists suggested that qualities of resilience are evident in the notion of adaptive capacity, which is generally used to analyze how a system does, or does not, respond to endogenous and exogenous changes and is defined as the ability of a system to adjust to change, moderate the effects of that change, and cope with a disturbance. A system characterized by diversity, potential for change (level of redundancy in the system), and connectedness (feedbacks, flexibility) usually has better adaptive capacity.

Resilience research between the late 1970s and the 1990s began to focus on an extended resilience definition strongly influenced by the theory of complex adaptive systems, which argues that ecological resilience concepts can be applied to human systems under the umbrella of social-ecological resilience. Brand and Jax (2007) argued that this marked the beginning of the notion of resilience as a “boundary object” between the natural and social sciences. An important building block of this research was Gunderson and Holling’s (2002) seminal concept of “panarchy,” which took fast/slow resilience dynamics and cross-scale interactions and interdependencies into account, and provided a
heuristic model of four nested adaptive cycles of resilience emphasizing cross-scale interplay ranging from periods of exponential exchange, to periods of growing stasis and rigidity, periods of readjustment and collapse, and periods of reorganization and renewal. The Resilience Alliance based in Stockholm (Sweden) – an influential international consortium of 15 research groups and institutes from many disciplines who collaborate to explore the resilience of social-ecological systems (SESs) – has since expanded this work and has suggested several methods and approaches to analyze the resilience of interlinked social-ecological systems (Resilience Alliance 2007).

Although SES approaches implicitly implied that social drivers of change and adaptation were important, their ecological or “scientific” approach was increasingly criticized for neglecting key social science processes such as power, agency, politics, and highly complex stakeholder interpretations of what makes a system resilient. The result was a lively debate in resilience research during the 1990s and 2000s that laid the foundation for current, more critical, and social science-informed resilience thinking. Authors such as Adger (2000), Wilson (2012a), and Brown (2014) highlighted that resilience of human systems could not be explained through linear processes of change, that memory in social systems plays a different role from that played in natural systems, and that human behavior affecting resilience can be irrational, unpredictable, and highly dynamic. The original natural science-influenced definition saw resilience as the capacity of a system to absorb disturbance and reorganize while undergoing change and still retain essentially the same function, structure, identity, and feedbacks, whereby resilience is measured by the size of the displacement the system can tolerate and still return to a state where a given function can be maintained. This began to change into a more malleable definition that included notions of uncertainty and unpredictability for assessing the resilience of human systems. The approach used in the social-ecological resilience framework was increasingly criticized for relying too heavily on the idea that complex system behaviors in multivariate space will typically fall within a stability domain around an attractor – behaviors that may not necessarily be true for the resilience of human systems. As a result, many argued that “measuring” social-ecological resilience is challenging, particularly because in order to clarify features that contribute to it, institutional and organizational processes must be understood as carefully as ecological ones. As a result, since the late 1990s the notion of “social resilience” has gained importance, especially as it focuses attention on the resilience of human systems with their intricate social, economic, and political processes that shape the resilience or vulnerability of systems and communities. A particularly important strand of research has been the focus on “community resilience” with a strong geographical focus on human communities (villages, towns, urban areas) and their ability to cope with disturbances – areas where human geographers have been particularly prominent.

Human geography, social science, and resilience research

As with other contributions to the International Encyclopedia of Geography, identifying clearly defined human geography contributions to a specific field of enquiry is difficult. This is because definitions of who and what “human geography” entails are becoming increasingly blurred. As the notion of resilience straddles several disciplinary and subdisciplinary divides (see above), inevitably some of the most interesting
research on resilience is done at the intersection between disciplines by researchers who often do not identify themselves with specific disciplines. In addition, while many of the contributors to debates on resilience are based in geography departments, they may not necessarily have been trained as human geographers (e.g., many political ecologists, political scientists, historians, sociologists, etc.). In the following, therefore, the boundaries of what constitutes human geography are seen as highly permeable, and reference is also made to non-geographers (i.e., “social scientists” more generally) who have contributed to resilience research by emphasizing human geography-specific issues of space, place, and the complexity of human systems.

Geographers have played a pivotal role in shaping resilience research since the 1990s, with seminal contributions by Adger (2000) on “social resilience,” Martin (2012) on “regional economic resilience,” Wilson (2012a) on “community resilience,” a recent intervention by Brown (2014) on conceptual issues of resilience from a human geography perspective, and a critical study by Rigg and Oven (2015) on notions of “liberal resilience.” These and other studies by social scientists have particularly criticized notions of linearity and “measurable” resilience responses assumed to be equally present in both social and ecological systems. As Adger (2000, 347) highlighted, “it is not clear whether resilient ecosystems enable resilient communities.” This was echoed by Davidson (2010), who argued that the panarchy model by Gunderson and Holling (2002; see above) implies that in the absence of disturbances, systems will tend toward increasing complexity, but that several problems arise with the transfer of this model to social systems.

The application of the social-ecological resilience framework to social systems, therefore, requires improved articulation of the multiple relationships between complexity and disturbance in a less deterministic manner than is afforded by ecological systems. As a result “the means by which social systems can be readily cast into the ecological terms encompassed by the resilience framework must be critically examined” (Davidson 2010, 1141). Thus, Davidson further argued, while the structural complexity of both ecological and social systems can be conceived of in similar terms, the feedback processes associated with each are incomparable: social systems are unique in that the tendencies toward complexity, and the responses of individual organisms to those levels of complexity, are defined not solely by structural variables but, crucially, also by agency. In this sense, many social scientists and human geographers argue that the four nested adaptive cycles suggested in the deterministic ecosystems-oriented panarchy cycle may not occur in a linear fashion in human systems, but simultaneously with strongly overlapping and, at times, contradictory behaviors associated with less predictable human agency. Reviewing social science and human geography studies on resilience, Brown (2014, 109) thus concluded that “the transference of ideas about ecological systems to the social realm is viewed as highly problematic.”

The result of these criticisms has been an emergent third strand of resilience research focused on the resilience of human systems and communities, referred to as social resilience. This has been shaped by both social scientists and human geographers (e.g., Adger 2000; Brand and Jax 2007; Davidson 2010). The social resilience focus is based on actor-oriented approaches and on social, political, and economic processes that better reflect power and scale imbalances that shape the resilience of human systems. In this sense, social resilience is an important component of the circumstances under which individuals and social groups adapt to change.
The focus on *community resilience* emphasized by several human geography resilience researchers (e.g., Wilson 2014a, 2014b, 2015) is a specific subset of research on social resilience defined “as the ability of groups or communities to cope with external stresses and disturbances as a result of social, political and environmental change” (Adger 2000, 347). It therefore concerns the ability of a social system to respond to and recover from disasters, and includes those inherent conditions that allow the system to absorb impacts and cope with an event, as well as postevent, adaptive processes that facilitate the ability of the social system to reorganize, change, and learn in response to a threat. Social resilience is, thus, about the necessity of human systems to learn to manage by change, and implies that uncertainty and surprise are part of the game. Social/community resilience can be preventative (avoiding poor outcomes by developing coping strategies), or it may facilitate recovery after a traumatic event or catastrophe. It also considers whether the worst-off stakeholder group (i.e., economically or politically weak groups within a community) can recover from a disturbance without necessarily reducing the wellbeing of any other community-based institution or individuals.

Critics of the SES approach to resilience research have particularly highlighted that recovery and adaptive capacity in human systems take on very different pathways from those in ecological systems, with notions of social capital and memory, institutional capacity, power, agency, governance, path dependencies, and “lock-ins” particularly important – notions that suggest that returning to an “original”/“pre-disturbance” state is most often not the most appropriate recovery strategy in human systems. There is, therefore, a growing recognition that the persistence of certain social and economic conditions hampers positive long-term resilience, but too often empirical work is still interpreting resilience in the narrow sense of return time and recovery, thereby possibly missing the broader use of the concept. As a result, Brown (2014, 109) emphasized from a human geography perspective the “depoliticized” nature of most resilience research and “the failure to recognize resilience as socially contingent, rarely addressing the question of ‘resilience for whom?’” and “that resilience fails to take account of politics and power relations.” A focus on social resilience, thus, suggests that rather than viewing humans as outside or apart from ecosystems, humans should be viewed as agents of change acting within SESs. In other words, persistence, adaptability, and transformability take very different forms and pathways in ecological versus human systems, with the critical literature increasingly suggesting that human systems can never be *fully* resilient (Wilson 2013) but that *multifunctional* human systems have a tendency to be more resilient (Wilson 2010). Brand and Jax (2007, 12), thus, argued that “the original ecological dimension of resilience is about to vanish.”

The notion of social resilience, therefore, assesses how communities develop adaptive capacity to respond to endogenous disturbances (e.g., political upheaval, revolutions) or exogenous threats (e.g., climate change, volcanic eruptions, flooding). As a result, human geographers have highlighted the complexity of forces affecting communities, from both human and natural causes operating across space and time. Wilson (2012a), for example, highlighted that such forces are referred to in various ways in the literature, including “threats,” “stresses,” “shocks,” “perturbations,” “disasters,” “hazards,” “disruptions,” “disturbances,” and so on, whereby the relatively neutral notion of *disturbances* is beginning to gain ground based on the argument that the resilience of human systems is affected by both anthropogenic (human-induced) and natural disturbances (Figure 1).
Not all disturbances shown in Figure 1 are necessarily negative for community resilience. Disturbances associated with globalization processes are particularly open to debate (Wilson 2012b), and some processes, such as technological change, can of course also positively influence community resilience. The disturbances shown in Figure 1 can have both internal (i.e., within the community; e.g., local pollution) and external (i.e., outside the community; e.g., hurricanes, wars) causes, and include both sudden catastrophic disturbances (e.g., earthquakes) and slow-onset disturbances such as climate change or shifts in global trade. The complexity of disturbances affecting communities suggests that communities

Figure 1  Examples of anthropogenic and natural disturbances affecting community resilience. Source: Wilson 2012a. Reproduced with permission of Taylor & Francis.
RESILIENCE AND HUMAN GEOGRAPHY

are never “stable,” but that they are continuously and simultaneously affected by several disturbances at any point in time. It is argued, therefore, that communities can never reach “maximum” resilience levels but can only strive towards the highest level of resilience achievable within community-specific contexts.

Although understanding human–environment interactions continues to form a crucial component of these approaches, human geography research on social resilience is often based on a “bottom-up” approach predicated on understanding human drivers and indicators of resilience, of which human–environment interactions are only one of many components. There is, therefore, an increasing need to question resilience theorists for a lack of attention to power relations, politics, and culture. As a result, social resilience and human geography research focuses more on the importance of politics, power, and socioeconomic, psychological, and moral parameters than “traditional” social-ecological resilience research.

There are obvious differences between the more ecologically informed notions of social-ecological resilience and those attempting to understand social resilience related, in particular, to issues of linearity/nonlinearity. A key issue of nonlinearity, for example, relates to the assumption that human systems can never return to their original state after disturbance (which ecosystems may be able to do) due to social learning processes and social memory. In human systems, therefore, adaptations can be both anticipatory and reactive, and depending on their degree of spontaneity they can be ad hoc or planned. The capacity to cope with nonlinearities or other forms of surprise and uncertainty, therefore, requires an openness to learning, an acceptance of the inevitability of change, and the ability to treat interventions as experiments. Adaptation in the context of human dimensions, thus, refers to a process, action, or outcome in a system (household, community, group, sector, region, country) in order for the system to better cope with, manage, or adjust to disturbances. This notion of “better coping” highlights that social learning implies human adjustment processes that propel the post-disturbance system to a different (sometimes “better”) state. Human geographers argue that this has crucial implications for the “management” of community resilience, as the goal for adaptive capacity after a disturbance should often not be to attempt to reinstate the original state but to use learning processes and social memory as a basis for the creation of a qualitatively different, more resilient community (Adger 2000; Wilson 2012a; Brown 2014). Thus, while technological adaptation to a disturbance is usually seen as an easier process (e.g., engineering solutions towards sea level rise), human attitudinal and behavioral adaptation is much more complex and usually takes much longer (e.g., changing recognition that there is a “problem”).

Social resilience is, therefore, about preemptive change which sees resilience as a desirable state, rather than simply a process to avoid disturbances. This is exemplified by Davidson’s (2010, 1146) suggestion that “rather than directing our attention primarily to identifying and prescribing conditions of sustainability, the [social] resilience framework directs our attention to information flows and cycles of change, exploring how our current institutions and connecting structures are likely to respond to disturbance, and how we can prepare for those outcomes.” The notion of social resilience is, thus, strongly focused on human learning pathways and how these may affect the resilience of communities. Resilience in this view is both an outcome, especially when linked to improved adaptive capacity of communities, and a process linked to dynamic changes over time associated
with community learning and the willingness of communities to take responsibility and control of their development pathways. It is this importance of human agency which defines an additional conceptual layer not present in ecological systems, and consequently not reflected in ecological theories of resilience – that is, human agency distinguishes social systems from ecosystems. While the ecological resilience literature has focused more on the ability of systems to return to function after a disturbance, social resilience is, therefore, about seeing disturbances as an opportunity for change and development. The focus on social resilience, therefore, shifts attention from controlling change in presumably stable community systems to managing the capacity of dynamic communities to cope with, adapt to, and shape change.

In essence, the notion of social resilience is about understanding a “positive” quality of a community under investigation, not dissimilar to the notion of “strong sustainability.” As a result, understanding social resilience is more closely associated with normative judgments about “good resilience” and “bad vulnerability.” The close association of resilience with the ability of a human system to absorb impacts/disturbance and to reorganize into a fully functioning (but qualitatively different) system is, therefore, closely associated with the notion of “positive” quality, while community vulnerability – usually used to describe exposure and sensitivity of a human system not able to cope with risks, hazards, and slow or catastrophic change – is generally associated with “negative” quality. A broad concept of resilience, therefore, includes normative dimensions. In contrast to ecological systems where resilience can be seen as an ideal linear end-point, some human systems, such as “resilient malign dictatorships” (i.e., a resilient system that maintains a malign dictator), or “resilient malign ideologies” (where ideologies (e.g., Nazism) can be resilient to change), can be resilient in a “negative” context for the wellbeing of communities/societies (i.e., “bad resilience” = vulnerability). Researchers involved with social resilience research increasingly, therefore, avoid the use of terms such as “recovery” and prefer concepts of “renewal,” “regeneration,” and “reorganization” following disturbance.

The latter point highlights that, from a social resilience/human geography perspective, resilience/vulnerability are, therefore, intricately linked to notions of “good” or “bad” community development pathways. Although several concepts of the interlinkages between resilience and vulnerability have been used, many human geographers argue that resilience/vulnerability can be expressed as a simple spectrum (Figure 2) (Adger 2000; Wilson 2012a; Brown 2014). Extreme ends of a spectrum are usually most easily conceptualized. For example, few would contest that the complete disappearance of a community due to destruction of the livelihood base (e.g., depletion of soils leading to desertification), or a malign dictatorship that has negative implications for the wellbeing of most of its citizens, can be seen as a “bad” development pathway associated with extremely vulnerable communities. This highlights that, ultimately, normative moral judgments based on specific conceptualizations of social resilience are generally rooted in measures of human survival – for example, complete disappearance of a community.

Figure 2 Resilience and vulnerability as opposite ends of a spectrum. Source: Wilson 2012a. Reproduced with permission of Taylor & Francis.
community means no resilience. However, these normative assumptions become more blurred as one moves along the spectrum. As Figure 3 suggests, it is, therefore, more difficult to find a common understanding of “good” development pathways associated with resilient communities after a disturbance or “transitional rupture” in community development pathways. Indeed, any notion of quality (such as resilience/vulnerability) is relational and, therefore, always subjective – in other words, different individuals and stakeholder groups will view quality in different ways. Finding a commonly or cross-stakeholder and cross-culturally acceptable definition of a strongly resilient community is, therefore, almost impossible, although most would agree that the complete disappearance/destruction of a human community is clearly associated with extreme vulnerability (i.e., pathway c in Figure 3).

**Conclusions**

This entry has critically discussed the notion of “resilience” and how social scientists and human geographers have contributed to recent research on resilience. The discussion has shown that resilience remains a relatively ill-defined and elusive term, and that different disciplines and subdisciplines use the term in often different and contradictory ways. This confusion in definitions and concepts of resilience has been criticized by many commentators, including several human geographers (e.g., Adger 2000; Wilson 2012a; Brown 2014). Indeed, most human geographers would probably agree with both Miller et al.’s (2010, 6) critique that the “tendency for each [resilience] community to redefine other communities’ terms in their own language, invariably situating their own
RESILIENCE AND HUMAN GEOGRAPHY

concepts on a higher ground and the other’s as a derivative, may have impeded collaboration,” and with Brand and Jax’s (2007, 12) caution that “the meaning of resilience [becomes] increasingly vague and unspecified … [and] that both conceptual clarity and practical relevance of resilience are at stake.” This underlines, therefore, that philosophical, moral, and epistemological differences in natural-science- and social-science-led resilience research need to be acknowledged and that it is unlikely at this juncture in resilience research that an overarching framework for understanding “resilience” can be found in the near future. Resilience will, therefore, continue to be a Janus-faced “boundary object” (Brand and Jax 2007). Indeed, with inclusion of ever more subdisciplines into the broad arena of resilience research, further fragmentation is most likely.

This discussion has nonetheless highlighted that disciplines such as human geography are ideally situated to make major contributions to resilience research in future, due to human geography’s strategic location at the intersection between several existing tensions regarding resilience research, in particular by contributing towards “socializing” and “politicizing” resilience research (e.g., by highlighting the crucial importance of power and politics within complex actor spaces in resilience research; cf. Brown 2014); by promoting resilience as a normative term with “real” potential for informing policy-making and changing attitudes, action, and behavior on the ground (cf. Wilson 2012a); and by further clarifying conceptual differences between “sustainability” and “resilience” (cf. Adger 2000; Davidson 2010).

As Adger (2000), Wilson (2014a), and Brown (2014) highlighted, it is key to analyze the nature of agency and governance as important drivers for resilience issues in a politically nuanced way and through hybrid and mixed methodologies that also allow investigation of “deep” sociopolitical processes, and that acknowledge the non-linear and heterogeneous nature of resilience pathways. In particular, researchers embedded in the social-ecological resilience paradigm need to acknowledge more that human systems can never “bounce back” to a pre-disturbance state, as social memory and learning processes mean that new resilience pathways emerge that may build on previous pathways and memories that are often also qualitatively different and may include unanticipated “surprise adaptations.” Thus, “the challenge from a [social] resilience perspective is to learn to live with change and develop the capacity to deal with it instead of trying to block it out” (Miller et al. 2010, 5). The social resilience approach, therefore, also acknowledges that no human system can ever be fully resilient, and that some components of the system (e.g., a weak stakeholder group) will still be vulnerable. It is in these resilience research arenas, in particular, that fruitful opportunities emerge for human geographers, as they are able more than any other discipline to provide a critical bridge between discussions on how space and scale, governance, power, and complex socioeconomic processes affect the resilience of human systems. Nonetheless, synergies are beginning to emerge with regard to responses to shocks and disturbances, interactions of slow and rapid changes (both in human and natural systems), and system and actor dynamics. What is particularly encouraging from a human geography perspective on resilience is that studies are increasingly acknowledging the importance of hitherto neglected forces and processes affecting resilience linked to human geography-related notions of power, space/place, agency, and governance.

Further reading

The resource curse has deep historical roots, including the consequences of Spanish exploitation of New World gold and silver mines that evoke echoes of King Midas. Recent interest arose from the failure of many oil-exporting countries to apply their large windfall revenues from the 1974–1981 oil booms to sustainable economic development. Country case studies revealed mostly adverse outcomes, which prompted a surge of statistical studies triggered by the pioneering work of Sachs and Warner (1995). So far, however, the statistical studies have failed to provide a definitive explanation of the resource curse. Rather, they have expanded the range of explanations from an initial focus on economic causes to institutions and policy. Some scholars now query the existence of a resource curse (Brunnschweiler 2008). Certainly, the causes and symptoms of the resource curse are more complex than many researchers initially thought. This entry compares the competing explanations; identifies systematic differences in natural resource characteristics and outcomes; notes how outcomes vary with shifts in development policy; and conceptualizes the resource curse as part of a broader rent curse. Future research can build on this more nuanced context to model systematic variations in the impact of natural resources on economic development.

Economists expect resource-rich economies to grow faster than resource-poor economies if their governments apply the natural resource rent (the surplus revenue after deducting all production costs, including a risk-related return on investment from total revenue) to sustain a higher rate of investment and greater imports of the goods required to build the infrastructure of a modern economy. This appears to have been the case in many countries prior to the 1970s when the per capita GDP of the resource-rich economies as a group was 50% higher than that of the resource-poor economies (Auty 2001, 5). The sharp increase in the global incidence of the resource curse that emerged during the commodity price volatility of 1973–1985 therefore presents a paradox that persisted until the late 1990s when the growth rate of the resource-rich economies improved (Table 1). But by then the mean per capita income of the resource-poor economies exceeded that of the resource-rich ones. This waxing and then waning of resource curse effects at the global level suggests the curse is not a deterministic law, as many statistical studies have sought to prove, but varies in its intensity through time.

Sachs and Warner (1995) offer an economic explanation for the resource curse, which is rooted in Dutch disease effects (deindustrialization caused by large inflows of foreign currency from booming commodity exports).

Dutch disease effects occur when booming commodity revenue strengthens the real exchange rate, which reduces the competitiveness of the non-booming tradeable sectors (agriculture and manufacturing) so that they contract. When commodity prices eventually fall, the economy may have less capacity to generate wealth than before the boom occurred because the adjustment by firms to the exchange rate is asymmetric: tradeable activity is rapidly destroyed in booms but revives much more slowly when a boom abates (Gelb and Associates 1988). Sachs and Warner show that in order to counter the employment–diminishing effects of Dutch disease, most governments closed their trade policy, especially when their dependence on primary product exports was greater. This policy is counter-productive, however, because protective trade policies repress competitive markets so the economy becomes less flexible and more vulnerable to a growth collapse. Such growth collapses are triggered by sudden falls in commodity prices/revenue, like those the world economy experienced through 1973–1985. They damaged those resource-rich economies where governments had stoked Dutch disease effects by expending the revenue from their natural resources too quickly.

For geographers, the economic explanation for the resource curse appeared to herald a new variant of environmental determinism. Yet resource-rich Botswana, Malaysia, and Indonesia, along with earlier resource-abundant developers like Australia, Canada, and the United States, are anomalies that sustained rapid per capita GDP growth. Their experience nurtured institutional explanations of the resource curse led by Acemoglu, Johnson, and Robinson (2001) who argue that the quality of institutions (the formal rules governing political and economic exchange) is more important than natural resources per se in determining whether resources are a blessing or a curse. They identify as detrimental to economic growth
those extractive (colonial) institutions associated with tropical lands that were too unhealthy for significant European settlement. Managers of plantations and mines in the tropics promoted extractive institutions to export goods and send revenues to owners overseas while squeezing worker income and local expenditure (Isham et al. 2005). They further constrained economic diversification by repressing the local production of rival commodities to limit competition for land and labor. In contrast, small-scale farmers in the resource-rich temperate regions of the Americas and Oceania created inclusive institutions that were more conducive to local economic development (Baldwin 1956). As incomes rose, the farmers paid taxes to develop roads, expand education, and maintain law and order for all citizens, facilitating incremental gains in productivity that boosted farm incomes whose local expenditure helped diversify the regional economy.

Yet Glaeser et al. (2004) relegate institutions to secondary status in promoting economic growth. They find that institutions improve as a consequence of rising incomes but do not cause that rise, which they attribute to increased education and choice of economic policy. In fact, institutions in low-income economies are highly flexible. They bend to accommodate elite demands for personal enrichment rather than constrain those demands, which effective resource-driven development requires. Moreover, North et al. (2009) argue that the first priority of many governments in developing countries is to apply rent to appease elite groups that are deemed capable of violence, so that political motives override economic ones in the allocation of natural resource rent.

Consistent with this outcome, Schlumberger (2008) identifies a patrimonial form of capitalism in oil-exporting countries (with wider applicability), the principal feature being the use of informal institutions to bypass formal ones to benefit the politically connected elite. The World Bank (2009) provides an illustration. It reports that almost two-thirds of a sample of Middle East and North African civil servants view the private sector as rent extracting and corrupt, being dominated by a few well-connected firms that sustain quasi-monopolies by barring competitors, bribing civil servants, lobbying for privilege, and underreporting earnings. Such a system undermines long-term growth.

In fact, the economic, institutional, and political explanations are not mutually exclusive and may interact to cause the resource curse. Windfall revenues from natural resources trigger contests among the elite to extract rent, that exert political pressure for governments to expend rent too rapidly in the domestic economy, which undermines macro-economic management (Torvik 2002). This policy failure triggers Dutch disease effects that retard the competitive diversification of the economy; impede institutional maturation; and hinder shifts toward political pluralism. But policy failure is not inevitable: the risk is higher where the rent is concentrated on a handful of economic agents, as with modern mining, as well as in the presence of strongly interventionist government policies.

Development outcomes from dispersed and concentrated resource rent

Natural resource rent can be extracted from minerals, cropland, forests, and landscapes, but the statistical research has focused on mineral rent. This is partly because the World Bank provides annual estimates of mineral and hydrocarbon rent for most countries from 1970 but not for crops – data for this only became available recently and at irregular intervals because of the high preparation costs. GDP data are available, however, and Table 1 indicates that the hard
mineral exporters performed worst through the phase of commodity price volatility associated with the oil booms of 1973–1985. The oil-exporting countries saw their growth slow down through 1973–1985 and then collapse. By comparison, small crop-exporting countries fared somewhat better and might have performed better still with less government intrusion.

Systematic differences between the rent streams explain the varied development outcomes. Crop rent tends to be smaller relative to GDP than mineral rent (Auty 2001, 131), and also less volatile, which facilitates macro management (Van der Ploeg and Poelhekke 2009). In addition, crop rent is more dispersed across economic agents than mineral rent (Table 2, columns 1 and 2), which renders it harder for the elite to expropriate and more likely to be deployed efficiently.

Mineral rent streams tend to be singularly large, volatile and concentrated on governments. They are large because most mining is capital-intensive and subject to economies of scale, rendering both mines and their rent streams large as a proportion of the GDP of the typical host economy. Small mineral economies secure the highest rent in relation to GDP and the oil exporters the most rent of all (Table 1), so they are especially prone to resource curse effects. In a sample of six oil-exporting countries, Gelb and Associates (1988) estimated that the rent windfalls during the 1974–1978 and 1979–1981 oil booms ranged from 10% of non-mining GDP per annum in Venezuela to over one-third of non-mining GDP in tiny Trinidad and Tobago. Some Gulf oil exporters had rent/non-mining GDP ratios higher still.

The rent stream of mineral economies is also volatile because mineral markets adjust less flexibly than soft commodity (crop) markets. New mining capacity requires large investments with lead times of five to ten years, so capacity is difficult to match to demand. Shortages boost prices but the investment to meet the extra demand takes several years to construct, by which time conditions may have changed and created a glut. Yet low prices do not encourage temporary mine closure to match demand and supply because mining companies continue to operate as long as revenues cover operating costs and a modest contribution to capital recovery.

These characteristics of mining also concentrate its domestic economic stimulus (linkage) on taxation, and therefore on the government. For example, backward linkages from mining are for specialized inputs that are most cheaply imported from established suppliers. Moreover, further processing prior to export (forward linkage) is most efficiently undertaken overseas rather than at a remote mine or oil well unless processing entails significant weight loss. Finally, the capital-intensive nature of mining creates little employment, so local expenditure by workers (final demand linkage) is limited. Hence, the principal economic contribution of mining to the host economy is taxation (fiscal linkage), which governments receive but often struggle to expend effectively (Lal 1983).

The economic policies required to manage large and volatile revenue streams are well understood and include a revenue stabilization fund to smooth the rate of domestic absorption and fiscal rules to ensure the rate is sustainable. However, many governments find it difficult to resist political pressure to boost expenditure through booms and to avoid cuts through downswings. Consequently, domestic rent absorption is invariably over-rapid and intensifies Dutch disease effects and rent expropriation by elite groups. This retards the diversification of the economy that is required to establish the productivity-driven growth upon which long-term prosperity depends. Instead, governments rely on higher rents to raise incomes. For example, the oil price required by Saudi Arabia and Russia to balance...
their budgets increased four-fold between 2004 and 2012. 

Research suggests that governments not only expend revenue too quickly but also favor consumption over investment. They boost consumption inefficiently, however, by reducing taxes for the wealthy, subsidizing basic commodities like food and energy, and over expanding the bureaucracy and protected infant industry so as to mask unemployment. Prior to the economic reforms demanded by international financial institutions (IFIs) in the late 1980s and 1990s, governments in resource-rich countries frequently pursued strongly interventionist policies. They invested windfall revenue in state-owned enterprises that proved inefficient and required subsidies (Gelb and Associates 1988, 94–123). Many public expenditure programs degenerated into conduits for enriching the elite or for delivering political support. Far from promoting the competitive diversification of the economy, governments over expanded social entitlements, which they struggled to reduce when revenues fell. This, along with subsidies to loss-making state enterprises, boosted public debt to levels that required IFI-backed assistance for economic reform.

*Most economies generate more than one rent stream.
In contrast, the smaller, less volatile and dispersed rent streams from small-scale farming lower the risk of policy failure. Windfall revenue that is scattered across many economic agents tends to be more beneficial for economic growth than rent spent by governments (Isham et al. 2005). Freed of political pressures, small-scale farmers are more likely than governments to save more of their windfall revenue and thereby smooth its absorption into the economy, limiting Dutch disease effects (Bevan, Collier, and Gunning 1987). Small-scale farmers also allocate revenue more judiciously between consumption and investment than governments, and their investment is more efficient because it reflects economic goals rather than political ones.

Baldwin (1956) illustrates successful agriculture-driven economic diversification with reference to the nineteenth-century US Midwest. There small-scale farms made modest incremental investments that steadily boosted productivity and rural incomes. This expanded demand for locally manufactured farm implements and household goods. They also paid taxes for education, infrastructure, and public administration that conferred social benefits that were widely shared. The dispersed linkages of Midwest farms built a prosperous, diversified economy. In contrast, as institutional scholars have argued, the Southern plantation economy’s large-scale crop processing system minimized local incomes and tax revenues, cementing dependence on the export commodity and perpetuating a skewed income distribution and mono-crop economy.

East Asian case studies suggest the dispersed economic linkages of small farms can sustain rapid GDP growth at 6–7% per annum. Unfortunately, through the 1960s to the 1980s, government policy in many developing countries viewed agriculture not as a growth engine but as a supply of cheap labor, cheap food and rent, which was exploited to subsidize urban industry. Many governments in sub-Saharan Africa abused their crop marketing boards to extract rent from farmers by paying them far less than the world price for their crops (Krueger 1992, 58–73). Some governments went further and extracted part of the return to capital and labor from farmers as well as the rent. In effect, government rent extraction transformed the beneficially dispersed cash crop linkages into concentrated linkages like those in mining. This transferred economic resources from competitive rural activity to subsidized urban activity to appease vocal political groups. The policy was self-defeating because it eroded farm incentives, which encouraged more farmers to migrate to cities, where they demanded subsidized jobs.

To summarize, concentrated rent flows increase the resource curse risk for small economies, especially mineral exporters, by feeding contests among the elite to extract rent for immediate personal enrichment at the expense of efficient investment for long-term economic growth. The resulting over-rapid rent expenditure ignites Dutch disease, that causes growth collapses in the absence of economic reform, which rent recipients resist. However, the smaller dispersed rent streams from small-scale cash crops confer lower risk of resource curse effects because they are harder for the elite to expropriate, and farmers apply them effectively, provided governments resist political pressure to convert dispersed rent into concentrated rent.

Development policy varies the incidence of resource curse cases

include data from the 1990s and 2000s and are more likely to generate a positive association between resource abundance and economic growth, leading some to reject the very existence of a resource curse (Brunnschweiler 2008). The inclusion of recent statistics increases the weighting of the post-1997 years of economic recovery relative to those impacted by the 1973–1985 growth collapses (Table 1).

The growth recovery coincided with a major change in economic policy (Van der Ploeg and Poelhekke 2009) when IFI assistance with debt management was made conditional on the adoption of policies to stabilize the economy and dilute interventionist government policies. The IFI stance reversed an earlier global shift toward interventionist policies after the Great Depression and World War II, when some economists advised developing country governments to override markets to promote industrial diversification and reduce dependence on the advanced economies. Many developing country governments duly closed their trade policy through the 1950s, 1960s, and 1970s to protect “infant” industry from competition with imports from advanced economies until it was efficient enough to survive unaided. Infant industry maturation rates need, however, to be no more than five to seven years if the costs of infant support are to be recouped from the benefits of the successful industry. In practice, industry maturation rates spanned decades.

The Achilles heel of industrial policy is policy capture by the prime beneficiaries, the owners and workers operating the plants, and the civil servants awarding the licenses (Altenburg 2013). Import protection blunts incentives to compete, so industrial policy risks degenerating into a vehicle for extracting rent and bestowing political patronage, usually at the expense of domestic consumers (including farmers and unsubsidized manufacturers) who pay prices above world levels, often for inferior goods. Moreover, infant factories import inputs but do not generate foreign exchange to pay for them because they are uncompetitive, so their operation widens the trade deficit and can boost public sector debt. The infant industry policy caused stop–go macro-economic crises, notably in Latin America, which pioneered the strategy.

Research suggests the rise and then decline in the global incidence of growth collapses associated with the resource curse reflect, respectively, interventionist government policies in many resource-rich economies through the 1960s and 1970s, and then economic recovery aided by IFI-backed reforms. Case studies reveal that over the same period, many resource-poor economies grew rapidly by investing to export labor-intensive manufactured goods in line with their comparative advantage, which lay in cheap labor due to the paucity of natural resources. The resulting competitive industrialization development trajectory rapidly exhausted surplus rural labor. This beneficially pushed up wages and forced firms to contain rising costs by boosting worker productivity through rapid diversification into skill-intensive and capital-intensive manufacturing. Examples include the resource-poor Asian Dragons (Hong Kong, Singapore, South Korea, and Taiwan), Mauritius, and post-Mao China but also resource-rich Malaysia and Indonesia. Malaysia and Indonesia shared large rural populations with low incomes that were courted by rebels and so posed a political risk to the leadership. The elite responded by promoting rural reform and green revolution techniques to ensure that their rent extraction did not prevent development benefits from diffusing to the poor, an outcome that helped avoid growth collapses.
The resource curse within a broader rent curse

Overall, resource-poor developing economies were more successful than resource-rich ones during 1973–1997 (Table 1), but there are anomalies that add further complexity to the resource curse. Some resource-poor economies, like those of the Sahel, experienced growth collapses. An important reason is rent streams other than natural resource rent: namely foreign aid, worker remittances, and regulatory rent. Table 2 compares the features of these revenue streams with those of the two basic natural resource rent streams (diffuse and concentrated). Each rent source can be 10–20% of GDP or more, potentially taking the total rent within an economy to between one-fifth to one third of GDP and more. Mauritania, for example, generated total rent of one-third to two-fifths of GDP per annum for over forty years after independence. Such windfall revenue is detached from its source and is up for grabs, so it is not surprising that contests for rent among the elite profoundly impact the political economy. Yet many statistical studies of the resource curse ignore these extra rent streams so they are, at best, impaired by background noise and, at worst, flawed in their conclusions.

Rajan and Subramanian (2011) confirm that domestic expenditure of foreign aid within the public sector can replicate features associated with a natural resource commodity boom, triggering Dutch disease effects that stifle competitive manufacturing. Moreover, foreign aid may be stolen by the elite for personal enrichment by biasing public expenditure toward targeted goods such as construction projects that are awarded to political cronies, rather than toward universal public goods such as education and health care that benefit everyone, supporter and foe alike. Nevertheless, overall development outcomes from flows of aid are equivocal (Table 2) because of variations in the rigor of aid supervision: donors became more discriminating in allocating aid in the 1990s.

“Regulatory” rent arises from manipulating relative prices to favor one group over another. It is frequently generated by closing trade policy to expand the scope for state intervention to create rent by changing relative prices. By its nature, regulatory rent is concentrated, which facilitates its theft by the elite (Table 2). Since economic reform shrinks scope for rent extraction by expanding competitive markets, it is often opposed by elite groups.

Finally, wage remittances are a diffuse form of rent with beneficial effects for very low-income countries because they boost domestic consumption, often of the poorest, and fund local investment where financial systems are underdeveloped (Giuliano and Ruiz-Arranz 2009). These positive impacts on economic growth attenuate, however, because as incomes rise remittances weaken work incentives, and financial intermediation improves. Moreover, as with most windfall revenues, large remittance flows can depress GDP growth through Dutch disease effects (Rajan and Subramanian 2011).

Further research on the resource curse

The literature on the resource curse has expanded rapidly since the 1980s and this review has of necessity focused on key issues, to the exclusion of more specialized debates, such as: the rentier state theory of autocratic governance (Ross 2001); the impact of resources on violence (Collier and Hoeffler 2004); and whether the appropriate measure of resource reliance is the export share or GNP share (Van der Ploeg 2011, 380).
The causes and manifestations of the resource curse are more complex than initially expected so it is not surprising that statistical analysis has struggled to demonstrate conclusively whether a resource curse exists and what may cause it. Future research might combine the insights of statistical and case study research to construct and test stylized models of the interaction of economic, institutional, and political factors with critical variables such as the scale of the resource rent, its volatility, and its distribution across economic agents. For example, the successful low-rent economies appear to follow a competitive industrialization development trajectory rooted in the incentive that low rents confer on the elite to grow the economy (and their own wealth) by promoting economic efficiency. This aligns the economy with its comparative advantage in labor-intensive manufactured exports. It proved remarkably effective at propelling economic diversification and absorbing labor to sustain rapid and egalitarian growth in per capita GDP with strengthening institutions and shifts, albeit lagged, toward political pluralism.

In contrast, high rent frequently incentivizes the elite to compete for rent for immediate self-enrichment at the expense of promoting long-term economic growth. This set of incentives locks the economy into a staple-trap development trajectory that retards competitive industrialization. It perpetuates surplus labor and prompts government intervention with subsidies from the resource sector to create urban jobs that markets would not otherwise support. The subsidies over burden and weaken the resource sector, eventually triggering a growth collapse that is protracted because rent recipients resist reform. Further research might therefore also seek practical strategies to incentivize the elite in high-rent economies to prioritize growth over rent extraction, perhaps by distributing most rent on a per capita basis or adapting the dual-track reform strategies of Malaysia and Mauritius.

Resource extraction

Gavin Bridge
Durham University, UK

Resource extraction refers to the separation and removal of natural resources from their immediate context. Extraction is widely interpreted as a physical process of displacement by which “gifts of nature” are removed from the Earth and transformed into useful raw materials: for example, the abstraction of water from rivers, the pumping of oil from underground formations, or the mining of coal, copper, and tin. In wresting materials from the Earth and mobilizing them into the economy, resource extraction exemplifies a classic “primary sector” activity. It is a process made epistemologically tractable primarily via the engineering and physical sciences: it is through hydrology, geophysics, and economic geology, for example, that raw materials are cleaved from their surroundings, enumerated in ways that enable their capture and insertion into markets, and are put to work in the service of trade and industry.

However, a more specific understanding of extraction interprets it as a political-economic process of expanding value and/or power via the identification, capture, and control of extractable materials. Because resources are not only materials but also arrangements of property, their extraction implies relationships of social power: the ability of a group (e.g., tribe, class, nation, corporation) to control land and reserve it against competing uses and users for extractive purposes; to marshal human labor and energy resources to the task of separating and moving materials; to achieve and control access to markets to realize value from the products of extraction; and to repress, legitimate, or otherwise contain the political tensions involved in controlling and appropriating natural resources. In short, resource extraction produces not only raw materials but also social-spatial distributions of power and geographically uneven forms of economic development. As such, extraction’s rationales and effects may be disclosed through critical social science.

A political-economic or political-ecological interpretation of extraction highlights how the reproduction of social power is at stake in the displacement and mobilization of raw materials. This is both a more specific and more expansive definition than physical removal, as it allows a wide range of natural resource gathering activities to be interpreted as extraction, beyond the iconic examples of vertical displacement associated with mining or other subterranean resources. The hunting and trapping of animals (e.g., the fur trade, or ocean fishing) or the gathering of plant material (e.g., rubber tapping) are also examples of extractive practices in that they involve the capture, control, and relocation of nonproduced materials in ways that generate value. The nineteenth century agricultural chemist, Justus von Liebig – whose analysis of nutrient cycling underpins Marx’s notion of socioecological metabolism – highlighted agricultural production as a process of nutrient export that impoverished the countryside by extracting its “mineral elements” and re-depositing them as “solid and fluid excrements” in the city. Extraction also occurs without the physical export of materials: the generation of electrical power via photovoltaic
RESOURCE EXTRACTION

cells and wind or water turbines, for example, is a form of resource extraction based on locating, controlling, and converting into electrical energy a particular concentration of productive forces (areas of reliable wind flow or insolation).

A political-economic interpretation of extraction foregrounds the question of what is being extracted, beyond physical materials. For Marxist analyses, an answer lies in the surplus value created by human labor. Resource extraction, in this sense, is no different to other forms of economic activity under capitalism which is an inherently extractive mode of production: although wages are represented as fair exchange, they do not fully compensate workers for their labor time as some of the value added by the power of labor (the “surplus” beyond that for which workers are paid) is appropriated by capitalists as profit. However, resource extraction is different from other forms of economy because the materials being extracted, and subsequently worked upon, pre-exist human labor: they are, in the language of classical political economy, “gifts of nature” as “the fundamental values in lumber, in minerals, oil, fish, and so forth, are predominantly in the good itself rather than in the labor incorporated in it” (Bunker 1984, 1054). The origin of value in natural resources thus turns out to be a surprisingly challenging question, revealing the limits of both orthodox and Marxist accounts of political economy.

In response, researchers have turned to the field of ecological economics which has sought, in different ways, to understand the relationship between the biophysical qualities of materials and the cultural metric of value. A common interpretation reduces value to physical properties, interpreting extraction as the capture and relocation of “natural values” in the form of low entropy (i.e., highly ordered) material forms. The energy density of crude oil, for example, arises from the processes of oil formation that effectively condense solar energy flows (received over extensive geographical areas and very long periods of time) into a material form with a very high capacity to do work: once brought to the surface, this capacity can be utilized (via combustion) to again compress the experience of space and time, in the form of enhanced mobility and speed. In a similar way, trade in agricultural goods like wheat, sugar, or cotton is a form of “time–space appropriation” as the calorific and nutrient content of these crops have been concentrated and upgraded by place-based processes of photosynthesis and nutrient cycling (Hornborg 2006). Such analysis enables trade to be understood as a form of unequal ecological exchange structuring uneven geographical development, in which highly ordered forms of raw materials are drawn from extractive peripheries of the world economy and consumed within the industrial core.

More recent research takes up the insights of ecological economics but aims for a nonreductionist account of resource extraction and trade, one that does not conflate the social category of value with physical measures of matter and entropy. By understanding industrial production as a process that simultaneously creates greater consumer value and greater entropy (see e.g., the pioneering work of Georgescu-Roegen 1971) it is possible to show how “the market exchange of finished industrial products for fuels and raw materials will inexorably reward the dissipation of natural resources in core areas of the world-system with economic access to more resources to dissipate … economic growth means that the more resources the core has dissipated today, the more new resources it will be able to dissipate tomorrow” (Hornborg 2015). In sum, contemporary approaches to the political economy and ecology of extraction decenter physical processes of material displacement and
identify how extraction sustains broader projects of capital circulation and/or the reproduction of social power (Huber 2013; Mitchell 2011).

Classifying the diversity of resource extraction

Resource extraction encompasses a bewildering diversity of practices, organizational forms, and materials, from birds’ nests and Brazil nuts, and coal and copper, to rubber, rutile, sulfur, seeds, and shrimp. Resources are extracted in all physical states (solids, liquids, and gases), and from all parts of the Earth’s system (atmosphere, lithosphere, hydrosphere, biosphere). Extractive economies involve diverse labor practices (hunting, cultivating, gathering, digging), and physical and chemical techniques (selection, concentration, disaggregation, transformation). Accordingly, extraction takes a diversity of organizational forms. Groundwater resources, for example, are abstracted for irrigation by private famers using gas-powered pumps in the western United States, mobilized from the Nubian aquifer by the Libyan state to supply coastal development, and drawn by hand from communal “singing wells” of the Borana region of Ethiopia. Coal is picked from slag heaps and waste piles as an informal source of energy the world over, but it is also mined deep underground with different degrees of technological assistance, and extracted in giant bucket-wheel excavators by state firms in Greece.

Organizing the diversity of extraction

Extraction’s diversity can be organized by reference to three broad criteria: the potential of the resource base to renew itself, the rationales underpinning extraction, and the industrial dynamics through which raw materials are appropriated. The first criterion centers on the timescale over which extracted materials will regenerate, where the primary differentiation is between stock (nonrenewable) or flow (renewable) resources. Stock resources exist in finite supply: removing these resources diminishes the physical stock available for future use, and so all nonrenewable resources are exhaustible by definition. Extractive resources that have significant regenerative capacity are classified as flow resources or renewables, although they too can be exhausted if consumption exceeds the rate of regeneration: this category of exhaustible renewables includes groundwater, fish, game species, and soil resources, all of which can be “mined” to depletion/extinction. Because a threshold exists beyond which further consumption exceeds the capacity of the resource to regenerate, exhaustible renewables are also known as “critical zone” resources. Many contemporary environmental challenges relate to the failure to manage critical zone resources effectively by maintaining rates of extraction within the boundaries of biophysical systems. The capacity of many biotic and abiotic resources to renew themselves is dependent not only on natural regeneration times but also on levels of social investment. Studies of traditional agriculture, for example, show human labor playing a vital role in maintaining soil fertility, and contemporary agro-industrial practices invest large energy and financial resources (in the form of synthetic fertilizers, or pumping for irrigation or drainage) to maintain the utility of the soil resource and offset the effects of nutrient depletion, soil erosion, and soil degradation. Similarly, development of an extensive infrastructure for collecting and recycling aluminum would enable society to treat this metal more like a flow resource than a stock. Advocates of a “closed loop” approach to material demands seek to expand secondary recovery of anthropogenic material flows in a bid to lessen the demand on primary forms of resource extraction.
RESOURCE EXTRACTION

Approaches to “mining the technosphere,” for example, highlight the potential for recovering materials accumulated in above-ground stocks, such as waste piles, materials in use, and a range of “hibernating” materials currently incorporated into abandoned urban infrastructures (Johansson et al. 2013). For this reason, it is helpful to think of a continuum of extractable resources running from nonrenewable stock resources which are consumed by use (such as fossil fuels) to the infinitely renewable resources of solar energy, tidal power, and wind.

The second criterion centers on a distinction between, on the one hand, extraction for subsistence and the reproduction of livelihoods and, on the other, intensive extraction on a scale that massively exceeds local consumption and is driven by a logic of export for commercial gain. Guha (2006, 233) differentiates *ecosystem people* from *omnivores* as a way of expressing the “basic and massive asymmetry” between these two resource extraction rationales. The terms capture two contrasting scales of “resource catchment” and suggest there is an important difference in the meaning and significance of extraction in each case. Development, Guha argues, is a state-assisted project to channel an ever-growing volume of extractive resources toward urban and rural omnivores. Moreover, it is a project that comes at the expense of ecosystem people, who have seen their subsistence extractive activities curtailed and replaced by large-scale forestry, dam schemes, mining, and agricultural plantations. In a similar way, Gudynas (2013) has coined the term *extractivismo* to reflect a particular modality of extraction that has dominated the history of Latin America: large-scale or high intensity resource extraction, geared for export as either raw material or with minimal processing. Coined initially in the context of the large-scale mining projects that materialized in parts of the Andes during the 1990s, *extractivismo* can equally apply to plantation agriculture, forestry, or fisheries. Importantly, these analyses are not a critique of extraction per se but of the sociopolitical context within which it occurs. There are parallels here with the challenge laid down by Howitt (2001) to find ways of rethinking resource extraction outside of a “colonial” frame in which extraction is directed by and serves nonlocal interests.

The third criterion recognizes that all extraction is a process of “primitive accumulation” through which economic value is captured via the appropriation of raw materials that, in significant ways, are produced independent of human labor. However, the industrial dynamics involved in generating this flux of materials take two broadly different forms. In some instances value is generated by the simple expedient of expanding the scale of appropriation: that is, by laying claim to a larger proportion of the Earth’s stock of resources and biogeochemical flows. The geographical extension of the “extractive frontier” and the subsequent development of property rights that license extraction of fish, timber, and mineral resources, for example, are illustrative moments of this “formal subsumption of nature” (Boyd, Prudham, and Schurman 2001). However, there are also instances where extraction involves laying hold of biogeochemical processes more directly, in order to harness and improve their productivity. The extraction of liquid oil from bituminous sands, for example, requires capital-intensive interventions in heating and hydrogenation to “upgrade” the raw material to a synthetic equivalent of crude. Similarly, the application of bacterial mining techniques (e.g., for the extraction of copper and gold) requires optimizing biological conditions for the reproduction of thermophillic bacteria able to liberate the target element from sulfide ores. Extraction in these cases involves a partial capitalization of the ecological conditions
RESOURCE EXTRACTION

required to generate the resource, with technology and the application of energy inputs substituting for the deep-time “geological” processes upon which conventional forms of oil and mineral extraction rely. This “real subsumption of nature” effectively “squeezes” or tailors natural production processes to accelerate raw material production or maximize particularly valued traits. The distinction between formal and real subsumption as modes of extraction is neatly illustrated by the difference between extracting timber from plantations or via old-growth forestry or the harvesting of fish via aquaculture or ocean fishing.

The distinctiveness of extraction

Juxtaposing extraction to industrial production highlights its distinctiveness as a mode of economy (Bunker 1984). First, materials extracted from the Earth are “fictitious commodities” (Polanyi 1944): we exchange them like industrial commodities but, unlike cell phones, chairs, or automobiles, they cannot be fully produced because societies are unable to replicate the geological, hydrothermal, and deep-time processes of which they are made. Second, extractive economies are marked by a low ratio of capital and labor relative to the value of the final product. This is strikingly illustrated by alluvial diamonds (which may be picked by hand from gravel with limited capital or labor), shallow oil and gas wells, or highly prized animal parts like ivory, although it is a general feature of all extraction including large mines, trawler vessels, dams, and offshore oil platforms. A corollary is that a large portion of the capital invested in extraction is tied up in export infrastructure tailored to handling a particular resource, which can be difficult to adapt to alternative demands once extraction is over. Third, the heterogeneous character of most natural resources means that economies of scale in extraction do not work the same way as in manufacturing. Scaling up often involves drawing upon resources located deeper or more remote from the initial point of extraction or working with lower quality materials. As a consequence, an increase in the volume of throughput tends not to reduce unit costs in the same way as in manufacturing, unless it is accompanied by changes in extractive technology or labor regime.

Fourth, the state frequently has a more central role in resource extraction than in industrial production. This is not only because many “strategic” resources are reserved to the state rather than being held in private hands, but also because the ability to access a resource is often more important than nominal patterns of ownership. The capacity of the state to authorize, enforce, and legitimate extraction is significant because resource development frequently overturns existing norms around land/resource ownership and access. Fifth, practices of extraction are shaped to a greater degree by the encounter with physical materials than are those of industrial production. The biophysical capacities and affordances of materials influence the forms of property, class relations, labor regimes, and technologies adopted for their extraction. Long-term extractive economies like the Amazon or California/Nevada illustrate a progression through several distinctive “modes of extraction,” with social relations laid down in one mode shaping the next (Bunker 1985; Brechin 1999).

The scale and temporality of resource extraction

Resource extraction is a primal pursuit, evolving over time from relatively simple processes of gathering pre-formed materials to the application of greater quantities of labor and fossil energies to locate and liberate materials of social
value. The recovery of nuggets and flecks of gold from placer deposits via physical panning techniques, for example, has over time been supplemented with high-pressure hydraulic mining, the development of deep mining techniques, and chemical processing to extract gold from highly disseminated (i.e., ultra-low grade) and refractory reserves. In a similar way, as the extraction of fish from offshore waters has shifted progressively further offshore and to deeper marine environments, the energy inputs required to extract a given unit of resource have increased. In short, many resources have become progressively more difficult to extract over time, although this “depletion” effect has, for the most part, been offset by new technologies of exploration and extraction, the availability of low-cost energy inputs, and forms of regulation that have facilitated access to new “frontiers” of extraction.

Since the early nineteenth century, a progressively growing torrent of raw materials has been drawn from the Earth and directed toward the industrializing heartlands of the world economy, exemplified by an increasingly significant long-distance trade in bulk resources like coal, copper, and cotton. For many resources the rate of extraction has increased markedly in the second half of the twentieth century. This “Great Acceleration” has driven a material intensification of the economy in terms of absolute volumes/tonnages of resources extracted from the planet’s biogeophysical systems. The most intensely extracted materials – sand and gravel – are now equal in volume to physical flows associated with fluvial systems. These flows, together with the very large volumes of waste materials moved in mining, mean that humans rival wind and water as terra-forming geomorphological agents. Anthropogenic flows of elements like carbon, mercury, sulfur, and nitrogen, which are linked in different ways to extractive practices, now exceed background biogeochemical flows.

While some resources (like sperm whales or guano), around which entire extractive industries were built, have ceased to be regarded as commercial resources, for the most part the volume and range of extracted materials has grown. This massive scale and diversity of resource extraction is a signal feature of the Anthropocene.

Several other temporalities of resource extraction are overlaid on this secular trend of an expanding volume. Extractive economies are characterized by cycles of boom and bust, in which capital and labor are deployed around rises in the price of raw materials, only to see new investment marooned and workforces laid off when prices collapse. This recurring characteristic in the development of extractive economies is closely tied to the capital intensity of extraction and the fungible nature of many extractive commodities. From the late 1990s onwards, for example, prices for many raw materials were driven upwards by high and sustained rates of resource-intensive economic growth in Asia. Projections of further demand growth attracted investment into the extractive sector, leading to the development of new mines, forestry plantations, agricultural projects, and the infrastructure for resource export. This “super-cycle” of rising prices and new investment was sustained for around a decade by relatively high rates of growth in emerging markets and growing concern about physical scarcity constraints (e.g., debates concerning peak oil; Bridge 2010).

The cyclical character of raw material prices means that extractive investment tends to wax and wane over time, although this does not always have a straightforward geographical expression. The history of mining investment includes periods of geographical extensification, when mining capital scours the globe for new extractive opportunities. During the 1990s, for example, mining capital underwent a profound process of geographical extensification with a
series of large new mines opened in Latin America, South East Asia, and Africa and which gave rise to a new “geopolitical ecology” of extractive exports (Bridge 2004; Bebbington and Bury 2013, 16). Extension of the extractive frontier in this period was enabled by the adoption in many resource-rich countries of national policies of economic liberalization, often required by international financial institutions as part of a package of “structural adjustments” in the wake of the 1980s debt crisis. Extractive histories also include moments of intensification, characterized by processes of “in-situ” restructuring that center on reducing production costs via technological change and renegotiating labor conditions (Bridge 2000; Ó hUallacháin and Matthews 1996). Finally, there is the temporality of abandonment around resource extraction when the process of “bust” involves more than a temporary withdrawal of capital and labor. While the cessation of resource extraction is often represented as an orderly process of closure and remediation, in which land is returned to a semi-natural state, extractive projects frequently have an “afterlife” that confounds the neat temporality of an extractive “life-cycle” from discovery to closure. Sandlos and Keeling (2013), for example, have shown how the long-term environmental impacts of extractive projects beyond closure – from the accumulations of toxic waste material to the challenges of acid mine drainage – lend resource extraction a “zombie” quality: long after production has ceased legacies of extraction continue to haunt communities.

Governing resource extraction

Resource extraction is a target of several different national and international policy concerns, from financial transparency and revenue management to sustainable livelihoods, global biodiversity, and the self-determination of indigenous peoples. Extraction has become a lightning rod for discontent with economic globalization and mainstream models of development. The elevation of practices of resource extraction to formal policy concerns reflects, in part, their politicization over many years by communities at the sharp end of resource development. An uneasy alliance of activists and social movements from the Global North and South have, for different reasons, challenged prevailing corporate and state practices around resource extraction. Often disadvantaged by proposals to mobilize natural resources in the interests of “national” economic growth, these groups have sought to reform the extractive sector via direct action, new national legislation and/or recourse to international agreements. The diversity of these concerns, the plurality of spaces and scales in which extractive activities are being challenged, and the modalities of struggle around extraction (including both resistance and adaptation to resource development, as well as forms of “neo-extractivism” that promote resource extraction for progressive social ends), suggest that the governance of resource extraction is being profoundly re-negotiated. Four significant trajectories of concern are discussed here that also reflect the evolution of geography’s engagement with resource extraction: from habitat conservation to livelihoods, from optimal rates of extraction to informed consent, from enclave economies to contested territorial imaginaries, and from “Dutch Disease” to transparency.

From habitat conservation to livelihoods

The impacts of extractive activities on the biological productivity and quality of environmental systems are widely documented. Air, water, and soil pollution, the bio-accumulation of metals and toxins mobilized during extraction, and the impacts of extraction on pastoral, forest, and
aquatic ecosystems are long-standing concerns of environmental policy. While the land area dedicated to extractive industries like mining and quarrying is relatively small, these activities generate “environmental multipliers” via (i) extractive infrastructure, such as access roads, which accelerates the circulation of capital and labor (research on Amazonian deforestation, for example, demonstrates how logging and mining impacts regional in-migration, settlement and forest conversion), and (ii) systemic impacts to biogeochemical cycles. The mining and combustion of coal, for example, significantly modify the cycling of mercury, sulfur, and carbon.

A concern with the disruptive effect of extraction on “nature” – expressed in efforts to improve the environmental performance of extractive industries or in research documenting resource extraction as a driver of land-cover change and/or species loss (Swenson et al. 2011) – has been supplemented over time with a growing interest in how extraction affects already-existing livelihoods. While this is not a new concern – some of the earliest examples of “environmental” legislation around resource extraction centered on conflicts between miners and farmers over the effects of metal smelting and waste disposal on agriculture (Kelley 1959) – it is increasingly acknowledged that policy challenges associated with resource extraction extend beyond the conservation of biodiversity or the management of physical material flows. Placing livelihoods at the center of analysis, rather than nature, reveals how resource extraction is also a process of dispossession, because of the particular ways in which extraction intersects with pre-existing economies. Dispossession may take place via the introduction of new rules on access to land (e.g., for small-scale mining, grazing, or forest products) or to water resources (important for watering livestock, irrigating crops or for catching fish); the assertion of formal property boundaries that cross-cut customary trade routes; or the sterilization of biotic marine resources via the dumping of waste materials or the construction of port facilities. Extractive projects can affect ongoing livelihoods by introducing and overlaying new forms of property (e.g., mine claims, forest concessions) on established rights and entitlements. Extractive property rights also are “technologies of rule” that enable land to be held speculatively, as an option for future development: they introduce logics, forms of discipline, and uncertainties for other land users prior to – and even in the absence of – raw material extraction (Peluso and Vandergeest 2001).

From optimal rates of extraction to informed consent

If extraction is understood primarily as a physical flow of raw materials, a central policy concern is the rate at which materials should be taken from the Earth and consumed within economies. How one should allocate scarce resources over time centers on the balance between extraction and resource conservation, and is one of resource economics’ classic questions. The so-called Hotelling rule, for example, provides a guide to how fast exhaustible resources like oil, tin, or gold should be extracted in order to maximize its value over time (Hotelling 1931). The desire to establish a socially optimal pace of resource development reflected a growing concern in the early twentieth century – articulated in the “conservation ethic” of Gifford Pinchot, the first Chief of the US Forest Service, among other leading figures in an emerging resource conservation movement – that the accelerating pace of timber cutting, oil field development, and minerals extraction would be ruinous for future generations. In a similar way, mid-century models of “sustainable yield” provided a guide
for the management of renewable resources like fish or groundwater.

The conservation–extraction dilemma frames resource decision-making as a technical question of how to optimize revenue from a fixed or variable stock. In so doing, it reserves decision-making for an elite group of scientifically trained resource managers. More recently, these traditional concerns with resource optimization have been supplemented with a broader set of questions about how scientific knowledge is mobilized in the interests of economic and political power; and about who should make critical decisions about whether, where, when, and how resource extraction takes place. At issue here are two related questions: the administrative scale at which decisions should be made (i.e., how “local” objections to resource extraction articulate with wider regional or national objectives); and the right of affected communities to exercise free, prior and informed consent (FPIC) over developments that may impact their wellbeing. The call for FPIC and its underpinning principle of self-determination have become a key demand of nongovernmental organizations affected by resource extraction as a way of addressing the historic disempowerment of indigenous and other marginalized social groups. The principle is outlined in both the United Nations Declaration on the Rights of Indigenous Peoples and in the International Labor Organization Convention 169. Its implementation has gone hand in hand with a growing use of community referenda that, whether sanctioned by the central state or not, provide a way for a community to register its consent (or lack thereof) to resource development proposals. Indeed, harnessing administrative scales below that of the national state has proven an effective strategy for communities seeking to challenge national institutions that promote extraction: between 2003 and 2008, for example, 7 out of 23 provinces in Argentina challenged the central state by banning open-pit metal mining (Walter and Martinez-Alier 2010). Others have noted how community referenda allow those opposing resource extraction to redistribute “the potential for empowerment” by linking locally scaled political and moral claims with organizational structures at national and international scales (Haarstad and Fløysand 2007, 289; Perreault 2006).

From enclave economies to contested territorial imaginaries

Resource extraction’s territorial form has been a long-standing concern for those seeking to harness resource extraction for national and regional development. The relative weakness of “forward” and “backward” linkages and a general orientation toward the export of raw materials mean that resource extraction has a tendency to produce enclave forms of development that are more strongly tied to external markets and centers of finance than to the host community or nation. The truncated territorial forms of development associated with extraction and raw material export occupied an earlier generation of scholarship grounded in the economic history of resource exporting regions (e.g., Innis 1956; North 1955; Bunker 1985). More recently, the imaginary of the “enclave” has been recycled to describe a particularly neoliberal modality of extractive development associated with both a minimal build-up of social infrastructure and flexible or “variegated” forms of sovereignty designed to facilitate the expansion of extractive capital (Ferguson 2006; Emel, Huber, and Makene 2011). In seeking to understand the link between resource extraction and territorial form, recent work focuses less on economic linkages and more on the ways in which historic and contemporary struggles over
RESOURCE EXTRACTION

extractive resources give shape to questions of citizenship, community, and identity (Perreault 2013; Valdivia 2008; Watts 2004).

From revenue management to transparency

Resource extraction poses a number of challenges for revenue management that belie the apparent simplicity of converting natural resource riches into social wealth. The scale of resource revenues can be difficult to absorb in states with limited infrastructure or consumption potential. The volatility of revenues over time, and the ways in which extractive exports interact with other forms of economic activity, can pose additional obstacles to achieving broad-based forms of growth that are economically sustainable. Historically these challenges have been framed as the problem of “Dutch Disease” (named after the counter-intuitive effects on the Dutch economy of developing Europe’s largest gas field in the 1960s), in which the revenues from extraction drive an appreciation of the domestic currency and a corresponding loss of competitiveness for manufacturing exports (Auty 2002). In this view, large-scale resource extraction and export can drive a process of de-industrialization in economies where manufacturing is already well-established. In economies with limited manufacturing and where the state is the principal recipient of large revenues from extraction – such as in the case of oil in Venezuela and Saudi Arabia or natural gas in Qatar – the state’s “rentier” character creates challenges not only for economic management but also political accountability. The dominance of resource rents in the state’s revenue stream, and the correspondingly limited role of general taxation, lends the rentier state a high degree of autonomy from its population. Such autonomy frequently expresses itself in authoritarian forms of government and political patronage.

These well-rehearsed policy concerns regarding the under-performance of extractive economies (Ross 2001), the “resource curse,” and the supposed “paradox of plenty” (Karl 1997) have been supplemented over the last decade or so by a growing recognition of the need for greater transparency and accountability in the management of resources, payments, and revenues associated with large-scale resource extraction. Calls for greater disclosure of the payments made by extractive companies to governments, from development-oriented nongovernmental organizations (NGOs) like Oxfam, Global Witness, and Publish What You Pay, contributed to establishment of the Extractive Industries Transparency Initiative (EITI) in 2002. This created a series of international standards, practices, and validation procedures that center on disclosure by host governments and investing corporations. High-profile projects like the Baku-Tblisi-Ceyhan oil pipeline from the Caspian to the Mediterranean confirm transparency’s role as political norm in an emerging liberal mode of resource governance. The politics of transparency go beyond placing information in the public domain, demanding the creation of publics able to bear witness to its operation and effects (Barry 2013).

Conclusion

During the first decade of the twenty-first century a commodity “super-cycle” helped push resource extraction to the center of public and scholarly attention. The intensification of logging, fishing, mining, and other extractive activities, and their geographical extension, created for those at the sharp end of extraction a series of ecological and political conditions
that have enabled popular mobilization around extractive projects. One result is a rich body of accumulated knowledge among activist networks and social movements that increasingly shapes corporate and state strategies for resource extraction. At the same time, overlapping concerns about looming resource scarcity, habitat conservation, the anthropogenic flux of carbon, dispossession of indigenous peoples, and the particular challenges of sustaining broad-based development from extractive economies have ensured resource extraction is a focal point for a range of national and international policies. The governance of extractive resources, then, is changing in significant ways, although the mobilization of raw materials from the Earth continues to grow in scale and complexity. Scholarly work on resource extraction has responded to these developments. On the one hand, the physical science base for understanding the scale of raw material extraction and its environmental and human health effects has grown considerably. On the other, critical social science analyses of resource extraction have identified how the political, economic, and environmental significance of resource extraction extends well beyond the physical mobilization of raw materials.

Further reading

The relationships between natural resources and development are profoundly important, but contingent and contradictory. Indeed, the evolutionary paths of different resource industries, and even different areas with similar resources, are remarkably diverse, and debates over the role of resources in development rage around the world. For some nations, resources have been an evolutionary stepladder for high incomes and diversified economies, while others seem cursed and trapped by their resource dependency. In Canada, with its long tradition of resource exploitation and of its theorization, these debates continue to engage different (optimistic and pessimistic) approaches (Gunton 2003). More evocatively, Canada’s Athabasca heavy oil deposits became both a vital national growth pole and national target over its environmental consequences and a polarization of views that fuels an oil pipeline extension controversy in the United States, where energy security and competition are also issues. Meanwhile from local perspectives, resource communities around the world grapple with the myriad problems associated with booms and busts while all levels of government seek approaches to parlay resource riches into long-run, place-based development (Markey, Halseth, and Mansen 2012).

The goals of resource exploitation have long focused on regional and national economic development and economic growth, conventionally measured by increases in per capita GDP (gross domestic product). In tandem, resource exports have long been emphasized as a driver of development for regional peripheries. Indeed, for new resource-based economic spaces, resource policy was industrial policy that privileged the commodification of nature and the industrial values of resources. In recent decades, however, this thinking has been questioned, even turned on its head, and criticized for its failure to cope with distributional inequities, quality of life, and environmental considerations. In this rethinking, the nonindustrial values of resources should define development rather than vice versa. The globalization of resource conflicts is a visceral indicator that the relationships between resources and development are in a transformative phase.

This entry’s objectives are to summarize the problematical implications of resource exploitation for economic diversification, and to discuss the implications of resource conflicts for development, particularly with respect to resource peripheries. The review is necessarily selective of the vast literature on these and related themes, within and beyond economic geography. That said, the entry focuses on fundamental perspectives and broaches new concerns. Economic geography’s long-standing interest in the human use of nature has been reinvigorated in recent decades from neoclassical, institutional, and Marxist perspectives, and from their offshoots.
such as political ecology, sustainable development, and environmental economic geography. This entry reflects an institutional perspective on environmental economic geography (Patchell and Hayter 2013).

In terms of format, the study begins with the interlocking concepts of resource cycles, governance, and multifunctionality. Second, we examine the role of resources as inputs to industrialization with respect to their diverse impacts on resource peripheries. Third, resource conflict and resolution are discussed in relation to a rethinking of the meaning of development.

**Key dilemmas of resource-based development: governance, multifunctionality, and cycles**

Relationships between resources and development are problematical. Their meanings and values are socially driven and judgmental, and vary over time and space and between people at particular times and places. Always intimately local, resource–development relationships have become global in scope, “officially” signaled by the United Nations (Brundtland 1987) following earlier alarms of environmental destruction. Resource and development relations are complicated because: resources are viewed as birthrights whose governance raises questions about public interest and the flow of benefits into the future; resource use offers multifunctional (industrial and nonindustrial) values that are often incompatible; resource cycles based on industrial exploitation generate significant positive and negative externalities; and – because resources are distributed according to nature’s endowment – they are often remote from where people need or want them. These themes are interrelated.

Resource endowments are derived from nature but are culturally defined. Social evaluations of nature typically evoke deeply rooted attachments and the bias that resources should be used or designated to enhance broadly based “local” (national, regional, community) development goals. Given that air, water, and food are necessities for life itself, the wise use of resources in general typically invokes reference to the public interest. This challenge of wise use became manifestly greater following the Industrial Revolution, which began in the late eighteenth century and heralded sustained increases in economic growth, population, and demand for resources. In tandem, the governments of leading nations prioritized economic growth through the spread of market institutions, industrialization, and trade. In this pursuit of the public interest as the wealth of nations, the privatization of resource ownership and/or control became widespread, often at the expense of common property resources. The search for productivity and new markets in turn stimulated processes of discovery and innovation that created new or diversified existing resource use. Indeed, even if it is not often recognized in contemporary literature, innovation, with its high-tech focus, has been a significant, often sophisticated impulse in the resource sector, creating new products while opening up new resource spaces and extending existing ones. In the case of oil, for example, the opening up of conventional and unconventional sources in deep sea and Arctic locations, and of oil sands and shale oil deposits, has depended on important technological improvements, as well as generating increased (financial and environmental) risks.

Yet, significant government involvement, inevitably justified as in the public interest, has proceeded, inter alia, with the privatization of resource exploitation (Bridge 2013). Governments remain vitally entangled in resource management, stimulated by their role as resource owners, by society’s demand for the wise use
of nature, by the need to adjudicate between competing diverse values, and by the social and economic externalities generated by industrial exploitation. Government stipulation of conditions on resource use has long-lasting effects. Among New World economies, for example, settlement was encouraged by the assumption of terra nullius and incentives to immigrants and business through stakeholder rights and land grant schemes that were deemed vital to economic development via resource exploitation. The recent explosion of oil shale fracking activity in the United States is based on subsurface rights awarded decades ago under privately owned farmland allocated even earlier. In the case of Canadian forests, past government decisions to retain public control over forests, even as they encouraged their private use, now help to stimulate broader debates over their wise use.

In recent decades, resource privatization is often criticized as part of a neoliberal agenda, not least in the context of water, the quintessential public good (Bakker 2010). Yet, when resource ownership and control have been privatized, governments have sought, perhaps increasingly so, to regulate on myriad issues in areas such as health, safety, and the environment. Even in resource peripheries with strong commitments to free enterprise and free trade, neoliberal attempts to privatize and deregulate resources to empower markets at the expense of community interests have limits (Hayter and Barnes 2012). Further, government interventions over resources are frequently pragmatic, reflect diverse motives, and include critical questions pertaining to water access (Agnew 2011). Interestingly, the strongly pro-market Canadian oil industry began requesting a stronger, more transparent commitment to the environment from the previous (pre-2016) recalcitrant federal government as a precondition for a stable business environment.

Moreover, resource privatization or nationalization can be reversed. As one interesting historical precedent, the privately developed British coalfields were nationalized for decades (1945–1987) before being privatized again. Less equivocally, the nationalization of oil resources has been a widespread trend around the world, beginning in the 1950s and 1960s, with state-owned companies now having larger reserves and output than established Western-based multinational corporations (MNCs), which remain larger in terms of market value. Moreover, to sustain biodiversity and offset global warming, national governments have agreed to the global expansion of conservation areas, many focused on Northern boreal forest regions (Affolderbach, Clapp, and Hayter 2012), in which private rights, for example those held by forest companies, have been removed or substantially modified. In many resource peripheries the empowerment of aboriginal rights is further complicating established notions of property rights.

In practice, resource governance features complex bundles of property rights, obligations, and limits on resource extraction whether the resources are fixed or mobile, land-based or beneath the surface. These resource rights define resource regimes that vary from place to place and refer to (formal) de jure and (informal) de facto rules of governance regarding resource use and transfer. Indeed, it is difficult to generalize about appropriate forms of resource property rights from a development perspective with one exception: open access resources that lack governance are widely condemned for encouraging overexploitation and stimulating negative externalities whether in the form of congestion on a beach, global climate warming, or fisheries depletion in open oceans.
**RESOURCES AND DEVELOPMENT**

**Resource cycles**

In response to industry’s escalating materials needs, export-driven resource exploitation has been pushed to all parts of the globe. In that process peripheral regions and communities have been created and subject to patterns of development and decline shaped by resource cycle dynamics. Resource depletion is an obvious reason for decline, but competition from other places and substitution by new materials and technologies also threaten resource-based development. While the distinction between renewable and nonrenewable resources is a basic dichotomy, defined by the implications of depletion and renewal, the sustainability of the former is not necessarily inevitable, or likely. If finite mineral deposits will inevitably be depleted, fish and forest resources similarly experience resource (S-shaped) cycles of discovery, boom, bust and collapse, or rationalization. In practice, the evolutionary trajectories of resource cycles vary. Typically reliant on distant, specialized markets, resource cycles are punctuated by short-term business fluctuations that in turn complicate longer-term trends and understanding of fundamental turning points. Indeed, the trajectories of resource industries during lengthy periods of postmaturity can be geographically and temporally uneven, with highly varying entry and exit rates of firms among subindustries, as illustrated by British Columbia’s forest sector (Edenhoffer and Hayter 2013).

Initiation and expansion of resource exploitation occurs through many configurations of firms with different size, networking, and ownership characteristics. Irrespective of these configurations, all firms must respond to market demands and with repercussions for the viability of production facilities and communities. Although most closely interrelated with the community, small local firms are the most fragile in terms of dependence on distant markets because they often lack the capacity to ride out market fluctuations or to diversify. Larger firms may have such capacity and may be able to switch resource locations. In either case, given concerns about community or regional welfare, governments typically play a large role in resource development.

The developmental role of governments varies during resource cycles. In the early stages and the opening of new resource spaces, governments facilitate growth by providing attractive governance conditions, low taxation or royalty payments, incentives for exploration and testing, massive investments in infrastructure, and support for research and development. In the nineteenth century, in Europe and the United States, local wealth and relative proximity often allowed the private funding of transportation for access to resources. In Canada, with a sparse population spread over vast distances, governments have needed to fund and often control transportation networks up to the present (Gunton 2003). Canadian governments also became increasingly involved in providing social or community infrastructure. Early resource towns were literally often company towns where the corporation provided housing, services, and local administration. After 1945, however, new resource towns with their own municipal powers were planned by senior levels of government, beginning when Kitimat in a remote part of British Columbia’s northwest coast was chosen as a location for an aluminum smelter.

In some resource sectors, especially where producers are small-scale, such as agriculture and forestry, governments have long played key roles in developing and transferring technology through networks of specialized laboratory operations. Recently, governments have been closely engaged with the private sector in developing renewable energy technologies, for example in...
In the late stages of resource cycles government attention becomes more focused on problems of decline, especially in regions and communities that remain resource-dependent. Declining coal mining and depressed rural areas in Europe and North America gave birth to the original regional problem areas. They stimulated the introduction of regional development policies in the 1930s and expansion in the 1950s. In practice, the challenges of rejuvenating resource communities in these regions have proven enduring while in recent decades the number of declining resource towns has increased. In the decline stage, the established community often adds local perspectives on development plans that are “placed-based,” highly varied, and made in the context of changing social structures (Markey, Halseth, and Mansen 2012). To pre-empt the building of communities only to see them painfully closed, companies and governments have developed a strategy of using fly-in fly-out workforces for resource projects in new spaces. Proponents are spared significant sunk costs and future policy challenges while providing companies with employment (albeit high-wage) flexibility.

Resource exports and regional (community) development

Can resource exploitation generate long-term development? In evolutionary explanations of capitalist development over the last 250 years (Patchell and Hayter 2013) resource inputs have been recognized as significant to, but not a primary causal factor of, industrialization. Rather, “paradigmatic” transformations evolve through interdependent institutional developments in science, technology, society, politics, and the markets that are favorable to entrepreneurship and innovation.

That said, resources nevertheless played a role in the development of industrial cores, if this is not always appreciated. For example, referring to a hearth of the Industrial Revolution, Potter and Watts (2010) interpret the evolutionary trajectory of Sheffield’s metalworking activities (steel, cutlery, and tools) as the quintessential example of localized Marshallian (positive and negative) externalities in the form of local skilled labor pools, suppliers, and knowledge spillovers. In their model, without reference to dates or periods (or institutions), “Embryonic agglomeration … starts with a mutation process … in which Geography is crucial” (Potter and Watts 2010, 421–422), by which they mean various knowledge-based advantages that accrue to pioneering new and growing firms from clustering together. However, Sheffield’s case also reveals the importance of local access to resources during the embryonic stage that culminated in Benjamin Huntsman’s innovation of crucible steel in the 1760s. Thus Sheffield’s dispersed metalworking sites enjoyed close access to several key industrial resources (charcoal, coal, iron, clays, sandstones, millstone grit and limestone, plus local agriculture), while the rivers and streams that crossed the city once powered the largest concentration of water wheels in Europe (and were organized along common property lines). Huntsman himself relocated to Sheffield to access these resources and conduct his experiments in relative secrecy.

Elsewhere, the evolution of North American industrial agglomerations pointed to resource access as part of their “initial advantages” that generated the continent’s industrial heartland. In Europe, Ruhr Valley coal deposits helped establish Germany’s industrial prowess. China’s steel mills and heavy industry are located near the coal and mineral deposits of the northern
RESOURCES AND DEVELOPMENT

provinces. In contrast, major steel and heavy industry locations in Korea and Japan relied on imported raw materials. Now, whether local supplies have never existed or have been exhausted, core regions and cities see resources as inputs to diversified ranges of manufacturing goods that can be imported. For new resource-based economic spaces, however, resource exports are their rationale and the specter of declining resource cycles, however implicit and vague, has stimulated resource peripheries to contemplate how to use resource exports to diversify and achieve self-sustaining growth (Auty 2001).

Resource periphery diversification

Understanding the role of resource exports in regional and urban diversification is sensitive to scale and context. At root, however, the implications of export-based resource exploitation for local economic development and diversification has long been conceptualized as a process of local linkage development within poor and rich country contexts and in densely populated and empty resource spaces (Baldwin 1956). Within geography, mesoscale studies have elaborated these linkage-based models, for example, to explain the early development of California (Walker 2001) and recent restructurings in British Columbia (Gunton 2003).

In broad perspective, the “virtuous” diversification of new resource-based economic spaces is rooted in the creation of backward, forward, fiscal, and final demand linkages. Backward linkages are investments in activities that provide inputs to the resource sector such as machinery, components, materials, wholesaling functions, research and development and engineering, decision-making and related services, and more broadly to the establishment of transportation and community infrastructure. Forward linkages add value to resource sector outputs (while generating further backward linkages); fiscal linkages are payments to governments from the resource sector; and final demand linkages are created by the demands by (growing populations of) local consumers for goods and services. Geographically, successful linkage diversification around export-based resource sectors is associated with urbanization and the generation of core–periphery relations, especially at national and regional scales. Potentially, related linkage development and Marshallian-type localization economies (Potter and Watts 2010) can stimulate more broadly based urbanization economies that help cities and regions diversify in new, creative directions and related localization economies.

California’s experience illustrates the extent to which urban and regional diversification can draw on and move well beyond resource dependence (Walker 2001). Meanwhile, if questions can be raised about sustainability, the growth of Calgary and Edmonton, Canada’s most dynamic metropolitan areas of recent decades, reflects the continuing urbanizing power of resource-based linkages.

In general, resource periphery diversification is related to integration into rich market economies, and is shaped by the establishment of local entrepreneurial and labor pools, by government policies for stimulating resource cycles, and by their resource endowments. Thus, the ability to diversify and urbanize around a resource base has geographic foundations, most obviously in the richness, scope, and variety of resources, their costs of exploitation, and access to markets. Extensive, high-quality, diverse resources facilitate economies of scale and scope, rival investments, cumulative advantages, stronger justifications for infrastructural investments, new resource discoveries, and intersectoral innovation, while growing technological expertise can create processing efficiencies that offset higher costs of exploiting less accessible, lower-quality
resources. Innovative activity has also often been stimulated by locally distinct resource conditions (Walker 2001).

Regional and national contexts and situations further shape urban and regional diversification. Among rich Western economies, for example, Canadian and Scandinavian approaches to export-driven forest exploitation evolved differently. The latter emphasized forest privatization, domestic companies, and in-house research and development (R&D) investments that have collectively stimulated stronger export-oriented forward (e.g., furniture) and backward linkages (e.g., machinery). In Canada, forests are publicly owned by provincial governments, foreign direct investment (FDI) is significant, government R&D is important, and linked developments are less export-oriented. In the oil sector, while Norway exerts control through a state-owned company (SOC), Statoil, and taxes it heavily (78%) to fund a national heritage fund (over US$900 billion in 2014), Alberta welcomes foreign ownership and prefers low taxes and a stronger role for the private sector in reinvesting profits. Its heritage fund of US$16.7 billion in 2014 is relatively small. If Alberta’s oil industry’s backward linkages are considerable, provincially and nationally, its forward and fiscal linkages are modest, as illustrated by debates to add refining capacity prior to export.

In part, the Albertan reticence to demand larger oil rents reflects geographically ingrained geopolitical realism. Alberta’s political and business community has been committed to North American “continentalism” which casts Canada as a resource supplier to the United States as a major market and hegemonic power. This role counsels against government interference over profits or industrial organization. However, Canada’s resource exports, for such a large country, are remarkably dependent on US consumption, rendering it vulnerable to US trade protectionism and policy shifts.

Resource enclaves and policy debates

Local linkage generation around resource exports is not automatic but can be arrested. Resource enclaves are those peripheral regions and communities that struggle to escape from narrowly defined resource dependency, and whose linkages are largely generated elsewhere. Enclaves include mining operations, agricultural plantations, logging camps, forest product complexes, and oil fields that are characterized by remoteness, isolation, control by distant decision-makers, reliance on imported technology, and exports of low-value commodities to be processed in cores. Enclaves involve the branch plants of MNCs (or government agencies), and their viability in particular locations is closely tied to resource cycle dynamics and exploitation, and also to the discretionary powers of MNCs (or governments) that have location options. Enclave operations are mandated by organizational dicta with regards to scale, commodity mix, and markets, with any expansion or restructuring decided by head offices and related to broader organizational strategies. Vertically integrated MNCs may further enjoy discretionary powers over pricing such as imposing low internal transfer prices to reduce payments of taxes in peripheral regions.

The challenges to the long-run diversification of enclaves are geographically widespread. Thus the underlying dilemmas are referred to as a staple trap in Canada, addictive behavior among American resource communities, and a resource curse among poor countries (Auty 2001) – metaphors that readily connect with the functional, cognitive, and political lock-ins of path-dependent behavior. There is considerable debate on the interrelated causative factors
that conspire to restrict enclave diversification. These may be summarized broadly in terms of geographic, institutional, and boom and bust perspectives. In this context, geography implies site (endowment) and situational factors that shape resource cycles. Markets have enormous centripetal tendencies, and the ability of resource towns and peripheries to diversify may be limited by their small size, isolation, increasing costs, resource exhaustion, vulnerability to competition, and possibilities of substituting other inputs. However, whether or not resource peripheries inevitably suffer declining terms of trade is debated.

“Staple traps” and “resource addiction” are virtual synonyms with respect to institutional constraints on resource diversification. The terms describe narrowly based competencies, capital and human inertias, and conservative attitudes among corporations, governments, and communities that mutually reinforce resource dependence. Thus resource-based corporations tend to be powerfully locked into established strategies, constrained by highly specialized managerial expertise, immobile resources, dedicated machinery, and the expense of large-scale investments to modernize operations and maintain market share. Further, the implications of flexible mass production in resource industries are variable, and often not an option. It is worth recalling that the local role of MNCs in resource exploitation has long been criticized, not only within radical literatures such as dependency theory but also in Baldwin’s (1956) neoclassical analysis. In Baldwin’s comparison of the production functions of MNCs with local entrepreneurs, the resource plantations of the former were less likely to diversify local economies than local pools of entrepreneurial risk-takers who reinvest profits locally, purchase locally, and stimulate external economies and more accessible infrastructure. Nevertheless, FDI in resource exploitation is an important influence, increasingly originating within developing countries. Resource-based and global production networks are typically orchestrated by large organizations with influence over the location of value-adding activities.

Governments can perpetuate resource dependency, not only by investing in dedicated infrastructure and incentives, but also through bureaucracies and politics ingrained in the primacy of resource exports as the growth mechanism. As noted, resource peripheries tend to be strong supporters of free trade agendas even when trade agreements counter their interests. If poor countries have become more skeptical in this regard, domestic political conditions can pose powerful limits on resource diversification. In Southeast Asia, for example, the patron–client model of governance has facilitated deforestation and log exports as much as the behavior of Japanese MNCs. More widely, corruption and political instability in poor countries directly and indirectly stimulate tendencies to exploit resources quickly while dissuading investments diversify economies.

With respect to how the boom and bust of resource cycles thwart local diversification, the resource curse, or Dutch disease, has received much attention. Originally developed in the context of oil exports from the Netherlands, the curse now mainly refers to poor resource-specialized countries whose booming resource exports increase local currency values to render imports cheaper than local supplies (Auty 2001). Further, the ability of resource sectors to pay high wages and high prices for land and other local inputs can crowd out other endeavors, including at the resource-town level (Argent 2014). Even without the Dutch disease, business cycles can reduce local diversification as local governments and labor unions are uninterested in attracting alternative businesses in boom times
and unable or unwilling to seek alternatives during recessions. Unfortunately, when permanent downsizing occurs resource towns are frequently unprepared, and start contemplating diversification only when financial resources have become limited, labor pools specialized, and competition for alternative opportunities considerable. How rates of resource cycle growth relate to diversification is an interesting question. If too fast growth implies shortened cycles and Dutch disease effects, too slow growth may fail to generate positive externalities and attract investment.

Redefining resources: conflict or compromise

The multifunctionality of resources has increasingly imposed highly contested choices on developmental paths. The crux of the issue is whether conventional resource exploitation can coexist with increasing demands for ecological preservation. The first perspective emphasizes the jobs and rents directly generated by resource exploitation, and the second seeks to control exploitation while promoting alternative (nonindustrial) resource values with different consequences for economic development. Economic benefits such as ecosystem services or ecotourism have been demonstrated, but they differ fundamentally from those generated by the resource industry. Moreover, the empowerment of aboriginal rights is complicating property rights in resource peripheries around the world, from poor developing countries to rich economies such as Australia, Canada, and New Zealand. Aboriginal rights invoke self-determination and self-governance as aboriginal peoples seek their own industrial and ecological goals.

Stakeholder diversity and analysis

In practice, resource conflicts feature diverse, internally differentiated groups and evolving alliances between governments, labor, local and international businesses, community economic leaders, local and international nongovernmental organizations (NGOs), aboriginal peoples, and distant consumers. The conflicts involve political processes, civil disobedience, litigation and court challenges, intensive public relation campaigns, and what Clapp and Mortenson (2011) refer to as “adversarial science.” For so-called conflict minerals, confrontations are violent, involving myriad cultural allegiances and armed groups, official and otherwise, and development goals are illusory (Le Billon and Cervantes 2009). In general, even in violent places, environmental and cultural arguments seek to systemically rethink the resource–development nexus and the global role of peripheries. If these debates focus on resource peripheries they crisscross national borders and reflect a search for (new) forms of development that incorporate new global as well as local imperatives.

Resource conflicts have a long history but have escalated within contemporary globalization processes, driven by society’s heightened ecological and cultural concerns, debates over whether free trade is fair, and emergent community and business interests. New information technologies have provided the key infrastructure to mobilize opposition to industrial interests and to shape public opinion. Resource conflicts are widespread and contingent. Hundreds of forestry conflicts have occurred around the world, for example. In one case, British Columbia’s durable “war in the woods” comprises trade, environmental, and aboriginal conflicts, all conjointly sparked in the severe recession of the early 1980s (Hayter 2003). The main protagonists – US trade protectionists, environmental nongovernmental organizations (ENGOs), and Aboriginal
peoples – have different interests but have cooperated to oppose vested industrial interests, and to stimulate profound changes in the rules of the game for British Columbia’s forest industry.

Analytically, stakeholder models have been used to conceptually frame resource conflicts and to identify relevant stakeholders and their diverse powers, economic and noneconomic motivations, global–local connections, and relationships to one another (Affolderbach, Clapp, and Hayter 2012; Hayter and Barnes 2012). Predominantly, stakeholder models have been elaborated in democratic, pluralist market economies that tolerate social action and criticism, and where protesting stakeholders are striving for legal and political acknowledgment of the resource values they promote. In the United States, for example, the idea of a public trust doctrine for natural resources such as oceans, shorelines, air, and (some) land, has been pioneered since 1970 when Michigan was the first state to legally adopt this principle, with other states following. This doctrine itself is part of the trend toward the adoption of environmental legislation at the state scale, hitherto most effective at national and local levels, which has directly and indirectly imposed conditions on or prevented industrial resource use. Aboriginal protests around the world are similarly driven to have aboriginal rights recognized and enforced (Mander and Tauli-Corpuz 2006).

Ecological and cultural imperatives driving resource conflicts are hard to reconcile with export commodity interests that are often allied with geopolitical concerns for supply security and stability. Indeed, conventional cost–benefit frameworks, and market solutions have limited potentials for resolving such conflicts. As an alternative, stakeholder approaches emphasize the importance of learning and bargaining processes among stakeholders in specific contexts. Bargaining (and learning) can evolve from confrontation when participants recognize that their powers are limited by the desire for social legitimacy and when some common ground or currency is identified – which in forestry can literally mean land (Afforderbach, Clapp, and Hayter 2012). Learning (and bargaining) can be enhanced by exchanging adversarial for cooperative science, for example, by the creation of boundary organizations that help coordinate scientific expertise from different sources into an acceptable form such as a multifaceted geographical information system (GIS). Boundary organizations also point to the role of social innovations in conflict resolution.

In this regard, the idea of a social license to operate (SLO) is an important initiative that has gathered momentum since the 1990s, especially in mining. SLOs, a form of corporate social responsibility and recommended by the World Bank, emphasize dialogue with community and environmental interests to ensure environmental sustainability and equitable flows of local benefits. SLOs encourage senior governments and corporations to incorporate all community and environmental interests in negotiations for new projects from the beginning to build trust and achieve less political risk to business in exchange for sustainable community development. Counterparts to SLOs are the various forms of small-scale community developments that have evolved in poor peripheries, in part as elaborations of intermediate and appropriate technology themes.

Emergent processes and values

Given extraordinary geographic variations, the relationships between resources and development are being transformed in terms of decision-making processes, purpose, and outcomes. Decisions over resource exploitation were long dominated by industrial interests, especially
large corporations and big government, often with the tacit support of labor. Increasingly, however, resource decision-making is pluralistic and contested, and engages multiple institutional perspectives that crisscross geographic scales. In tandem, environmental and cultural impact studies have become routine parts of these processes in many peripheries. Moreover, the “emerging geographies” (Moorcroft and Adams 2014) of these decisions are privileging environmental and cultural resource values and the local redistribution of benefits and rents (Argent 2014) to a greater degree than in the past. The global expansion of conservation areas, the associated designation of ecologically and culturally based world heritage sites, the remapping of resource peripheries, and the spread of environmental certification and SLOs reflect this rethinking and reregulation of resource peripheries (Affolderbach, Clapp, and Hayter 2012; Hayter 2003; Zimmerer 2006). The increased emphasis on tourism, ecotourism, and ecosystem services are related trends that offer employment alternatives to the industrialization of resources.

Moreover, pressures on resource peripheries to give greater priority to environmental values are strengthening, stimulated by the recognition that nature’s ecosystem benefits are huge; Costanza et al. (2014) have estimated that ecosystem services amounted to US$142.7 trillion globally in 2014, bigger than global GDP, and calculations can be made at regional levels as well. Such estimates are controversial, not least within the environmental movement, and the benefits identified apply abstractly to “everyone,” while incorporating intangible development goals related to quality of life considerations and moral obligations. Nevertheless calculations of ecosystem services are escalating concerns over global climate change that is both altering biotic resource endowments and raising the intensity of debates over resource use, especially with respect to energy (Bridge et al. 2012). With the major exception of the Montreal Protocol, however, global governance of climate change has proven elusive. It may be that these negotiations focus too much on the energy sector itself and need to shift to emphasizing MNCs in end product industries without vested ties to conventional energy sources. In the meantime, an important question is whether continued resource conflicts lead to desired long-run outcomes. Conflict may be necessary to provoke necessary changes in resource–development relationships but conflict solutions require consensus and involve forms of global social cooperation that are diverse and complementary.

Conclusion

In recent decades a profound shift has occurred in social attitudes to resources. Resource peripheries are being asked by a host of diverse local and global interests to serve an increasingly wide range of economic, cultural, and environmental benefits. No longer are they seen as just sites for specialized (but marginal) inputs drawn from peripheral places to supply industrial cores, which are readily substituted and cast aside, whether or not communities develop around them. Rather, according to the green paradigm or sustainability transition models, resource territories need to sustain values that link the local with the global in environmental, cultural, and quality of life as well as economic terms. In understanding this transformation in resource–development relationships, geography, with its inherent appreciation of variation and the need to integrate economic, political, social, and environmental perspectives, has an important role to play.

Restructuring

Elliot Siemiatycki
York University, Canada

Restructuring is one of the most important, and contentious, terms in urban, economic, and labor geography. The dictionary defines restructuring straightforwardly as “the process of organizing a system or business in a different way.” Yet this term is shrouded in confusion and ambiguity because of the rather important word embedded within it. Restructuring is a direct extension of the word “structure,” which in this context is defined as “the arrangement or interrelation of all the parts of a whole.” This complex relationship between structure and restructuring implies that a system or business has an initial form which, for some reason, undergoes a change. Indeed, as John Lovering commented in one of the key contributions to the geography literature on this topic, the term restructuring “suggests a qualitative change from one state, or pattern of organization, to another” (Lovering 1989, 218).

Restructuring happens in many different realms of life and is studied in academic disciplines ranging from biology to psychology and sociology. In all cases, the study of restructuring is about the causes and consequences of change for a given system or structure. The focus of this entry is on the way in which restructuring has been treated by human geographers. For the most part, restructuring has been examined as it relates to the economic sphere and with particular attention to the changing locations of economic activities. Three major questions are the focus of this entry: (i) what are the different types of economic restructuring; (ii) how have geographers studied these different types of restructuring; and (iii) what do geographers think causes restructuring of systems and organizations.

Types of restructuring

There are four main types of economic restructuring which refer to different, though often related, processes. The terms used here to describe these different types of restructuring are descriptive terms that have sometimes, though not exclusively, been used in the literature to examine the various forms of economic restructuring.

Sectoral restructuring refers to the changing structure of a given economy in terms of its key sectors. Economists have long divided economies into different activities, though perhaps the first formal example was British economist Colin Clark’s three-sector hypothesis (Clark 1951). The primary sector consists of agriculture and resource extraction. The secondary sector consists of those activities, namely construction and manufacturing, through which raw materials are transformed into products that can be consumed, such as bread and cars.

The tertiary sector is a broad term that is usually synonymous with the service sector. Since this last sector includes highly dissimilar services, such as babysitting and banking, in more recent times economists have identified a quaternary sector that involves finance, business services (including law, accounting, management consulting, etc.), and public administration which help to create markets. This leaves the tertiary sector as
RESTRUCTURING

consisting of transportation and infrastructural services, wholesale trade and distribution, and retail services.

This framework enables economic thinkers to compare the structures of different economies across space and time. Sectoral restructuring, then, is about the transition points when a given economy (at whatever scale) shifts from one dominant economic sector to another. Many economists follow Clark (1951) in arguing that economic growth naturally involves the evolution of economies between these three sectors. According to the economist Michael Porter (1990), David Ricardo’s classical treatment of comparative advantage is not a static outcome but rather economic entities ranging from the corporation to the city to the nation-state often need to change their economic orientations to suit new environmental, technological, or market realities. Economic geographers have played a key role in detailing these sectoral shifts and have developed alternative theories of how and why urban, regional, and national economies evolve over time.

The second form of economic restructuring surveyed here is industry restructuring. As will be seen, it is important to note the differences between an economic sector and an industry. A sector is a broader category that tries to compartmentalize various economic activities based on the type of production being carried out. An industry, on the other hand, refers to the many parts of producing a single good or service, and thus an industry often crosses the four main sectors. For example, the agricultural industry (or agribusiness) involves agriculture, food processing, food distribution, food retail, and the financing of all these activities.

Industry restructuring refers to the changing business strategies, locational decisions, market trends, and technologies that shape the production process for a certain good or service. Economic geographers have been particularly attentive to this form of restructuring, as it enables a closer view of how the owners of capital make locational investment decisions (Bradbury 1985). Often in the early literature the terms sectoral and industrial restructuring were conflated, but geographers were really concerned about the fate of certain regions that were facing difficult economic times.

The third type of economic restructuring is closely related to the previous two as it underscores the ways in which cities are often disproportionately impacted by economic change. Urban restructuring refers to the changing structure of the city in terms of its physical and social morphology. Morphology is a term that comes from the biological sciences; it describes the relative shape, size, and anatomy of a cell. Similar to how biologists might talk about cell morphology in terms of the location of the nucleus relative to the mitochondria, geographers have discussed the relative locations of different physical and social parts of the city.

Geographers have developed different models of urban morphology to understand where certain economic activities are located, where various social classes or ethnic groups tend to live, how natural resources may impact urban growth, and the relationship between the city and its peripheries. Often these models have used an exemplar of a certain form of urban morphology: Chicago as the industrial city, Los Angeles as the postmodern city, New York or Tokyo as the global city. These models have been the subject of serious debate and disagreement, but they have been useful in that they provide a comparative framework to understand the different form and functions of cities around the world.

Again, however, the past half century has been one in which the structure, feel, and function of many cities has changed significantly. Some cities have grown considerably, while others have
withered. Some cities are defined by the same basic industries while many others have seen their economic sectors and industries change. Urban restructuring has been a key process that contemporary economic and urban geographers have tracked across space and time.

The fourth, and final, type of economic restructuring is one that has received relatively less attention from economic geographers. Corporate restructuring refers to the changing legal, organizational, and operational functions of a corporation. Like the other forms of economic restructuring discussed thus far, corporate restructuring involves a change to the basic structure of a corporation or company. Often, corporate restructurings take place when companies are in a distressed position, such as mounting debts or bankruptcy proceedings. Other forms of corporate restructuring include mergers and acquisitions, market repositioning or market exit. In his studies of corporate restructuring in the food retail business, Neil Wrigley (1999, 288) acknowledged that the field of economic geography “has traditionally underemphasized types of restructuring that involve transformations of the capital structure of firms.”

While corporate restructuring has been studied in more depth by business and legal scholars, economic geographers have made important contributions to the literature. Gordon Clark intimated the increasing “financialization” of corporate strategy, where operations are valued less for their productive capabilities and more for their asset potentials (Clark and Wójcik 2007). Social commentators today have extended that very point to argue that markets have become inherently more volatile and unstable due to the rise of what has been termed “vulture capitalism,” an economy in which corporate restructuring and strategic liquidation of assets becomes endemic. As “financialization” becomes an ever more important theme in economic geography research, it can safely be assumed that corporate restructuring will become a more prominent part of disciplinary debates.

Now that the different types of economic restructuring have been detailed, the ways in which geographers have studied these processes can be examined.

Economic geographies of restructuring

Restructuring has been studied in different ways by geographers, reflecting the contemporary diversity of the field. First and foremost, it has been one of the main political and economic phenomena studied by urban and economic geographers since the late 1970s. This is the use of the term implied by the above discussion on the different types of restructuring. At the same time, restructuring has also been conceived by some as an “approach” to economic geography research (Lovering 1989). In this application of the term, the restructuring approach refers to the complicated emergence of Marxist thinking in economic geography during the 1980s. To be sure, these two different dimensions of restructuring were intimately related in that the rise (and ultimate decline) of the restructuring approach was connected to the academic interest in restructuring as an economic phenomenon.

The first major studies of restructuring as an economic phenomenon by geographers were focused on sectoral and industrial restructuring occurring in the Global North. Beginning in the 1970s, many regions that had been dominated by manufacturing activity began to see job losses and plant closures (Massey 1984; Peet 1983). Perhaps the most important term related to restructuring at this time was deindustrialization (Bluestone and Harrison 1982). Economic geographers of the 1970s and 1980s were preoccupied with explaining why traditionally dominant industrial
Restructuring

regions were losing their primary and secondary sector activities such as mining, shipbuilding or automobile assembly. Manufacturing, especially, had been the engine of industrialization for countless Western nations and yet very quickly the stability of economic, social, and political structures was being compromised.

By the 1980s, a specifically urban variant of these issues was starting to take focus in geography and this would mark an important contribution to the literature. Ever since David Ricardo used the examples of cloth and wine production in England and Portugal to explain his notion of comparative advantage, economists have mostly focused on restructuring at the scale of the nation-state. Yet it was becoming clear that city-regions were differentially impacted by restructuring forces depending not only on their dominant industries but also on other factors such as demographics, rates of unionization, and institutional capacity to attract capital investment (Soja, Morales, and Wolff 1983). While “industrial” cities such as Detroit and Manchester may have been hemorrhaging jobs, so-called postindustrial cities such as Los Angeles and London were assuming new positions of power in a hyper-globalizing economy.

What would come to be known as the “restructuring approach” really emerged out of these issues in the mid-1980s as economic geographers obsessed not only over explaining the problems of Western “industrial” cities but also what might be done about them. The “restructuring approach” was developed by Marxist economic geographers that were involved in the “locality debates” of the 1980s (Cooke 1989). The locality debates refer to a set of intense and highly contentious studies of the impact that increasing global competition might be having on local economies.

In the context of widespread economic upheaval and conservative political sentiments in the United States and United Kingdom, which viewed industrial workers as spoiled and entitled, scholars argued that capitalist economies were prone to regular bouts of restructuring as profit levels declined and new markets opened up. Instead of a momentary lapse in economic equilibrium, this moment of economic crisis was seen as an inherent part of the capitalist system.

Analytically, much of this research focused on the inner workings of multinational corporations (MNCs) and their locational decisions. Massey’s (1984) conception of the “spatial division of labor” identified firm-level decisions as being strategically constructed based on the potential profitability of different locations. With the rise of information and communications technology, it became technically feasible for the most profit-maximizing worker at each stage of production to be used no matter what part of the world they inhabited. The division of labor for a product or service was moving beyond the confines of a single workplace and was increasingly becoming part of a “global supply chain” (Sturgeon, Van Biesebroeck, and Gereffi 2008). In some instances, workers were protected from globalization based on their skills, tradition of innovation, or local rootedness of employment clusters. But in many cases, especially for those workers in the secondary sector, there was very little protection against manufacturing workers in the newly industrializing countries of East Asia who could do similar work at a fraction of the cost.

As radical economic geographers were developing a “restructuring approach” to understand urban industrial decline in the Western world, other economic geographers were examining economic restructuring and rapid industrialization at the nation-state scale in emerging economies of East Asia, Central and South America, Eastern Europe, and parts of Africa.
(Dicken 1998). For Dicken and other geographers interested in the new international division of labor (NIDL) it was not a coincidence that the moment of sectoral restructuring and deindustrialization in the 1980s, which so concerned Marxist economic geographers, corresponded with the rise of the Asian “tiger” economies. Faced with the challenge of competing on cost, many Western countries and city-regions shifted their economic orientations away from the secondary sector and toward the tertiary and quaternary sectors where they had an apparent advantage in “knowledge work.” Cities in the Western world have repurposed industrial-era factories and homes to fit a reconstructed “creative city” defined by knowledge work in office towers and creative districts, leisure opportunities in retail and entertainment districts, and an emphasis on urban design and architecture.

According to scholars of the “restructuring approach,” the transformation of sectors and industries as well as national and urban economies was one of the main costs of a dynamic capitalist system driven by the profit motive and competition between workers in different places. Depending on the nature and history of local and national economies, certain places would be disproportionately deprived by broader processes of economic restructuring while some places would be left alone or even benefit from restructuring. Beyond these very basic conclusions, however, scholars could agree on very little. More strict Marxists saw the restructuring approach as it related to the locality debates as a retreat from theory building and a return to descriptive empiricism in economic geography. For others, the policy implications of trying to engineer local economic revitalization plans at the urban scale were problematic (Lovering 1989).

More than two decades after these debates took place, what has become clear is that different forms of restructuring have had a dramatic impact on national, regional, and urban economic fortunes. The restructuring of places has certainly not stopped since the locality debates withered in the 1990s, and, if anything, the rise of China, India, Russia, Brazil, and other developing economies means that restructuring is happening on an ever larger scale and impacting greater numbers of people. It is more urgent now than ever before to understand the root causes of economic restructuring.

The causes of restructuring

Why places and companies change their economic orientations is perhaps the oldest and most important question in economics. According to mainstream economic thinking, there are two fundamental mechanisms through which restructuring occurs: Ricardo’s comparative advantage explains restructuring of the space economy and Schumpeter’s creative destruction explains how companies try to profit from the introduction of new goods, services, and production processes.

Some geographers, such as Dicken (1998), note that places tend to follow their own comparative advantage to improve economic prosperity in ways originally described by David Ricardo. Poorer countries can excel by extracting their natural resources or by developing manufacturing sectors that enable their citizens to contribute to the overall production of goods and services. This model of development has shown its benefits most clearly in East Asia, where economic performance and living standards have improved dramatically since the 1970s. Yet as Dicken recognizes, the industrialization process provides no guarantee of economic success. Natural
resource markets are highly unstable and prone to rent-seeking behavior by elites, contributing to what has been termed the “resource curse.” Similarly, many countries in Latin America, the Caribbean, and Africa have attempted to establish manufacturing sectors with very little success, due in part to excessive competition from other industrializing countries.

For Marxist economic geographers, however, an understanding of the structure of an economy must come before restructuring can be evaluated. Theories of social structure have come to be defined by notions of uneven development that work at a variety of different scales. Smith (1984) used the metaphor of a “see-saw movement of capital investment” to explain geographically uneven development. Corporate investment decisions are nothing more than strategic attempts to discipline workers and reduce labor costs in order to find the location that will produce the highest profits. But this is a restless process because, in time, workers tend to demand their fair share of profits and this means that capital often goes back to the places it previously abandoned. There is always the hope of economic redemption in a capitalist system because places and people are most attractive when they are at their most desperate.

The mainstream and Marxist view of economic restructuring may appear to be very different but, in actuality, they are describing the same processes from very different ideological perspectives. Both approaches see competition between places and companies as the key mechanism that causes different forms of restructuring. Mainstream market economists view this mechanism as the source of efficient resource allocation and technological innovation. When goods and services are produced more cheaply, it not only lowers prices but it frees up capital to be invested in new projects, products, and services. This is how our quality of life has improved so dramatically over the past few centuries according to many economists and economic historians.

If mainstream economists tend to view economic phenomena in the aggregate, Marxist and other radical commentators try to expose the localized economic pain brought on by restructuring. The decline of industrial cities, the rise in income inequality across all Organisation for Economic Co-operation and Development (OECD) nations, the persistent poverty in various parts of the world (including Western countries), the unequal access to health services, education, safe streets, stable jobs, and a clean environment; all of these are signs that economic restructuring is not a benign or beneficial process. Like most issues in the social sciences, individual views about economic restructuring differ based on personal values and priorities as well as the evidence which is seen as most relevant.

Conclusion: structure and restructuring

Geographers have made important contributions to the understanding of economic restructuring in its various forms. The particular interest of geographers has been to detail the movement of economic activities across space and the impacts of changing trade relationships between different places associated with globalization. The past half-century has been one of immense economic transformation. Most countries have seen a dramatic shift in the goods and services they produce as well as the products available for local consumption. Within most countries, there is significant diversification of economic activities between different city-regions. Indeed, the fastest growing economies of the twenty-first century are at once postindustrial, industrial, and agrarian societies. In China, for example, coastal cities such as Shenzhen and Shanghai represent
the postindustrial economic future while industrial activity moves further inland and Western China focuses on primary activities such as resource extraction and agriculture. Yet despite these dramatic shifts in the global space economy, perhaps the most important question that remains about economic restructuring today is in the temporal, rather than spatial, sphere. How has restructuring changed over time and what might this suggest about the future geographies of economic development?

The social, economic, political, and technological bases for the changing speed of economic relations are little understood. When David Ricardo was writing about comparative advantage in the 1800s, he used examples of national economies producing wine and cloth. A country that had natural advantages in the way of soil and growing seasons could reasonably expect to have a comparative advantage that would last long enough to produce durable trade relations. The notion of economic restructuring, in any of its forms, hinges on there having been an initial structure that can be expected to last long enough to inform rational economic decision-making. If that structure is subject to almost constant change, restructuring ceases to be an exceptional moment when places or entities shift their economic orientations and, instead, becomes the new normal of disorienting economic relations.

There are very good reasons to believe that the early decades of the twenty-first century represent just such an era of constant, complex, and confusing economic restructuring. Despite supposedly radical improvements in information, data analysis techniques, and communications technology, scholars in economics, geography, and urban studies continue to have a hard time making sense of a fast-changing world. Economists failed to prevent, or indeed even to identify, one of the largest financial crises in modern history. Western nations are becoming increasingly unequal, undermining the long held notion of the Kuznets curve in development economics (that inequality decreases as countries industrialize). Predicting economic outcomes is as hard as ever.

The source of this disorienting change in the nature of restructuring is simple: never before in the history of human relations have so many people, in so many different places, had the ability to engage in economic activity that is so fundamentally connected. Market-based economic theories are based on the elegant idea that everyone is ultimately better off if they specialize in producing the good or service they know best and then trading with people to consume a diverse basket of goods. Specialize and trade. If we are entering a period of pronounced economic restructuring driven by new markets, new technologies, and intensifying competition for jobs and investment, geography’s penchant for studying places from close to the ground may be the only way of truly understanding structural economic change.

Rights, labor

Jamie Doucette  
*University of Manchester, UK*

Labor rights are sets of normative and applicable legal rights as well as presumed geographically and politically universal human rights. They may be exercised by workers individually and on a collective basis. Individually exercised labor rights often pertain to the terms of employment contract, the length of the working day, protection against unemployment, the right to equal pay for equal work, and the right not to be subject to forced labor. However, depending on the jurisdiction, such rights can extended to include other rights pertaining to the length of the work week, daily breaks, paid vacations, among other items. Labor rights that are collectively exercised often involve the right to freedom of association such as the right to establish unions, the right to collective bargaining, and the right to strike (which is considered to be the most contentious and often least guaranteed labor right in various national contexts).

Most but not all of these rights have been encoded in a number of international declarations such as the United Nations’ Universal Declaration of Human Rights (Articles 23 and 24) and the International Labour Organization’s Declaration of the Fundamental Principles and Rights at Work. More recently, the United Nations Global Compact (2013) has incorporated the content of the ILO’s declaration to recognize four broad principles concerning labor rights:

- Principle 3: Businesses should uphold the freedom of association and the effective recognition of the right to collective bargaining;
- Principle 4: the elimination of all forms of forced and compulsory labour;
- Principle 5: the effective abolition of child labor; and
- Principle 6: the elimination of discrimination in respect of employment and occupation.

These principles are considered to be universally applicable; the UN Global Compact (2013) states that “consensus now exists that all countries, regardless of level of economic development, cultural values, or ratifications of the relevant ILO Conventions, have an obligation to respect, promote, and realize these fundamental principles and rights.” Nonetheless, the compact depends on the voluntary compliance of member countries for the enforcement of these rights, which means that in practice there are many hurdles that obstruct the effective exercise of labor rights.

The spatial configuration of labor rights

While considered universally applicable, in practice labor rights tend to be unevenly observed and enforced by nation-states, transnational corporations, and other actors involved in the configuration of labor relations. Many countries act to restrict a number of basic labor rights in practice, such as the right to strike, particularly for public service workers but periodically for workers in other sectors deemed to be key priorities for national development as well. Furthermore, international organizations such as the ILO refuse to object to national laws.
or regulation withholding the right to strike for the police and armed forces as well as for “essential services,” which can often be loosely interpreted. While nation-states may strongly recognize labor rights in their national laws and labor standards, the reality is that core labor rights are often not enforced and, quite often, all too easily suspended in practice. Scholars thus distinguish between de jure and de facto labor rights: between rights that are recognized in principle and those exercised in practice. This conceptual distinction opens up the study of labor rights to an analysis of how legal and exercised labor rights tend to be distributed in an uneven and spatially variegated manner.

Legal scholars and geographers have pointed out that the representation of labor rights as universal human rights is a contentious topic, as rights discourse can often mask the collective or class-based nature of effective human rights within capitalist economies where collective labor rights are unevenly exercised under the law relative to individual property rights. Geographers have also shown how the courts sometimes regulate the spatial performances of such rights in an uneven manner. For example, Mitchell (2003, 42–80) examines how in the early twentieth century American courts came to regard forms of workers’ speech such as picketing and public assembly as acts of violence that disrupted employers’ private property rights; thus, numerous restrictions were placed on the ability of workers to use public space during industrial disputes in ways that restricted their use of the right to strike. While these restrictions eventually shifted from the formal denial of rights to a language of formal protection that regarded picketing as a legal form of speech, Mitchell shows how the court, through the language of law, has remained an instrument that is used to contain workers’ speech in the name of wider social order. This is often accomplished by prioritizing the rights of employers to have their workplaces and the public spaces that surround them free from disruption by pickets or other forms of collective action. In this sense, by treating both employers’ and workers’ speech as equal, the courts ultimately favor more powerful and property-based voices that benefit from the existing “orderliness” of the public realm over the marginalized voices that need to speak in public space. For workers that don’t have recourse to private property, speech takes on the characteristics of a disruption of a supposedly consensual ordering (the right of employer to freely appropriate an individual’s labor power). This logic of the securitization of public space from the collective action of workers can be witnessed in many contexts where strikes and the right of the individual to withdraw labor are easily made illegal and where workers can be held individually responsible for “economic damages” caused by strike activity and other forms of collective action. Furthermore, many governments raise elaborate legal hurdles to the collective exercise of labor rights such as complex rules for union accreditation, strike votes, and mandatory arbitration and/or “cooling-off” periods. Nonetheless, for Mitchell and many others it makes little sense to abdicate the language of rights; rather they see the potential of continuing to exercise the discourse of rights in order to bring relations of domination and subordination into greater visibility as part of wider campaigns for social justice.

Labor rights in a global context

The ability to claim labor rights has important geographical dimensions as labor rights are often decided through social struggles that are deeply spatialized, and involve contextual dimensions of particular places, territories, networks, and other
spatial registers. Increasingly, the study of labor rights involves an examination of the unevenness of institutional labor rights and the ways in which the very configuration of geographical space can affect the rights of workers either as a tool for the control and containment of the agency of workers or as a site for exercising and demanding rights. As Kelly (2002, 405) argues, the precise combination or configuration of such practices itself varies across space, reflecting diverse historical–geographical contexts. Furthermore, the extension of labor rights has often hinged on the importance of place-based social struggles and legal victories. Both the spatial variability of rights and contextual histories surrounding the ability to claim rights has important implications for the strategic assessment of the appropriate scale at which the rights and entitlements of collective labor should be sought and negotiated; however, a strategic focus on scale should not neglect the ways in which the exercise of labor rights involves connections across multiple scales, from the scale of the body to the scale of the global economy. Feminist geographers have been particularly sensitive to the importance of such interscalar relations in the configuration of labor and human rights.

Increasingly, scholars have been interested in the changing global context of labor rights, particularly alongside processes of globalization, and have focused their attention on labor rights and workers’ agency within global production networks and global value chains (Hess and Coe 2013). Campaigns for labor rights can be quite diverse in these spatially extended networks, with some struggles targeting the brand recognition of leading firms, using both adversarial and cooperative campaigns. Such campaigns have led to the increasing popularity of corporate social responsibility (CSR) codes of conduct as well as international framework agreements (IFAs) (Wills 2002). Nonetheless, scholars have pointed out that, while the compliance-based model of the UN Global Compact and many CSR codes of conduct may improve labor standards, they do not always improve workers’ rights surrounding freedom of association and collective bargaining. Furthermore, critics have pointed out that many CSR codes and compliance-based regulations seeking fair labor standards tend to naturalize relations between wage labor and private-property, leaving intact exploitative class-based mechanisms within capitalism. In contrast, IFAs tend to allow more room for unions to establish the terms of good conduct in a way that endorses workers’ rights and supports union organizing efforts across the company and, by extension, geographical space, often with the help of global union federations. Furthermore, IFAs also create the conditions for workers to upscale their organizing efforts from the local to the global, by providing an extra lever that can be used during local labor struggles.

Similar to global union federations and trade union representatives in international organizations like the ILO and OECD (Organisation for Economic Co-operation and Development), IFAs can be interpreted as an important manifestation of labor internationalism, one that is complemented by a range of contemporary consumer-oriented campaigns involving labor rights and fair labor standards such as Jubilee 2000, Trade Justice Movement, Students against Sweatshops, Clean Clothes Campaign, Worker Rights Consortium, and Women Working Worldwide, to name but a few prominent examples. These prominent campaigns notwithstanding, there is a complex politics surrounding the ability of different forms of labor internationalism to secure workers’ rights. During the Cold War, nationalist and protectionist forms of labor internationalism (sometimes labeled “labor imperialism”) often prevailed and a number of northern trade unions were criticized for aiding
in the repression of the rights of workers in developing countries through their participation in Cold War foreign policies. Based on a critique of such conservative forms of internationalism, in recent years initiatives such as the Southern Initiative on Global Trade Union Rights (SIGTUR) have sought to strengthen workers’ rights at an international scale through promoting the development of democratic and independent trade unions.

SIGTUR regards an alliance of Southern unions as its critical constituency and embraces social movement unionism as a strategy to “bridge space” between social movements and trade unions. Furthermore, the initiative’s Southern identity denotes a political experience of exploitation and subordination in the global economy rather than an explicitly geographically bound network of unions (Lambert and Webster 2001); though, in practice, SIGTUR key participants have been located predominantly in Asia, Africa, and Oceania. In many ways, strategies such as SIGTUR have arisen in part from the uneven territorial configuration of labor rights, particularly in contexts where labor movements have become involved in wider social movements for democracy. The success and failure of movements such as SIGTUR and other attempts at social movement unionism as strategies of exercising labor rights are, in many ways, related to the ability of trade unions to involve popular social movements and ongoing democracy struggles in their campaigns. The articulation of labor rights in relation to democratic struggles for freedom and equality is particularly important in the context of Southern unionism owing to the ways in which these movements coalesced in many developing countries during the past decades. At the same time, labor activists have stressed that social movement unionism is a relevant strategy for workers and social movements in subaltern positions in the Global North as well.

**Territory, mobility, and labor rights**

Beyond a focus on the global and/or international scale of struggles over labor rights, scholars have also enriched the analysis of labor rights by focusing on other spatial registers including the territorial configuration of labor rights and, in particular, the ways in which contemporary processes such as labor migration and spatially selective zoning policies have often involved a disaggregation of labor rights from the national-territorial context in which they have been won. For instance, Ong (2006) examines how Asian states have used various “zoning technologies” such as export-processing zones, special administrative regions, and special economic zones to effectively reterritorialize spaces within and beyond the national territory, creating exceptions to normalized administrative practices in order to attract or produce specific economic activities. Many of these zones offer exceptions on national labor standards and many have included prohibitions on collective bargaining and strike action. Furthermore, Ngai (2005) has examined how special economic zones combine with other forms of territorial zoning, such as China’s household registry or hukou system, uneven development, and constructions of gender subjectivity/identity to produce relations of power and difference that deprive female, rural migrant workforces in export-oriented production zones of the effective capacity to exercise their labor rights.

Shifting focus from territorial strategies to the influence of mobility on labor rights, other scholars have examined how both documented and undocumented labor migration can lead to the scattering of citizenship rights across different jurisdictions in ways that weaken worker abilities to claim their rights and entitlements across place. As Pratt (2012) shows, guestworker programs such as Canada’s Live-in Caregiver
Program violate workers’ rights by paying below market rates, limiting the labor market mobility of foreign workers and subjecting them to perpetual vulnerability to deportation. Similarly, the rise of business migration programs and other entrepreneurial migration strategies has contributed to the fragmentation of rights across jurisdictions inasmuch as such programs involve an uneven extension of rights. In this case mobility becomes a political process in which entrepreneurial migrants are often able to take advantage of significant, differential citizenship rights that are not often extended to labor migrants owing to the more temporary and often more restricted nature of their work permit. In this case, the migrants’ deportability, experienced as either a lack or fragmentation of effective citizenship and labor rights, becomes a key aspect in the appropriation of their labor power within a global market in migrant labor arbitrage. This market has, in part, been successfully produced through the incorporation of a systematic fragmentation of rights into the political order of territorially delimited nation-states. Migrant workers are thus denied labor rights and made to be “indispensably disposable” through their status as deportable labor (De Genova 2010, 47). Furthermore, global regulations seeking to embed migrant mobility into a more substantive set of effective rights for migrant workers such as the United Nation’s International Convention on the Protection of the Rights of All Migrant Workers and Members of Their Families remain limited to date, inasmuch as such protections remain unratified by most migrant-receiving countries, particularly in North America and Western Europe.

Finally, while labor rights are often constrained through multiple geographical dimensions, the attempt to exercise effective labor rights in practice has the potential to produce new geographical relations between places, scales, networks, and bodies. While a geographical analysis of labor rights can bring attention to the forces that constrain workers’ agency, it should also seek to show how the actual practice of labor rights, and whatever contestations or “disruptions” such exercise may bring, have the potential to create important changes to existing geographies of rights and regulations not only in particular places, but also within the wider networks, territories, and practices of mobility that exist within the global economy.

Riparian ecosystems

Jacob Bendix
Syracuse University, USA

The term “riparian” is generally used to denote terrestrial organisms or locations that are close enough to rivers to be affected by them, so riparian ecosystems are essentially linear phenomena, distinguished by their proximity to the rivers that they parallel. This proximity allows for multiple interactions between the river and the nearby vegetation, which distinguishes riparian ecosystems from the surrounding landscape.

The means by which rivers affect the adjacent ecosystems fall into three categories: through the direct biological consequences of floods, including plant damage or mortality and propagule transport; through the indirect consequences of floods, including substrate modification and creation of colonization sites; and through the high water tables found close to rivers. All of these factors combine to influence the composition and population structure of riparian plant communities. Very often there are feedbacks involved, as riparian vegetation, where dense, impedes flows, reducing the river’s velocity and promoting sedimentation.

The effects of floods may be seen not just in the destruction of plants in the flood’s path but also in the absence of species that are more vulnerable to flooding. For example, one of the most obvious means by which floods affect vegetation is for plants to be broken or uprooted and washed away by high-energy events. In some cases, this will be evident from the absence of any plant cover following a flood, but in other instances the influence may be more subtle, as plant cover remains but is limited to species with adaptations that allow them to survive the flooding. Such adaptations may include deep root systems, coupled with either large impervious stems or flexible ones that allow the plant to bend rather than breaking in the face of the floods energy.

Flood energy may also remove riparian plants by washing away the substrate in which they are rooted. Thus, the distribution of plants may be influenced not only by their own characteristics but by the characteristics of their substrate, in terms of its resistance to erosion. Plants rooted in cobbles and boulders may survive a flood that would have scoured away gravel or sand.

In the United States, much of the research on riparian ecosystems has focused on rivers in which floods generally occur every 1–2 years and last for only hours or days. There are, however, many low-gradient rivers in which floods occur annually and may last for several weeks or months. These can be found on the coastal plain of the United States, but such rivers are perhaps best exemplified in the lowland portions of the Amazon watershed. Flood energy is often less of an issue in these low-gradient rivers; however, the extended hydroperiod of these floods creates a different set of stresses, as prolonged inundation imposes anoxic conditions in the soil. Again, there is a winnowing effect on species composition. The more frequently a given site is subjected to long-term flooding, the more its composition will be dominated by species that are adapted to survive in saturated soils.

Floods may also have a direct impact on plants by transporting their seeds, either downstream or across the floodplain. For some riparian species,
RIPARIAN ECOSYSTEMS

the timing of seed production is apparently linked to the hydrological regime. Dispersal may also occur when plant fragments are transported to new sites allowing for vegetative reproduction.

The effects of floods are also felt indirectly, because the sediment they transport and deposit serves as the primary substrate in which riparian vegetation grows. Because the texture of sediments deposited at any given point reflect the energy the river had at the moment that material was deposited, substrate texture is directly tied to the details of flood history. As outlined, substrate texture may affect vulnerability to flood scour. Perhaps more importantly, texture exerts a strong control on water availability. This is particularly important for germination and seedling survival, so substrate texture may control the sites at which some species become established.

For plants in a given location, water availability reflects not just soil texture, but also the height of the water table. It is almost axiomatic that the water table is high near river channels, and depending on the environment this may be either a boon or a constraint to the riparian vegetation. In dry regions, the high water table is a resource that typically allows denser and more productive growth, and a different species mix, near the river than in the surrounding landscape. Conversely, in humid regions, the shallow water table may be a limiting factor, as it excludes deeper-rooted species.

These factors work in combination to determine the distribution and composition of riparian vegetation. In some river settings, the hydrologic and sedimentary characteristics of particular landforms may be consistent enough that they support distinctive vegetation. Thus, there may be particular species that typically occur on point bars, on the active channel bank, on floodplains, and so on. This is not universally the case, however; in many rivers the correspondence between landforms and hydrogeomorphic variables is less clear.

The energy of floods (and thus also the amount and texture of sediment they deposit) is strongly influenced by the hydraulic roughness, or frictional resistance, that they encounter. Riparian vegetation forms a key component of this roughness, as dense riparian thickets can very substantially reduce flood velocities. This means that complex feedbacks exist between the influence of floods on the vegetation, and the influence of the vegetation on floods. Part of the complexity derives from temporal change in the vegetation. The roughness provided by a given patch of vegetation will depend not just on its species composition (and associated growth forms), but also on its age, which may, in turn, depend on the interval since the last major flood.

The influences and interactions outlined here are all distinct from the factors affecting vegetation outside the riparian zone. As a consequence, riparian vegetation is usually compositionally distinct from the surrounding landscape, and often structurally distinct as well (as where riparian gallery forests contrast with surrounding shrubs in arid regions).

The riparian zone is also an important habitat for a wide range of animal species, which are drawn by the structural and compositional details of the vegetation as well as the proximity to water. Some, especially amphibians, are entirely limited to riparian habitat, while others depend on it at least some of the time for food or nesting sites.

River basins in historical context

In common language, the concept of the river basin pertains to the field of physical geography, and is well established in secondary classrooms: river (or drainage) basins are extents of land that drains all streams and rainfall toward the same terminus, generally a river or the sea, or sometimes an inland water body. River basins are also often called catchments in British English, while watershed, which in American English designates smaller basins of a few thousand square kilometers, refers to the line dividing two river basins. River basins which drain to an inland water body are called endorheic basins, and form large areas of Central Asia and desert regions, like the Sahara or the Arabian Peninsula. River basins can also be seen as nested “rainfall collectors,” with small tributaries converging to larger rivers.

Although there are indications of sophisticated knowledge of both river systems and the hydrological cycle by the Chinese as early as the third century BC (with a clear description of how vapor generates clouds and clouds rivers), and despite the refined hydraulic skills of ancient civilizations and later of the Romans and the Arabs, the conceptualization of hydrology remained limited. Land and water resources were in general exploited through piecemeal projects destined for channeling, lifting, storing, poldering, or diverting water in places deemed suitable, based on the characteristics of the land, the understanding of the flow regime, and the available technology.

The clear articulation of the notion of the river basin was probably hindered by difficulties in comprehending the hydrological cycle, most particularly the origin of springs and why and how rivers were flowing despite the absence of rainfall for long periods of time. In 1674 Pierre Perrault, a French geographer, wrote the treatise De l’origine des fontaines (On the Origin of Springs), which established a crude water balance of the upper Seine river basin, where he compared the river discharge with “the rainwater that falls around its bed,” a calculation which would later be extended by Mariotte to the flow of the Seine through Paris. In 1752, Philippe Buache, a French cartographer attached to the court of King Louis XV, published an essay attempting to describe the structure of continents based on the study of mountain ranges, streams, and rivers which defined a river basin as “the set of all the slopes on which fall the waters that converge to a same river or creek.” His theory was rapidly taken up by Gatterer in Germany who improved it and made it the basis of a theory of the division of the world into lands and regions.

Industrialization paralleled by scientific and technological development would subsequently project the river basin as the locus of the human conquest of nature. Ambitious national water projects including irrigation schemes or
RIVER BASIN MANAGEMENT AND DEVELOPMENT

ydropower generation were often discursively rooted in the promotion of the river basin as a natural unit for planning development or organizing societies. The river basin concept, beyond its alleged naturalness, thus came to embody a number of ideologies and was instrumentalized by different constituencies. In the late nineteenth century the concept of a river basin nurtured utopias and political struggles concerning the relationships between central and local power in several countries. In France, the concept was captured by political interests to serve as a weapon against the revolution and centralization, and was supported by the landowning aristocracy who sought to re-establish the pre-eminence of the “local.” In Spain, the *regeneracionismo* movement embraced the river basin as a “natural unit” that signaled a natural and harmonious order that was in contrast to the traditional political and administrative divisions inherited from the past; it was used against the traditional landowning elite. In the United States, John Wesley Powell advocated the establishment of self-determined “commonwealths,” independent of both capitalists and bureaucrats, organized along hydrographic basins and based on natural resources rather than on the prevailing township and county system.

Although its relation with the basin scale was not always prominent because early developments occurred in the context of a relative abundance of water, irrigation development became the center of water resource development during the second half of the nineteenth century, with enthusiastic private investments in places such as the western United States, Australia, and India often meeting with bankruptcy and calling for public intervention. As a result of this financial failure and given various national objectives, the states stepped in and endorsed the role of (large-scale) developers of water resources. Imbued with the fresh legitimacy of technical marvels and the presumably unlimited power of science, inspired by the colonial deeds of the British in India and the Sudan, the Dutch in Indonesia, and the French in Vietnam, hydraulic bureaucracies were created to take up the challenges of flood protection, large-scale public irrigation, and hydropower generation. These bureaucracies took as their motto the promise that not a single drop of water should reach the sea without being put to work for the benefit of humanity: the “hydraulic mission” was born (Molle 2007).

The beginning of the twentieth century was thus marked by the creation of many hydraulic bureaucracies in different parts of the world. These include the US Bureau of Reclamation (1902), the National Irrigation Commission in Mexico (1926), the Department of Canals in Siam (1902; now the Royal Irrigation Department), the General Directorate of Public Works in Turkey (1914; now DSI), the Inspeetoria de Obras Contra as Secas in Brazil (1909; later DNOCS), and the strengthening of many of the corps of engineers that had been created in the eighteenth and nineteenth century in European countries, as well as colonial irrigation administrations in Indonesia, Egypt, and India. But the mission of reducing flood damage or irrigating fields was soon to be enlarged with hydropower and the task of generating electricity, fueled by progress in technology in high dam construction, turbines, and high-voltage transmission lines at the beginning of the twentieth century.

These technological innovations and the many “missions” entrusted to hydraulic bureaucracies were pooled and came to be associated with river basin planning and management, as epitomized in the 1930s by the advent of the Tennessee Valley Authority (TVA), launched by Roosevelt in the aftermath of the economic crisis. River basin development was taken to new heights by combining the concept of *unified development*
(the damming of all the streams of a given river basin to bring the river under total control), the benefits of multipurpose dams (hydropower, flood protection, transportation, irrigation, and other uses), and the idea of regional development (associating water development with other interventions such as reforestation, production of fertilizers, industrial development, etc.). These ideas were soon expanded to the Columbia Basin in the United States which was to become the “battery” of the west coast, with the first concrete for the grandiose Grand Coulee Dam poured in December 1935. Similar large-scale projects and planned development were floated in Stalin’s Russia, in a political and parallel contest, where technology, mechanization, and large-scale centralized planning and production processes were part and parcel of a vision of what Josephson (1995) called a “supremely rational society,” which would plan massive hydropower plants and canals (e.g., the infamous White Sea–Baltic Canal), as well as “domesticate” rivers like the Volga.

In the postwar period of the 1950s and 1960s, which was marked by the need for reconstruction and to grow food for a world in shambles, grandiose water resources development schemes were soon in high demand. In the United States, the Bureau of Reclamation and the United States Army Corps of Engineers engaged in a sweeping damming of the country’s rivers (Reisner 1993/1986) and envisaged megaprojects like the transfer of water from Alaska to Mexico. In the Soviet Union, electricity production, and how it would transform society and the economy (a vision long nurtured by Lenin), received much attention from Stalin who launched the Volta Project – epitomized by the Kuibyshef dam – and the 1948 Plan for the Transformation of Nature. This plan and the later Siberian river reversal project to divert water to Central Asia were echoed by what Shapiro termed “Mao’s war against Nature” and its major flood control, canal and hydropower projects in the 1950s. In Spain, Franco undertook the relentless construction of 800 dams (and irrigation schemes) as a way of legitimizing his power and buying support from rural elites. Hydropower development soared in countries like Canada, Norway, and Sweden, where rivers were, in the words of Jakobsson, “industrialized.”

In the developing countries, particularly newly independent ones, elites and governments enthusiastically embraced the icons of modernity and development epitomized by large-scale irrigation schemes and dams – in India famously referred to by Nehru as “the temples of modern India.” In that, they were supported by either Western countries or the Soviet Union, which had both economic and geopolitical interests in fueling this postcolonial hydraulic mission. Massive investments – most pre-eminently in dams and irrigation systems – in countries with potential rural instability were thought by the United States to be the best defense against the spread of communism. It was in this context that the TVA, marketed in particular by the prophetic tone of Lilienthal’s book TVA: Democracy on the March (1944), was to become both an icon of modernity and development and a major asset of US overseas development and diplomacy (Ekbladh 2002): in a matter of years the TVA would become the “grand-daddy of all regional development projects,” embodying the social engineering drive that Scott (1998) has termed “high modernism,” and inspiring a multitude of TVA-like projects in river basins such as the Jordan, Danube, and Mekong, and in countries as diverse as Sri Lanka, Afghanistan, Colombia, China, and South Africa. This further spurred the creation of national water bureaucracies entrusted with river basin planning and the construction of hydropower dams, reservoirs, and canal networks for irrigation.
The four decades following World War II witnessed massive investments in reservoirs (large dams increased globally from 5000 in 1950 to around 50 000 at present, while irrigated areas doubled from 140 million ha to 280 million ha). All the ingredients of nineteenth-century scientism, hubris, and utopias were alive and well and the hydraulic mission was in full swing, predicated on an ideology of the domination of nature, where “conquering,” “harnessing,” and “taming” the wilderness were touted as part of a civilizing mission, and rooted in the conviction that water flowing to the ocean was a waste that called for infrastructure to capture and manage the resource in each river basin.

Beyond promises to feed the masses, raise rural income, or meet energy requirements, the development of public irrigation and associated dams was central to Cold War geopolitics as well as to wider national state policies, whether it was to settle nomads (as in the Middle East and Tunisia); to provide jobs to returning servicemen after the two world wars (as in Australia and South Africa); to break up haciendas and colonize them, with farmers practicing “revolutionary irrigation” (Mexico); or to strategically occupy land (as in the United States, Israel, and Sri Lanka). As a result, the hydraulic mission era was characterized by a massive injection of public money in all countries, with associated subsidies and political favors.

In industrialized countries the hydraulic mission started to lose momentum in the early 1980s, with the growing recognition of associated social and environmental costs, and also with the decreasing availability of suitable dam and irrigation sites. A similar trend was observed 15 years later in developing countries, although infrastructure development remains largely unabated in a number of countries. This change was due to the rise of environmental concerns (priority shifting toward water quality and environmental sustainability), the public costs of such water resources development, and increasing criticism from affected groups and the civil society at large. Challenges to conventional river basin development also resulted from the shift from government to governance, whereby water issues came to be considered as societal questions requiring participation from, or co-management with, concerned stakeholders. In the early 1990s these concerns were reflected in the Dublin Principles and the formulation of integrated water resources management (IWRM) approaches, which were later formalized by the European Union in its Water Framework Directive. The directive sanctioned the river basin as the appropriate unit for managing water, partly under the influence of some national models (e.g., France and Spain), and partly as an embodiment of the promotion of basin-centered management by mainstream international organizations. But the appeal of river basins as an organizing principle also came from its “naturalness,” as the locus of hydrological processes where the integration of water-related issues, as well as the participation of stakeholders, should be facilitated. The promotion of the river basin as a universal unit for water management has triggered wide discussion and scholarly debates from various disciplines.

Current research agenda

Basin management, modeling, and hydrology

River basin management is a subject of predilection for modelers. Hydrologists and engineers have developed numerous models to reproduce hydrological processes and to study and optimize the allocation of resources. Models, long limited to the study of surface water, have grown in sophistication and now increasingly include groundwater modules coupled with surface
water. However, it often remains difficult to appreciate, for example, time lags and two-way interactions between surface water and ground-water resources, how changes in land use, in particular deforestation, alter runoff and ground-water recharge. Likewise, actual management rules of dams and irrigation schemes, and more generally the change in actors’ behaviors at all levels in the face of extreme events, are difficult to model. A growing body of literature is also addressing the evolution of supply and demand in river basins under varied scenarios of climate change. Economists have developed their own models to optimize the economic efficiency of resource allocation within river basins. Despite growing sophistication, these models generally work at a high level of aggregation and are often unable to reproduce local dynamics and to capture the complexity of the interaction between physical and human systems.

The question of efficiency in water use within river basins has also been the subject of many works that have emphasized the concept of river basin efficiency, as opposed to local user or system efficiency. They have shown how local “inefficiencies” associated with leaky canals, reservoir spills, return flows from irrigation, or other system “losses” are often the primary source of water for other users or for ecosystems within the basin. Successive reuses of water across nested scales greatly complexify water balances and accounting, and introduce additional and intertwined questions about changes in water quality and energy costs. Although this important work has critical implications for the concepts of efficiency and allocation, it is not always well understood, and reasoning based on conventional point-of-use efficiencies often prevails, partly because of adherence to classic engineering conceptions but also because it provides easy justification for investments in water-saving technologies.

River basin overbuilding and trajectories

Long-term interactions between societies and their river basin environment are sometimes described by the term “river basin trajectories,” which examines human efforts to assess, capture, convey, store, share, and use available water resources in the face of changing physical and social environments, as well as how the distribution of decisional and discursive power results in specific water regimes, with particular patterns of distribution of costs, benefit, and risk across space, time, and social groups. Other concepts and approaches within the field of political ecology, such as the hydrosocial cycle or the socioecological concept of the waterscape, although seldom applied to river basins as such, also emphasize relations of power behind the manipulation of the water cycle.

One commonplace aspect of a basin trajectory is basin closure, which occurs when the quantity of water abstracted from the river or the aquifer is so high that it can no longer ensure the supply to downstream users, dilute pollution, control salinity intrusion, flush sediments, or sustain healthy ecosystems at the river mouth (or terminus). This imbalance can manifest itself only during a few dry months (where the basin is said to be closing), or almost permanently (where the basin is said to be closed). Closure and resulting scarcity can sometimes occur in sub-basins or small catchments, while the larger basin remains open. Rivers hardly reaching the sea, or contracting lakes, are the most visible signs of basin closure, as exemplified by the Colorado or Yellow rivers, the Aral Sea, and the Dead Sea. In some cases, like in the Lerma–Chapala Basin (Mexico), overabstraction of groundwater, and excessive surface water withdrawals can lead to water depletion exceeding annual renewable water.

The natural interconnectedness of ecosystems and users across a river basin increases with
basin closure. As the amount of available water is insufficient to dampen or absorb fluctuations in supply and demand, or to dilute salt and pollutants, conflicts and negative externalities increase, posing increasing challenges to regulation and management. What particular actors do at a particular point in space and time (e.g., digging farm ponds, tapping groundwater, harvesting water, lining canals, changing cropping patterns, or irrigation techniques) modifies the circulation of water, salts, sediments, and biota, disrupting the environmental processes and human activities associated with the prevailing water regime. The lack of data on, or knowledge of, both hydrological processes and actors’ behaviors often makes it difficult to comprehend, evaluate, or anticipate how the water cycle is altered and what positive and negative social and economic externalities are produced. Externalities travel across space and time and sociopolitical categories of stakeholders. They amount to a constant redistribution of costs and benefits along lines of power that eventually tend to determine who are the winners and the losers between diverse stakeholders. Third-party impacts must be regulated, with the state usually playing a critical role.

Basin closure is generated by the overbuilding of river basins, a socially constructed process of overextension of the water abstraction capacity, in general for irrigation. The process is fundamentally driven by the vested interests of politicians, water bureaucrats, private construction firms, and development banks and the powerful incentives they face in sustaining water resources development. Overbuilding is also caused by regional politics and issues of equity, whereby differences in relative wealth between regions are used by poorer ones to claim for hydraulic (and other) investments even if hydrologic and economic conditions should discourage them. In other settings, between federal states (e.g., India) or between nations (e.g., Nile), it is commonplace to see a rush toward infrastructure development in order to lay claim to or to support a prior claim on the shared resource. Supply augmentation options are more attractive to decision-makers because they avoid politically costly reductions in use or reallocation, but are often adopted at the expense of the public purse and environment preservation, with opportunistic, optimistic hydrologic or economic hypotheses that have to be paid for later: overallocated resources, managers having to tap reservoirs’ security stocks, helplessness in the face of aquifer overexploitation, and the necessity of reallocating water between sectors by fiat or stealth, in general toward municipal and industrial users and to the detriment of agriculture, the environment, or weaker constituencies.

The overdevelopment of water use infrastructure, principally irrigation schemes, generates water scarcity “mechanically.” When most available resources are committed, little slack remains in the stock and fluxes of the river basin, and any disruption caused by hydrologic variability (compounded by climate change) or mismanagement (notably the tendency to overallocate the resource) generates crises that are opportunistically seized by politicians or interest groups to further develop supply. Politicians then often “naturalize” water scarcity and “securitize” the debate by framing and justifying their responses and policies under the cloak of national or food security or other overriding metaphysicifications. In both discursive and material ways, scarcity is manufactured.

Critique of the river basin scale and boundaries

River basins are promoted as the integrative locus of human uses and the environment, the scale at which the resource can be efficiently
managed and allocated, and where participation of actors with a stake in the basin’s water should naturally occur. It is therefore not surprising that river basins have been associated with IWRM and promoted as one of its cardinal “best practices.” They have also been justified by the alleged necessity to improve “spatial fit,” that is, the matching of resources boundary and institutional regimes governing them. A growing scholarship has challenged this prescription. From a management point of view, it has been pointed out that river basin boundaries may not be relevant, for example in the case of small islands, deltas, arid areas, floodplains, and coastal areas; that surface and groundwater interactions need to be considered; that aquifer systems are often noncoterminous with river basins; and that interbasin transfers are also frequent and demand consideration of an expanded scale.

From the government’s point of view – with a focus on the structure of power and processes of decision-making – river basin boundaries are problematic in different ways (Norman, Cook, and Cohen 2015). The accountability and legitimacy of organizations or policies based on river boundaries can be weak, and may generate conflicts with the existing layers of sectoral or political administration and agencies.

More crucially, river basins are affected by social or ecological processes which unfold at different scales and spatial units (e.g., climate change, invasive spaces, etc., which therefore have different “problemsheds”), and basin regulations or management practices may intersect in sometimes conflicting ways with other “policysheds,” or geographical units in which policies (e.g., on land-use planning, reforestation, urban or industrial development, spatial conservation, or protection areas) are implemented. Thus, there has been a recognition that many drivers and consequences of river basin dynamics can be located outside the basin, where solutions to local problems may also lie. This recognition in particular speaks to the relationships between food production, water, and energy, and has triggered calls for integrating policy thinking at a higher level, through what is commonly referred to as a “nexus” approach.

Hydrologic boundaries are a starting point but often beg to be pragmatically adjusted to particular geographic, administrative, and political realities. Mechanisms to harmonize policies, resolve conflicts of prerogatives, and ensure participation in the coordination of multiple levels of organization and administrative layers need to be established. Coordinating existing state and nonstate actors may therefore be the primary goal, rather than creating a new basin organization. Eventually, the selection of boundaries for water or environmental management, whether of the river basin or otherwise, is a political choice.

Ecosystemic approach and environmental management

Intensive river basin development has resulted in major ecological changes. Dams have radically altered the natural flow regime of rivers and the circulation of sediments; large-scale irrigation schemes have withdrawn and depleted large amounts of water; cities, industries, and agriculture have injected massive amounts of chemicals and pollutants. Although hydraulic infrastructures have provided huge benefits in terms of flood control, energy and food production, or navigation, the dramatic alteration of existing hydrologic regimes in terms of quantity, quality, and timing have often undermined or destroyed rich ecosystems, together with the elaborate human uses that had developed around them.

Dams, irrigation, and pumping schemes have led to the loss of springs or wetlands, to the gradual disappearance and contamination of
terminal lakes or seas, and to the many benefits associated with floods (source of nutrients, recharge of aquifers, support of wetlands and biodiversity, flood recession agriculture, reproduction of fisheries, etc.), which have been severely curtailed.

Not only has development, in most cases, resulted in a shift of benefits from the local population to other, often urban, populations, but the overall economic assessment has sometimes been negative, the loss of ecosystem services and existing productivity used being higher than the benefits generated by the investments, as the cases of the Hadejia’ Jama’a floodplain in Nigeria and the Kafue Flats in Zambia famously illustrate.

The necessity to view a river basin as a continuum of interconnected ecosystems in order to understand how changes in one part of a basin affect both water availability and environmental health in other parts of the basin has spurred the development of an “ecosystem approach,” defined by the Convention on Biological Diversity as a strategy for the integrated management of land, water, and living resources that promotes conservation and sustainable use in an equitable way. It has contributed to raising people’s awareness about the diversity of services obtained by people from ecosystems, either directly (fresh water, food, fuel, fiber, genetic resources, recreation, aesthetic experiences, spiritual enrichment, etc.), or indirectly (air quality maintenance, climate regulation, erosion control, regulation of human diseases, water purification, etc.), and has substantially enriched the conception of river basins and the understanding of their management.

This concept has also spurred work in the field of economics, with the development of methodologies for valuing ecosystem services to reveal the hidden costs of interventions and contest cost–benefit analyses and feasibility studies that routinely justify projects by ignoring their negative environmental externalities. They also argue that higher water prices could encourage conservation (thus increasing river flows) and have developed the concept of payments for environmental services.

Environmentalists have also promoted the notion of environmental flow, defined as the flow regime required to ensure the maintenance of particular environmental functions in a river ecosystem. Although the scientific determination of these environmental flows is problematic, and although these flows are often the result of negotiations between different interest groups, claiming a share of the available water for the environment has contributed to the political recognition of environmental requirements, and influenced major policy shifts and regulations such as the European Water Directive Framework. It even gave way to more radical claims, as illustrated by the movement for the removal of dams, which symbolically heralds a nascent paradigm shift.

Basin governance or management models: river basin organizations

The international promotion of the river basin as the natural or adequate scale for water resources management has contributed to the creation and spread of river basin organizations (RBOs). “River basin organization” is a generic term for organizations that come under a variety of names, including agencies, committees, commissions, authorities, associations, administrations, directorates, councils, hydraulic confederations, boards, and trusts. If the diversity of those denominations is partly due to the approximate translation into English of local administration names, it also reflects the historical pathways of the different basins and does make clear from the start that those organizations may sometimes be so different that grouping them under a single
category might actually be misleading: basins may be managed without RBOs, and some RBOs have a very narrow mandate that does not amount to basin management.

Discriminating factors first include the size of the basin (both the problems and the solutions, and how different stakeholders may contribute to them, vary greatly between small watersheds and international river basins) and the mandate of the organization: an RBO may be responsible for any combination of tasks that include construction, maintenance and management of infrastructures, development of basin master plans, allocating water or administrating rights, monitoring and collecting hydrologic or water quality data, law enforcement, fee collection, and promotion of public participation and awareness. But, from a governance point of view, an RBO can be typified, first, by its vertical integration within the state administration and, second, by its horizontal integration with nonstate actors.

Within the state, an RBO can be given all-encompassing powers that include planning, construction, and management, as well as regulation, in which case it will often be an autonomous authority, with prerogatives that override those of line agencies. But it can also be entrusted with a more limited mandates, in which case it will often be located under a particular ministry or department. The idea of integration has also promoted the concept of regulation, where an RBO is often supposed to define the rules of the game (like water quality standards, maximum aquifer withdrawals, user fees, and water rights) by which different sectors, users, and governmental agencies must abide. Unsurprisingly, the creation of a layer of governance at the basin-level results in the redistribution of bureaucratic power and often generates tensions or conflicts with other segments of the bureaucracy, as well as with local administrations. Because of the political difficulties of reshuffling prerogatives, RBOs often end up layered on top of existing institutions rather than replacing or complementing them. The development of a regulatory RBO, often located under the new and weak ministry of environment, is often not well accepted, especially if it threatens sectoral vested interests associated with the planning and construction of infrastructure or with unchecked pollution.

The degree of horizontal integration indicates how nonstate actors, such as representatives from the agricultural or industrial sectors, environmental nongovernmental organizations, and various civic groups, are contributing to decision-making. Nonstate actors can be called on to participate in different ways, from just consultation or participation in basin councils or platforms to representation in executive boards and decision-making, to being the driving force of RBOs that are partly independent from the state (which will be more common in small watersheds).

Integration is often taken as a justification for centralizing decision-making power and internalizing decision-making in a powerful organization, with the frequent risk of combining regulation and operation, and limiting accountability. However, it can be used to promote polycentric governance, where both different levels/scales and the views and interests of state/nonstate entities are expected to be harmonized, with the risks of stalemate by fragmentation of decision-making power and high transaction costs. These patterns of vertical and horizontal integrations define various forms of governance that must be further analyzed and characterized, for example by looking at their efficiency in terms of delivering sustainable or equitable management, the way their legitimacy is built and affirmed, their degree of accountability to society, and their capacity to be financially self-sustaining.
Collaborative arrangements for river basin governance are growing, as a result of the failure or limitations shown by models of decision-making restricted to state bureaucracy and experts, of the increasing demand from the private sector, interest groups, and civil society to have a seat at the table, but also of the new emphasis on, and the interest of the public in, restoring environmental quality in line with new values and uses, such as recreation and aesthetics. These factors have been at the root of the surge in the 1990s of the US watershed management movement, which includes over 1000 watershed experiences in collaborative planning, whereby local stakeholders decide the issues and discuss their options, with some technical assistance and funding from both federal and state agencies.

The mandate and prerogatives of an RBO may evolve with time, as a reflection of changes in the problems and challenges, in societal values, and in state–civil society relationships, and of political changes. More generally, these changes refer to the continuous adjustment of governance frameworks to ever-changing context and challenges, a need advocated by scholarship on adaptive management and governance.

The recent work of geographers on the politics of scale and processes of rescaling addresses the social production of scale and its impact on the distribution of power. Here the issue is how actors gain or lose influence as a result of authority being reconfigured around new spatial levels or by virtue of their own ability to work across different scales or levels.

Transboundary basins and hydro-hegemony

Scholarship on transboundary river basins examines how water is managed in the 263 basins that cross national boundaries. They represent 60% of total river flows and 45% of the Earth’s land surface, while being home to about 40% of the world’s population. A first focus is on legal issues, including the 1997 UN Convention on the Law of the Non-navigational Uses of International Watercourses, with its two main principles of “equitable and reasonable use” and the obligation not to cause “significant harm” to neighbors, treaties between two or more countries sharing a river basin, or other institutional arrangements for transboundary river basins on issues such as pollution and navigation (as with the Rhine and the Danube), water allocation (the Indus and the Nile), and joint management (the Mekong and the Senegal).

Despite such arrangements, binding agreements are rare or nonexistent; transboundary management organizations are only given limited power; mechanisms for monitoring and enforcement are lacking; hydrological data remain secretive; and historical political relations between neighboring countries, as well as strong sentiments of territorial sovereignty, make it difficult to ensure equitable and environmentally friendly management.

One way forward has been to respond to the lack of public involvement in interstate water agreements by developing river basin councils, platforms, and forums in which water user representatives discuss plans and allocation issues within a country, like in the Zambezi basin, where a basin strategy has been developed with the active involvement of stakeholder groups in all eight riparian countries. Another way has been to develop the concept of benefit sharing, whereby the stalemate in negotiations over water allocation is overcome by introducing other benefits related either to the use of water (e.g., sharing the benefits of hydropower between countries) or to other issues such as trade.

Yet, the topic remains a favorite of political scientists, who have in particular developed the concept of hydro-hegemony to describe
relations of power between countries sharing a same river basin.

**Future research directions**

This brief review of ongoing scholarship about river basin development and management points to a few questions and areas of research that deserve further inquiry. Modeling approaches and stochastic hydrologic models are crucial to providing information on management options and associated levels of risk, but the study of extreme events must be paralleled by an understanding of policy and political processes that are difficult to model. Although often limited by the availability and quality of data, hydrologic modeling needs to refine the representation of the interaction between surface water and groundwater, and to better take into consideration water quality issues.

Given the baffling diversity of physical river basin environments, the combinations of problems faced, and the multilayered institutional arrangements, more effort should be put into understanding the relationship between the nature of water governance regimes and their effectiveness. More elaborate typologies of river basin organizations and other institutional arrangements should consider the wider historical, social, and political contexts in which these governance regimes emerge and evolve, and provide insight into the administrative configurations which should be favored in a particular context.

These typologies also require a more nuanced understanding of bureaucratic dynamics and reforms, in particular a closer look at the structure of incentives available to different actors and organizations, when the structure of decision-making power is reconfigured to address issues of basin-level environmental management.

More work is needed on the societal and political drivers of river basin closure, as a means of challenging discourses that naturalize water scarcity and water crises or frame them in Malthusian terms. The preference for supply augmentation and capital-intensive solutions results in the generation and compounding of water crises, and is therefore self-sustaining; this preference must be explained by analyzing the social distribution of costs and benefits attached to different policy responses, in particular the convergence of the interests of politicians, bureaucrats, and interest groups.

Urban studies focusing on water and sanitation issues have produced a substantial body of scholarship in the field of critical geography. Insights from urban studies need to better fertilize, and to be integrated into, studies on river basin dynamics and governance, and vice versa. More generally, studies of river basins provide an opportunity for multidisciplinary work integrating approaches from hydrology, economics, human geography, and policy studies, among others.

Multisectoral or nexus approaches also have the potential to refine understanding of the systemic complexity of resource use and economic activities, although it is unclear whether they can substantially influence sectoral policies and practices.

Last, the transfer, operationalization, and adaptation of river basin-based management or governance reforms in different contexts must be accompanied and scrutinized. Critical work on the ideologies, interests, and social mechanisms that sustain the reproduction and dissemination of particular practices and policy models is needed. Europeanization, for example, and the application of the European Water Directive Framework provide an opportunity to assess the confrontation of uniform policy guidelines.
with the diversity of environmental and human contexts.

River ice and ice jams

Étienne Boucher
Université du Québec à Montréal, Canada

Ice covers are distinct features of cold-environment rivers. From the formation to the breakup of ice covers, a wide array of key biological, hydrological, and environmental components of hydrosystems can be affected. More particularly, the transition from an ice-covered regime to an open-water regime is a crucial moment in the hydrological year of cold-environment rivers. During this period and when conditions are favorable, severe ice jams can occur that may potentially threaten riparian communities and infrastructures, and transform the fluvial landscape in the long term.

Ice cover formation and breakup dynamics are both climate-sensitive phenomena, meaning that ongoing climate changes are susceptible to having an important effect on the timing, magnitude, and frequency of extreme ice-induced events (Beltaos and Burrell 2003). However, despite the ubiquity of ice-covered rivers in cold regions of the world and the sensitivity of river ice processes to climate change, scientific knowledge relating to ice cover formation and breakup remains limited, due to the complexity of the physical mechanisms involved and the difficulty of studying ice properties, especially at breakup. Here, a review of the most important processes associated with river ice formation and breakup is presented, along with a description of hydrological, biological, and geomorphological impacts.

River ice formation

River ice covers can form at any location where the air temperature drops below 0 °C for at least a month. This area extends north of 30° N in North America and north of 25° N in Eurasia (Prowse 1995). The length of the ice season therefore varies with the latitude, with longer ice seasons in high-latitude and high-altitude environments.

River ice forms because, under frigid weather, water loses heat to the atmosphere. Ice cover formation must therefore be seen as a thermally dependent phenomenon. Water phase changes, however, do not strictly relate to absolute temperature but are strongly linked to the presence of nucleating agents (or freezing nuclei). Freezing nuclei are microscopic particles (e.g., dust, bacteria, ash, spores, etc.) present in all natural freshwaters and that favor the crystallization of water molecules into ice.

Typically, river ice first forms in tranquil flow sections. The freeze-up of turbulent sections happens later in the cold season, when persistent, frigid weather become more common. Ice crystallization initially occurs in low-flow sections adjacent to the riverbanks, and tends to grow laterally, from the sides to the center of the stream. This results in the formation of laterally growing ice strips often referred to as border ice. If the growth of border ice is uninterrupted, strips eventually coalesce, leading to the complete and rapid closing of the river reach.

In the central section of a watercourse, however, turbulence is often more important, impeding (and often stopping) the lateral
expansion of border ice, even if air temperature
drops significantly below freezing point. Tur-
bulence causes the rapid mixing of the water
column, which in turn favors the replacement
of cooled water from the surface by less cool
waters from the bottom. These specific turbulent
flow conditions, along with the presence of a
strong (negative) heat gradient between water
and the atmosphere, result in the supercooling
of the water and in the formation of frazil ice.
Frazil crystals are small (0.1–5 mm) subrounded
ice particles that are transported downstream
by streamflow. Once formed, frazil ice crystals
typically grow in size and present more angular
shapes as the crystallization process advances.

Frazil ice crystals can be seen as “buoyant
sediment.” This is because the analysis of frazil
ice dynamics is somehow quite similar to the
study of sediment origin, transport, and fate in
rivers and generally consists in the identification
of frazil production zones, the description and
modeling of transport mechanisms, and the
characterization of deposition contexts. In that
sense, frazil ice has very important physical
characteristics that need to be underlined.

First, frazil crystals are formed in turbulent
reaches where, as mentioned earlier, surface
water loses significant amounts of heat to the
atmosphere. For that reason, frazil ice produc-
tion typically (but not exclusively) occurs during
cold, windy, and cloudless nights associated with
important heat losses to the atmosphere.

Second, frazil ice crystals are buoyant and can
be transported downstream. In fact, when they
form in the initial stages of supercooling, frazil
crystals present a buoyancy that is comparable
to that of water and thus can be transported
even at small flows. For that reason, frazil crystals
can be transported far (downstream) from the
zones in which they were initially formed. Once
produced and incorporated into the water col-
umn, frazil crystals usually agglomerate within
hours, forming flocs that rapidly grow in size.
Frazil flocs can be described as relatively loose
agglomerations of frazil ice crystals. If the air
temperature keeps decreasing, frazil flocs become
continually exposed at the water’s surface and
gradually freeze, solidify, and consolidate as
sheets. The proportion of ice to water aug-
ments within frazil agglomerations, and as a
consequence, they become even more buoyant
(in fact, more buoyant than freshwater). For
that reason, frazil ice flocs become less and less
affected by turbulent waters and easily float
downstream. Floating ice flocs often result in
the formation of ice pans (often referred to as
pancake ice). Ice pans are circular agglomerations
of frazil flocs that drift downstream and that can
be easily recognized by their upturned edge.

Third, frazil ice crystals are sticky and can
adhere to rough underwater surfaces (Ettema
2002). Rough underwater surfaces are numer-
ous: aquatic plants, irregular gravel beds and
banks, and the ice cover itself. Since supercooled
waters and frazil flocs are affected by turbu-
lent flow, they can be transported downwards
towards the river bed where they agglomerate
(or “anchor”) to form anchor ice (often called
bottom-fast ice). Anchor ice corresponds to a
relatively flat accumulation of frazil crystals in
submerged portions of the river bed. At breakup,
anchor ice might be mobilized by the flood wave,
carrying and transporting lag deposits on its way.
Another surface where frazil flocs tend to accu-
mulate is beneath a static ice cover. Ice cover
bottom presents an irregular topography against
which frazil ice crystals agglomerate. The sus-
tained agglomeration of frazil flocs under a dense,
thermal (black) ice cover results in the construc-
tion of a hanging dam. Hanging dams grow
from the surface in a downward direction, and
frazil ice tends to be highly consolidated near the
black ice surface and looser near the frazil/water
interface. Rapid hanging dam growth may cause
important flow constriction, and often result in abnormal ice thicknesses ranging from a few tens of centimeters to a few meters. Hanging dams tend to form in the vicinity of slope breaks, where frazil ice is produced massively in favorable hydroclimatic conditions.

In very cold environments, river ice can sometimes freeze to (or close to) the bottom of the channel, due to the length of the cold season, or following important frazil ice accumulations. The result is a flow occlusion that can be significant enough to prevent the normal evacuation of water. In such conditions, water can sometimes find its way to the top of the ice cover, and refreeze there. This event is often referred to as an aufeis (icing or nalled), and produces a typical upward-growing ice cover where layers of black ice (corresponding to successive icings) alternate with snow deposited between aufeis events.

River ice breakup

River ice breakup is a crucial moment in the hydrological year. It corresponds to the moment (usually spring or late winter in the northern Hemisphere) where rivers transit from an ice-covered regime to an open-water flow. This has drastic hydrological and environmental consequences. River ice breakup is a complex and multivariate progression of events that is best described by a succession of thermal and mechanical processes through which river ice decays, degrades, deconsolidates, fractures, and ultimately, gets washed away.

Breakup occurs when factors and processes that tend to maintain the ice cover in place (cold temperatures, snow precipitation, etc.) become less important than those that contribute to its thermal or mechanical degradation. Thermal processes control the rate at which the ice cover melts in situ, while mechanical processes are mainly hydrodynamic forces that contribute to fracture and break the ice cover into floating rafts, before its complete thermal degradation.

Thermal breakups

Degradation and decay can be defined as a loss of mechanical strength and integrity of the ice cover (Figure 1a). Speed and timing of ice cover degradation are driven by two major variables: incoming solar radiation and water-to-ice or air-to-ice heat transfers. Of the two variables, radiative processes have the most important influence on river ice cover degradation and decay (Prowse 1995). The influence of short-wave incoming solar radiation augments through time, particularly through changes in surface albedo. In early breakup stages, the ice cover is often entirely covered by snow, so a considerable amount of energy is returned directly to the atmosphere. However, as the ice cover decays, surface albedo decreases with superficial ponding, therefore accelerating ice cover degradation. The speed of this process and the amount of water ponding at the surface sometimes depend not only on the amount of incoming radiation, but also on the quantity of fresh snow covering black ice.

Radiation influences surface melt, but river ice cover also melts from the bottom as water temperature rises. Most of the heat transferred to the water at the time of breakup originates from the friction caused by the movement against the ice cover and/or the channel. This effect amplifies with increasing velocities due to rapid snowmelt.

The speed and timing of river ice cover degradation by hydrothermal processes is likely to vary with river ice thickness. At locations where frazil accumulations have been important during the antecedent winter, hydrothermal processes may need more time to degrade the multiple and often imbricated layers of black ice and consolidated frazil ice. By contrast, in river
sections where black ice dominates, ice decay is much faster. It is therefore common to observe an important spatial irregularity in the timing of thermal breakup in river reaches that are located next to one another, owing to nonuniform ice thicknesses.

Thermal breakup in rivers can be compared to the process of breakup in lakes (see Lake ice). The progressive thinning of the ice is accompanied by an increased water content and a general loss of structural integrity, characterized by a progressive reduction in ice density and strength that results from the augmentation of ice porosity. Degradation by hydrometeorological processes advances to a point where the ice cover weakens enough to lose most of its original mechanical properties. Ice cover remnants can then be easily washed away by the flood.

Mechanical breakups: onset and triggering

In particular hydrometeorological contexts, thermal degradation of the ice cover is not completed
when the spring flood wave propagates downstream. As a consequence, at the time of breakup, the ice cover is mechanically unaltered (i.e., intact or undegraded), but the hydraulic action of the flood is such that the ice cover is rapidly fractured and forced to move downstream (Figure 1b). This critical situation is referred to as a mechanical breakup and announces the formation of ice jams.

Mechanical breakups occur when hydraulic forces provided by the flood wave are greater than the forces that tend to maintain the ice cover in place. It is generally admitted that the strength, resistance, and density of the ice cover are properties that are “inherited” from the succession of cold events that prevailed during the preceding winter (Beltaos 2003). In other words, the ice cover’s resistance is maximal just prior to breakup, but its strength progressively (and inevitably) weakens under the effect of hydrothermal degradation. On the other hand, increasing velocities and water levels during flood may force the ice cover to lift and break into rafts. The amount of hydrodynamic force required to fracture the ice cover during a mechanical breakup episode depends on multiple factors such as ice cover thickness, water temperature, and most importantly, the state of degradation and decay of the ice cover (Beltaos 2003). Thus, the timing of the flood is crucial for the triggering of a mechanical breakup. It can be assumed that very large and early floods are required to fracture the ice cover at the very beginning of the breakup season, because the ice cover presents a full structural integrity. However, as the breakup season advances, fewer and fewer important flood events are required in order to break the ice covers into rafts. With the progression of thermal decay, increasingly smaller flood events are required to wash away the ice cover.

Hydroclimatic conditions and thresholds associated with the triggering of mechanical breakups in rivers are complex and often site-specific, although some generalities can be identified. In most cases, both flooding and ice conditions are important.

Floods volumes do not need to be extreme to trigger a mechanical breakup. On the contrary, mechanical breakups are usually much more sensitive to the timing of the flood. Early and rapidly rising floods are more likely to fracture the mechanically intact ice cover. In cold regions where snow precipitations are important, rain-on-snow events occurring early in the season may provide sufficient energy to the flow to fracture the ice cover before its degradation by thermal processes. This phenomenon is amplified in northward flowing (large) hydrosystems. In such environments, the southernmost portion of the river melts first, while the northernmost portion of the river ice cover remains intact and undegraded. Floodwave propagation (northwards) augments the risk of mechanical breakups in the lower portion of the watershed.

While the timing of the flood is crucial, mechanical properties of the ice cover are also important. The thicker, denser, and more resistant the ice cover is at the time of breakup, the greater will be the probability of a mechanical breakup. Thus, all variables that prevent the ice cover from melting, and that control the mechanical properties of the ice cover, are important. Overall, the length of the frost season usually has a significant effect. Colder frost seasons may lead to thicker and denser ice covers and may also result in an abundant frazil production which accelerates the formation of hanging dams. Ultimately, abundant snow precipitation, especially in weeks preceding breakup, may slow down the thermal degradation of the ice cover.
RIVER ICE AND ICE JAMS

Mechanical breakups: ice jam localization

Ice jams may be defined as in-channel accumulations of ice that prevent the normal evacuation of streamflow. More formally, jams occur where ice discharge exceeds transport capacity. They can occur at freeze-up, but are most common at breakup.

Ice transport capacity is not uniform along a watercourse. Numerous obstacles exist along a watercourse that prevent the free circulation of ice rafts in the downstream direction. Channel constrictions associated with a marked reduction in velocity and width are clear examples of sites that can lead to significant congestion. Channel constrictions may be natural or man-made. Bridge piers are the most common man-made obstacles. Natural constrictions are often associated with the presence of geological obstacles (e.g., rock outcrops) that force the passage of water into a bottleneck. The presence of island as well as sharp meander bends can also be identified as possible obstacles for the free circulation of the ice. Finally, the ice cover itself, owing to the nonuniform patterns of decay along a river, may be seen as an obstacle for the circulation of ice rafts drifting downstream. Depending on the thickness of the “ice wall” (e.g., hanging dams) and as a function of water velocities and ice discharges from upstream, the magnitude of the blockage by the ice cover might vary considerably between years. Ultimately, ice jamming sites tend to be located where a combination of the above-mentioned obstacles is found.

Hydrological impacts of ice jams

One of the most perceptible threats associated with the occurrence of ice jams is flooding. Flooding occurs upstream of the jam when floodwater passage is significantly obstructed by the presence of an ice dam. Ice-induced flooding is considered extreme in many ways when compared to floods produced in open-water conditions.

The first reason why ice-induced floods are considered extreme is their amplitude. Ice jam floods often reach much higher levels than those produced in open-water conditions, at comparable discharge. This effect is mostly attributable to the resistance exerted by the ice cover and the jam itself. The second reason relates to the speed of flood rise. In fact, ice-induced water level rises are much more rapid and sudden than those observed during open-water conditions. Actually, in minutes, waters close to freezing point can rise by a few meters and threaten riparian communities and infrastructures. The menace of a rapidly rising ice flood must be interpreted in light of the difficulty to predict both timing and location, due to the complexity of processes involved and also because of the lack of systematic observations on breakup dynamics in most rivers. Thus, the development of modeling tools that would serve as a basis for the deployment of warning systems is a goal that, even today, seems far from being achieved.

Geoecological impacts of river ice jams

Breakup ice jams are channel-forming events. They have major and long-term impacts on channel geomorphology and ecology and are associated with a distinct signature in fluvial landscapes. This signature exists because ice is an abrasive agent that combines with flood waters and significantly augments the erosional capacity of the flood at breakup. The type and extent of ice-induced erosional features and landforms, as well as their long-term maintenance in the landscape, depend on many factors such as the characteristics of the ice-flood regime (frequency,
magnitude, type of ice event) and the nature of bed and bank material available for erosion.

Influences of ice processes on bed forms and morphology are sometimes difficult to measure because they occur underwater. Ice runs and jams can nevertheless significantly scour the riverbed through a variety of processes. Since, under the jam, speeds tend to increase to accommodate for friction losses, flow may promptly become more competent and transport a larger amount of sediments. This typically occurs under thick hanging dams where flow is diverted downwards towards the bed. Another process affecting bed morphology is the removal of anchor ice at breakup. Anchor ice strongly attaches to riverbed sediments during the winter but when breakup arrives, rafts may detach from the river bottom and transport sediments glued to the floating anchor ice rafts. Ultimately, in meandering streams, river ice jam floods may cause channels to avulse (Smith and Pearce 2002), that is, to shift position abruptly while abandoning the ancient channel. This phenomenon, however, remains poorly documented.

The most obvious effect resulting from ice jams and ice runs is bank gouging and abrading (Figure 1c). In sandy rivers, lateral erosion that occurs during ice jams and runs typically results in the formation of two-level ice-scoured riverbank morphologies that consist in (i) a steep erosional talus located just above the bankfull stage and, (ii) depending on the height of valley walls, an aggradation surface covered with fresh alluvia deposited during ice-induced floods. The erosional talus results from the mechanical abrasion by thick and dense black ice rafts that are pushed, during ice runs, against the recently unfrozen and thus weakened riverbanks. Erosion typically occurs slightly higher than the bankfull level that is constructed by regular open-water floods. Contrarily, vertical aggradation during ice-induced floods occurs on top of ice terraces, at levels rarely attained by typical open-water events.

Whether or not this two-level ice-scoured morphology can possibly be constructed during a single event or, alternatively, is the product of recurrent ice floods that maintain the erosional feature in place for decades, remains difficult to verify, owing to the lack of long-term and large-scale data on river ice processes. Studies from dendrochronological investigations of river ice processes (e.g., Boucher, Bégin, and Arseneault 2009) nevertheless associate the occurrence of such lateral erosion features with river reaches that are commonly affected by ice jams. Other studies have even proposed that cold-environment rivers may, in the long-term, adjust in terms of both size and shape to local ice conditions. For example, in several Albertan rivers where ice jams occur relatively frequently, channels were possibly enlarged (at bankfull stage) by a factor of 2–3, by comparison to channels where ice effects were negligible (Smith 1979).

Where riverbank material is coarser, ice-induced erosion will often take the form of boulder pavements/ridges or bechevniks. Boulder pavements and ridges form where heavy ice push events occur. Coarse sediments are pushed by ice rafts against the (often steep) valley walls, resulting in a subparallel alignment imbrication of cobbles and boulders, forming either an extended flat erosional surface (pavement) or a bow-like structure (ridge). Fine sediments are usually rapidly washed away from these surfaces during open-water floods. Bechevniks are quite similar but also include overbank deposition on the upper portion of the river bank. Bechevniks form by the erosion of the riverbed and the subsequent transport and deposition, by ice rafts, of eroded, unconsolidated coarse sediments on the upper part of the riverbank, at heights that are much higher than the bankfull stage.
RIVER ICE AND ICE JAMS

Such features were named by Hamelin (1979) in reference to the strip of land adjacent to several Russian rivers, where boats were towed manually.

Finally, ice-induced lateral erosion is a dominant process in the riparian landscape because it has the potential to deeply transform riparian ecosystems (Scrimgeour et al. 1994). Impacts on the vegetation are multiple, and the responses, also, depend on the species affected and the resilience of the ecosystem. In most cold-environment rivers that are commonly affected by ice jams and runs, vegetation found on riverbanks is typically composed of erosion-tolerant species. Such species (e.g., shrubs such as Alnus rugosa in northeastern North America) vegetatively reproduce quite efficiently and may survive even the most abrasive ice-scouring events. For that reason, erosion-tolerant vegetation is often found immediately adjacent to the riverbed in cold-environment rivers. At slightly higher levels, vegetation becomes less resistant to flooding and erosion, producing a recognizable vertical stratification of riparian vegetation. At this level, vegetation is often scarred and damaged (trunks, branches) during high-intensity events, but will not be completely destroyed unless extreme ice push conditions are encountered. In rare occasions though, severe ice push may destroy the ecosystem (Figure 1d) and interrupt forest succession, a situation that ultimately results in an important rejuvenation and sometimes replacement of the original vegetation.

Rivers and river basin management

Naho Mirumachi
King’s College London, UK

Rivers are a major source of fresh water. They play an important role for livelihoods and economic development, and the river basin is vital to both terrestrial and freshwater ecosystems. River basins also represent a political space where different interests of water use and allocation are negotiated, reflecting conflict and cooperation between various stakeholders. River basin management is often bound by the hydrological unit but with varying purposes, including engineering the river flows and conserving ecosystems. River basin management is mediated through legal principles, agreements, river basin organizations, and other institutions at multiple spatial scales. The river basin becomes the context in which ideologies of nature and modes of environmental governance are played out.

Developing the river and basin closure

Broadly speaking, rivers have historically been the object of control and exploitation by societies attempting to utilize the water resources and to prevent hazards such as flooding. River basin management has been centralized to roll out large-scale irrigation schemes and to develop dams. Often described as the hydraulic mission, the state organizes engineering projects so that the benefits of abstracting water resources from the river are maximized. Irrigation projects utilizing dams and canals are iconic of the hydraulic mission, embodying a masculine representation of approaches to river basin management (Zwarteveen 2008). Water transfers between and within basins provide the means of supplying water resources where needed, reconfiguring the river flow. For example, in the American West engineering interventions have transformed an arid landscape. The South–North Water Transfer Project in China is another major scheme to address water scarcity in the northern regions.

This mode of river basin management is also an expression of modernity, employing technology to subject nature. The river becomes the means through which economic development is achieved and a utilitarian view of water resources is prioritized. Moreover, the mix of centralized, large-scale engineering with ideals of modernity enables political control over land and peoples, as can be seen in the example of Spain during the fascist regime (Swyngedouw 1999). The river and river basin can be geographies where political ideals are projected and made to symbolize state power.

However, relying on infrastructure to manage the river can pose unique temporal problems. While dams can benefit economic development, these infrastructures do have a life span and become obsolete after decades in operation. Nowadays, countries that have long achieved their hydraulic mission face the issue of decommissioning dams. In the United States, consideration of the removal of dams has come late: dam removal procedures were only formalized in 1994 after prompting from the Congress and civil society (Doyle et al. 2003). The problem of removing dams touches upon not only issues
RIVERS AND RIVER BASIN MANAGEMENT

of hazard risk and safety from deterioration but also impacts on ecosystems as a result of removal, and its socioeconomics costs.

This extensive and intensive river basin management has led to situations of basin closure. Basin closure occurs when the river flow is not sufficient in quantity and quality for downstream uses and ecosystems, and does not function to control saline intrusion in delta areas and to transport sediments (Molle et al. 2007). The Colorado and Yellow rivers, in addition to the Aral Sea are considered to have experienced basin closure; the Jordan, Indus, and the Murray–Darling rivers are nearing closure. The increase of rivers facing closure has meant that 1.4 billion people lived in closed basins at the turn of this millennium (Falkenmark and Molden 2008). In situations of basin closure, not only is water scarce but also the health of ecosystems is at risk. This has implications for livelihoods and poverty, especially rivers in the Global South where many communities are directly reliant on resources from the river basin.

Assessing environmental flows to address basin closure

To ensure water is allocated in a way that does not cause tradeoffs with the environment, different methods to calculate environmental flow requirements have been developed. The concept of environmental flows explicitly considers water for the environment, not just in terms of quantity but also the quality and timing of available water within the river basin (Smakhtin 2008). Reallocation of water from one use to another can be informed by knowledge of environmental flows. Assessing environmental flows as part of river basin management may change the rationale of controlling the river for maximum utility to one based on sustainability principles.

Environmental flow assessments have been utilized to facilitate river basin planning in the Murray–Darling River in Australia. Intensification of irrigation, based on a hydraulic mission of storing and transferring water, has reduced the quantity and also quality of water resources in the river basin (Figure 1). In order to curb extraction and also restore the environmental health of this basin, river basin planning has focused on increasing environmental flows. However, in many river basins around the world, the concept of environmental flows has yet to be fully embedded in planning and management. This process requires not only robust science to assess the requirements, costs, and benefits of environmental flows but also institutional changes to river basin management. In developing countries where water policies may be weak, the institutional setting may not enable reallocation water from existing uses to the maintenance of environmental health based on environmental flows. Even in the case of Murray–Darling River basin, the different governments of New South Wales, Victoria, Australian Capital Territory, Queensland, and South Australia lacked a clear policy for implementing environmental flows despite the recognition of their importance (Pittock and Finlayson 2011).

Integrated water resources management (IWRM)

Pollution, watershed degradation, and scarcity of water resources have prompted serious consideration about the sustainability of water resources and how river basin management can reflect it. In this regard, policy innovation in river basin management in the last twenty years cannot be detached from the debates of sustainable development. Water resources feature prominently in documents such as the Agenda 21, which was
the output of the Earth Summit in 1992, the first major global forum that called for concerted action for sustainable development. In Agenda 21, the scope of water resources management was not limited to the mere prevention of pollution or conservation. It also included the holistic treatment of multiple water uses to sustain lives and livelihoods. Consequently, managing water for health and sanitation, agriculture, energy, ecosystems, and other purposes within a river basin was understood to require an integrated approach that is distinct from management under the hydraulic mission.

Integrated water resources management (IWRM) has been promoted widely since the 1990s. It reflects the discourse of sustainable development and is defined as “a process which promotes the coordinated development and management of water, land and related resources, in order to maximize the resultant economic and social welfare in an equitable manner without compromising the sustainability of vital ecosystems” (GWP 2000, 22). IWRM is based upon three key principles. The first principle is economic efficiency to guide water use. Underlying this notion is the assumption that water resources are already scarce and will face increasing demand. Equity between water users is a second principle that is to inform water access. The third principle considers the environmental and ecological sustainability so that present water use is not at the expense of future uses. The river basin, defined by its hydrological basin, is seen as the optimal unit to practice integration and coordination under IWRM. IWRM at the river basin level allows the consideration of river use with other water resources, such as groundwater and coastal water resources.

In Latin America, Brazil has been the forerunner in national-level efforts to establish
IWRM strategies. An example of efforts beyond national governments to adopt IWRM is the European Water Framework Directive. As a regional policy, the framework directive requires each of the member states to make provisions for water resources planning at the river basin level. IWRM can also be applied to international transboundary river basins, as can be seen in the example of the Niger River, shared between ten countries. The riparian governments recognized IWRM in a statement on the “Clear and Shared Vision” of the river basin, which aims to achieve sustainable development by 2025.

IWRM attempts to better coordinate water use by society. Equity is considered from the perspective of water use by humans only, excluding ecosystems. Sustainability is also understood as a means to ensuring continued water use for societies. This strong emphasis on human water use is underscored by a set of global principles established for sustainable development, widely known as the Dublin Principles. These principles, derived from the Dublin Statement on Water and Sustainable Development established in 1992 to inform Agenda 21, focus on human agency, highlighting the importance of public participation for decision-making and recognizing the role of gender in managing water.

IWRM often requires major water policy reform as it rejects the traditional top-down decision-making process as the only way to manage river basins. The role of the government is to contribute to an “enabling environment” where public participation is the basis of decision-making (GWP 2000). This means that businesses and civil society also play an important role in IWRM. IWRM encourages economic instruments such as pricing, tariffs, and water markets to be introduced for efficiency. Policy and legislation need to be revised for efficient water use and also to underscore how river basin management impinges on other sectors such as land and energy. These rules and instruments need to be practiced on the ground by implementing agencies that may not necessarily be mandated or equipped with the appropriate resources to accommodate these changes towards IWRM. Capacity building has been important in facilitating the transition towards IWRM. International organizations such as the Global Water Partnership have set up capacity building initiatives and programs. Overseas development aid has also been directed towards achieving IWRM in developing countries.

While IWRM has been mainstreamed in many government policies, there are many critiques. IWRM is ambitious, with the goal of balancing water use and sustainability, to the extent that it has been criticized for being unrealistic. The three principles are broad so as to be applicable to various river basins with differing hydrological, ecological, and socioeconomic conditions. However, this risks IWRM becoming a framework that has little utility for practices on the ground. IWRM also assumes that public participation is the best way forward for decision-making. Introducing public participation may be difficult in cultures where bottom-up decision-making has not been practiced. In addition, it does not necessarily mean that inclusion of all stakeholders is ensured or in a way that is meaningful, and actual changes to water management may be hard to come by. The debate on IWRM calls into question broader questions of water governance, on the values over the water resources and environment that is being contested, and also the process of decision-making when different rationalities, interests, and motives exist across a range of stakeholders.
International transboundary river basin management as a context for conflict and cooperation

Developing the river for sustainable development calls for river basin management that considers improvement to efficiency of use, including recycling water, reducing demand, and reallocation of water resources. The process of changing existing patterns of allocation and identifying rights to water use is inherently a political process. River basin management is imbued with power relations between various stakeholders: both conflict and cooperation play out in negotiating and implementing river basin management (Mirumachi 2015).

The management of international transboundary river basins is particularly noteworthy, as there are concerns that rivers can be the source of tension between states. There are 276 river basins that are shared by two or more states around the world. These shared rivers can form political boundaries between states or traverse through territories of sovereign states. As rivers change course, boundary disputes may arise. Another problem is often described as potential water war, pointing to the risks of water scarcity. International transboundary river basins are unique in that they pose problems of balancing sovereignty of states with other principles such as sustainable water use.

Especially in a current world order where there is no supranational structure to police state behavior, cooperation over the international transboundary river basin is up to the goodwill of states. Nonetheless, historically, there have not been any incidents of militarized conflict over water resources between states sharing rivers. Rather, joint river management is common practice that can be expressed in the form of bilateral and multilateral agreements and treaties. These agreements can be project-based, such as the bilateral treaty between Lesotho and South Africa in the Orange–Senqu River basin concerning a water transfer scheme. Agreements can also be broad frameworks, as in the case of the Lower Mekong river basin between Laos, Thailand, Cambodia, and Vietnam concerning sustainable development. Often, river basin organizations (RBOs) are set up to facilitate decision-making and as agencies for policy development, like the Niger Basin Authority in West Africa. The International Boundary and Water Commission between the United States and Mexico is responsible for the management of the Rio Grande and Colorado rivers. This RBO has evolved in its mandate over time, originally established to deal with river border issues but now including water and sanitation as well.

River basin management facilitated with agreements and RBOs has seen some diffusion of global norms (Conca 2006). The United Nations Convention on the Law of the Non-Navigational Uses of International Watercourses (UN Watercourses Convention) is a source of reference for global principles such as equitable and reasonable utilization, prevention of significant harm, and prior notification of the water resources development plan to other states. This convention is buttressed by the doctrine of limited territorial sovereignty, which sets forth entitlements to states for the utilization of shared waters so long as it does not cause undue harm or deprive other basin states of their rights (McCaffrey 2007). As a framework convention, the UN Watercourses Convention provides a set of principles that is to be localized to help guide practice for individual basins. For example, with a high concentration of transboundary river basins in the Southern African region, member states of the Southern African Development Community (SADC) have relied heavily on the UN Watercourses Convention text to draw up
the Revised Protocol on Shared Watercourses in the SADC signed in 2000.

However, the extent of cooperation over river basin management requires scrutiny. While there was a remarkable increase in the number of RBOs established around the world after 1950, there are still only 61 organizations. Moreover, they tend to have limited authority and there are cases of overlaps between organizations within a basin (Lautze et al. 2013). Research has focused on the institutional design of river basins to identify how effectiveness can be improved. It has often been suggested that the function of data and information sharing could enhance cooperation over the management of shared rivers. Many RBOs have the task to generate scientific studies and baseline reports of the environmental state of the basin and to facilitate the exchange of information and data, such as the International Commission on the Protection of the Danube River. However, it has been found that rather than exchanging actual quantitative data, indirect mechanisms of data and information sharing such as prior notification are much more widely used between basin states. Data and information exchange can be costly for states; the reluctance can also be attributed to data of the river and water resources utilization considered as a matter of national security (Gerlak, Lautze, and Giordano 2011).

Negotiating river basin management underscores the role of power and power asymmetry between states. The concept of hydro-hegemony demonstrates that decisions of water allocation are subject to the ways in which both hard and soft power are exercised to control and capture water resources, with implications to equity of outcomes (Zeitoun and Warner 2006). The stronger basin state, or the hydro-hegemonic state, may capture water resources by physically building infrastructure to store and divert water, or by ensuring compliance to water sharing arrangements through negotiation and other discursive means. This means that even if RBOs and other river basin management institutions exist, they may not ensure equity, especially for those with less power. The insights on power highlight that geography and riparian position are not the sole determining factor. In other words, while upstream basin states may be privileged to have better geographical access to water resources, downstream states can exercise hydro-hegemony to secure preferable allocation. This is the case of the Nile River basin where Egypt has historically been able to influence water allocation so that it can access a majority of the water resources despite its being the downstream state.

National and local institutions for river basin management

Conflict over water resources in basins at the subnational level can be even more intense than at the international level, with actual instances of violence and death. The Water Conflict Chronology published by the Pacific Institute provides a useful list of violent conflict over water (Pacific Institute 2016). River basin management is compounded by issues of water rights, especially in cases where they are not necessarily formalized in legal entitlements or are complex, tied up with issues of land ownership. Water users’ associations (WUAs) are often set up to ensure rights are recognized to groups of stakeholders.

Moreover, disputes may not necessarily occur between local water users. The issue of “land and water grabbing” shows how actors from outside of the river basin also play a major role in managing water. Land grabbing, or acquisition of lands by both domestic and international investors, reflects the competition for land largely
for agriculture, helped by the globalization of investment and food commodity trade. Land grabbing has implications for water resources because access to land also offers access to rivers and aquifers, not to mention soil moisture necessary for agricultural productivity. The changes to land and thus water entitlements can disrupt the livelihoods and local practice of land and water resources management.

In order to avoid and resolve conflict and to ensure sustainable river basin practices, it is assumed that decentralization of decision-making at the “lowest appropriate level” is necessary, as exemplified in IWRM (GWP 2000). Various institutions have been tested to foster collective action between stakeholders with disparate interests and motivations at the local level. In addition to WUAs, catchment management committees are common mechanisms that enable decision-making at a more localized level than at the larger, basin-wide level that can be led by state actors through national policy and legislation. Multistakeholder platforms (MSPs) refer to the different types of fora that facilitate participatory decision-making.

However, the effectiveness of devolved decision-making has yielded mixed results, showing that it is not a panacea to river basin management. South Africa presents an interesting example where catchment management agencies (CMAs) have been set up as statutory organizations to implement IWRM. These CMAs work in tandem with WUAs made up of actors such as irrigation boards (who may have already organized as a stakeholder group before the formal introduction of WUAs) and other stakeholders such as small-scale farmers. The experience in the Komati basin showed that these new institutions do not necessarily change the power asymmetries between stakeholders and may even risk further marginalizing those with less power (Waalewjin, Wester, and van Straaten 2005). Devolving decision-making is particularly challenging for river basins in developing countries. In these situations, formal institutions recognized by legislation and governmental policy may coexist with informal institutions that have been established over time, based on traditional and cultural practices. In this regard, river basin management entails more than just changes to policy but also to the culture of decision-making.

Consequently, there are scholarly debates about the variety and plurality of decision-making rather than a narrow consideration of river basin management techniques per se; these discussions ultimately touch on the issue of water governance. IWRM has largely drawn criticism because it presents a generalized river basin management model and does not offer ways to deal with the complexity of water governance. There are attempts to understand the polycentric nature of water governance as multiple and nested loci of authority and decision-making. River basin management would thus be informed through a range of stakeholders and experts that can provide tailored solutions for different scales of management (Lankford and Hepworth 2010). Moreover, multiple institutions may interact in a way that they cannot be designed a priori. The implication is that river basin management needs to recognize the ecological and social conditions through which institutions influence each other in a process of institutional bricolage (Cleaver 2012).

The limitations of IWRM have brought about discussions of how river basin management can accommodate the changing nature of socioecological processes that throw up issues of complexity and uncertainty. Collaborative water governance is suggested as one way of taking into account different worldviews, knowledge, and interests of different stakeholders so that they
RIVERS AND RIVER BASIN MANAGEMENT

engage in problem-solving jointly. Public participation is not a given solution in this case, but as something that needs to be developed through time and with trust between stakeholders. Adaptive water resources management has also been suggested as a way to address complexity through social learning. River basin management is thus shaped by the various governance mechanisms put into place and no longer a mere technical issue dealt with by the state alone.

Managing beyond the river

River basin management increasingly requires the consideration of impacts to and from issues beyond the hydrological unit, such as those relating to international food trade, regional energy demand, and global climate change. For example, understanding how demands for energy drive hydropower development is useful and provides a more comprehensive picture of the ways in which water use and allocation can be regulated. This means seeking solutions beyond the river basin. Globalization has also facilitated the expansion of international food trade. Climate-proofing the water sector requires a renewed look at the ways in which river basins are managed. In this regard, considering the river basin as a fixed unit of management may not be helpful anymore. Adaptive and collaborative water governance emphasizes the multiscalar networks of power and knowledge that go beyond the spatial boundary of the hydrological river basin. It can be argued that the river basin is not a fixed spatial entity but a sociopolitical arena in which environmental governance is established and challenged.

Rivers and streams

Edgardo M. Latrubesse
Edward Park
University of Texas at Austin, USA

Definition

“Stream” is a general term used to define water bodies that flow downslope due to gravity through a natural open channel. The channel will contain water for at least part of the year. Streams with a significant flow and volume of water are generally considered rivers. Rivers and streams shape the emerged surface of the Earth and ideally reach the ocean, which is the general base level for geomorphologic systems. In other cases, they end inland due to climate (water scarcity), diversions and use by humans, or even geologic controls that impose local or regional base levels (interior basins).

Runoff, drainage basins, and channels

When rain or snow fall onto the Earth, part of this precipitation seeps into the ground to replenish groundwater (infiltration) while another part returns to the atmosphere through evapotranspiration. The remaining water starts to flow on the surface as runoff. The amount of runoff depends on the amount, intensity, and temperature of the rainfall as well as on biophysical factors such as vegetation cover and terrain characteristics such as elevation (rock and soil types), slope characteristics (steepness and length), and landscape modifications produced by human land use. Additional sources, such as melting ice and snow, trigger overland flows which, together with groundwater flowing beneath the surface (throughflow), are the sources for streams and rivers.

Surface water has the capacity to produce erosion and to transport sediments. Runoff tends to concentrate in self-made channels that can be: shaped by the erosion of the terrain surface in a self-building channels network; formed by the alluvial materials that their own system transports and deposits; or built by a combination of both processes. Thus, a channel is a landform outlined by its bed and banks where water, sediments, and solutes are flowing through. Channel development is controlled by the lithological substrate and both water and sediment flows, which results in a variety of channel geometries in nature. They can be relatively stable or unstable features as they can constantly be modified by erosional and aggradational processes. Channels adjust and evolve over time and a wide range of channel types (discussed in the section Channel patterns and floodplains) are found in nature. During flooding periods, when water flow exceeds the channel capacity, flooding waters overtop the channel and diffuse across the surrounding terrain.

Drainage basins include both the streams and rivers that convey the water and the land surfaces from which water drains into the channels. A drainage basin is separated from adjacent basins by a drainage divide, which acts as a geographical barrier such as a ridge, hill, or mountain. Other terms that are used to describe a drainage basin are “catchment,” “catchment basin,” “river basin,” “water basin,” and “watershed.” In a
RIVERS AND STREAMS

technical sense, a watershed refers to a divide that separates one drainage area from another, but in the United States and Canada, the term is often used to mean a drainage basin or catchment area itself. Drainage networks are present in different types of patterns and the channel arrangements depend mainly on geological factors (lithology and structure). Depending on the scale and geologic and geomorphologic complexity of the basins, not only one but several styles may be present. Thus, a drainage basin is formed by a hydrographic channel network that carries runoff and sediments produced by erosion in the drainage basin. Except under certain circumstances, all watercourses in a hydrographic network must be able to flow without interruption from their headwaters (sources) to their mouths (outlets).

The drainage network can end in a river, lake, reservoir, estuary, wetland, sea, ocean, or some flat dry interior basins. The basins can be also classified in function of either their connections or their lack of connection to the ocean. Exorheic basins are those where the drainage systems can reach the ocean while endorheic basins are inland basins with interior drainage.

The scales of the basins are highly variable. These range from small networks of rills with ephemeral or intermittent channels generated by erosion during a single storm event on agricultural land, to a huge and incredibly interconnected channel network of more than 6 000 000 km² such as the Amazon basin. The role of large rivers draining continents is very relevant. For example, the 10 largest fluvial basins of the world (Amazon, Congo, Nile, Mississippi, La Plata, Obi, Yenisei, Lena, Niger, and Amur) are responsible for draining nearly 21.5% of the emerged land of our planet.

However, nearly 20% of all land drains to endorheic basins such as lakes or interior seas. In endorheic basins evaporation is the primary factor of water loss and the water is frequently more saline than the oceans. The largest endorheic basins are in the interior of Asia, such as the Caspian Sea and the Aral Sea basins. Other large basins include the interiors of Australia, the Great Basin in the United States, the Chad basin in Africa, and some basins in Mexico and the Andes, such as Salar de Uyuni and Titicaca basins, among others.

Rivers as conveyors of water and sediment

A drainage basin is the basic unit of the fluvial system. Fluvial systems are open systems, where energy and materials are exchanged in the fluvial basin. The major inputs of the fluvial system are water, sediment particles, and solutes (solid load and dissolved load).

Sediment load consists of particles of mineral and rocks that can be transported as bedload, rolling, sliding, or saltating along the bed, or wash load, which consist of the finest particles transported in suspension by the water flow. Dissolved load consists of ions in solution derived mainly from weathered rocks and, secondarily, of organic materials from soils and other sources of organic matter such as organic litter.

In fluvial geomorphology, the fluvial system is normally described as a process-response system, where the interrelations and adjustments between the geomorphological processes and forms take place through continuous feedback between them. The fluvial system can be divided into ideal-schematic reaches or zones, each operating as a process-response subsystem with its own inputs. Certain processes dominate within each reach or zone. The zone of erosion is located at the headwater regions where most of the sediment originates through erosion processes, supplying sediment to the channel network of
the drainage basin. Sediment moves downslope through the channel network towards the *zone of transport*. The *zone of transport* acts rather like a conveyor belt for water, sediment, and solutes. As the river approaches the ocean or a local base level, sediment transport energy is greatly reduced mainly due to the decline of channel gradient in the *zone of deposition*. In other cases, discharge simply decreases downstream, as can happen in arid regions.

In perennial rivers, the drainage area and water discharge typically increase downstream while slope or gradient generally decrease. This means that slope is normally steeper in the upper reaches and becomes gentle downstream, and that discharge is commonly inversely proportional to the slope. For that reason, the longitudinal profile of a river typically exhibits a shape like a smooth concave curve. In the lower reaches close to the base level, the longitudinal profile is almost flat. The ideal longitudinal profile can be broken in knickpoints by natural factors such as structural controls (hard rocks on the river bed, faults) where rapids or falls can develop, or by human interventions such as dams.

**Channel patterns and floodplains**

Channel form adjustment is largely a function of the water and sediment supplies. Channel adjustments are produced in the channel dimensions (width, depth) and slope, as well as in planform. Along a given reach, channel adjustment can be constrained within certain boundaries or *boundary conditions* that are imposed by local conditions such as valley confinement, valley slope, channel substrate, and riparian vegetation.

Channels can be thoroughly classified as alluvial or bedrock. *Bedrock channels* are cut directly into the underlying bedrock, while *alluvial channels* are formed in alluvium that has been stored in the valley floor by fluvial processes. Channel patterns of bedrock rivers are strongly influenced by the resistant nature of their substrate (structural controls and underlying geological rocks). Bedrock rivers may represent single or multiple channels. Single straight reaches often follow a fault, fractures, or a lithological contact. Multiple channel bedrock rivers are formed by several individual channels cutting their own courses to flow around bedrock “bars.”

In alluvial channels, banks and beds are almost exclusively formed by alluvial sediments. Because water flow and sediment supply change through time, alluvial channels are continuously adjusting the channel shapes through erosional and depositional processes. The alluvial channels are diverse in their three-dimensional (planform and cross-section) style as consequences of the variability of the alluvium property, vegetation covers, and valley settings.

Classification of alluvial channel patterns as a continuum from straight to meandering to braided rivers has been adapted widely in fluvial geomorphology and only slightly changed ever since. For decades, meandering and braided patterns have been the focus of fluvial research. However, anabranching multichannel patterns dominate the largest rivers of the world (Latrubesse 2008). In this context, the most reasonable classification of alluvial channels is considered to be (i) straight, (ii) braided, (iii) meandering, and (iv) anabranching patterns.

*Straight rivers* are a single channel system without significant bends and represent low sinuosity (ratio of channel length to valley length), with an index typically below 1.1. This channel type rarely persists over a long term in an alluvial reach.

*Braided rivers* occur where the flow divides the channel into a series of braided bars by
RIVERS AND STREAMS

accumulating sediment. Braided rivers are bedload-dominated systems characterized by unstable networks of channels, ephemeral bars, and limited riparian vegetation (Ashmore 2013). They possess a relatively high slope in relation to the available discharge and an abundant proportion of bedload in relation to the total load. Mid-channel bars are typically covered by water during the bankfull discharge stage, acting as a single channel system.

Meandering rivers wander across a floodplain forming a series of bends, with a sinuosity index typically above 1.3. The water flow patterns through meanders encourage erosion and undercutting of banks on the outside of bends while deposition and the formation of point bars happen in the inner bends, generating asymmetric cross-sections of sequences of pools and riffles. With river processes, meander bends tend to grow outward followed by chute cutoff and neck cutoff, leaving oxbow lakes and scroll bars on floodplains.

Anabranching rivers consist of multiple channels that are clearly separated at bankfull discharge stage by vegetated semipermanent alluvial islands excised from existing floodplains or formed by within-channel accretions. These rivers occupy a wide range of environments, from subarctic to the tropics. Anabranching rivers construct semipermanent multiple channel systems to concentrate streamflow and maximize bedload transport by constantly adjusting the optimum channel width-to-depth ratio under the conditions where there is little or no opportunity to increase gradient (Nanson 2013). Branches of the anabranching rivers can have a tendency to meander or braid; however, they are generally restricted to short distances laterally from the main channel. The particular importance of the anabranching channel pattern has been emphasized after the observation that Earth’s large alluvial rivers (typically defined as mean annual discharge $>1000$ m$^3$s$^{-1}$ and having very low slopes) predominantly follow the anabranching channel pattern (Latrubesse 2008). Although the anabranching pattern is the ultimate planform adjustment of large rivers, small to mid-sized anabranching rivers displaying various styles can also be found extensively in different climatic and geological regions around the world, indicating the representative nature of the anabranching channel pattern in the fluvial system of our planet.

In alluvial rivers, floodplains are a fundamental component. Floodplains can be defined from hydrological or geomorphological points of view. Floodplains are flat depositional surfaces adjacent to the active channel that are constructed by river processes and built with alluvial sediments. This means that the floodplain is related to the present-day dynamic. However, older units of alluvial materials can be frequently flooded. Because a fluvial system is a natural system with a history, it can be considered that some recent alluvial units of Holocene age that are frequently flooded can be also included as part of the active floodplain.

Engineers usually apply a hydrological definition for floodplains, where it is demarcated as a flat surface supporting river floods with some particular recurrence interval of flooding (10–100 years). The 100-year recurrence criterion has been thoroughly used by urban planning and insurance companies to delimit the areas of flood risk. However, the delimitation of that area is not necessarily a well-delimited natural unit as 100-year floods can spread on different kinds of lithology and landscape components. Floodplains are very important in the fluvial system because they support a variety of environments and habitats, act as an erosional–depositional buffer area during extreme events, provide aquifer infiltration and agricultural land for humans, and can be a sink of sediments and pollutants.
Rivers and Streams

The role of rivers in shaping Earth

Rivers continuously reshape Earth’s surface, mainly through erosion or deposition in sedimentary sinks (sedimentary basins) where alluvial plains form. Depositional environments include floodplain, alluvial fans and megafans, deltas, and complex areas with rivers and swamps in a variety of tectonic settings. However, on Earth’s surface the balance is in favor of erosion, as huge amounts of sediments eroded from the emerged lands reach the oceans each year. Erosion depends on the regional climate, geology, topography, and land cover. The variations of river discharge through time are defined as the river or hydrological regime. River regimes are typically linked to the regional climate and, secondarily, to the catchment characteristics (topography, lithology). However, large basins can spread in a variety of climates and on diverse landscapes.

In erosional processes, about \(1.316\times10^6\) m\(^3\) s\(^{-1}\) of surface waters shape the Earth. Of this total, the Amazon River alone is responsible for approximately 17%. Erosion by rivers annually produces approximately 19 billion tons of sediments, 3.8 billion tons of dissolved solids (Milliman and Farnsworth 2011), and probably nearly \(0.9\) Pg of carbon (1 Pg = \(10^{15}\) g) (Aufdenkampe et al. 2011) that are transferred to the oceans. The proportion of sediments eroded by streams and rivers stored in the continents and not reaching the oceans is still a matter for analysis. Small rivers draining mountain areas such as the islands of Southeast Asia, the Himalayas, the Andes, New Zealand, and others are responsible for producing the major part of the sediments. Other highly productive areas are regions with highly susceptible sediments and rocks (such as the Loess Plateau in China) or small catchments in semiarid Mediterranean climates.

Rivers and humans

Rivers and streams have been used as a source of water in various ways, such as for waterways, as a source of food and water for human consumption, for irrigation, for recreation, and also as a major energy resource through hydroelectric power generation. For these reasons, many of the world’s big cities have been developed close to rivers. Rivers have been altered by humans since the early stages of civilization. Humans produce direct and indirect impacts on rivers and creeks. Changes in land cover and urbanization of drainage areas produce some of the common indirect impacts, while channelization, dams that regulate flows and trap sediments, flow diversions, dredging, mining, and bank stabilization produce common direct impacts. The impacts produced on rivers by humans in the twentieth and twenty-first centuries are dramatic and >45 000 dams above 15 m retain 96 500 km\(^3\) of water, or about 15% of the total annual global river runoff (Nilsson et al. 2005). Hundreds of new dams are planned for construction, mainly in countries of Asia, Africa, and Latin America. Currently approximately 18% of the total electric energy is produced by hydroelectric power.

Rivers, ecosystems, and biodiversity

River systems are like corridors that sustain a diverse mosaic of landscape units. The floodplain mosaics and channel-related elements (islands, fluvial bars, beds, and banks) can hold different types of riparian vegetation (alluvial forests, marshes, meadows), lakes and floodplain channels, alluvial aquifers, and are the habitats for a diverse fauna of aquatic, mixed terrestrial-aquatic, and even groundwater communities. Through hydrological and geomorphological processes, fluvial systems support
and control ecosystems of channel and riparian zones of the floodplain. Abiotic processes, such as floods and erosional and depositional bank processes, constitute a dynamic variable for biological processes (e.g., migration, predation, and competition) while the mosaic of landforms, sediments, and alluvial soils provide sustenance to the alluvial vegetal communities. Biological communities inhabiting fluvial systems include a rich diversity of plants and animals. Plant diversity is greater in tropical rivers than in other regions. More than 900 flood-tolerant species were recorded in the Amazon (Wittmann et al. 2006). Plant species can often be rooted to the channel substrate or can float on the water surface.

Fauna communities inhabiting fluvial ecosystems include reptiles, amphibians, waterfowls, and mammals, such as freshwater dolphins, manatees, beavers, hippos, capybaras, and many others, as well as a large variety of insects. Microorganisms play substantial roles in primary production by storing chemical energy through photosynthesis, decomposition of organic materials, and nutrient recycling.

Invertebrates include an array of benthic communities such as freshwater shrimps, worms, and insect larvae. Types of plants and animals inhabiting fluvial environments depend on geographical locations, because ecosystem functions are characterized by the energy and flows of the channel.

Although freshwater habitats represent around 0.01% of the world’s water and cover only about 0.8% of the Earth’s surface, they support at least 100,000 species (Dudgeon et al. 2006), approximately 40% of global fish diversity (over 10,000 fish species), and one-quarter of global vertebrate diversity. When amphibians, aquatic reptiles (crocodiles, turtles), and mammals (otters, river dolphins, platypus) are added to this, in total it is estimated that one-third of all vertebrate species are confined to fresh water. The richest fish diversity is found in the Amazon basin, where a single river can sustain more than 1000 species of fish. With 801 species, the United States ranks seventh in the world, after Brazil, Venezuela, Indonesia, China, Democratic Republic of the Congo, and Peru, for the greatest variety of fish species.

However, due to the impact of dams, pollution, and other human interventions, fluvial biodiversity is in a state of crisis. It is estimated that at least 10,000–20,000 freshwater species are extinct or at risk as a result.

Road transport

William P. Anderson
University of Windsor, Canada

Road transport (alternatively called “highway transportation”) has become the dominant mode for personal transportation and the fastest-growing mode for freight transportation in many parts of the world. In the United States, automobiles and light trucks account for between 85% and 90% of passenger miles traveled and are the principal means of travel to work for over 85% of employees. (Hereafter “cars” is used to refer to the aggregate of automobiles and light trucks used primarily for personal transportation.) While the railways still move slightly more ton-miles of freight than intercity trucks, the value of the goods shipped in trucks is much higher (Bureau of Transportation Statistics 2013, tables 1-40, 1-41, 1-49, 1-58). Despite the greater use of transit in the European Union, cars still account for about 83% of domestic passenger miles and trucks have a much higher share of domestic freight than railways (Eurostat 2014). However, road shares are somewhat lower for intercountry personal and freight transport in the European Union. While the share of road transportation in most of the developing world is lower than in the United States or Europe, it is growing quickly. It is estimated that by 2035 China will have more cars on the road than the United States.

The rise of road transport has been spurred by a combination of technological innovations and supportive investments in public infrastructure. While the first self-propelled steam-powered vehicles date back to the eighteenth century, the commercial production of four-wheeled automobiles with internal combustion engines began in the late nineteenth century. Initially automobiles were just for the very wealthy, but the application of production line methods, pioneered by the Ford Motor Company in the United States, led to lower prices and much broader market penetration by the late 1920s. Following the Great Depression and World War II, US automobile sales exploded in the 1950s, almost quadrupling their prewar value by 1955; truck sales grew at a similar pace. The combined US sales of cars and trucks peaked at almost 17.5 million in 2005, with total motor vehicle registrations reaching over 240 million – more than the number of licensed drivers (US Census Bureau 2012, table 1098).

A salient characteristic of road transportation is that, while most vehicles are owned by individual households or firms, the infrastructure they travel on is provided by the public sector. This is in contrast to rail, where a few large firms own both the vehicles and the infrastructure. In the first half of the twentieth century the network of paved roads in the United States and most other countries was very limited, especially in rural areas. This limited the scope of road transport, especially for intercity trips. The dominance of road transport was made possible by policies of massive public investment into networks of paved roads. The networks are made up of a hierarchy of road types, with freeways (limited access, no signalized intersections) at the top followed by...
ROAD TRANSPORT

arterials (major roads with intersections), collectors (which feed traffic to arterials), and local roads for access to individual addresses. Local roads generally account for about two-thirds of the network mileage, but carry only about 10% to 30% of the vehicle miles traveled. However, this dense network for local access endows road transportation with one of its greatest advantages over other modes: the ability to provide point-to-point passenger or freight transportation in a single vehicle to a very large number of origins and destinations.

The creation of the Interstate Highway System, beginning in the 1950s, created a network of freeways connecting all major US population centers. At the same time, massive residential and commercial development in the suburbs required the creation of millions of miles of local access roads, along with collector and arterial roads to complete the hierarchical network. This was perhaps the largest and fastest transformation of the built environment via infrastructure development in human history. It had profound impacts on the private economy, on the public sector, and on land-use patterns.

The need to provide road infrastructure places major fiscal burdens on all levels of government. In some cases, dedicated funding mechanisms have been instituted. For example, in the United States a federal gasoline tax is paid into a separate trust fund administered by the Federal Highway Administration and distributed to the states for freeway and major arterial projects. Roads at lower levels of the hierarchy are often the responsibility of municipal governments, who may impose impact fees on new residential and commercial developments to offset the cost of road and other infrastructure required to service them. In many cases, however, such special funding arrangements are not sufficient, so road construction and maintenance must be funded from general public revenues.

Spatial impacts of road transport

The rising dominance of road transportation has had a profound effect on spatial patterns of settlement and economic activity, especially in metropolitan areas. Geographers have long recognized that new transportation technologies affect urban form, as for example when the introduction of electric streetcars enabled the creation of suburbs beyond walking distance from the central business district (CBD) (Borchert 1967). The substitution of the private car for public transportation took this process a step further by undermining the role of the CBD in urban spatial structure. While cars are good at accessing a broad range of dispersed locations, they are not good at delivering large numbers of workers to a compact district because they require too much space for parking. Cities that have maintained strong CBDs (New York, Chicago, Toronto, London), therefore, generally have higher transit shares because rail transit systems are best suited to delivering workers to high-rise office buildings. In more dispersed cities, employers may locate in peripheral industrial parks, preferably situated close to highways, which are easily accessed by car and can provide cheap parking. Shopping and other personal services may choose similar sites. Furthermore, employees who commute by car are free to choose between a much greater range of residential settings, as long as they are on local roads that connect to the broader road network.

The design of highway systems has also served to undermine the CBD and reduce densities. Urban rail systems, as well as early urban highway systems, tend to have hub and spoke structures that create uniquely high accessibility at the central node. The construction of ring roads (known as “beltways” in the United States) that run around the periphery of the urban area, connecting the spokes of the initial network,
creates secondary points of high accessibility where highways intersect, and generally reduces the dominant position of the CBD (Anderson, Kanaroglou, and Miller 1996). Overall, the rise of road transportation is a principal driver in the process of urban sprawl. Furthermore, highways connecting metropolitan areas tend to support the spread of commercial and residential growth along corridors comprising several cities and the rural areas between them.

For large cities in most parts of the world, the dominance of road transportation has led to increasing urban traffic congestion. Congestion may be viewed as a common resource problem. As there is generally no restriction on the use of the public highway network, the number of cars on the road tends to exceed the number that can be accommodated without overcrowding. Addition of new capacity often fails to solve this problem because the availability of new or expanded roads tends to increase the volume of travel, so that congestion relief is short-lived (Downs 1992).

The dominance of road transport is almost as great for intercity trips as for urban trips. In the United States almost 90% of all trips of over 50 miles are made in cars. The number of passenger miles on intercity passenger trains, by contrast, fell by more than 60% between 1960 and 2010. While airplane passenger miles increased eighteenfold over the same period, they still account for only about 7% of trips of over 50 miles. However, because airplane trips tend to be longer, they account for 40% of passenger miles, compared to 55% for cars (Bureau of Transportation Statistics 2013, tables 1-40, 1-41, 1-42).

Road freight

The decision to move goods by road (truck) rather than by rail or water is affected by the relative cost for shipments of different distances. Total transport costs may be decomposed into terminal costs, which are the cost of loading and unloading goods at either end of a trip, and line-haul costs, which are the cost of moving the goods between origin and destination. As Figure 1 shows, terminal costs are higher for rail and water transportation, which require specialized terminal infrastructure, but lower for road, which does not. Because road transportation uses more labor and energy per mile, however, its line-haul cost is higher. Since line-haul costs vary directly with distance, the terminal cost advantage of road transportation is offset by higher line-haul costs for trips of
sufficient length. This partly explains why the average distance for US domestic rail shipments in 2007 was 728 miles, while the average for truck shipments was only 206 miles (Bureau of Transportation Statistics 2010). Airfreight costs are higher over all distances than the three modes shown in the figure, so its use is justified only by the fact that it is faster.

The dominance of road transportation also reflects its wide availability. Since most spatial markets in the United States do not have access to inland waterways, for example, water transportation represents only a small share of domestic freight movement. Reliance on trucks is also reinforced by the low-density urban form associated with dependence on cars for personal transportation. Since most retail stores, warehouses, distribution centers, and factories are located in dispersed patterns around highways, direct delivery of freight by some mode of transport other than truck is often not possible. Shipments moved by rail have to be transferred to trucks at the rail terminal in order to reach their final destinations, and the cost of this transfer offsets the line-haul cost advantages of rail freight. For very long distances, however, intermodal service, where goods are shipped in containers that can be cheaply transferred between marine, rail, and road vehicles, is the best option. This kind of service is especially common for the delivery of internationally sourced goods that are moved by rail from marine ports to inland ports, where they are transferred to trucks for final delivery.

Environmental impacts

A major concern with the growing dominance of road transportation is its poor environmental performance relative to other modes. In the United States, for example, energy use per passenger mile for light-duty highway vehicles is about 2.4 times as great as for intercity passenger rail and even 50% higher than for domestic air travel, although it is only 16% higher than for transit buses. Furthermore, the prospects for long-term reduction in energy intensity is not good, given that this value actually increased by 8.6% between 2000 and 2011 (Bureau of Transportation Statistics 2013, table 4-20). The main reason for the increase is that, despite technological improvements in engine efficiency, consumers are opting for more powerful light trucks (especially sport utility vehicles) over the sedans that formerly dominated the market for private cars. The impact of Americans’ preference for large cars is reflected in the fact that US energy use per vehicle kilometer is about twice the equivalent measure for the European Union (Global Fuel Economy Initiative 2011, figure ES1).

Despite growing energy consumption by cars and trucks, their contribution to urban air pollution problems has actually declined. Emissions of the precursor pollutants to ground-level ozone – principally volatile organic compounds and oxides of nitrogen – have declined dramatically, largely as a consequence of advances in emissions control technologies mandated by federal regulation. As a result, the number of days in which urban ozone levels exceed government standards has fallen.
by one-half or more in many American cities. However, the broader environmental problem of greenhouse gas emissions from cars and trucks keeps growing in pace with energy consumption. Over the period from 1990 to 2009 – during which industrial emissions of CO₂ declined by 17% – emissions from the transportation sector increased by 17% (Bureau of Transportation Statistics 2013, table 4-53). Since cars and trucks generate most of those emissions, America’s dependence on road transportation and its failure to make progress in vehicle energy efficiency are among the greatest impediments to progress on greenhouse gas emissions.

Of even greater concern are the environmental impacts that are likely to occur as cities in the fastest-growing economies achieve levels of car ownership and use similar to those found in the United States and other Western countries. Typically, countries experience rather sudden growth in car ownership when per capita incomes reach a critical level of around US$7000. Many cities in Asia and Latin America are currently reaching that level, and others in Africa are likely to do the same in the next few decades. Because of the lack of environmental standards, and the widespread use of motorbikes (which are especially intensive producers of ozone precursor pollutants), major cities such as Beijing, Mexico City, and New Delhi have pollution levels high enough to cause serious health problems for most residents, and some smaller cities in Pakistan, Iran, and other countries are even worse. Furthermore, the growth in car and truck transportation in such cities generates greenhouse gas emissions that are sufficient to more than offset the reductions achieved in higher-income countries.

Romania: Asociatia Profesionala a Geografilor din Romania (APGR) (Professional Association of the Romanian Geographers)

Founded: 2008
Location of headquarters: Bucharest
Website: www.apgr.eu
Membership: 290 (as of November 15, 2013)
President: Ioan Ianos
Contact: ianos50@apgr.eu

Description and purpose

APGR aims to increase knowledge about regional change in Romania, the impact of some extreme events and to promote the scientific communication related to the problems encountered in regional planning.

APGR wants to promote the multiscale approach on space among decision-makers at all levels to increase geography’s general visibility. APGR acts through its central office and seven regional divisions, each of which decides how best to get involved in community support. APGR believes that geographers have the power to influence decision-makers and other professionals to have more respect for space and its place in regional and community planning.

Description and purpose

The Institute of Geography (IGAR) is the main institution of fundamental and applied geographical research in Romania. It has two branches in Ia¸si and Cluj-Napoca and carries out integrated research in physical geography, human geography, environmental geography and geographic information system (GIS) focusing on investigating the relationships between the components of the physical and biotic environment and of the social and economic milieu, as well as their spatial distribution in connection with global environmental change. Its expertise in studying man–environment relations (integrated studies of natural and technological hazards; studies of community vulnerability to extreme events) has been the focus of several national and international projects.

Journals or major publication series

Current activities or projects

The members of the institute participate in a variety of national and international interdisciplinary programs and hold membership in several IGU commissions. IGAR is involved in projects financed by the Romanian Academy, such as the Environmental Geographical Atlas, integrated studies of the Lower Danube River and of the Carpathian Mountains; studies of the settlement system in Romania in the context of sustainable development; and in international projects (Framework Programs 6 and 7 of the EU).

Brief history

The Institute of Geography was established in 1944 by the Ministry of Culture and National Heritage on the initiative of Professor Vintila Mihailescu. The then Geographical Research Institute of Romania, as it was named, had two branches, one in Cluj, the other in Ia¸si. In the beginning it was staffed by members with an interest in research, but without professional training. After 1952, the Institute trained its own specialists in various fields of geography. Between 1958 and 1974, it functioned as the research institute of the Romanian Academy, one year later (1974–1975) it moved to the Ministry of Education and Instruction. In 1975, its administration passed to Bucharest University. As of February 7, 1990, it returned to the Romanian Academy. Today, the Institute’s scientific activity is coordinated by the Section of Geonomic Sciences of the Romanian Academy.
ROMANIA

The Institute of Geography sponsors activities at PhD level and has six doctoral supervisors. IGAR annually hosts an International Summer School on Natural Hazards and Sustainable Development at its research station located in the Carpathian Mountains.

Description and purpose

The Societatea de Geografie din România (SGR), one of the oldest geographical associations in the world, was founded to bring together geographers, educate them, and help them develop scientific activities. It is the leading association of Romanian geographers and collaborates with other professional associations (geomorphology, human geography, limnology, and professional geographers). Its purpose is to develop geography, mainly among teachers of secondary and high schools and establish relations with geographical societies from abroad. The society has a management board and coordinators at county level.

Journals or major publication series

Current activities or projects

The SGR continues the traditions of Romanian geography developing several educational programs with a focus on conferences, symposia, and roundtables in various regions of the country; maintains contacts and participates in meetings of professional societies, especially those from neighboring countries; organizes various educational activities (summer schools and different training courses); and publishes scientific research results in two journals.

Brief history

In 1875 the SGR was established, with the king of Romania as its president. This act was the result of geographical activities developed within the framework of the Romanian Academy (founded in 1886). The society had three sections: mathematical geography, physical geography, and ethnology. In 1884, the bulletin of the SGR (*Buletinul Societății de Geografie din România*) was sent to 72 foreign geographical societies. Between 1886 and 1896, 32 geographical and historical dictionaries of Romania’s counties and the *Great Geographical Dictionary of Romania* (1900) were published. Before the communist regime came to power in Romania, the society was coordinated by Professor Simion Mehedinți, the founder of modern Romanian geography and author of the volume *Terra: Introduction to Geography as Science* (still relevant in terms of global human pressure on the environment). In 1912, the SGR was renamed the Romanian Royal Society of Geography until 1947, when the communist power was instituted. From 1949
ROMANIA

to 1968, the name was the Society of Natural Sciences and Geography. From 1968 to 1989, and then after the fall of communism in 1989, it has been known by its current name.

Routing and navigation

Kai-Florian Richter
University of Zurich, Switzerland

Navigation is a coordinated and goal-directed movement of one’s self through the environment (Montello 2005). It combines two different skills: locomotion, which is proximally coordinated movement, and wayfinding, which is distally coordinated planning.

Routing is the process of path selection in a network. In a geographic context, it refers to determining a path from an origin to a destination through a transportation network, such as a street network, a subway system, or a system of corridors in a building. While in principle navigators themselves can and do perform routing, that is, plan the path, routing is typically considered an activity that comes from the outside, that is, it is delivered by some external aid (another human or a computational system).

Navigation is sometimes considered to be a technical activity executed only by experts, such as pilots or ship captains. But in fact, it is a fundamental process in the daily lives of humans and nonhuman animals, and a crucial ability for mobile robots (machines). Without navigation, we literally would not get anywhere. This entry will focus on human navigation and path selection, and algorithmic routing to support human navigation.

Human navigation

Navigation consists of two components: locomotion and wayfinding. Locomotion is used to move the body in a coordinated fashion through an environment, that is, without bumping into obstacles or tripping over one’s feet. It is especially relevant for the proximal surrounds, that is, the environment that is directly accessible to sensory and motor systems (Montello 2005). Generally, locomotion solves immediate behavioral problems, such as standing sure-footed, obstacle avoidance, and moving in the right local direction. There are various ways of performing locomotion (walking, running, crawling, etc.) and modes of locomotion (on foot, on a horse, by bike, driving a car, riding a bus, etc.). These different modes of locomotion have a large influence on how we perceive the environment and, therefore, how we acquire and process environmental information.

Wayfinding, on the other hand, is a goal-directed and planned activity. It is about getting around an environment in an efficient way (Montello 2005). Being a planning act, it requires higher cognitive functions and much more conscious thought than locomotion. In most cases, wayfinding involves reaching a specific destination in an environment, which is often not in the proximal surrounds but rather somewhere not directly accessible to the navigator’s senses. Successful wayfinding requires memory, that is, knowledge about the destination’s location and a way leading to it, or external aids, such as maps, a human guide, or a navigation system, that direct the way. Wayfinding also addresses behavioral problems; however, they are less immediate (to an extent) but of a decision-making nature, such as choosing a route or planning a multistop trip.

The term “wayfinding” was introduced by Kevin Lynch (1960) in his seminal book The Image of the City (actually as ‘way-finding’).
ROUTING AND NAVIGATION

Lynch had then already looked back at a long list of previous research, but dismissed the idea of seeing our ability to find our way as being some “mystic ‘instinct’, but rather as the consistent use and organization of definite sensory cues from the external environment” (1960, 3).

The distinction between coordinated movement in the proximal surrounds (locomotion) and the efficient getting to distal locations (wayfinding) already imposes some kind of hierarchy in the processes involved in navigation. And viewing wayfinding as decision-making, the planning process itself has a hierarchical nature. Once a destination has been chosen, intermediate locations will be identified that need to be reached successively in order to get to the final destination. Reaching these intermediate locations may again require more fine-grained planning, for example, even more intermediate locations, or changes in transportation mode, or switches between goal-directed and search behavior (see below). Often, these hierarchical plans will not be fully fleshed out before embarking on the journey to the destination. This may happen because not everything is known beforehand and some of the required information needs to be retrieved from the environment directly once in situ. Alternatively, some unforeseen changes may occur while traveling through the environment, for example road blockages or canceled public transport, that require finding an alternative route. Or some possible pathways (shortcuts), which are known in principle, may only be remembered when passing them in the environment, which will lead to updates of the plan.

For example, reaching a specific office on a university campus first requires getting to that campus, which may be a known route. Once on campus, the navigator will look for signage or a map pointing to the building in which the office is located. Once the building is identified, a route to that building from the current location will be planned and executed, which may involve reaching some in-between locations, for example, the central square on campus. Upon entering the building, information on how rooms are laid out in the building will be sought, along with discovering on which floor the office in question is located. Assuming the office is located on the fourth floor, the next task will be to find an elevator and take that up to the floor in question. Leaving the elevator, the corridor in which the office is located needs to be searched, which may either involve looking for more signage or employing some exploration strategy.

The decision-making involved in such a wayfinding process makes use of different levels of spatial knowledge. This knowledge changes over time. Repeated navigation in an environment will lead to changes in the structure of spatial memory about that environment. Initially, when new to an area, a navigator will have no knowledge about this specific environment; however, from life experience there will be some background knowledge about how environments of that kind are generally structured and how they function. After a little exposure, landmark knowledge will emerge. This kind of knowledge describes the state where a navigator is able to recognize certain geographic objects and places in the environment, having seen them before. But connecting these places, that is, directly navigating from one to another, is still difficult, as the routes are not (fully) known. Acquiring this route knowledge will be the next step, which happens after even more exposure and repeated travel in the environment. The final qualitative change in spatial knowledge comes once the environment is so well known that navigators can detect shortcuts between places and connect places and routes to form new routes that previously have not been traveled.
This model of spatial knowledge acquisition by Siegel and White (1975) simplifies and idealizes aspects of learning environments – as any model does. For example, it assumes that navigators never consult external aids or ask other people for assistance, which would accelerate knowledge acquisition. In general, the separation between the three stages, landmark knowledge, route knowledge, and survey knowledge, is not as clear-cut as the model postulates. It has been shown that some form of survey knowledge, namely metric distance information, is acquired early on in learning an environment. Still, this model provides a useful taxonomy of different types of spatial knowledge that is the foundation for a range of other research in spatial learning, and spatial cognition more generally.

To sum up this far, in a nutshell the wayfinding process can be described as getting to a location at which a decision has to be made (a so-called decision point), taking that decision, and then moving on to the next decision point. Locomotion keeps us on track in-between. Still, not every wayfinding process is the same. Consider the differences between commuting to work, taking a pleasure walk through the local woods, finding an office in a university building, or getting to a hotel from an airport. These wayfinding tasks differ in the amount of attention they require, the knowledge needed to successfully execute them, the importance of making the right decisions, and the need for external aids.

Several classifications – or taxonomies – of wayfinding and its different tasks have been proposed over the years. A very first broad distinction is the separation discussed above of locomotion as the process of moving around in the immediate surroundings, and wayfinding as the process of planning to move to distal targets. A further broad distinction can be made between unaided and aided wayfinding. Unaided wayfinding either requires at least partial knowledge about the environment under consideration, or it becomes a search task where navigators try to locate their destination. Aided wayfinding essentially only requires the correct execution of the instructions provided, which may be more or less cognitively demanding depending on the kind of aid used.

Allen (1999) defined three different wayfinding tasks. He distinguishes between exploratory navigation, travel to a familiar destination, and travel to a novel destination. We experience exploratory navigation, for example, when relocating to a new place to live and then exploring the neighborhood to familiarize ourselves with the surrounds. Our daily commute is a typical example of traveling to a familiar destination, and finding the way from the airport to our hotel at our summer holiday destination is a typical example of traveling to a novel destination.

Wiener, Büchner, and Hölscher (2009) introduced a more elaborate taxonomy of wayfinding tasks. Their taxonomy specifically takes into account different levels of required knowledge and task constraints. They focus on unaided wayfinding; aided wayfinding is subsumed as a single high-level item of their taxonomy. In unaided wayfinding, their first differentiation is between undirected and directed wayfinding. Undirected wayfinding occurs if there is no specific destination, for example, if taking a one-hour pleasure walk where the aim is to get some exercise but it does not really matter where one goes. If a navigator has survey knowledge about the environment, such a kind of wayfinding may be considered an actual pleasure walk; if no survey knowledge exists, it may rather be considered to be exploration or roaming.

Directed wayfinding, on the other hand, has a destination, that is, the aim is to get to some specific location. If this destination is unknown, search behavior needs to be evoked in order to get there.
It is conceivable that the exact destination is unknown even though the environment is well known (the navigator has survey knowledge). This may be the case if looking for a friend who is supposed to be in some downtown bar. In this case, it is possible to execute an informed search. If one has no knowledge about the environment (neither destination, nor route, nor survey knowledge), the person is likely to embark on some uniformed search quest for the destination.

If the destination is known, a target approximation behavior can be used. If the route to the destination is known, this behavior becomes relatively simple, as simple route following will get the navigator to the destination (e.g., the daily commute). If the exact route is not known, this route needs to be found first. If the navigator does not possess survey knowledge of the area, this will be a proper path search behavior. If survey knowledge is present, finding the route is a matter of path planning – (at least partially) previously untraveled but known path-segments need to be connected such that a route emerges between origin and destination.

Many of these tasks are now supported by devices in our cars or on mobile devices, which guide our way using digital maps and/or voice instructions. Their algorithmic foundations and communication principles will be discussed in the remainder of this entry.

Routing and routing algorithms

Routing is the process of path selection in a network. Routing determines which parts of the network have to be traversed in which order to get from some origin to a destination. Several criteria may drive the routing process. Typically, the shortest (in terms of distance) or fastest (in terms of time) route is being sought. However, other criteria that may be selected include the most scenic route, the safest route, the route easiest to describe, or the route that avoids specific parts of the network altogether.

Routing usually has to account for static and dynamic aspects of moving through a network. In other words, it is important to distinguish between the features physically present in an environment independent of any navigation and their role in the process of navigation. Klippel (2003) introduced the concepts of structure and function in wayfinding. With structure, he refers to an environment’s physical features. The structural level describes a static configuration of these features. Function denotes the relation of these structural elements to actions performed in the environment. The functional level demarcates those features relevant for a navigation action. It describes a dynamic navigation situation.

This distinction between structure and function is reflected in routing by differentiating between path and route (Klippel 2003). A path is a linear, unbounded feature in the environment upon which travel occurs. A route represents a behavioral pattern. It is directed and bounded by having an origin and a destination. A route demarcates a path, that is, it determines those parts of a network that are traversed during a trip. These parts are called path-segments. The points where path-segments meet are termed branching points. The paths, that is, branching points and path-segments, form a path-network, a graph-like structure, which reflects the geometric layout of the paths in an environment. Branching points correspond to nodes and path-segments to edges in the network. From a functional perspective, route-segments become relevant, which correspond to those path-segments demarcated by a route. The point where two route-segments meet is termed decision point. At a decision point, a navigator needs to decide on the further
direction to take. Decision points correspond to branching points on the structural level.

Simple routing ignores the dynamic aspects of navigation and adopts a static view of the network. It focuses on the structural level. The two best-known path search algorithms are Dijkstra’s shortest path and A*. They operate on a graph representation of the network, whereas the vertices (the set $V$) represent branching points and the edges (the set $E$) the path-segments. Both algorithms require that the edges of the network be annotated with a “cost” greater than zero of traversing this edge (e.g., geometric distance or travel time). In a nutshell, starting at an origin node, Dijkstra’s shortest path algorithm selects in each step that node that can be reached from any of the already visited nodes with the lowest costs. It stores for every node the cheapest, that is, shortest or fastest, path found so far for reaching this node from the origin. Therefore, in the end, for each node the shortest path to the origin is known. The A* algorithm uses a heuristic to speed up the search; it performs a best-first search. Similar to Dijkstra’s algorithm, A* stores for each visited node the costs to reach this node from the origin. Different from Dijkstra, it uses an admissible heuristic to estimate the distance to the goal from the current node. “Admissible” here means that the algorithms must not overestimate the distance to the goal. With these prerequisites fulfilled, it can be implemented efficiently (i.e., it runs faster than Dijkstra’s algorithm) and is guaranteed to find the shortest (“cheapest”) path.

From a dynamic perspective, the focus is on direction changes at decision points, that is, turning from one route-segment onto another at decision points. These turns may differ in their costs, for example, because of differences between turns in the need to slow down, or in terms of the cognitive complexity of understanding what to do. In terms of the graph used for routing, modeling these turns involves two edges and the vertex at which they meet. If cost functions for path search are to account for the dynamics of navigation, the basic network representation of a graph $G = (V, E)$ will not work because efficient algorithms assign a single cost value to each edge. Therefore, to capture the dynamics of navigation the complete line graph is used as a representation of the network (Winter 2002). The complete line graph is the graph $G' = (E', \varepsilon)$, where $E'$ is the set of edges in $G$ – though direction of edges is ignored. $\varepsilon$ is the set of vertices in $E$ that share their “middle” vertex, that is, $\varepsilon = \{(v_i, v_j), (v_j, v_k) \in E \times E\}$. That is, in the complete line graph, each possible turning action is represented by an individual edge, whereas nodes in the complete line graph represent the edges of the original graph. By traversing an edge from one node to another in the complete line graph, in the underlying original graph the said turning from one route-segment (edge) onto another via a decision point (vertex) is manifested.

Over the years, several routing algorithms have been developed that account for cognitive aspects of navigation. Duckham and Kulik (2003) presented “simplest paths,” an algorithm that accounts for the cognitive complexity of correctly turning at a decision point. Different types of intersections are classified according to complexity of describing a turning action at this intersection. This classification determines the costs for the routing. That is, the underlying cost function applies to the complexity of navigation decisions rather than to travel distance or time. “Most reliable paths” (Haque, Kulik, and Klippel 2007) minimize the chance of choosing a wrong turn at a decision point. The fundamental assumption is that navigation instructions (e.g., “turn right”) are generally easy to understand, but they may result in wrong decisions being made if they are not unambiguous, that is, if there are several possibilities to turn right
at a decision point. The algorithm calculates an unreliability measure for each turn. This simply counts the number of turns that are instruction equivalent – all turns that are described by the same linguistic variable. Another algorithm, the “landmark spider” (Caduff and Timpf 2005), routes navigators through a network along local landmarks located at decision points. Costs are determined by a landmark’s salience, its orientation with respect to the navigator, and its distance to the route-segment. The “landmark spider” algorithm calculates the “clearest” path, that is, that path that leads a navigator along the most suitable landmarks.

Richter and Duckham (2008) extended “simplest paths.” Their “simplest instruction paths” algorithm also finds the route associated with the lowest costs in terms of instruction complexity. The algorithm is based on Dijkstra’s original algorithm, but additionally uses optimization criteria that reflect dynamic aspects of navigation and direction giving, and avoid ambiguity in instructions. When selecting the node with the currently lowest costs, the algorithm spreads all the instructions with which that node has been reached forward through the graph. This step checks whether neighboring nodes can be reached with the same instructions. Spreading of instructions through the graph corresponds to traversing several decision points with a single instruction (as in “follow the river until the roundabout”). In the routing process, this reduces costs as the number of instructions that need to be communicated gets reduced.

Routing services and route instructions

Routing services employ additional strategies beyond the path search algorithms (Dijkstra or A*) described above. As most of them operate on a national or even world-wide scale, path search would be much too slow – in fact computationally infeasible – if every street was treated the same. Therefore, the street network is organized into a hierarchy to expedite search. The environment is divided into several regions. Search on local streets is only performed within these regions. If the path requires leaving a region, connections are only made via a network of major streets. This can be further nested. For example, when calculating a path from a residential address in one city to a residential address in another city, routing services would first find a path from the local residential streets to the major streets of the city. Next, along these major streets a connection to the system of highways is calculated, which is then used to get path search (close) to the second city. Here, search is reversed. From the highway system, an entry to the network of the city’s major streets is determined, along which the destination’s region is reached. Finally, within the destination region a path to the actual destination is calculated using the network of local streets. For such path search strategy to work, it is important that each network level has some dedicated entry (and exit) points to each region. For the highway system, this is straightforward as dedicated entries and exits (the ramps) already exist. For the other network systems, for each region these points need to be defined. The more points are defined, the closer the calculated path gets to the actual shortest path, but also calculation will get slower as more nodes need to be taken into account. Thus, a challenge for routing services is to find the right balance between accuracy and calculation speed.

Most conventional routing systems only account for distance and travel time in their calculation. They ignore cognitive factors as they have been outlined for some of the algorithms discussed above. Many of the navigation systems commercially available today are also able to
dynamically adapt to changes in the environment. This not only refers to their ability to calculate a new path on the fly if the navigator deliberately or accidentally decides to ignore an instruction. More importantly, they also account for network load, namely congestions or slow moving traffic, in calculating a path. This information may be received via radio transmission (as the driver would from traffic news on the radio) or be inferred from behavioral (movement) data of other users using the same system. Users’ movement behavior may be sent back to a central server, which then updates the network status. If several users move only slowly along some part of the network, there is most likely some congestion through which other users should not be routed.

In communicating the calculated routes, navigation systems also rely on distance and time. Typically, they provide information about the distance and length of time a street has to be traveled on before the next turn. Additionally, they name the street into which a navigator has to turn. A typical instruction would be “turn left into Beach Road and stay on it for 748 m (3 min).” In dynamic situations, that is, if the system travels with the user, the approaching turn would be announced as well, for example, in an instruction such as “in 100 m turn left,” which then gets repeated (with a different distance) once or twice when getting closer to the turn (“in 50 m turn left”; “turn left now”).

Human communication of route information uses different principles. People make extensive references to landmarks, that is, salient objects in the environment that (they believe) are easy for others to identify. Landmarks are fundamental in our mental representation of an environment, as discussed above in the context of the Siegel and White (1975) model. Humans use landmarks as anchor points in their spatial knowledge and arrange other spatial objects relative to these landmarks.

Given the high prominence of landmarks in human spatial memory, not surprisingly they feature prominently in human route instructions as well. Landmarks serve several purposes in such instructions. Importantly, they identify decision points. In other words, landmarks anchor wayfinding actions in space. They indicate when and where a specific action needs to be executed (“turn left when at the church”). Further, landmarks can be used to indicate whether a wayfinding error has been made (“you have gone too far if you see the church”), or indeed that the correct route is still being followed (“along the way you will pass a church”). Any object that stands out from the environment (in the given context) may serve as a landmark. An object may stand out visually (the red house among all white houses), structurally (the house located at the major intersection), or culturally (the old town house).

Overall, the following principles of good route directions have been identified in cognitive and linguistic research (Denis 1997; Lovelace, Hegarty, and Montello 1999).

- The principle of spatiotemporal order: route instructions should mention locations and actions in the same order as they will be experienced when traveling along the described route.
- The principle of referential discrimancy: as already mentioned, landmarks should be mentioned at points where decisions have to be made in order to link the action to the event of detecting the landmark.
- The principle of mutual knowledge: when describing a route to somebody else, the instruction giver should choose objects and delimiters describing topological, directional, and distance relations according to the
ROUTING AND NAVIGATION

communication context, in particular what the instruction receiver can be expected to know. Specifically, this also includes referring to objects (landmarks) such that they become identifiable (e.g., “the big red house” instead of “St Mary’s College” when talking to someone unfamiliar with an environment).

Furthermore, human route instructions usually have more linguistic variations than computationally generated ones. Navigation systems tend to have a single template for instructions, whereas people use general discourse principles also in route instructions, even if the focus is strongly on delivering relevant information. In particular, they employ a strategy termed “spatial chunking” (or aggregation), which combines several local instructions into a single higher-level instruction that subsumes those local instructions (e.g., “turn left at the third intersection”; “take the third exit at the second roundabout”). The intermediate local instructions are left implicit, but are also not needed for someone to follow the described route successfully.

More generally, people are well able to adapt the level of granularity in their instructions to the context, particularly the complexity of wayfinding situations or the knowledge about a route they can assume their communication partner to have. For example, significantly more information is needed to reach the train station from some distal origin than is required to travel by train between cities. Or people usually do not require detailed instructions for getting to the highway from their home location, given that they will have traveled that route several times before. But they may then need detailed instructions for taking the right exit and navigating to an unknown address in a foreign city. Human instruction givers consider all these with ease (even though there are still misunderstandings, of course). Navigation systems, on the other hand, always use the same level of details for instructing their users. They always deliver detailed turn-by-turn instructions and, indeed, always use the same instruction structure for all cases.

Current developments

The discrepancy between the principles of good human route directions and the way routing services instruct their users still sees a range of active research – even if it has been researched for more than a decade now. Recent developments with respect to user-generated content and “big data” have spurred researchers to seek these new data sources for improving automatically generated route directions. One direction of approaches exploits the newly available vast data resources (e.g., photo sharing repositories, panorama views of streets, user-contributed mapping approaches) to mine for information that may support navigators. For example, using methods of machine learning and geographic information retrieval, some approaches aim at identifying landmarks in an environment based on how many photographs of a particular location have been contributed and by whom. Others use methods of image processing to extract shop signs from street panorama views and then present them to navigators in a highlighted fashion to ease orientation at intersections.

Another direction of research looks at a dedicated collection of information relevant for navigation using principles and methods of user-generated content. This may be a direct approach, that is, setting up a system for explicitly asking users to contribute landmark information (“which object in your surround is a landmark and why?”). Or it may use a more game-like character where such systems are supposed to entertain their users while the game setup
requires them to contribute relevant information (e.g., photographs of salient geographic objects) as a byproduct. This byproduct may then be exploited to augment navigation instructions, possibly employing techniques similar to those used in the first direction of research, albeit with less noise in the data as the collection process has been more controlled.

Given the universal access to outdoor positioning via the Global Positioning System (GPS) and the many location-based services that can be built on the availability of a user’s position, there is increasing interest in also transferring such services to indoor spaces. However, for indoor spaces, no such universal positioning infrastructure exists, and GPS simply does not work indoors as it requires line of sight to the satellites. Different approaches have been developed for determining a user’s (or device’s) position indoors; the most promising at the moment seems to exploit existing wireless network infrastructure. By dividing an indoor space into a regular grid and then mapping the signal characteristics received from different antennas at each grid point (so-called fingerprinting) it becomes possible later on to calculate the most likely position by matching current signal readings with the stored ones. An object’s position can be determined by the grid point associated with most similar signal characteristics from the wireless access points.

On the assumption that indoor positioning will become available eventually, researchers further look into the integration of outdoor and indoor services by, for example, enabling a seamless routing from some indoor location to an outdoor location – or another indoor location with the route crossing through parts of outdoor space. A particular challenge here is to unambiguously determine whether a user is actually indoors or outdoors, which is most challenging in the transition spaces where signals from both indoor and outdoor positioning systems may be received. Recent work has shown that while users in their navigation can easily cope with being mispositioned by several meters, they consider services as highly unreliable that accidentally position them as being outdoors while they are actually indoors. This is true even if the geometric error is not greater (or even smaller) than a mispositioning error that still positions them in their actual environment. The semantic error is seen as much more severe than the geometric error, which is important to consider when designing such indoor/outdoor positioning services.

Finally, the increasing use and ubiquity of navigation services affects spatial knowledge acquisition. Using a navigation service to guide to a destination has consequences similar to the backseat driver effect – we hardly learn anything about the traveled route, let alone the environment in which we navigate. This is not surprising. One of the main ideas of navigation systems is to largely take over the wayfinding part of the navigation process. Users are still required to locomote (e.g., not to bump into other cars on the road), but any planning is done by the system. The users only need to execute one local instruction after another (“turn left here,” “turn right next” …) without getting any overview on what the overall plan is. That is, these systems generally fail to provide proper spatial context. In combination with the discrepancies between human direction giving and the way such systems instruct their users, it becomes difficult for navigation system users to remain oriented towards the destination (or origin for that matter) and to remember the route later on. This may not seem like a problem since the system is there to support; however, if that system breaks down, people may be unable to recover and would be essentially lost. Also, the lack of context results in users feeling insecure in the navigation
ROUTING AND NAVIGATION

process and dependent on the device. Research has identified all these issues; the next step now would be to design navigation assistance that at the same time supports users and lowers cognitive demands of the navigation process, but still provides a context and allows users to learn about the environment during a navigation.

Rural citizenship

Richard Yarwood
Plymouth University, UK

“Citizenship,” like “rurality,” is a highly contested term. It has widely been used to describe a person’s relationship with a nation-state and, in particular, the rights and duties that are associated with it (Smith 2000). Of late, this idea has been challenged by geographers who have pointed to the importance of spaces above and below the nation-state in the formation and practice of citizenship (Desforges, Jones, and Woods 2005; Yarwood 2014). The concept of transnationalism recognizes that the practice of citizenship may cross national boundaries and engage citizens with political and cultural processes at a global level. At the same time, localities provide an important context for engagements such as voting in local elections, writing to councilors, volunteering to provide local services, staging protests, or simply living out daily life as a citizen. Citizenship is therefore fluid and multiscalar and much more than just a person’s relationship with his or her nation-state. Anderson et al. (2008, 34) contend that:

Citizenship is increasingly organized and contested through a variety of non-state as well as state institutions. This extends citizenship in the cultural sphere, to describe people’s senses of belonging in relation to places and people, near and far; senses of responsibility for the ways in which these relations are shaped; and a sense of how individual and collective action helps to shape the world in which we live.

Investigations of citizenship have tended to focus on urban areas, perhaps reflecting that its etymology refers to the inhabitants of cities. Yet, emerging research has suggested that distinctive forms of citizenship are becoming associated with the countryside and deserve closer scrutiny.

It is widely acknowledged that rurality does not shape social relations per se. Distinct forms of economic development and political conflict, together with different ways of imagining rural space, influence how citizenship is imagined, contested, and performed in rural places. Although significant differences exist within and between rural spaces in the majority and minority world, it is possible to discern a “global countryside” that has common characteristics. These include the presence of:

- globalized commodity chains and agri-food systems;
- the growth of transnational corporate investment and networks;
- the supply and employment of migrant labor;
- flows of global tourists;
- non-national property investment;
- the commodification of nature;
- large-scale exploitation of primary resources;
- social polarization;
- new sites of political authority;
- political contest. (Woods 2011)

Halfacree (2007) argues that rural space has three facets. It is simultaneously a locality that reflects the outcome of productive and consumptive economic activities; it is represented, for example through the much contested rural idyll; and it is something that is played out and given
meaning through the performance of everyday lives. Significantly, political contest means that these three elements do not always sit easily with one another, with the result that rural space may be disjointed or chaotic in nature. These three aspects of rurality have the potential to shape, and to be shaped by, different practices of citizenship, as the following sections reveal.

The imagined countryside and citizenship

As Halfacree’s (2007) model recognizes, social constructions of rurality have significant bearings on rural society. Hegemonic views of the countryside have been enrolled into discourses of citizenship and national identity. Heritage and folk traditions have been appropriated to evoke the idea that a nation is somehow more authentic if it has rural roots. This is evident in museums that link imagined folk cultures with nationhood and in folk songs that associate rural landscapes and people with national identity. In Sweden, for example, rural folklore was used to instill a sense of national identity in the early twentieth century (Buttimer and Mels 2006). By contrast, those unable or unwilling to appreciate these hegemonic views of the countryside were positioned as “anti-citizens” (Matless 1996). The active exploration and understanding of the countryside was seen as important in developing these forms of citizenship. In the 1930s the Scottish Youth Hostel Association sought to develop a sense of national identity by encouraging working-class youths to engage physically and bodily with the Highlands (Lorimer 1997).

Indeed, the countryside has often been viewed as a training ground for citizenship. One contemporary example is provided by the Duke of Edinburgh’s Award, a voluntary scheme undertaken by young people in Commonwealth countries. Participants are required to undertake an “unaccompanied, self-reliant expedition with an agreed aim” in a rural or “wild” setting. The countryside is seen as a testing ground in which young people perform skills that are deemed to make them good citizens, including teamwork, leadership, self-sufficiency, fitness, inquiry, resolve, and confidence. Organizations such as the Scouts, the United Kingdom’s National Citizen Service, and the annual Ten Tors Challenge in Dartmoor National Park (UK) also draw on rurality to test and shape future citizens through camps, residential projects, and challenging walks respectively (Yarwood 2014). Rural settings are seen to provide opportunities for citizenship to be embodied and performed, although there is an expectation that the skills learned will then be applied in everyday (perhaps urban) settings.

These kinds of practices reproduce dominant views of rurality and certain expectations of citizenship. At the same time, hegemonic and conservative visions of the countryside combine to exclude some groups of people from full participation in society. Thus, the discourses of heritage and citizenship discussed earlier often imply a white history, contributing to a sense that rural space is white space. Equally, indigenous people, such as Native Americans or Indigenous Australians, are curiously absent from both the imagination and the reality of rural space. Indeed, Aboriginal Australians were not granted full citizenship until 1968 and, until then, were only allowed limited access to rural towns.

Painter and Philo (1995) state that, if people cannot be present in public spaces without feeling “out of place,” it is hard for them to consider themselves full citizens at all. While these issues are not confined to rural areas, they are nevertheless exacerbated in rural settings because of greater visibility, the hegemonic imagination of rural space, and a lack of support.
services. Women are also expected to conform to particular gender roles, especially in farming; gay people may hide their sexuality because of conservative values in their society; racial and ethnic minorities may feel isolated; nomadic lifestyles may be illegal; young people may be barred from public space; and disabled groups may find it harder to access rural places. At the same time, rural areas can also be seen as a place to which others can be banished: rural places have been used to house prisoners, asylum-seekers, the mentally ill, or indigenous people, who are kept out of sight and mind in remote reservations and institutions.

The next section examines how the language of rights and duties has been deployed to understand and resolve some of these issues.

Rural localities, rights, and duties

There are significant differences in the standard of living between urban and rural places. According to the United Nations, 71.6% of rural people at a global scale live in extreme poverty, including 1801 billion who live on less than $2 a day and 1010 million on less than $1.25 a day. In the United States, the most persistently poor counties are nonmetropolitan; in Australia infant mortality rates in remote communities (12 per 1000) are significantly higher than in major metropolitan areas (6 per 1000). Tonts and Larsen (2002, 135) frame the differences between urban and rural areas in the language of human rights: “as governments withdraw, or fail to provide, certain services and infrastructure the human rights of rural people are diminished.” By implication, rural people are unable to achieve full citizenship because they are unable to access the welfare rights afforded to their urban counterparts.

In some countries, this reflects a form of local rather than national citizenship (Smart and Smart 2001). In postwar China, for example, there was a formal divide between urban and rural hukou. In the countryside welfare was place-specific, whereas urban welfare was based on particular enterprises. This has meant that citizens only have access to welfare in specific parts of the country, which limits their ability to travel and seek work. Outside their home areas they have been treated as second class citizens and tolerated only if the state did not need to provide for them. This has limited their ability to travel not only to urban areas but also to more prosperous rural ones too. The situation is similar to the experiences of international migrants seeking work outside their own country.

The example illustrates Cresswell’s (2009) assertion that one has to be mobile to be a citizen. In the West the development of national systems of welfare untied people from their home localities by offering welfare based on universal rights rather than a reliance on local charity. Yet poor or nonexistent transport networks render many people living in rural areas, especially the old, young, poor, disabled, and women, into immobile, semi-citizens trapped by rural localities. Cresswell (2009) argues that citizenship relies on “prosthetic” materials, such as shops, services, employment, and transport, to achieve full social and welfare rights. The daily trek for clean water or the closure of a local post office suggests that many rural citizens lack the supports needed to enable them to participate fully as citizens of their wider society.

There have been various efforts to develop rural places that have had important implications for rural citizenship. Forms of endogenous development have been associated with the “modernization” of rural places. These include state-led (or quasi-autonomous) development agencies that may not be directly accountable
RURAL CITIZENSHIP

to local people, as well as forms of private capital such as food-processing plants of global corporations that are powerful by virtue of their position as monopolistic employers. In terms of citizenship, exogenous development is frequently associated with the imposition of new forms of political authority that cut across and restrict existing networks of governance. These center on economic productivity rather than social and political equality, reinforcing existing structures of inequality. Thus, efforts to modernize rural China have improved per capita incomes and led to a boom in consumer spending but, at the same time, have contributed to a growing gap between country and city.

In an effort to counter these effects, more endogenous forms of development have been encouraged that rely on forms of active citizenship that emphasize the duty of citizens to contribute to their localities. Citizens are increasingly required to fill gaps left behind from the neoliberal rollback of the state by, for example, running their own services and working as a community to supplement state provision. There are three reasons why this form of development has been favored in rural areas. First, rural areas have been more likely to suffer from the withdrawal of state services (as witnessed by the decline and closure of public services), and are therefore more likely to rely on citizen action to fill gaps in state provision. Second, there has been a long-standing obligation, evidenced in many countryside policies, that rural areas should provide for their own needs. Examples include community-run shops, voluntary policing, locally built housing, and health care. Finally, rural areas are perhaps better placed to engage in this form of local participation. The lowest tier of formal government, such as parish councils in England or communes in France, are found in rural places, perhaps offering greater opportunities for citizens in rural areas to engage with government than their urban counterparts. Many rural policies have encouraged partnerships between the state and private and voluntary sectors, which offer further opportunity for citizenship engagement in local decision-making and action. The European Union’s LEADER program is one such example that has not only encouraged local action but a form of transnational citizenship that links rural localities to other places in the wider EU supra-state.

Yet, rural communities are far from autonomous and local action in them is usually scrutinized and managed by government agencies, especially where it draws on state funding. Local organizations act as a proxy for government and, rather than empowering communities, these schemes simply aid the rollback of the state.

Furthermore, the idea of community is frequently used to impose unity and obscure diversity beneath a banner of communal identity. Notions of community can exclude as well as include, and often imply a rather bounded, insular view of rural space that seems oblivious to the significance of outside connections. Often “community views” are those of the elite or wealthy: powerful farming interests still dominate local politics in some places, and in others the interests of new rural elites are to the fore. In South Africa, McEwan (2005) has argued that established gender roles made it difficult for women to participate in consultation exercises, rendering the practice of citizenship “a meaningless concept.”

Marginal/third space

Although policies of active citizenship have failed to transform the countryside profoundly, rural places can offer space for new, more radical, forms of citizenship to emerge. Reimagined rural places have provided spaces for new utopian communities to emerge that are based
on faith, gender, green politics, political extremism, nomadism, or a desire to live sustainably (Halfacree 2007). These have their own forms of membership, structures of decision-making, and, by implication, forms of communitarian citizenship that seek to disengage their members from the state. Although these groups strive toward new forms of citizenship, they are prone to disintegration as a result of internal tensions or state legislation to counter them. As the next section explores, people have been more successful when they have adopted transnational rather than isolationist stances.

**Transnational ruralities**

One of the characteristics of the global countryside has been a “depeasantization” of rural places (Woods 2011) by neocolonial, exogenous, and exploitative forms of transnational capitalism. This has led to landlessness, loss of rights, and the suppression of local cultures, and contributed to migration from rural places to urban ones or, more significantly, across borders to work (legally or illegally) in spaces of primary production. At best, these denizen workers have few rights and can be subject to exploitation or even slavery. Despite this, many countries have focused on tightening their borders and placing ever more stringent requirements on migrants who have sought to gain citizenship. Such actions remind us that de jure notions of citizenship are still closely regulated by nation-states.

At the same time, transnational actions have been launched to support those marginalized by global capitalism. The campaign for fair trade emerged in the 1980s to connect Western, urban consumers more closely with “distant,” “other” producers of food in the majority of developing countries. The movement seeks to develop non-exploitative trading relations by paying producers a guaranteed price to ensure the sustainable production of crops and by investing a social premium in social, environmental, and economic projects. By acting as consumer-citizens, those in the West are encouraged to use their purchasing power not only to make personal ethical decisions but also to support a politics of change. These types of transnational coalitions have the potential to empower the most excluded rural citizens. Thus, cooperatives of female artisans have not only used transnational opportunities to develop trade, but also provided an important and alternative platform for local women’s voices.

Depeasantization has also prompted local resistance and the emergence of transnational networks aimed at empowering poor rural populations. In South America, peasant movements have successfully mobilized indigenous communities and identities to address common concerns. Building on social networks left in place by prior rounds of political and religious organizing, indigenous groups have used unions, churches, nongovernmental organizations, and even state networks to mobilize across communities in order to demand rights and resources (Yashar 1998). As well as linking local sites of resistance, networks have, crucially, been used to foster transnational support.

One of the most prolific networks has been the Zapatistas, a Mayan resistance movement from Chiapas, Mexico, which emerged in response to unfair trade, exogenous exploitation of resources, and the loss of power and land. The movement gained international support through effective use of the Internet and collaboration with activists at a global scale. Another example is the Via Campesina (International Peasant Movement), which was formed in Belgium in 1993 to defend small-scale agriculture against corporate and transnational companies. It aims to bring together “peasants, small and medium-size farmers, landless people, women farmers, indigenous
RURAL CITIZENSHIP

people, migrants and agricultural workers from around the world” and claims to have 164 organizations in 73 countries representing 200 million farmers. These forms of new social movements are autonomous, pluralistic, and transnational, occasionally crystallizing in particular (and often urban) protest sites. Their actions represent a form of transnationalism that is concerned with global rather than national citizenship.

Conclusions

This entry has used the lens of citizenship to examine a range of actions in rural areas. On the basis of this evidence, it is possible to draw two broad conclusions. First, citizenship is beneficial to rural studies and, second, better understandings of citizenship can be gained by a focus on rural places.

Within rural geography, Paul Cloke (2006, 26) has argued that there is a need for “theoretical hybridization which can combine, for example, the concerns of the cultural turn with those of political and economic materialism.” Thinking more closely about rural citizenship is one way of fulfilling this call. Citizenship is concerned with understanding how broader political structures shape, and are shaped, by wider changes in society. At the same time, it is concerned with individual identity and performance. It offers a chance to bridge the personal and performative aspects of the cultural turn with the structural and institutional foci of political and social geography within various fluid spaces and places. As Susan Smith (2000, 83) argues, the concept of citizenship “marks a point of contact between social, cultural and political geography.”

Whether there is a distinct form of rural citizenship is open to debate, and reflects the way in which rurality is conceptualized. Using Halfacree’s (2007) model reveals that rural localities have been subject to distinctive but differentiated forms of social, economic, and political restructuring that, on the one hand, are leading to a “global countryside” with common characteristics but, on the other, are producing very different experiences of rurality. Nevertheless, these wider structural changes provide the context for citizenship action (or inaction) in rural places. Social constructions of rurality have also been deployed to fix the identity of and to mobilize citizens, be it “country people” in the United Kingdom or landless campesinos in South America. Thus people who consider themselves “rural people” may be coerced to engage with a variety of issues and rights that are broadly associated with the countryside. Recognizing the diversity of identities and actions under the banner of “rural” contributes to understandings of citizenship as multilayered and fluid. Rural citizenship is also performed in a variety of different ways. These range from overtly political actions, perhaps campaigning for rural issues, to more everyday performances required by rural citizens simply trying to live out their lives in rural societies. Closer investigations of citizenship therefore have the potential to improve understanding of rural areas.

A closer focus on rural places can benefit understandings of citizenship. Rural citizenship in the West has often been associated with rather parochial concerns and small-scale disputes concerning the impact of development on the rural setting (Woods 2011). Very often these debates revolve around different ways in which rurality is represented (idyll or productivist workplace, for example), which in turn reflect changes in the social structure of a locality. Too often rurality has been associated with “community” and, as a result, has been rather inward-looking and concerned only with local places.

Yet, as this entry has shown, rurality in the developing world has the potential to frame more
radical transformative forms of citizenship. As the example of the Zapatistas shows, rural space, often considered peripheral, offers a site for radical, transformative actions that have the potential to jump scales to impact on wider society. Transnational rural actions represent an attempt to develop a global civic society and, with it, a citizenry that challenges the conventional association of citizenship with the nation-state. It is perhaps significant that campaigns such as fairtrade are rural campaigns, aimed at supporting and transforming the lives of people in rural places. Although urban areas often provide the setting for rural protests (the Zapatistas, for example, first occupied cities in Chiapas), it is from and within rural places that some of the potentially most transformative citizen actions are occurring. Far from being peripheral to citizenship, rural places have the potential to develop truly radical forms of citizenship.

The development of rural geography

Rural geography has emerged as an increasingly important subdiscipline of human geography during the last two or three decades. Rural geographers have engaged productively with critical theory and methodological innovation to make important contributions to human geography. “The rural” has also emerged as a more significant arena of investigation for other human geographers, particularly in relation to research and publications on nature and food. This increasing interest in rural geographies has occurred during a period of rapid urbanization in global terms, with 54% of the world’s population now residing in cities and this proportion predicted to increase to 66% by 2050 (United Nations 2014). While these two trends would at first sight appear contradictory, the growth in the urban population has been largely concentrated in countries of the Global South whereas rural geography has almost exclusively been concerned with rural spaces, issues, and processes in the Global North.

Using the Journal of Rural Studies as a proxy measure of recent scholarship in rural geography, we find that 64% of articles published between 2012 and 2014 were written by authors from Europe, 17% by those in North America, and 16% were produced by scholars based in Australia or New Zealand. Only 2% of authors contributing articles were from Asia, 1% from South America, and no articles were published by academics in Africa. Although urbanization processes are apparent in Global North countries, these have been much less pronounced than in the Global South. There have also been strong counter-urban processes evident in many of these countries with rural areas witnessing economic growth and population increases resulting from movements of urban residents to rural regions. In addition, rural spaces are increasingly being drawn into national and international debates surrounding climate change and the security of food, water, and energy supplies. Consequently, rural spaces have continued to attract considerable research attention.

A more detailed reading of these bibliometric data reveals another spatial peculiarity – that of the significance of the United Kingdom to rural geography, with 31% of all articles published in the Journal of Rural Studies in 2012–2014 written by scholars from the United Kingdom. This figure is equivalent to the total output of authors from all other countries in Europe, more than double the output of Australian scholarship, and almost triple the number of articles published by US academics. Indeed, when we explore the development of rural geography, and particularly that relating to recent theoretical and methodological advances, we are largely talking about the changing face of UK rural geography. Elsewhere, rural scholarship has been associated with other social science disciplines, which has perhaps taken away some of the impact of rural geography. In the United States and some European countries, for example, rural sociology and agricultural economics have largely provided the institutional settings for rural research, while

in many countries of the Global South rural scholarship has predominantly been undertaken within development studies.

How one measures the significance of a sub-discipline is a question open to debate. Certainly, rural geography has an institutional base within human geography: for example, it has a presence within the main geographical associations in the United Kingdom and the United States; and rural geography can be found within the courses of many geography degree courses in the Global North. As with most subdisciplines, though, the nature and influence of rural geography has waxed and waned over the years. It is generally accepted that rural scholarship occupied a prominent position within human geography for much of the first half of the twentieth century as regional and ethnographic studies contained a strong rural component. As these accounts of regions and places became marginalized by human geography's increasing engagement with spatial modeling, so rural geography lost its prominent position within the discipline. Not only did the burgeoning quantitative geography lose touch with individual places, but spatial modelers constructed urban space as offering more opportunity to practice their newly acquired skills, allowing them to more easily package people, firms, and services into neat geographical units for the purposes of spatial analysis. That said, the translation into English of Christaller's central place theory and Von Thunen's agricultural land-use model in the 1960s did provide a rural dimension to quantitative geography.

The emergence of humanistic and structural approaches within human geography in the 1970s did little to raise the profile or change the nature of rural scholarship. There was some engagement with humanistic geography as rural places and landscapes were explored in relation to their position within art and literature, but this work involved those based outside rural geography. In relation to structuralist geography, it can be suggested that there was a double neglect of rural spaces, with rural scholars largely eschewing Marxist theory and the new generation of radical geographers using the city as a case study of the crises in and of capitalist systems in the 1970s. Indeed, throughout the 1970s, rural geographers seemed to identify more with long-established empirical themes in rural planning, rural sociology, and agricultural economics – such as land use, services, community, and agriculture – than to emerging geographical approaches.

The early 1970s did mark a major milestone in the development of rural geography. In the seminal text on the subject, Clout (1972) sought to assemble what he saw as the key components of rural geography. His book included material on rural population change, the urbanization of the countryside, rural land use, economic restructuring in rural areas, agriculture, rural transport, and integrated rural management. While noting the decline of rural geography, Clout did feel able to point to signs of a resurgence of interest in rural scholarship, evidenced by increased numbers of rural geographers in UK universities, an expanding policy based research agenda, and more rural geographers employed by the planning profession and rural policy organizations. Unfortunately, not only are recent theoretical developments in human geography largely absent from the book, but Clout appears to celebrate the applied and policy relevant nature of rural geography and its close relations with rural planning.

By the early 1980s, calls were being made, in the United Kingdom at least, for more sophisticated forms of rural scholarship that could engage with emerging theoretical and methodological approaches in human geography and cognate disciplines (see Cloke 1980). The establishment of the Rural Economy and Society Study Group...
(RESSG) in 1979, partly as a reaction to the uncritical and narrowly focused research agenda of the Agricultural Geography Study Group of the Institute of British Geographers, provided an important platform for the development of theoretically informed research on political economy, feminism, localism, and welfare (see Bradley and Lowe 1984; Lowe, Bradley, and Wright 1986; Marsden, Whatmore, and Lowe 1990). The work of the RESSG together with a small number of other rural geographers did much to shape the future directions of the subdiscipline, encouraging rural scholars to engage critically with theory and method, and to detach themselves from the worlds of planning and policy. By the mid-1980s, the first book on rural social geography had emerged (Phillips and Williams 1984), which applied theoretically driven work in urban social geography, particularly concerning political economy and managerialism, to rural geography. By the end of the decade, not only had political economy become a widely accepted theoretical lens with which to view rural restructuring, but these more critical accounts were beginning to appear in mainstream geographical publications (see Cloke 1989).

The 1990s witnessed the “coming of age” of rural geography, with increased engagement on the part of rural researchers with emerging theoretical and methodological approaches in human geography, leading to rural geography being taken more seriously by the geography community as a whole. Political economy, particularly relating to agricultural restructuring, remained an important focus for rural scholarship but it was the emergence of the so-called cultural turn within human geography that provided the spark that ignited rural geography. Prompted by Philo’s (1992) review essay on the neglect of “others” within rural geography, a growing number of rural geographers began to explore cultural differences, identities and marginalization processes in the context of rural places. What followed were influential debates about the role of power and culture in processes of exclusion and marginalization (see Murdoch and Pratt 1993) as well as a series of case studies of various groups, including women, young people, travelers, people living in poverty, gay men and lesbians, and minority ethnic groups, who had been largely hidden from the gaze of rural geographers (see Cloke and Little 1997; Milbourne 1997).

The changing relations between nature and society also began to attract increased attention from rural geographers. Ideas of sustainability were utilized by some to explore existing tensions and potential synergies between economy, society and environment in rural areas. Others engaged with actor network theory to highlight the complex relationships between human and nonhuman actors in the rural environment. Still others pointed to the commodification and exploitation of rural nature within the capitalist system. The politics and cultures of rural nature were also subject to academic scrutiny. Research highlighted the significance of nature within dominant discourses of rurality, and how such discourses had been embedded within certain national planning systems and utilized by campaign groups to contest rural development. In addition, place-based studies pointed to the importance of nature to the experience of rural living and how the natural attributes of and nature-based activities in rural areas could cut across social class divisions (see Bell 1994; Whatmore 2002).

In more recent years, rural geography has continued to flourish, deepening and broadening its theoretical, methodological, and empirical interests and making important contributions to critical debates in human geography. Rural scholars have made important interventions in relation to political economy and neoliberalism, including research on the agri-food system,
globalized ruralities, workfare, and new governance arrangements. Critical attention has also been given to how emerging themes in cultural geography, such as consumption, embodiment, performativity, nonrepresentational theory, and mobilities, are played out in rural settings. However, it has been food that has emerged as the most significant research theme with rural geography during the last few years. Returning to the *Journal of Rural Studies*, 13 of the 25 most downloaded articles in the first three months of 2015 were on this subject. In a sense rural geography would appear to have gone full circle, reconnecting with early research agendas that were dominated by agriculture, but the more recent focus on food has been different in three senses. First, food has been explored in much broader and critical terms, with attention given to processes of production, regulation, and consumption, alternative as well as conventional food systems, and issues of food poverty, justice, and security. Second, food research has blurred the boundaries between rural and urban spaces, with some of the most exciting developments concerning alternative food systems in the city. Third, and connected to this last point, recent work on food has been undertaken by rural and other geographers.

**Questions of rural definition**

Rural geographers have had a keen interest in, and some would say an unhealthy obsession with, defining the spatial limits of their field of study. If this were a review of urban geography then little would need to be said about how researchers define urban spaces and places. Cities are seen as clearly delineated and possessing neat boundaries that lend themselves to precise statistical definition. By contrast, the question of how “the rural” is defined has emerged as a major concern for rural geographers. Early attempts to define rural space were very much focused on its physical attributes and functions, including such things as extensive usage of land, low population densities, dominant forms of economic production, and distance from urban centers.

Recognition of the changing physical and social composition of rural space together with engagements with postmodern geographies in the early 1990s led rural scholars to approach “the rural” less as a functional entity and more as a space that is socially and culturally constructed by multiple actors. While the idea of “the village of the mind” had been in circulation for many decades, attention was given to how meanings of rurality are constructed and circulated through works of art and literature, advertising, mass media publications, political and policy discourse, and direct experiences of rural spaces. It is now widely recognized that any particular rural place will comprise multiple social spaces, as different users of rural spaces experience and understand rurality in a variety of ways, some of which may conflict with each other.

Drawing on Lefebvre’s writings on the production of space, Halfacree (1993) proposed that “the rural” is most appropriately understood in relation to three components – its sign (rurality), its signification (meanings associated with rurality), and its referent (rural space) – with the relations between these components becoming more complex as more diverse meanings are attached to rurality. Important questions have also been asked about who has the right to define rurality. With conventional definitions devised by academic and policy actors, it is argued that rural geography has tended to marginalize “lay” discourses of rurality and there have been calls for the development of more sophisticated and sensitive accounts of rurality that can navigate a course between academic, policy, and lay discourse.
The contours of contemporary rural geography

Shifting demographics and sociocultural recomposition

Interest in demographics and sociocultural change has long been evident within rural geography. For much of the twentieth century, academic (and policy) attention was paid to rural depopulation given that this was the dominant form of demographic change in countries of the Global North. Associated with job losses and low levels of pay, particularly in primary industries, this outflow of (mainly young) people became a potent symbol of rural decline, both “on the ground” and within human geography. From about the 1970s, this situation began to change in some countries, with rural researchers in the United States and United Kingdom identifying what has come to be termed counter-urbanization (see Boyle and Halfacree 1998). Initially involving rural places located close to major cities and then rippling out to remoter rural areas, these urban to rural movements of people have received considerable scrutiny from rural scholars over recent decades. Research has highlighted the spatial, temporal, and social characteristics of rural migration as well as the motivations behind relocations. Hidden within this meta-narrative of rural population growth, though, are rather complex geographies of migration within rural regions, with overall population growth often masking pockets of depopulation, particularly in remoter areas. In addition, many rural regions continue to record net outmovements of young people.

There has been particular interest in the social and cultural dimensions of these population shifts. Migratory processes have been awarded a great deal of symbolic value, acting as a proxy for the vitality of rural regions and places, and being drawn into debates about the meanings of rurality. Attention has been given to the ways in which migrants have reshaped rural society and altered many of its cultural norms. In the United Kingdom there has been a clear class dimension to inward migration with urban middle-class groups gentrifying rural housing markets and displacing low, and, in some places, middle-income groups from their home communities (see Phillips 2002). The middle classes have also imported particular cultural constructions of rurality, most notably those bound up with rural idyll and landscape aesthetics, which are often at odds with the realities of the working countryside. In other countries the situation is more complex as rural population growth has been associated with the migration of different class groupings. Indeed, there is evidence of lower income groups relocating to declining rural regions in order to take advantage of low-cost housing opportunities.

Linked to this last point, attention has been given to the movement of international economic migrants to rural places. In the United States, work has highlighted how the rapid growth in the Latino rural population is offsetting population loss in declining rural regions. In the United Kingdom, economic migration has involved workers from eastern and central European countries, following the enlargement of the European Union. Unlike traditional types of economic migration, large numbers of these migrant workers have bypassed cities and moved directly to towns and rural areas. In economic terms, these types of migration are reinforcing the low wage nature of many rural economies as migrants gravitate toward low skill and low wage agricultural and service sector employment. In other ways these migrants are challenging established cultural norms through the import of new forms of culture and cultural interaction into rural places that have little history of multiculturalism.
RURAL GEOGRAPHY

In many countries of the Global South, rural depopulation continues to represent the dominant demographic trend as significant numbers of rural residents relocate to cities in search of employment and improved quality of life. The consequences of these movements are significant for both rural and urban areas in several ways. First, cities have become increasingly hybrid spaces as rural and urban cultures and cultural practices coexist within these expanding urban spaces. A second consequence is that rural migrants often find themselves in vulnerable situations, occupying poor quality housing, in insecure and low paid employment and, in some countries, excluded from the welfare rights enjoyed by urban residents. Third, these movements have impacted detrimentally on the places and people that migrants have left behind, draining rural regions of their young and economically active populations.

Another important feature of changing rural demographics is aging. Although research has largely concentrated on countries of the Global North, it remains the case that, across the world, aging represents a significant trend impacting on rural places. The main reason for this is perhaps obvious from reading previous sections of this entry. As younger groups leave rural areas, so they alter their population structures. Added to this, in countries of the Global North the attraction of rural places to retirees in metropolitan areas has accentuated the rural aging process. When we look at statistics on rural demographics in different countries, it is clear that older people comprise a much larger proportion of the population in rural areas than in cities and that rural places are aging at a faster rate. There are both positive and negative consequences that flow from this aging of the rural population. In terms of the former, older people provide an important community resource, with their ability and willingness to act as volunteers enabling local services to be sustained. In other ways, though, large and increasing numbers of older people impose additional pressures on the local welfare provision in rural areas, particularly in terms of health, social care, and public transport services (see Skinner and Hanlon 2015).

Recently, researchers have begun to reposition rural migration within the more critical context of mobilities. It is suggested that too much attention has been placed on uni-directional, longer distance, and permanent relocations between urban and rural places, which has simplified the complexity of rural population movements. Not only does demographic change involve movements to, from, and through rural places, but mobility represents a significant shaper of rural places and rurality. Within the mobilities literature, the city is viewed as the archetypal space of hypermobility whereas rural places tend to be discussed in terms of stability and stasis as anchor points that provide a sense of tradition and belonging. The reality of rural living, though, is that mobility has become an increasingly important prerequisite for remaining in or moving to a rural place, particularly when many services and retail facilities have ceased to be provided locally. However, some of the taken-for-granted aspects of physical and virtual mobility in the city, such as public transport, pavements/sidewalks, high speed broadband and 4G mobile phone technologies, are more difficult to access in rural areas, which means that being mobile presents a set of challenges to rural residents. Beyond the everyday realities of mobility, engagement with the mobilities literature also permits new ways of interpreting rural places – seeing them less as static and bounded entities and more as spaces that are continually being made and remade by complex flows of people as well as nonhuman actors, objects, and images (see Milbourne and Kitchen 2014).
Rural economies

For much of the twentieth century research on the rural economy was focused on primary industries and agriculture in particular. Indeed, for a long period rural geography was synonymous with agricultural geography. In the United Kingdom, for example, the Agricultural Geography Study Group of the Institute of British Geographers only renamed itself as the Rural Geography Study Group in 1982. Furthermore, in some countries rural research continues to be institutionalized within departments of agricultural economics. It is now widely recognized that the rural economies of countries of the Global North have witnessed a transition from agriculture and other primary sector industries toward the manufacturing and services sectors during the last few decades. In some cases, this transition has been caused by the decline of and crisis in the primary sector resulting from global economic competition, which has created problems for particular (remote) regions largely reliant on resource industries, such as mining, forestry, or fishing for employment. In others, the primary sector has declined in relative terms as manufacturing and service sector firms have increasingly constructed rural locations as attractive spaces for investment.

Notwithstanding these economic trends, it should be recognized that rural areas remain important in terms of natural resource industries. In some countries, forestry and the production of timber and pulp remain significant components of the rural and national economy. In others, major opencast mining activity continues in wilderness areas. Rural spaces also supply essential natural resources to urban populations. Upland lakes and reservoirs provide the bulk of drinking water to cities. In terms of energy production, nuclear and hydroelectric power production tends to take place in rural regions, and wind and solar farm developments are being increasingly located in rural spaces. Attempts have also been made to use natural resources for the purposes of creating sustainable forms of economic development in rural areas. Labeled by some as the eco-economy, the aim has been to create synergistic relations between economic development and the environment, through such things as eco-tourism and green energy businesses.

It is claimed that many rural labor markets provide mainly low skill and low wage employment opportunities. One consequence of this is that young people with qualifications and skills are required to migrate to urban areas in order to secure appropriate work. Another is that rural labor markets are characterized by high levels of underemployment, with people in jobs for which they are over-qualified; in-work poverty resulting from low rates of pay; and multiple job holding, which is how many rural workers secure a sufficient income. The fact that rural labor markets are dominated by small and medium enterprises has implications for securing employment in rural areas. With these companies utilizing largely informal methods of recruitment, social standing in the community can have a significant influence on people’s ability to secure work. In some rural places, the public sector represents a significant employer, providing jobs in education, local government, and health care. Such employment tends to provide improved working conditions and levels of pay than those associated with the private sector, although the introduction of austerity policies in many Global North countries has led to public sector cuts and reductions in local government employment.

While agriculture now comprises a small proportion of the rural workforce in many countries, it has retained its prominent position within rural policy discourse and rural research. For example, the European Commission’s rural
development program remains largely focused on agri-environmental initiatives rather than dealing with structural obstacles facing the rural economy. In terms of research, rural geographers have continued to dedicate considerable attention to agriculture and in recent years have focused on the changing composition of the agri-food sector and its role within global food security. In relation to the first of these themes, it is generally agreed that the second half of the twentieth century was associated with the industrialization and globalization of the agri-food system as farm sizes increased and food production and processing were scaled up and operated as capitalist enterprises. Accompanying these processes were new forms of state regulation of agriculture as national governments introduced policies to ensure a sufficient supply of food at affordable prices for their populations.

By the turn of the twenty-first century, some researchers began to identify a postproductive turn in the agri-food system, involving a shift away from industrial production methods and a broadening of the role of farming to encompass environmental and social considerations. Key characteristics of this new form of agriculture included less intensive modes of production, the reduced use of industrial chemicals, the diversification of farm businesses, the development of eco-system services to benefit rural landscapes and environments, and the production of niche commodities, such as regional foodstuffs. Others have questioned the significance of this transition, arguing that postproductivism remains a niche activity that should be positioned within rather than as having displaced the dominant industrial agri-food regime (see Evans, Morris, and Winter 2002). Furthermore, it is argued that the emergence of postproductivist modes of agriculture has been associated with only a small number of countries in the Global North, most notably those located in the European Union where the Common Agricultural Policy has sought to encourage these new forms of agriculture.

More recently, multifunctionalism has been proposed as a more appropriate lens through which to understand changing modes of agricultural production (Wilson 2007). Within multifunctionalism farming is constructed as making a range of contributions to the rural economy, rural society, and rural environment, in relation to food production, conservation, biodiversity, and economic support for peripheral rural areas, with the specific mix of functions provided varying across different rural regions and types of agriculture. Multifunctionalism has been viewed by some as an alternative to dominant industrial regimes of agriculture. Others have claimed that it represents merely another twist in the neoliberalization of the global agri-food system and a further attempt to commodify the (positive) impacts of farming on landscape and nature.

Elements of postproductivism and multifunctionalism have also been discussed in relation to forestry. Research in North America and the United Kingdom has highlighted how state agencies and private corporations are reconstructing industrial forestry in more-than-productivist terms. Important here has been the emergence of community forestry, whereby forestry is viewed as providing environmental and social benefits to local populations as well as contributing to wellbeing and social inclusion policy agendas. This connects with broader discourses of multifunctional forestry that place value on forests and trees in noncommodity terms, for example, in relation to the social goods they provide and their contribution to environmental improvements and landscape restoration.

Returning to agricultural research, food security has emerged as an important theme in rural geography in recent years. The growth in the global population has exerted new pressures
on the agri-food system and climate change is threatening the viability of agriculture in particular regions of the world. In addition, we have witnessed dramatic fluctuations in food prices resulting from the devastating impacts of extreme weather conditions, such as floods and droughts, on the production of food, which has led to food riots in certain countries. Critical attention has been directed to neoliberal responses to these “crises” and particularly those that involve the application of technical fixes. One such fix has been the development of genetically modified organisms (GMOs) that are capable of producing crops more resistant to disease and the impacts of climate change. More recently, academic attention has shifted to another proposed technical solution to food security problems, that of sustainable intensification, which promises to increase crop yields from the existing agricultural land resource without damaging the environment through the use of new biotechnologies. Research has focused on the political economy of these developments and, in particular, the position of multinational corporations in promoting technical fixes that maintain the integrity of the industrial agri-food regime.

As with other aspects of rural geography, the focus of much of this agricultural research has been on the Global North. References have been made to Africa, Asia, and South America, but largely in relation to how the global agri-food system relies on the import of cheap foodstuffs from these regions. The practice of “land grabbing” is also beginning to receive scrutiny from rural scholars. Involving national governments and major corporations purchasing or leasing large tracts of rural land in developing countries in order to supply food to their domestic markets, land grabbing has been constructed as a new phase of neo-colonialism, involving the displacement of people from their lands, the downgrading of farmers to laborers, and the imposition of new forms of industrial production out of balance with the environment. Indeed, it has been suggested that the solution to global problems of food security lies not through the expansion of industrial agriculture but through the promotion of local, small-scale, and sustainable farming that the agri-food corporations are actively seeking to destroy.

New food geographies

Food has emerged as one of the most exciting areas of rural geography. Moving beyond discussions of the conventional agri-food system, food researchers have engaged with alternative processes of food production, exchange, and consumption as well as the different scales and spaces bound up with the food system. While this interest in food has done much to raise the profile of rural geography, it is has also blurred its subdisciplinary boundaries in three senses. First, food research has been increasingly associated with geographers working beyond the rural subdiscipline. Second, food scholars are located in a range of disciplinary areas, including human geography, economics, sociology, anthropology, and cultural studies, and there now exists a loosely defined body of research labeled food studies. Third, the focus on food has complicated the boundaries between rural and urban spaces.

In relation to this spatial complexity, we have witnessed increased research interest in urban food systems. Food has always been a key part of the fabric of the city, grown in domestic gardens and allotments, displayed and sold in markets and shops, and publicly consumed in restaurants and cafes. More recently, food has entered the city through other mechanisms. Farmers’ markets have emerged in many cities to allow the direct exchange of foodstuffs between producers and consumers, and, in so doing, have developed
new relations between urban residents and rural farmers. However, it has been through new forms of collective growing that food has really entered into urban spaces. Whether labeled as urban agriculture, city farming, or community gardening, there has been an exponential growth in projects that are using the cultivation of plants to transform (largely abandoned) urban spaces and bring about environmental improvement, political empowerment, and sociocultural change. Of course, in many countries of the Global South, agriculture has never left the city. Indeed, it is claimed that agriculture in and around cities in the developing world plays an important role within the conventional food system, delivering significant amounts of locally sourced food to urban populations.

Food is also being increasingly discussed in relation to justice. The agricultural and food processing sectors of the Global North have long been associated with unequal power relations, low wages, and the exploitation of the workforce, with migrant labor and tied accommodation utilized to maintain unfavorable working conditions in rural areas. In the context of the Global South, hunger represents a potent symbol of injustice and absolute poverty in rural areas and has led to a series of high profile interventions by the United Nations and charitable organizations. Food poverty has also been on the increase in countries of the Global North since the economic downturn of the mid-2000s, with a dramatic increase in the number of food banks reported in countries such as the United Kingdom. Issues of justice have entered the global food system in other ways. The ethics of distant responsibility toward farmers in Global South countries has been transformed from an issue of minority interest to a mainstream element of mass consumption through fair trade initiatives. Justice has also taken on a more-than-human dimension with increased academic interest in animal welfare themes, including welfare friendly farming practices and cruelty toward wild animals associated with traditional hunting activities in rural areas.

The growing interest in food geographies has been particularly associated with food consumption and the cultures of food. Food has become part of the cultural fabric of contemporary society and bound up with our personal identities. While recognizing the growth in food poverty, food banks, and low-cost supermarkets in Global North countries, where we shop for our food, which restaurants we frequent, and what foods we eat now reflect our cultural tastes and choices more than our nutritional needs. In some countries, food has exploded on to our television screens through cookery programs and celebratory chefs have become powerful agents in the food system. In some countries, rural areas have witnessed the rise of the gastro-pub, providing high-end cuisine utilizing locally and ethically sourced foods. Food festivals are now a feature of many rural towns, bringing together food producers, retailers, chefs, and consumers to celebrate local and regional produce. In addition, some market towns are actively creating clusters of niche food shops and restaurants to market themselves as places of food, while others have become known for their resistance to the industrial food system through, for example, their promotion of “slow food” and their opposition to proposed developments of supermarkets and fast food restaurants.

Rural politics, governance, and conflict

There has been a long tradition of work in rural geography on rural politics. Early research focused on how the historical control of local government by rural elites – such as landowners, farmers, and owners of industry – led to the development of paternalistic and antiwelfarist political cultures and policy discourse in many
rural areas, elements of which continue to cast a shadow over contemporary rural politics. Engagements with theories of class then followed as rural researchers sought to make sense of processes of social change and conflict. In the United Kingdom, for example, conflicts surrounding demographic change in rural areas previously discussed in terms of disputes between “newcomers” and “locals” began to be reframed in relation to economic class-based conflicts as the interests of in-moving middle-class groups clashed with those of the more established working classes. Others pointed to the formation of new alliances between existing rural elites and in-moving middle-class groups as each attempted to protect their vested interests from development and, particularly, the provision of new housing. Employing more sophisticated accounts of class theory, rural scholars began to give attention to intra-class conflicts between established and newly arrived middle-class groups in rural places as well as domestic property class theory to provide new understandings of conflicts bound up with the production, regulation, and consumption of rural housing.

The shifting system of rural governance has attracted the interest of researchers during the last couple of decades. Some have examined the changing regulatory framework of the global agri-food system, highlighting shifting sets of scalar politics bound up with local, national, and supranational forms of regulation. Reflecting broader developments in political geography, other researchers have considered the changing relationship between the state, market, and civil society in rural areas (see Goodwin 1998). Of particular interest has been the transition from a system of government to one of governance within national and rural policy, involving the enactment of a wider range of nongovernmental organizations into the governance of rural areas. This has led to more complex policymaking processes with new networks and partnerships delivering an increasing array of rural services, from economic development to social welfare, and health to housing. It is claimed that there has been a “hollowing out” of the local state with many of its core functions transferred to other agencies to the extent that it now represents more an enabler than a provider of key services. In a sense, these changes have had a more limited impact in rural areas given that the rural local state has been less interventionist than in its urban counterpart for the reasons mentioned previously. Indeed, the provision of rural services has long involved third-sector agencies, sometimes working in partnership with the local state. Nevertheless, these shifts in governance structures have produced more complex geographies of public service delivery in rural areas as increased reliance has been placed on local coalitions of state and nonstate actors.

In recent years there has also been a switch in research emphasis from rural politics to the politics of “the rural” as rural issues have become increasingly embroiled in national political debates (see Woods 2005). At the core of these debates is the question of who has the right to regulate rural spaces and places. This question of regulation has been bound up with a series of scalar conflicts that have pitched local rural interests against national regulatory systems. In many countries, rural space is regulated in ways that protect particular landscapes and environments in the national interest – as designated national parks, wilderness areas, or spaces of ecological significance. Such designations essentially construct rural spaces as sites of national consumption – as spaces of spectacle, leisure, and pleasure. However, some rural spaces continue to be constructed by national government in productivist terms as resource spaces that need to be exploited in the national interest to provide such things as food, timber,
RURAL GEOGRAPHY

minerals, energy, and drinking water. These different constructions and uses of rural space are clearly prone to conflict, particularly in areas where resource extraction and special landscape designation coexist. What is also apparent within both types of designation is a scalar tension between local and national interests, with “the rural” viewed principally as a space that exists to meet the needs of nation.

Three examples of this scalar tension can be presented. First, national planning policies devised to protect the landscape and environmental attributes of rural spaces tend to restrict local economic and housing development and work against the needs of rural communities. These restrictions reduce employment and housing opportunities for working-class residents in rural places, fueling the out-migration of young people and perpetuating the low-wage economy. In the United Kingdom there is also evidence that campaign groups and middle-class migrants utilize natural discourses of rurality to contest new housing development in rural localities. A second example centers on the introduction of new forms of environmental regulation that conflict with traditional norms of rural living and working. For example, the global recognition of the ecological significance of the ancient temperate rainforests in British Columbia, Canada has led to a series of high profile debates and conflicts over the environmental impacts of industrial forestry involving the government, forest companies, loggers, environmental campaigners, forest communities, and First Nation people. Across the Atlantic, the proposed introduction of legislation to outlaw hunting with dogs in the United Kingdom in the early 2000s resulted in a significant campaign of opposition coordinated by the Countryside Alliance – an organization established to represent hunting interests. While hunting was eventually banned, the Alliance’s campaign constructed the government’s actions as a national imposition of urban values on local rural ways of life. Third, the expansion of renewable energy production by national governments in order to meet climate change targets has resulted in considerable debate about the location of wind and solar farms in rural areas. These farms have not only been constructed by opponents as industrial developments that are detrimental to rural ecosystems and landscapes of rural areas, but as exploiting local rural resources to satisfy national and urban needs.

Rural welfare

Welfare represents a rather neglected area of rural geography. While rural social problems were discussed for much of the twentieth century, it was not until the late 1980s and early 1990s that the first studies of welfare were conducted (see Milbourne 2004; Tickamyer 2006). Based on analyses of official statistics in the United States and bespoke surveys of rural households in the United Kingdom, this work highlighted the significant presence of poverty in rural places. Indeed, research in the United States pointed to higher levels of poverty in rural areas than in metropolitan centers as well as the persistence of poverty in certain rural regions. Notwithstanding this statistical visibility, poverty remains largely hidden within the physical, political, and sociocultural fabric of rural space. Not only are the poor scattered across the rural landscape but some of the taken for granted sites and sights of poverty, such as social housing estates and welfare support centers, are largely absent in rural places. In addition, the social profile of the rural poor cuts against dominant (urban) discourses of poverty in terms of economic activity, household composition, and ethnicity.

Also apparent are some distinctive cultural attributes of poverty in rural areas. It would appear to be the distance from rather than
dependency on the welfare state that forms a striking feature of rural poverty. In part this relates to the less developed nature of state welfare provision in rural places but also to local cultures of “making do” and antipathy toward state-based welfarism. Indeed, the presence of poverty in rural areas is often denied by local residents and by local people living on low income in particular. Research has referred to moral discourses of rurality, whereby material hardship is downplayed, self-sufficiency is promoted, and welfare dependency very much despised, which leads to those on low income internalizing their financial problems and relying on informal systems of support provided by family and friends. A further consequence of these cultural norms is that rural poverty tends to be hidden from the gaze of state agencies, which perpetuates its neglect.

Housing problems and homelessness have also emerged as important welfare themes within rural geography. Although rural housing needs have been widely discussed for several decades, homelessness only emerged as a research topic in the late 1990s. Research on rural housing in the United Kingdom has highlighted processes of unequal housing competition as affluent ex-urban migrants buy into rural housing markets, the role of the planning system in restricting the supply of new housing, and the limited provision of social housing, which collectively have created sets of housing problems for low income households in rural areas. More recently, attempts have been made by researchers in the United Kingdom and United States to relabel these types of housing problems as homelessness. Questioning why homelessness tends to be discussed as an urban problem, a small number of researchers have explored the rural dimensions of homelessness. As with poverty, the hiddenness of homelessness in rural places emerges as a significant theme, with dispersed settlement patterns combining with the absence of support services for homeless groups to remove the presence of homeless people from the dominant gaze of academics and politicians. Homeless people are also constructed as “out of place” in rural spaces; they are forced to camouflage their presence in prime rural spaces and journey to urban places to secure vital support services. The spatialized provision of welfare for the homeless in rural places also leads many to relocate to proximate urban settlements, reinforcing the hiddenness of rural homelessness (see Milbourne and Cloke 2006).

Critical attention has been given to the impacts of national programs of welfare reform in rural places. Again, it has been in the United States and United Kingdom where rural researchers have been most active. In these countries, the principle of universal welfare support has been gradually undermined during recent decades through a transition from a welfare state to a welfare society, whereby state responsibilities for welfare provision have been devolved to a broader range of nonstate organizations, local communities, and individuals and through a shift from a welfare state to a workfare state, involving a move from universal welfare entitlement toward labor market inclusion as the central plank of welfare policy.

Four themes arising from rural research on welfare reform in these two countries are worthy of mention. First, and most significant, workfare appears to be a blunter policy instrument in rural places given that low paid work represents a more significant problem than unemployment. Second, the particularities of rural labor markets and the structural underpinnings of rural poverty have undermined the key policy goal of labor market integration: lower wages, increased distances to employment centers, and the limited availability of training, public transport, and childcare in rural areas present significant barriers to work. Third, although workfare has produced significant reductions in rural welfare
RURAL GEOGRAPHY caseloads, welfare recipients have tended to move to low paid jobs, meaning that levels of rural poverty have remained largely constant. Fourth, the devolution of welfare powers and responsibilities has encouraged the development of new place-based approaches to labor market inclusion that are better able to deal with local obstacles to work. However, welfare devolution has been utilized by local elites to reinforce local antiwelfare discourse and maintain unequal power relations in rural places (see Milbourne 2010; Pickering et al. 2006).

Future rural geographies

Rural geography is now much better aligned with key theoretical and conceptual developments in human geography than it was in previous decades. Rural geographers have made important contributions to human geography in terms of publications and there is a sense that in relation to certain research areas, such as food, rural scholars are leading rather than following research in other areas of the discipline. Looking to the future, it is possible to identify emerging themes as well as existing gaps in rural geographical scholarship that could usefully warrant increased attention. The first concerns the geographical coverage of rural research. Rural geography remains too narrowly focused on a small number of countries in the Global North and the United Kingdom in particular. While this does not mean that important rural research has not been undertaken in the Global South through other disciplines – most notably development studies – it suggests that rural geography lacks the global reach and relevance of other subdisciplines of human geography. Broadening its spatial outlook will no doubt be unsettling for some within rural geography as the spatial core of scholarship will inevitably shift.

For example, poverty and development themes would increase in significance; the dominant narratives of change would be those concerning rural depopulation, declining rural regions and enforced economic migration; and work on agri-food would include more coverage of small-scale and subsistence farming in rural areas as well as the global significance of agriculture in and around cities.

It is likely that boundaries between “the rural” and “the urban” will become increasingly blurred in future years. As processes of urbanization accelerate in Global South countries, so many more rural residents will relocate to urban areas, and cities will emerge as hybrid spaces combining urban and rural cultures and lifestyles. Although such migratory processes are evident in northern countries, they are largely restricted to younger age groups, and it is processes of counter-urbanization that will continue to dominate spatial demographics, with the movement of ex-urban groups to rural places continuing to complicate the meanings attached to rurality. It is also the case that the rise of urban agriculture in northern and southern world contexts is leading to new forms of rural–urban hybridity. What follows from these trends is that some of the divisions between rural and other subdisciplinary areas of human geography will become less distinct. The themes of migration and food, together with the global challenges of climate change and water and energy security, will necessitate multiple and complex geographical approaches; they will also require more productive working relations between human and physical geographers, as well as social, physical, and natural scientists.

Linked to these points is the increasing globalization of rural areas. International migration will continue to alter the sociocultural composition of many rural places, establishing multiculturalism as a key part of the fabric of rural towns and
providing new possibilities for rural living. Rural labor markets will be drawn more into global economic systems and regulatory frameworks, with rising numbers of goods as well as people flowing across national boundaries. The growth in international tourism will open up new rural regions to larger numbers of visitors in search of “authentic” rural places and cultures. Improvements in digital communications technologies will also provide new virtual possibilities, opening up (remote) rural places to wider worlds and creating new options for social networking, home working, economic development, and the provision of key services in rural areas.

The global challenges of climate change, population growth, and the security of food, energy, and water supplies will undoubtedly continue to impact on rural communities, economies, and environments. Rural spaces will be required to provide greater amounts of renewable sources of energy through wind farms, solar projects, and hydroelectric schemes. These energy projects will generate further debate and conflict concerning the ways in which rural areas are constructed as spaces of development, protection and/or consumption. Important here will be the increased flow of natural resources between rural and urban spaces, which will require the development of new forms of infrastructure, such as roads, pylons, and pipes. In terms of food security, it is likely that the neoliberal agri-food regime will continue to dominate, adopting new bio-technological fixes to produce increasing amounts of food in ever more efficient ways. However, there are signs that other approaches to the production, exchange, and consumption of food are now challenging the dominant agri-food model. Community supported agriculture, collective growing in cities, ethical consumption, and the localization of the food network are examples of current alternatives that may well emerge as mainstream aspects of, and research on, the food system in future years.

Moving toward the social research agenda, population aging will represent a more important rural theme in the future. Reflecting the general aging of the population in most developed countries, but also age-related processes of population movements to and from rural areas, older people will comprise a larger proportion of the rural population in future years. While this aging of rural society will no doubt provide social benefits, such as increased levels of volunteering and social support, it is likely to generate some significant challenges in relation to the provision of social welfare and health care in rural places. Welfare as a more general theme will also require increased attention from rural geographers. Inequality, injustice, and poverty remain rather marginalized research issues within rural geography even though many countries of the Global North have witnessed economic downturns, recessions, and rising levels of poverty during recent years and poverty remains a significant feature of rural life in the Global South. The neoliberal response to these problems has been austerity with dramatic reductions in public spending, cuts to welfare programs, and the withdrawal of the state from key areas of welfare provision evident in northern countries. With many rural places already poorly provided for in terms of welfare services, it is likely that austerity will hit vulnerable groups and welfare support agencies particularly hard in rural communities. Researchers need to engage more with these themes to ensure that the poor and the vulnerable in rural areas are positioned more prominently within rural geography.

Further reading

The changing governance of rural places has long been of interest to geographers. To begin with, agriculture is in most cases a dominant land use, and of all sectors in industrialized economies it has one of the longest and most controversial histories of state intervention and influence (Potter 1998; Sheingate 2001). However, attempts by governments in jurisdictions like the United States and the European Union to reform the (very substantial) subsidies offered to farmers in response to mounting budgetary pressures and a shifting global market context have proved controversial and been subject to challenge. Geographers and rural social scientists have helped explain why this is and have documented the powerful impact that farm subsidies have had (and continue to have) both on the way agriculture is practiced and on how rural land is used and managed (see, e.g., Winter 1996). They have also contributed to politically charged debates about the need for agricultural policy reform, specifically for “greening” farm support in order to provide better incentives for environmental management on private lands. Forestry policy in most industrialized countries constitutes a separate domain but, traditionally, it has often shared with agriculture a heavy state-bureaucratic emphasis. In European Union countries such as Finland and Sweden, for instance, strong state involvement in forest establishment and woodland management dates back to the early twentieth century. Here, too, geographers have been at the forefront of analysis and critique.

But rural policy covers more than the governance of agriculture and forestry as productive sectors and as the basis of rural livelihoods. A second major theme of rural policy and politics has been how best to respond to economic pressures and accommodate social change while ensuring that the public goods of rural landscapes, habitats, and wildlife are safeguarded in the postindustrial countryside. Rural areas have been changing socially as well as physically in the postwar period, with profound shifts in the geographical distribution of economic activity and populations. This has increased development pressures while at the same time creating new demands from more pluralistic rural communities for better control of farm pollution and improved countryside access and recreation, among other things. Geographers have documented these trends and reflected on what they might mean for a countryside that is as much a lived-in space as it is a site of production or consumption. What might be called “rural environmental policy” has a complex history of institutional adaptation and change, with early interventions to designate or reserve land in order to protect natural assets giving way more recently to more politically ambitious attempts to integrate rural areas into broader debates about resilience and sustainability. In an era of climate change, rural areas are now poised to be key sites of adaptation and mitigation, but it remains unclear how far this will require continued governance by the state. New, arguably more neoliberal, models of conservation are emerging, and geographers are reflecting on what the emergence of “ecosystem
services” thinking in particular could mean for rural policy as traditionally conceived.

Agricultural policy and the rural politics of decoupling

Rural geographers have made major contributions to our understanding of agricultural restructuring and change (see, e.g., Ilbery and Bowler 1998). They have also tried to explain the apparent ability of the farm lobby and wider agribusiness networks to resist reform at a time when deregulation means that the state has been withdrawing from most other sectors of the economy (Potter and Lobley 2004). Dating from the Depression years of the 1930s, and continuing more or less intact ever since, a state assistance paradigm has asserted a large role for governments in subsidizing agricultural production and underwriting farming incomes. The earliest farm policies, such as those introduced in the United States as part of Roosevelt’s New Deal, involved offering marginalized farmers guaranteed prices for their output. After World War II, government subsidies were needed to bring about agricultural recovery here and throughout Europe. This food security emphasis soon gave way during the 1960s and 1970s to modernization and intensification, with governments intervening to offer incentives for farmers to expand output in order to achieve, first, self-sufficiency and then to exploit the scope for exporting their output to overseas markets.

These strictly productivist motives have often been coupled with a concern to maintain family farming as a cultural asset and are one of the defining features of rural space. Family farms are seen as cornerstones of rural society and guardians of the rural environment and thus deserving of state support. Policy scientists have long been interested in the role of ideas, social framings, and mental paradigms within the policy process. There has been increasing recognition of the way certain historical constructions of understanding can frame and stabilize a policy field, often for long periods, and also mounting scholarly interest in the scope for new ideas to emerge as recruiting devices for policy change and even wholesale reform (Stogstad 1998). In relation to agricultural policy, geographers have pointed to the way in which state support has for a long time been justified publicly by certain taken-for-granted notions about the nature and constitution of the agricultural industry and the privileged status of farmers in supplying public goods such as food security and environmental quality. These understandings have proved to be powerful defensive weapons in the subsequent battle to reform farm support in an increasingly globalized context. In the European Union, for instance, policymakers struggled throughout the 1980s and 1990s to reform an increasingly expensive and trade distorting Common Agricultural Policy (CAP). Despite a well-rehearsed economic efficiency case for reform, they have found it difficult to agree any significant reduction in the overall scale of public subsidy because of resistance from a farm lobby that has a deeply vested interest in maintaining the status quo.

The nature of this resistance and the political battles that have ensued, not just in Europe but also in the United States and various other developed countries, have been studied by scholars of many disciplines, among them geographers. In Wilson’s (1977) classic analysis, agriculture is a defining example of “client or corporatist politics,” in which a powerful and well-organized set of interest groups has colonized government departments and agencies in order to defend their (often very generous) state entitlements. Their success, as has been noted, is reflected in the extraordinary persistence of the state
welfare model to the present day. That being said, the emergence of a global agri-food system in which stateless transnational corporations (TNCs) have growing control over the production, processing, and marketing of food through increasingly integrated supply chains has brought new players onto the scene. These actors take a very different view of state support and have, to some extent, driven a wedge between the large-scale agribusinesses that are able to compete on world markets and the more traditional family farming concerns that have been the main focus of policymakers’ concern. Concerned to see the opening up of markets rather than their continuing state-led regulation, agribusiness interests have campaigned for the liberalization of agricultural policy, organizations representing many of these TNCs such as the Confederation of Food and Drink Industries of the EU and the Food and Drink Federation lobbying within the World Trade Organization (WTO) to promote freer world trade. A campaign to decouple the subsidies farmers receive from their production decisions in order to make sure that they do not give domestic producers an unfair trade advantage over other competitors has continued to gain support internationally. With traction from trading nations such as Australia and Brazil, anxious to gain improved access for their own producers to European and US domestic markets, this agenda has continued to gain ground within the WTO. Policymakers in the European Union have finally abandoned the trade-distorting price supports that for decades made up the lion’s share of farm support, putting a system of still expensive but less trade-distorting direct payments in their place. Nevertheless, little progress has been made in reducing the overall scale of support, and agricultural policy remains an object of exceptionalist fascination for many rural geographers.

Conservation and the neoliberal turn

The protection of public goods such as biodiversity, landscape, and open access that are closely associated with rural land has been a major rural policy concern throughout the twentieth century, beginning with the first national park and other protected area designations in the United States and in most EU member states. As Adams, Hodge, and Sandbrook (2014) observe, the dominant motive has been “territorialization” – the designation and setting aside of land in order to protect it from development and change. For a long period the focus of conservation policy in countries such as the United Kingdom has been on how best to manage national parks and various other types of designated or reserved land. Not until the 1980s did conservation policy begin to address how to protect nature outside these protected areas, largely driven by concerns about the impact of agricultural intensification on farmed landscapes in places such as Western Europe. Geographers were at the forefront of debates at this time about the need both to restrain intensification and to better integrate agricultural and environmental policy domains (see, e.g., Cox, Lowe, and Winter 1986).

Agri-environmental policy (AEP) can be traced back to the early 1980s, a time when the state project for agricultural modernization in industrialized countries was coming under attack from critics of the heavy domestic budgetary costs of farm support. Pressures toward budgetary retrenchment and the market liberalization described earlier coincided with the emergence of an environmentalist and social critique of modern agriculture (Potter 1998). While explicitly critical of the state’s role in subsidizing agriculture, sustainability advocates bolstered support for continued state engagement by arguing for a redirection of, rather than a net reduction in, the farm spend, albeit in favor of rural
development and agri-environmental policy objectives. In rural political terms, this was attractive to farm interests anxious to maintain overall levels of state support, and it made possible a new and, in retrospect, durable consensus between farming, conservation, and state bureaucracies.

Subsequent research and commentary by geographers and others has demonstrated how the resulting agri-environmental policy programs profoundly reflect the historical-institutional context in which they were made (Sheingate 2001; Potter 1998). A major source of funding for environmental management on private lands, these programs stand as classic examples of the second-best, politically compromised, arrangements that policymakers and those who lobby them invent in order to address a range of policy problems — in this case rural environmental degradation, the support of farmers’ incomes, and the overproduction of agricultural commodities. Indeed, from the beginning, agri-environmental payments to farmers have served purposes other than conservation, and their wide scope and the tradeoffs they embody are important explanations of their durability. For example, the Conservation Reserve Program (CRP), the most expensive federal AEP program in the United States, enrolling over 10% of all farmed land, serves both environmental conservation and supply control goals while contributing significantly to farm incomes. As a policy field, AEP is state-centered and characterized by formal bureaucratic procedures, but it has been maintained politically by a diverse set of nonstate actors who have contributed to the renegotiation of policies and administrative practices in response to changing external and internal policy conditions. Closely interconnected AEP networks have developed in these countries. Actors such as the National Farmers’ Union in the United Kingdom and the American Farm Bureau Federation in the United States have worked with commodity groups and environmental NGOs and rural advocacy organizations to shape the creation and evolution of agri-environmental policy. Subsequent adjustments and policy redesigns have been the result of negotiations by this relatively stable and closed set of elites.

While the political foundations of AEP over the past 25 years have exhibited tremendous stability, there have been significant changes in specific policy aims and administrative arrangements. Over time, new ecological risks and new frames for articulating the public interest in agriculture and rural landscapes have entered the picture. The tendency has been to move up in scale from field-level conservation objectives (e.g., soil erosion control) to incorporate whole farm (e.g., water quality) and landscape-level management (e.g., biodiversity). These reforms have added new layers of justifications and administrative controls onto the existing state-centered framework without destabilizing the basic institutional arrangements and political constellations. The recent increased advocacy of offering farmers and other land managers payments for ecosystem services (PES), a neoliberal policy idea which emphasizes the scope for nonstate actors to get involved in the contracting of environmental goods from farmers and other land managers, however, has been seen by some commentators as posing a challenge to the settled state-bureaucratic way of doing things (Potter and Wolf 2014). PES is part of a wider shift in discourses about nature that has resulted from the development of “ecosystem service” thinking, a set of ideas which emphasize the flow of benefits that nature provides and which benefit human wellbeing. As Fish, Winter, and Lobley (2014) have argued, the currency of this idea has grown steadily in the interdisciplinary resource management literature and its influence is now being felt in the rural sphere.
Geographers like Higgins, Dibden, and Cocklin (2012) in Australia and Wynne-Jones (2012) in the United Kingdom point to new lines of rural geographical inquiry that are needed to better understand what the resulting model of hybrid governance will mean for policy actors, local communities, and the use of land.

Climate change and the new governance of rural areas

The emergence of climate change as a new public policy justification for environmental management on farms, and on rural land more generally, nevertheless adds significantly to the external and internal pressures for change. This is especially true if the requirement to bring agriculture and rural areas within the carbon economy means further extending the environmental remit of farming and farmers. While there are currently no specific international targets for the agriculture or forestry sectors, the Intergovernmental Panel on Climate Change (IPCC) has identified the maintenance of extensive grassland systems, improved livestock manure management, and more controlled fertilizer applications as key climate mitigation measures. This and other assessments are leading to a further reappraisal of agriculture’s environmental footprint and to the emergence of a new research and policy agenda around climate adaptation, carbon sequestration, bioenergy production, and the need to achieve greenhouse gas (GHG) emission reductions. At the same time, growing concerns about food security (an agenda that is partly driven by worries about the impact of climate change on future agricultural productivity) means that this must all be achieved without compromising productivity or output.

The resulting “new land use debate” (Winter and Lobley 2009), centered around the idea of “sustainable intensification,” is one that geographers and others are still struggling to understand. For instance, in the European Union, climate change imperatives are behind moves to establish a new soils directive and to strengthen biodiversity protection, while larger strategic questions concerning how best to steer the future management of land remain firmly within the purview of the CAP and the huge financial resources at its disposal. In the United States, the most recent Farm Bill, the 2008 Food, Conservation and Energy Act, empowers the US Department of Agriculture (USDA) to facilitate farmer, rancher, and forest landowner participation in carbon mitigation activities. But, rather than offering direct subsidies for the deintensification of cropping systems to mitigate GHG emissions, for example to reduce reliance on inorganic nitrogen fertilizer inputs, the dominant response in the United States has been public and private investment in corn ethanol production, a development that enjoyed an initial wave of broad support but was then found to have unintended consequences and highly questionable carbon mitigation benefits (Wolf 2014). The carbon and food security debates, taken together, strengthen the case for more integrated public policymaking, posing larger policy questions such as: What is the best balance between extensive and intensive modes of land use? How can investments in carbon mitigation contribute to water quality and biodiversity conservation goals? How far should climate change policies mesh with efforts to address food and energy security? Geographers will remain deeply involved, both in the research that is required to address these global challenges and in the policy debates and public discourses that follow.

Rural society in the Global North

Lisa Mathis Butler Harrington
Kansas State University, USA

Although the world’s rural population is now less than half the total, and proportionately even smaller in the more developed countries of the “Global North,” rural residents work to provide the food and natural resources upon which the world’s population relies, and have held an important place in the historical development of today’s most influential countries. The vast majority of ecosystem services supporting human populations and global society are in rural areas, including the many natural resources utilized directly and indirectly in local to global economies. The characteristics and situations of people living in rural areas, including villages and small towns located in rural regions, are highly variable around the globe. There is great variability even in the part of the world known as the “Global North,” particularly those countries that are economically well-off and that frequently have their historical development closely linked to Western Europe (e.g., European countries, the United States, Canada, Australia, New Zealand), but also including other countries that are considered more developed, such as Japan. There is no universally accepted listing of countries of the Global North, but these countries overlap with those identified as “developed,” “First World,” and “advanced economies.” The most clearly connected group of countries belonging to the Global North would be the Organisation for Economic Co-operation and Development (OECD) member states.

The more developed Global North countries tend to differentiate urban and rural environments more than is done in the Global South, although specific definitions of what is rural vary among countries and among differing governmental agencies and applications within individual countries. Policy and statistics-oriented definitions generally focus on rural as “not urban” (with definition of urban coming first) or are based on low population densities and settlements below a certain threshold of population size. Even when consistent definitions are applied there are variations in proportions of populations living in rural areas and in rural population densities. General considerations regarding rural society include key economic activities and configurations; connections to the landscape; characteristics and change in rural populations, particularly regarding age, education, and migration; and availability of social services and connections to urban areas.

Resources, landscapes, and economics

The characteristics of rural societies are linked to the resources, physical situations (especially accessibility), and economic activities of their locations. Rural people often are considered to be more closely connected to and cognizant of the environment and natural processes than people living in the (generally dominant) urban society. Rural areas are more economically diverse than is frequently perceived, however; the most commonly associated activity with rural areas is farming or agriculture, although
there are several other focal activities depending on resources available in rural regions. The farming identification may be based upon the most widely practiced rural activity – and the basis for family and national population support – in Europe and other areas for centuries and in European-colonized countries (e.g., the United States and Australia) at least since Europeans first arrived and often dating to pre-Columbian social groups. Many rural regions are resource-dependent; that is, most of the income for the area is derived from a specific set of natural resources, such as forests, mineral resources, fish, scenery (for recreation and tourism), or agricultural resources (land, soil, and climate). The interactions of rural people with their environments lead to varying landscapes, from open rangeland to dense forests, from seemingly continuous flat wheat fields to small communities in hilly patchworks of farm fields and woods, and from strip mines to coastal fishing villages. The creation of interdependence of rural society and local landscapes, including variations in physical accessibility, has led to the development of some social variability among rural residents connected to their differing livelihoods even when they are clearly also a part of a larger national society.

In cases of dependency on a single resource and a dominance of one type of livelihood/economic product, rural regions often undergo boom-and-bust periods. When a given resource is in demand and prices are high the local economy appears to be quite healthy, but when prices fall, resources are depleted, or conditions limit resource availability, the local area may face a great deal of stress and even population loss. Boom-and-bust economic oscillations have historically been clear with respect to mining districts. However, other types of resource-dependent areas also can display sudden declines. In the cases of some renewable resources, overuse can cause collapse and a loss of resiliency. For example, the Canadian North Atlantic cod fishery collapsed in about 1991 because the cod population could not sustain heavy fishing pressures, fueled partly by changes in fishing technology. Following the collapse, fishing-dependent communities in the Canadian Maritime provinces were depopulated as residents were forced to move elsewhere for employment. In forested areas, employment also can be cyclical, depending on the level of timber harvest and amount of growth since the last harvest.

A useful categorization of core economic activities in rural regions has been developed by the US Department of Agriculture’s Economic Research Service (USDA ERS). The ERS identifies rural counties as farming-dependent, mining-dependent, manufacturing-dependent, federal/state government-dependent, or services-dependent based on the proportion of earnings coming from the specified source; nonspecialized counties are those that do not meet the threshold for dominance by any one of the specified types (USDA ERS 2012). The ERS typology is incomplete, however, as it does not include some other important activities in rural areas, including fisheries, forestry/timber production, and tourism. There also should be recognition of seasonality in many activities and employment as well as supplementary livelihood activities like hunting (which may be either a supplementary household food provisioning activity or primarily a recreational activity, depending in part on income and social position). In some regions, government employment is significant particularly where much of the land base is in public ownership. Transfers of payments – that is, government disbursements to particular classes of citizens through retirement or disability programs and government support for social services (health and education), for
example — can be of high importance in retirement destination areas and in low-opportunity regions with significant indigenous or minority populations.

Even in areas that have traditionally been dominated by farming activities, there have been recent shifts to what often are known as pluriactivity and to multifunctional agriculture. In the case of pluriactivity, farmers have generally taken up additional income-earning activities, such as vacation or holiday rentals, farm-based retail sales, and tourism-based events. This is most common on small farms where the land base no longer can produce at the scale expected to support a family under modern conditions, particularly in parts of Europe and in regions of countries like the United States and Canada where settlement happened early on relatively small tracts of land. In addition to farm-based pluriactivity, one or more members of the farm household often will have off-farm employment in another industry such as services or manufacturing. In the case of multifunctional agriculture, which may be connected to but is not the same as pluriactivity, there is explicit recognition that agricultural land and activities provide goods and services beyond those traditionally considered. That is, in addition to food and fiber (e.g., wool and cotton) production, farmland may provide social benefits and ecosystem services including aesthetically attractive scenery, biodiversity enhancement, and control of the movement of water and other materials. Government policies often explicitly recognize these broader benefits of lands used for agriculture, forest, or other cover types to local and broader scales of society.

Another shift in approaches to the use of natural resources has been the partial move toward “postproductive” agriculture and forests by some landowners, rooted in changes in social attitudes toward the environment and health. By this, authors have generally meant a shift from the highly industrialized/high input versions of production to agriculture, forests, and land management focused on alternative production (e.g., organic farming) and greater recognition of alternative values or benefits from land resources, including recreation and other ecosystem services such as wildlife habitat provision and aesthetic enjoyment. These alternative approaches, often combined with multifunctional land management, contrast and are in tension with continued “productivist” (industrialized and profit-maximizing) approaches which continue to dominate many areas of the Global North (see, e.g., Wilson 2001; Evans, Morris, and Winter 2002; Mather, Hill, and Nijnik 2006).

Social considerations

In addition to numbers and densities of rural residents, natural resources and related livelihoods, and economic characteristics, aspects of rural society include other demographic characteristics, cultural practices, religious and political tendencies, and sense of place. Oftentimes rural society is associated in public perceptions and popular culture (e.g., film) with traditionalism and higher levels of religiosity, self-reliance, and low educational attainment, although any such generalizations must be recognized as oversimplifications and often not reflective of rural society in a given locale (and certainly not reflective of all individuals living in rural areas). In contrast to some of the negative views of rural inhabitants, in many countries the perceived independence and simpler ways of life closer to the Earth also are highly valued and even romanticized, creating a dichotomy in views of rural society.

Rural society has seen significant relative and total population change since about 1900. For
some rural areas in the United States, populations peaked before the Great Depression and have been in near-continuous decline since the 1930s. Continued population decline in rural areas, both in terms of absolute numbers and in terms of proportions of total national populations, has been widespread (Table 1), but countries varied from less than 5% to 50% rural in 2010. It is important to note, however, that definitions of rurality for statistical descriptions vary by country. For most countries, a majority of national territory is considered rural.

Table 1 Proportion of population living in rural areas in selected countries of the Global North.

Source: Data obtained from World Bank (2014). Definitions of rural areas vary by country.

Much of the rural population decline has been a result of changing technology, and economic trends have contributed to outmigration from rural to urban areas. Mechanization and technological changes led to a need for fewer workers on farms and ranches or stations and in other rural industries during the twentieth century. These changes have merged with broader socioeconomic trends toward urbanization and creation of urban-focused economic growth. Landholdings have often increased in size with shifts in technology and needs to produce more to provide sufficient income while rural products...
fail to increase in value at the same rate as many other goods and services. Corporate ownership of land and facilities connected to food and timber production has increased, although in some cases this is in the form of family corporations. In other cases, very large multinational businesses have come to control large parts of the rural economy, and rural regions have come to be closely tied into the globalized economy.

The characteristics of rural residents also have changed over time. In many areas, loss of population has been particularly connected to departure of the young to gain education and take up employment in more urban locales. This has been associated with an aging of the local population, and a form of “brain drain” and loss of social capital. A sort of vicious cycle of population loss and loss of services has become common, with closure of schools, grocery stores, and other services leading to further stress. Reductions in post offices and postal services have been a growing concern in Australia, the United States, and other countries, and a lack of sufficient medical facilities, especially given aging rural populations, is another widespread concern. As a means to battle population loss, some rural communities and small towns in rural regions of the United States and Canada have created land giveaways (free to a very nominal cost) to try to attract new residents.

Population loss is not the only picture for rural places, however. After decades of rural population loss, the 1970s brought a “rural turnaround” or period of counterurbanization to parts of North America, Australia, and Western Europe. The period of movement from cities back to rural areas was particularly dramatic for a period of 10–15 years. Shifts back to population loss in some areas followed the mini-boom. In other areas, retirement in-migrants and second homeowners are playing a role in maintaining or increasing rural populations. With greater opportunities for telecommuting, high amenity value regions also attract new residents who are able to rely on technology for their work connections, as long as sufficiently high speed Internet connections are available. The picture is mixed when it comes to movement of retirees and higher income new residents to rural locations. Oftentimes they bring differing attitudes and expectations than long-time residents. New residents often expect a level of local services that local governments cannot economically provide, and may not have an understanding or appreciation of traditional ways of life – the odors and sounds associated with farming, for example, may be objectionable to new residents, even though the landscape created by farming may have attracted them to the area in the first place. Differences may lead to conflict in local decision-making, and may cause resentment if new residents gain too much power too quickly.

Adding another dimension to changes in local populations and culture, with potential conflict, is the in-migration of ethnic minorities into rural communities. For example, in parts of the United States, Hispanic immigrants have come to be a significant part of local populations since the 1990s. This type of change can cause social strains where there is prejudice, a lack of understanding, or simply a stress on services like a need for multilingual education. In some communities, however, an influx of immigrants, even if ethnically dissimilar to the original inhabitants, is seen as an opportunity for survival of places in danger of dwindling to near disappearance. Rural locales in Europe also have seen the stress of shifting ethnicities or nationalities as movement follows economic shifts, with, for example, Poles and Brazilians moving into and out of Ireland depending on relative economic and employment conditions.

Pockets, and even entire regions, of rural poverty also exist in parts of the Global North as well as in the developing world. In many countries there is a greater incidence of poverty in rural regions than in urban areas although there are variations in poverty rates among countries and among national subregions (Figure 1). The nonmetropolitan US South, for example, shows a much higher rate of rural poverty than other regions, and far higher poverty levels than in southern cities.

Several conditions affect the economic status of rural society, beyond resource demand and availability as mentioned above. The European Commission (EC) (2008) noted that several common characteristics of rural areas (particularly those that are less well-off) contribute to poverty, including their demography, remoteness, education levels, and labor market. The EC also noted that negative situations regarding these characteristics may result in “vicious circles” that reinforce conditions of poverty. For many rural areas, having few young people and age distributions tilted toward the elderly contributes to low incomes and to further out-migration of younger residents. Rural areas may be physically remote from more societally central locations, particularly in mountainous and semi-arid regions, and may also have the difficulties of poor infrastructure regarding transportation networks as well as health care and communications technology. Low educational levels are common in rural areas. This in combination with lack of accessibility can lead to few employment options, contributing to local low incomes/poverty and more out-migration for jobs and education. Demographic, educational, employment, income, services, and accessibility conditions contribute to common – but not universal – differences between rural and urban areas, sometimes known as the rural–urban (or urban–rural) divide. Rural areas more accessible to cities generally are in much better situations regarding opportunities and economic status.

Policy and programs

Policies and government organizations to address rural conditions and policy administration in the Global North are generally separated from those oriented toward urban conditions. Some policies are oriented specifically around economic activities, such as agricultural or timber production, or environmental and natural resource considerations, such as prevention of excessive soil erosion. Additional policies are more directly aimed at addressing social concerns. For consideration of US federal policy, particularly expenditures, the USDA ERS (2012) has several overlapping categories for rural counties. Most are oriented toward rural social problems: housing stress, low education, low employment, persistent poverty and persistent child poverty, population loss, nonmetropolitan recreation, and retirement destination. The latter two are
less problematic although they can be associated with particular social concerns as well (including income and age-related needs). The types of issues identified for the United States are similar to those identified for Europe, and several are connected to poverty conditions. The US federal government has paid particular attention to conditions of rural society in Appalachia for decades. Administration-initiated programs include loans and services directed toward rural small businesses, support for rural health care, development of infrastructure to provide broadband coverage in rural areas, and support of rural public education through technology deployment. Other policies and programs have been established through legislation, often as parts of appropriations acts. Legislation also requires payments to local governments from revenues to federally owned property or “payments in lieu of taxes” to offset the loss of local tax dollars due to reduced private property. Such income may help to support schools and other social services. In addition to national-level policy and programs, individual states develop their own approaches to rural concerns.

European policy addressing rural regions includes the European Union’s major Common Agricultural Policy (CAP) focused particularly on farming and countryside protection, but other policies exist to address other rural concerns. Rural development is a focal area of policy for the European Union (EU) as part of the CAP. Member countries create their own national or subnational rural development programs and submit these to the European Commission (EC) for approval. Expenditures go toward such things as measures for rural quality of life, economic diversification, environmental and countryside improvements, and improvements to agricultural and forestry competitiveness. Some EU expenditures go toward sustainable development of villages and improved information and communications technology as well as promotion of adaptation of buildings to new uses and of new economic activities. Local areas often pursue development through tourism, “green” energy, and other alternatives for new income.

Rural environments and people will continue to be important to provisioning larger populations and supporting ecosystem services connected to planetary operations, even while the rural percentage of the Earth’s and Global North’s human population is likely to continue shrinking. Rural society is important to supporting transitions toward greater sustainability via its traditional provisioning activities combined with environmental management and stewardship.

Rural/urban divide

Katherine V. Gough
Loughborough University, UK

Although “rural” and “urban” are widely used terms, they are difficult to define. Their distinguishing features are becoming increasingly blurred, and there are multiple links between them across all scales. Consequently terms such as “rural–urban linkages,” “rural–urban interactions,” and “rural–urban dynamics” have become commonplace. These discussions most frequently take place in, but are not restricted to, a Global South context.

National definitions of “urban” abound and are composed of a range of factors used either independently or in combination, such as population size, population density, occupation, land use, infrastructure, and officially designated boundaries. Even in instances where the same factor is used, such as population size, the numerical value can vary greatly, making any cross-national comparisons highly problematic. “Rural” is often defined as the residual, that is, areas located outside of cities and towns. The term “peri-urban” refers to the transition zone between urban and rural areas typically located on the outskirts of cities.

Although urban and rural are defined as being different places, in practice the distinction between the two is far from clear-cut. There are many similarities in terms of the nature of the activities that take place in what are seen as rural and urban places, as well as numerous linkages that bind the two together. Rural areas are typically characterized as being primarily agriculturally based. While many people resident in rural areas still engage in agricultural production for at least part of the year, and often identify as farmers, farming is not necessarily their only or their major activity. Many rural residents engage in nonfarm activities and/or work elsewhere for part of the year. Similarly, urban residents may undertake agricultural activities either by moving temporarily to rural areas for work at times of high labor demand, or by engaging in agricultural production within the urban area where they are resident. Urban agriculture is widespread in many cities in the Global South as urban residents cultivate unoccupied plots of land, growing food for home consumption and sale. Households in some sub-Saharan African cities have been found to derive between 25% and 40% of their annual income from urban agriculture, with urban and peri-urban areas contributing 30% to 60% of food supplies such as vegetables, thus making an important contribution to food security (see Lwasa et al. 2014).

Linkages between rural and urban areas across space include flows of people, finance, commodities, and information. There is a constant movement of people between rural and urban areas in both directions and over differing scales and time periods. With increasing competition over scarce resources in rural areas, individuals and households move to urban areas in search of better opportunities as well as to gain access to services such as education and health. Many urban dwellers maintain strong links with their rural roots, returning to their home villages for short visits or, especially where conditions in urban areas have deteriorated, for longer periods. Numerous households straddle the rural/urban divide, creating mul-
RURAL/URBAN DIVIDE

tispatial households where members reside in rural and urban areas in an attempt to maximize incomes and minimize risk. Movement between rural and urban areas also takes place for social and cultural reasons, such as marriage and in order to satisfy the desire to experience other places and demonstrate the ability to survive in differing contexts.

Remittances sent by migrants are a key aspect of financial flows between rural and urban areas. Whereas these flows have typically been from urban to rural areas, with increasing economic hardship in the former the reverse is also occurring. Goods, especially agricultural produce, are another form of remittance sent between household members living in rural and urban areas. Most commodity flows, however, are for commercial reasons, regardless of the direction. While radio, television, and newspapers remain important for the spreading of knowledge, flows of information have been revolutionized by the rapid increase in mobile phone usage. In multi-spatial households, access to a mobile phone has transformed flows of information between household members, enabling them to have much more frequent communication. As well as facilitating contact for social and emotional reasons, mobile phones are also widely used for business purposes, for example to gain knowledge about prices and markets, and for financial transactions. These multiple types of flows, which illustrate how rural and urban areas are inextricably interlinked, are central to achieving balanced economic growth and reducing the vulnerability of the poor.

There has been renewed interest since around the mid-1990s in the role of rural–urban linkages in economic development and in how these links are affected by processes operating at global, national, and local scales (Lynch 2005). Starting at the global level, the liberalization of trade has resulted in a greater availability of imported goods, affecting consumption and production patterns in rural and urban areas, with local producers often being outcompeted. Trade in export crops tends to be controlled by international companies, which often bypass local urban centers for processing and marketing. At the national level, structural adjustment and economic liberalization policies have resulted in the reduction of subsidies to agricultural inputs, which has affected the incomes of small-scale farmers with limited capital, while the retrenchment of workers in the formal sector has deepened financial insecurity in urban centers. With the introduction of user fees for many services, and the rising cost of food, many households have increased their cash incomes through employment diversification, including nonfarm occupations and urban agriculture, and by migrating. At the local level, the nature and intensity of rural–urban linkages depend on access to agricultural land and farming systems, urban employment opportunities, population density and distribution, and roads and transport networks, all of which are shaped by local government policy. Furthermore, the nature and role of rural–urban linkages in contributing to livelihoods vary according to the wealth and status, gender, age, and ethnicity of household members.

As Tacoli (2003, 3) argues, the notion of a rural/urban divide “has become a misleading metaphor, one that oversimplifies and even distorts the realities.” While there is no denying the significant variations between rural and urban contexts, the increasing convergence of activities and the numerous links between the two make any dividing line imprecise. This has important consequences not only for research but also for policymakers, who tend to be split into separate rural and urban camps in their mandate and through their training. While the structure of local government means that responsibility for development planning often falls into areas that
are designated as urban or rural, even when they form part of a single metropolitan area, it is essential to take into account the multiple linkages and similarities between rural and urban areas when planning for the future.

Description and purpose

The Institute of Geography of the Russian Academy of Sciences is the oldest and the largest Russian multidisciplinary research center in physical and human geography coordinating geographical studies in all Russia. Its main research fields are the evolution of natural environment and land natural resources, natural cryogenic systems, geographical problems of land use and environment, interaction between environment and society, sustainable development, urban and rural geography, spatial patterns in Russia and post-Soviet countries, borders studies, political and cultural geography, GIS technologies, and mapping and remote sensing.

Current activities or projects

Apart from fundamental research and theoretical studies, the institute carries out applied studies, is involved in the work on environmental bills, and the monitoring and expertise of large projects of urban and regional development. It published the first maps and reports on the state of environment in the USSR, Russia, and several CIS countries. The institute has worked on a number of projects sponsored by UNEP, World Bank, and different EU programs. It developed the GIS currently used by the Russian Ministry of Emergencies and other governmental institutions. The institute has annually about 40–50 PhD students and hosts 50 visiting scholars.

Brief history

The institute was established in Petrograd in 1918, soon after the 1917 revolution, on the initiative of D.N. Anuchin who, in 1915, was the first to suggest the creation of a specialized geographical research center. The demand of Russia’s growing economy in the early twentieth century for geographic studies could be satisfied neither by the Imperial Geographic Society, involved mainly in expeditions to remote regions, nor by university geography. Systematic work was needed for the geographic description of the country and its newly
RUSSIA

reclaimed regions, such as the Arctic, Siberia, the Far East, and Central Asia. The institute’s work was based on the achievements of Russian geographical schools of the late nineteenth–early twentieth century’s academic legacy of V.V. Dokuchaev, P.P. Semenov-Tyan-Shanskii, A.I. Voeikov, and others. The institute was first called the Commission for the Study of Natural Productive Forces (CSNPF). Ten years later it was renamed as the Geographical Department of CNPF, which in 1934 became the Institute of Geomorphology. In the same year it moved to Moscow and adopted the name “Institute of Physical Geography” and since 1936 bears its present name – the Institute of Geography of the Academy of Sciences of the USSR (now Russian Academy of Sciences).

Russia: Vserossiyskaya obshchestvennaya organizatsiya (Russian Geographical Society (RGS))

Founded: 1845
Location of headquarters: Moscow
Website: www.rgo.ru
Membership: 14894 (as of December 31, 2014)
President: Sergei Kuzhugetovich Shoigu
Contact: rgo@rgo.ru

Description and purpose

RGS is a nonprofit organization and does not receive state funding. The main goal of the society is to consolidate the power and ambitions of the Russian population in the study and promotion of national geography. The president of Russia, Vladimir Putin, is the chairman of the society.

The society has members in Russia and abroad. Regional offices are present in all 85 Russian regions. The society currently focuses its activities on expeditions and studies, education and grant programs, environmental protection, and publishing.

Journals or major publication series

Izvestiia Russkogo geograficheskogo obshchestva
Lyod i sneg (Ice and Snow), in collaboration with the Institute of Geography RAS. http://ice-snow.igras.ru
Voprosi geografii

Current activities or projects

The society currently organizes expeditions and studies, education and grant programs, environmental protection, and publishing of its journals.

Major projects are: the Russian Geographical Society’s Award ceremony, archaeological and geographical expedition “Kyzyl-Kuragino,” the Russian Geographical Society Festival, the International Arctic Forum “The Arctic: Territory of Dialogue,” Arctic floating university, Far-Eastern floating university, summer youth school, the Geography Olympiad, national youth gathering, protection of endangered species, Arctic cleanup program, undersea exploration, technological platform (Technologies for Sustainable Ecological Development (TP)), lectures in Moscow and Saint-Petersburg, and “Great Russian Travelers” in libraries throughout Russia.

Brief history

The Russian Geographical Society was established by Nicholas I in 1845. The original idea for creating the society came from Admiral Litke, the mentor of the great Duke (Kniaz) Konstantin, who later became the first chairman of the society. Great explorers (Litke, Krusenshtern, Wrangel, Rickord), members of the St Petersburg Science Academy (Ber, Struve, Gelmersen, Keppen), great army leaders (Berg, Vronchenko, Muraviev), as well as outstanding Russian linguists (Dal, Odoevsky) were among those who established the society.

The society has never ceased operation since it was founded. Many great people led the society during its history, from the dukes to
famous explorers, travelers, and state leaders. RGS greatly contributed to the exploration of the European part of Russia, the Urals, Siberia, the Far East, the Caucasus, Iran, India, New Guinea, and the Polar territories as well as other lands. The society was traditionally very close to the navy and marine expeditions.

During the twentieth century many famous polar explorers, such as Papanin, Treshnikov, and Schmidt, were attached to the society. In Soviet times, the society promoted geographical knowledge by establishing special commissions, councils, and the auditorium.

Rust Belt cities

David Fasenfest
Wayne State University, USA

Traditional manufacturing regions across Pennsylvania, Ohio, Michigan, and Indiana in the United States, in the Ruhr Valley in Germany and the industrial centers in northern England and Japan were signified by prospering cities. These were home to industries like automobile production in Detroit and steel in Pittsburgh, and were exemplified by a growth in employment and a rapid increase in their populations. By the mid-1970s, a combination of shifting global production, technological change, and more recently an intensification of global competition has resulted in the hollowing out of these traditional smokestack industries. Cities that were once the center of growth became known as Rust Belt cities, reflecting disinvestment, population loss, economic decline, and bleak prospects for recovery. These old industrial cities experienced a decline in their urban infrastructure, losses in their local tax base, and a steady outmigration of residents unable to find work. Over the second half of the twentieth century cities like Detroit, Youngstown, and Pittsburgh lost over half of their populations.

Rust Belt cities are making efforts to return through a range of activities and decisions about restructuring and repositioning themselves for the twenty-first century. Many are now witnessing a growth in their downtown populations, especially among 18–24 year olds, as they become a mecca for the arts. Abandoned warehouses and factories afford cheap homes and studio spaces for artists and sculptors, and coffee houses and experimental chefs who focus on local food (the locavore movements and the new urban agrarianism) grown in and around urban spaces are imparting hipness to once declining cities. Some of the most distressed buildings and industrial spaces now have the cachet of “ruin porn” as they adorn the pages of photography books on coffee tables. The success stories and benefits of living in these resurrecting cities are promoted by sites like Rustbelt Living (http://rustbeltliving.com/) and rustwire.com (http://rustwire.com/).

Other strategies include embracing regionalism; building mass transit to connect these city centers to their surrounding areas; reversing job sprawl by bringing jobs back into the cities; repurposing abandoned structures to shift old to new industries with new jobs in areas like biotechnology, nanotechnology, and other green activities. Indeed, some of the smaller Rust Belt cities are in the forefront of creating environmentally conscious communities. Finally, these cities are attracting immigrants, who bring with them an entrepreneurial spirit, create local businesses, and improve services, and in many cities they have begun to reverse the decades-long population decline.

RUST BELT CITIES

Description and purpose

The SGC strives to encourage study and research on national and regional topics as they relate to geography in particular, and to cooperate in the development of geography in general. As an advisory board to the national government in geographical matters, it is always ready to provide the information requested and to advise in consultations related to different aspects of the national geographic reality. Similarly, the society tries to attend and solve geographic queries submitted by the general public. It also promotes studies and geographic research through open contests and by means of awards granted to distinguished students in upper-level courses.

Journals or major publication series

Sociedad Geográfica de Colombia, Bulletin Geoventana (newsletter)

Current activities or projects

The society currently has several activities, for example, the organization of ExpoGeografica, an academic event designed to provide opportunities for interaction and exchange of knowledge on products and services of geographic nature as well as to promote the science and praxis of geography, study, and research in geographic problems; and the organization of the National Center of Geographic documentation “Rafael Convers Pinzon.” The society is also in charge of assorted publications; courses on GIS; virtual geography courses; digitization of Agustin Codazzi’s original manuscripts; and other activities, including seminars, lectures, periodic conferences, and research.

Brief history

The first attempt at creating a geographical society in Colombia is credited to Carlos Holguin, when he was ambassador to Spain. Writing in 1893 to Manuel Ponce de Leon, then chair of the Colombian Society of Engineers, Holguin urged him to promote in Bogotá “the organization of a Geographic Society like the Spanish one.” Nevertheless, that initiative was delayed by the climate of political unrest that eventually led the country in 1895 to generalized civilian
COLOMBIA

strife (Thousand Days’ War). After peace was achieved, the national government issued a decree establishing the Sociedad Geografica de Colombia, which was confirmed by Mr. Jose Manuel Marroquin, vice-president of the republic, who inaugurated the society in an official meeting convened at the National Observatory. The event on August 20, 1903 was attended by distinguished members of the government, the army, intellectuals, and members of learned societies. During its more than one hundred years of institutional life, the SGC has been chaired by major researchers and writers related to geography, such as Julio Garavito Armero, Francisco Javier Vergara y Velasco, Jorge Alvarez Lleras, Belisario Ruiz Wilches, Julio Carrizosa Umaña, Alvaro Valencia Tovar, Julio Londoño, and Manuel Jose Forero, among others.

Submitted by Hector F. Rucinque
A “safe haven” refers to a geographic area designated as a place where people might find protection and freedom from violence, harm, persecution, and harassment. The phrase enjoys some recognition in international law (Koh 1994) and has historical connotations associated with concepts of refuge, asylum, shelter, and the welcoming of strangers. Religious institutions and government organizations have a long history of welcoming strangers and providing safe haven that well pre-dates the international systems, laws, and institutional structures put into place in the mid-twentieth century to govern human mobility.

Within geography, “safe haven” has been used in the context of migration and refugee flows and debates about the provision of protection in geographically designated areas. Scholars writing in the subfields of migration and refugee studies have used the term, often reflecting critically on geopolitical projects associated with its use (Chimni 1995; Hyndman 2003; Han 2013).

Contemporary uses and understandings of safe haven are broad and vary by context. Safe haven may refer, for example, to geographical areas such as shelters for those fleeing violence, whether domestic abuse at home or migrants and asylum-seekers in flight from conflict or persecution experienced in their hometown or home country. The safe haven may be as small as a building or a camp, or the designation of safe cities. These examples highlight the notion that a safe haven is a geographic area that operates simultaneously across a number of scales, connecting the intimate space of the body to household, local, domestic, and global economies and politics.

Safe haven for those in flight due to displacement or forced migration involves what the United Nations High Commissioner for Refugees calls “internally displaced persons” (people displaced from home, but still located within the boundaries of their country of origin) or those displaced who crossed an international border during their journey. At the point of crossing an international border, people may ask that government for safe haven in the form of protected legal status, either according to the 1951 UN Convention relating to the status of refugees and its 1967 Protocol, or some other legal designation that grants a person temporary or permanent status in this new “host” country. Those in search of refuge or asylum may register at ports of entry, in refugee camps, or be resettled from safe zones elsewhere.

Related to safe haven, but distinct, is the term “safety zone.” Chimni traces the notion of safety zones created in the Geneva Conventions as multilateral arrangements wherein “individuals fleeing danger can seek safety within their own country” (1995, 825). As Chimni notes, however, post-Cold War geopolitics make safe havens less about protection than they might appear.

Safe haven also references historical moments on the international stage when states have devoted resources to the designation of particular locations (such as refugee camps, cities, or bases) as protected. Since the 1990s, the politics surrounding asylum-seeking has supported the closing down of routes to safe haven, thus shrinking...
SAFE HAVEN

protection and spaces of safe haven through aggressive policing (often offshore) in the form of border enforcement and discursive othering.

A key issue is that there are always contradictions associated with designation of a territory as a “safe haven.” Projects to provide protection contain unintended consequences, underlying objectives, and more safety for some than for others. Safe havens “other” at the same time as they protect, through their spatial and temporal constitution of inside and outside.

While “safe haven” is a status that is well established in international law (Koh 1994), the purpose of this designation does not always correspond with its original intent. In the international realm of migration politics, for example, projects called “safe havens” may in fact be a way of controlling human mobility and inhibiting access to rights accrued when people reach sovereign territory. Thus, the geopolitics of asylum and actions carried out by nation-states in the name of safe haven often thwart the very protection they purportedly establish. As Hyndman (2003, 167) notes, in comparing United Nations-designated “safe spaces” to protect displaced civilians beginning in the 1990s, “Some safe havens and protected areas are safer than others.” Safe havens will prove safer for some than for others based on context, identity, history, and the particularities of the conflict and associated violence (Chimni 1995). Others will belie underlying projects to contain people and problems (Hyndman 2003, 168).

One such example involves enforcement activity of the United States in the Caribbean in efforts to control migration by sea in the 1980s and early 1990s. This was a period of mass migration by sea when Cuban and Haitian nationals (among others) embarked on boat journeys to the United States to seek asylum. During this time, Panama and Honduras agreed to provide temporary shelter for those intercepted by the United States at sea, and the United States arranged “safe haven” camps on US bases in Antigua, Dominica, St Lucia, Suriname, and the Turks and Caicos Islands (Koh 1994, 154). The most notorious safe haven camp in the region was on the US naval base in Guantánamo Bay, Cuba. There, President George H.W. Bush offered “safe haven” to Haitian nationals who fled the military coup against President Jean-Bertrand Aristide. This practice continued under President Bill Clinton’s administration. Haitian and Cuban asylum-seekers were held there after being intercepted at sea by US patrols. While narrated as a humanitarian response, detention was “indefinite,” and the only way out for most detained people was not a path to asylum in the United States but “voluntary” repatriation, or return home. The Guantánamo Bay Naval Base later became notorious under President George W. Bush’s administration for its continued use of indefinite detention, this time of foreign nationals arrested during the “war on terror.”

Offshore enforcement renders complex the ability of individuals to seek asylum, since they are often denied rights associated with landing on sovereign territory. Therefore, the US safe havens of the 1990s to house those seeking asylum but intercepted at sea offer an example of the contradictory and geopolticized uses of the term “safe haven.” Another similar pattern involves the use of islands designated as sites of humanitarian rescue but used as platforms for offshoring asylum through detention and deportation off the coasts of North America, Europe, and Australia. Camps set up in the name of humanitarian rescue can quickly become sites where racialized forms of exclusion are carried out and where people are denied the protections of human rights, access to legal representation, and due process. Military bases used as safe havens, for example, are often places where sexual violence threatens women on- and off-base.
Projects enacted in the name of protection through legislation also have other underlying political agendas. Sanger (2006) argues, for instance, that infant safe haven laws developed in the early 2000s in the United States were ostensibly designed to decriminalize mothers’ abandonment of their children: by leaving infants in a safe haven, the infant would be cared for by the state, rather than harmed. In practice, Sanger suggests, these functioned as part of US culture wars related to protecting infant life and working toward overturning Roe v. Wade, which allowed for the performance of abortions.

**References**

The term “safe space” has long been in operation to reference a physical location or shelter where people go to be safe from threats of physical harm. While the term has a lengthy association with sanctuary in safe spaces such as churches (Coyle 2004, 67), it has more recent associations with specific groups under threat and in search of safe haven. The term gained currency in the second wave of the women’s movement, in which “safe space” is used to refer to places dedicated to occupation by survivors of domestic violence and rape, and for demarcating places of safety in expression. More recently, this last usage has become commonly associated with queer, gay, lesbian, bisexual, and transgender people seeking space dedicated to freedom from homophobia, transphobia, and other forms of discrimination and violence. Particularly prevalent in educational institutions, “safe space” stickers featuring rainbows or pink triangles were a common sight on university campuses in North America in the 1990s and 2000s. Located on doors and bulletin boards of campus spaces, these indicated a space occupied by people supportive of LGBT communities, students, and staff.

The term is highly geographical as it dedicates space, assigns meaning, and draws parameters around particular locations. Accordingly, it has been used in various ways by geographers. Until recently, most of this usage remained casual; scholars did not study the genealogy of the term so much as simply reference it in their writing. In the 1980s and 1990s geographers made occasional reference to safe space and discussed safety more generally, particularly in feminist and gendered geographies of women and children and their perceptions of spaces deemed safe or unsafe (see Pain 2000).

In the 1990s and 2000s the term gained currency in geographies of gender, sexuality, and sexual identity in the discipline. Safe space operated across a range of scales in this literature, often referring to specific locations or gay neighborhoods within cities where LGBT individuals created positive spaces, whether communal or commercial, public or private. Borrowing from queer scholarship and activism, these scholars operationalized the term but generally used it loosely without necessarily defining or delimiting its meaning. As feminist and poststructural scholarship attended increasingly to the body and emotions, new uses of “safe space” emerged. The term arose in relation to emotional geographies of fear, for example (Pain 2000), and of the body (Coyle 2004). These approaches generated novel understandings of safe space. Coyle (2004), for example, conceptualizes safe space as domestic space where women suffering somatic symptoms of environmental illness are able to stabilize their health through the elimination of toxic chemical substances found in other places. The term is also used more widely in the subdiscipline of health geographies with reference to toxic environments for people with environmental, chronic illness, and other conditions, who may be highly susceptible to certain kinds of environments and require safe space that is healthy (Coyle 2004).
**SAFE SPACE**

Safe space is often discussed in relation to spaces of fear (of crime and physical violence), and debates recur about whether safety is more likely to be found in public or private space. While many associate danger with public space, much violence against women occurs in the private space of home (Pain 2000, 373). “Safe space” is also sometimes used interchangeably with “safe haven,” particularly by political geographers working on displacement and refugee issues in sites of conflict where people might seek refuge from physical violence. Physical scientists have also used the term in relation to climate change and planning safe space to sustain human life (Roestone Collective 2014, 1346–1347).

Current scholarship on safe space in the discipline continues in the fields of queer and feminist geography. Recent literature demonstrates that sites deemed safe spaces that may simultaneously protect and exclude or otherwise cause harm. The Roestone Collective (2014) published an essay that reviews uses of the term and suggests its reconceptualization. Observing that safe space has been defined statically in relation to imagined and constructed “unsafe” spaces, they advocate for “safe space as relational work” (2014, 1347–1348) that involves negotiation of differences. They review safe spaces deemed separatist (e.g., Take Back the Night) and inclusive (e.g., classrooms) and find some to be classist, racist, and sexist (Roestone Collective 2014, 1348). Put another way, safe space is paradoxical space (Roestone Collective 2014, 1356). The Roestone Collective (2014, 1360) concludes that “cultivation of safe space is a way of practicing social justice that recognizes, emphasizes, and in some ways encourages social difference.”

Beyond the discipline, scholars are also arguing that – like all spaces – safe spaces are racialized and classed, and more welcoming to some than others. In a recent book called *Safe Space*, Hanhardt (2013) traces LGBT activism surrounding safety in gay neighborhoods. She links these grassroots movements to neoliberal policing initiatives that drew on privatization, white supremacist imaginaries, and constructions of blackness in relation to LGBT communities, which proved devastatingly divisive in the racialized and classed exclusions that characterize urban redevelopment. Hanhardt complicates and advances debates about and historical records of safe space by showing how constructions of safety are embroiled in neoliberal policing projects that create safety for some (privileged people) at the expense of intensifying precarity for others marked by age, race, class, gender, and sexual identity. She reveals safe spaces as racialized, hegemonic constructions of exclusivity and privilege.

Like many other geographical locations designed for purpose of protection, safe space is a double-edged sword, or paradoxical in the Roestone Collective’s terms: it involves the likelihood of social exclusion at the same time as it is designed with the intention of protecting.

Saudi Arabia: Aj-jam’aiya Aj-joğrafiya as-Sa‘ūdiyya (Saudi Geographical Society)

Founded: 1985
Location of headquarters: Riyadh
Website: www.saudigs.org
Membership: 227 (as of December 31, 2013)
Chairman: Mohammed Shawqi Ibrahim Makki
Contact: sgs@ksu.edu.sa, makki14@live.com

Description and purpose

The Saudi Geographical Society at King Saud University was established to link national expertise in geography, whether in education, research, or training in various areas of geography and technology, so as to contribute to scientific progress in the discipline and to promote cooperation with other institutions at the national and international level. The SGS sponsors research, seminars, panel discussions, public lectures, scientific publishing, training courses, joint scientific projects, and specialized consulting to serve the nation and its development. The SGS is also keen to promote understanding of the role of geography and its applications in balancing environmental and cultural heritage in national development programs at all levels in the framework of the Islamic faith and within the context of Arab and Islamic heritage, as well as projects developed by members of the SGS and those aimed at helping the employment of new geographers.

The vision of the society focuses on the development of human culture and the environment. Thus, SGS seeks to play a leading role in deepening and expanding the geographical knowledge of specialists and members of the community in general, while enhancing communication with educational institutions. It also seeks to promote professional, research, and training within and outside the kingdom within the guidelines of Islamic concepts; to serve as an influential voice for the local community in the kingdom; and interact with the scientific world at large.

Journals or major publication series

Current activities or projects

The SGS has undertaken a number of research activities including forums and conferences attended by prominent geographical research figures from all over the kingdom. Such activities have contributed greatly in enriching the role of the society and making it a more effective research institution.

The board of directors applied to register the society with the International Geographical Union (IGU), with the approval of the king, so that the Kingdom of Saudi Arabia could be represented by the Saudi Geographical Society as a member to the IGU. The union approved this membership in November 2000 and we hope that this will help to highlight the society’s work globally and contribute to
communication between Saudi geographers and other geographers around the world.

The Saudi Geographical Society contributed to the establishment of the Gulf Geographic Society and has helped support this new organization. Members of the board of directors call upon senior officials of the state to introduce them to society activities and projects and to indicate the extent to which these projects need moral and financial support.

The Third Forum of Arab Geographers of the Saudi Geographic Society, entitled “The Major Cities in the Arab World,” was held at the King Saud University in Riyadh. The SGS has coordinated the event along with the Yemen Geographical Society and the Egyptian Geographical Society, which hosted the first and second meetings of Arab geographers.

Brief history

The establishment of the Saudi Geographical Society was approved during the 11th session of the King Saud University Research Council held on March 13, 1983. King Saud University became the sponsor and headquarters for the society, although it has the option to establish, if required, additional branches in other places.

The statute was amended within the guidelines regulating research societies operating in Saudi universities, which was ratified by the Higher Education Council by virtue of its decision No. 10/15/1420, and the endorsement by the custodian of the two holy mosques, chairman of the Higher Education Council, of the council’s decision made during its 284th session held on June 18, 2000. The first general congress meeting of the Saudi Geographical Society took place on December 21, 1984. Prior to the establishment of the Saudi Geographical Society, there were a number of small geographical associations operating within the geography departments of the Saudi universities. The society has published considerable research and has a number of projects underway or in process.

The measurement of scale is central to understanding how maps represent the Earth’s surface and in popular usage is still the most common meaning attached to the term. Beginning in the 1980s, however, the term “scale,” especially as it was used by human geographers, was dramatically broadened from its traditional definition as a measure of cartographic transformation. During this period, scale became one of the pillars of social theoretic reflection in geography, and for many geographers it became perhaps the central contribution of the spatial perspective to the social sciences more generally. The arguments were simple and appealing. If, as was being widely acknowledged at the time, the operations of social processes are to a great extent dependent upon the larger sociocultural, historical, and geographical contexts in which they are found, then might not these processes function differently, or even be sorted according to, various scalar contexts, such as the local, regional, national, and global levels? If yes, then geographers could argue that scale is foundational to social explanation more generally. What is more, if scalar contexts are the result of social processes, rather than being simply given as set categories of analysis, then social and spatial explanation would need to go hand-in-hand. This pairing offers compelling reasons why “geography matters,” or should matter, to the broader social sciences. Not only were many human geographers attracted to theories of scale in geography, so too were many theoretically-inclined social scientists outside the discipline.

Scale theory arose in the wake of, and is sometimes viewed as a component of, the sociospatial dialectic, an influential theory that maintains that social processes simultaneously produce and are produced by space, including all aspects of geography, from the forms and organization of our natural and built environments, the material, symbolic, and ideological aspects of place, and the everyday geographies forged through human lived experience. Scale is one concept within such dialectical thinking. Yet, at the same time that scale was being developed as part of spatial dialectics, the critical wing of the discipline was undergoing other shifts; in particular, away from what was perceived to be a strict materialist, economistic, and structural Marxism towards a more avowedly poststructuralist (née postmodern) body of theory. The ideas geographers brought to the concept of scale were affected by these transitions. Whereas initially theorists viewed scale as the product of capitalist social relations, later, under the sway of poststructuralism’s less centralized and more discursively-inflected forms of power, the boundaries and operations of scale became more uncertain. Indeed, under poststructuralism’s “crisis of representation,” questions arose as to whether scale is, in fact, an ontological bedrock of social space or merely an epistemological framework that we impute to space to help provide order and meaning. The local-to-global scaffolding upon which scale was initially theorized was challenged by such nonhierarchical theories as found in Gilles Deleuze’s and Félix Guattari’s philosophy and Bruno Latour’s actor-network theory. These issues are at the
center of a series of works that have made scalar and anti-scalar theories a much debated area in the 2000s.

**Scale as cartographic measure**

In its traditional, cartographic meaning, scale is defined as the ratio of the distance on a map relative to that same distance on the Earth’s surface. By convention, the first number in the ratio is the map’s unit (=1) distance, whereas the second number is the corresponding (i.e., same metric) distance on the Earth’s surface. So, for example, a map ratio of 1:100000 indicates that every, say, inch of map distance shows 100000 inches of surface distance, or roughly 1.6 miles (100000 inches/5280 feet/12 inches = 1.578 miles). This is a common ratio used by the United States Geological Survey for topographic mapping at an intermediate scale.

Map scales are distinguished as large or small based on the size of the ratio of the two numbers. A common USGS map at 1:24000 is said to be relatively large scale, owing to the size of the resulting number, relative to a map with a scale of 1:250000, which has a much lower value and is, therefore, referred to as smaller in scale. A point of common confusion is that since larger scale maps reduce the Earth’s surface to a lesser extent, they therefore show less surface area, while small scale maps are needed to show large areas. A 1:24000 map enables viewers to identify urban or rural features such as streams, roadways, and land use patterns, while maps at smaller ratios, such as the commonly used 1:100000 or 1:250000 maps, are used to discern the shapes of river basins and state political boundaries. The zoom function in digital mapping has made these fixed scales much less relevant. Seasoned map enthusiasts can tell you what scale a USGS map is by simply glancing at it, but we now commonly select our scales in a continuous fashion based on our needs by simply scrolling a mouse.

**Theorizing scale**

It was Peter Taylor who first offered a social theory of scale. In his 1982 article he makes two arguments. First, he maintains that political economy should be the theoretical basis for the subdiscipline of political geography. Second, he argues that scale should be the grounds for spatializing this body of theory. (Taken together, it is not surprising that, after Taylor, theories of scale have seen most of their influence in political and economic geography.) Inter alia, Taylor critiques several treatments of scale then extant in political geography, finding them to be drawn from commonsense understandings instead of rigorous theorizing. His avowedly materialist theory of scale derives from Immanuel Wallerstein’s world-systems approach, which Taylor affirms but identifies as deficient in its implicit horizontal approach to space (i.e., as areal extension rather than in terms of spatial levels). In its place, he proposes a “political economy of scale” with three vertically conceived levels: “the scale of reality (global), the scale of ideology (state) and the scale of experience (urban)” (Taylor 1982, 24). Here reality refers to the facts of capitalist accumulation at the global scale, while ideology implies a view of the state as an institutional apparatus “whose purpose is to simply separate experience [the urban scale] from reality” (Taylor 1982, 24). Crucially for Taylor, the global political economy is foundational, yet every scale is relational:

Hence we do not propose three processes operating at three scales but simply a single manifestation of capitalist accumulation within which the arrangement of three scales is functionally important. For instance, the needs of accumulation will be experienced
locally (e.g. closure of a hospital) and justified nationally (e.g. to promote national solvency) for the ultimate benefits organized globally (e.g. by multi-national corporations paying less tax). (Taylor 1982, 24)

The second important contribution to scale comes from Neil Smith in his 1984 book, Uneven Development. Throughout, Smith delivers an impressive presentation and unpacking of a wide range of concepts related to the “dialectic of [spatial] differentiation and equalization” (Smith 1984, 135) under capitalism. By the time we get to his chapter on scale and the “see-saw” of capital (Smith 1984, 131–154), we know that scales do not simply exist as given levels, but are at the heart of uneven development under capitalism: “Capital inherits a geographical world that is already differentiated into complex spatial patterns. As the landscape falls under the sway of capital (and becomes increasingly functional for it …), these patterns are grouped into an increasingly systematic hierarchy of spatial scales” (Smith 1984, 135). One of Smith’s advances over Taylor’s, it could be argued, lies in his departure from what he calls Wallerstein’s “perspective of exchange space” (Smith 1984, 176, footnote 7). For Smith, scale is produced by capital, while capital itself becomes bound to that spatial configuration:

I think it is possible to use the dialectic of differentiation and equalization to derive the actual spatial scales produced by capital, and to show that the result of uneven development is simultaneously more complex and [simpler] than a mosaic. There is little doubt about the impossibility of a spatial fix for the internal contradictions of capital, but in the doomed attempt to realize this spatial fix, capital achieves a degree of spatial fixity organized into identifiably separate scales of social activity. (Smith 1984, 135)

Smith agrees with Taylor that scales exist at the urban, nation-state, and global levels, but he is reluctant to assign to these levels a specific and allied social process (e.g., ideology to the nation-state, experience to the urban). Rather, as he shows in subsections devoted to each level, capitalism produces scales as part-and-parcel of its endless shifting between equilibrium and disequilibrium. It does so through the “spatial fixes” – that is, centralization, expansion, and jumping into new spaces altogether – that are inherent in solving capitalism’s fundamental contradictions. But however fixed these scales are made, they are subject to change, and it is through the continual determination and internal differentiation of spatial scale that the uneven development of capitalism is organized. The vital point here is not simply to take these spatial scales as given, no matter how self-evident they appear, but to understand the origins, determination and inner coherence and differentiation of each scale as already contained within the structure of capital. (Smith 1984, 136)

In the two decades following these two important works, the discipline saw many extensions and refinements to the concept of scale. These took several interrelated lines of analysis. The first was a focus on the “politics of scale” – a result of the recognition that, while capital might attempt to produce space in its own image, scales could also be strategized and fought over. Among those who made important contributions in this area was John Agnew, who demonstrated that Italian political parties organize around spatial categories of the local, regional, and national so as to “define the geographical scales that channel and limit their political horizons” (Agnew 1997, 118). Similarly, Byron Miller showed how social movements, such as peace activists in Massachusetts, deploy different scalar strategies as political opportunities suggest themselves (Miller 1994). More generally, as Erik Swyngedouw puts it:
Geographical configurations as a set of interacting and nested scales (the “gestalt of scale”) become produced as temporary stand-offs in a perpetual transformative, and on occasion transgressive, social–spatial power struggle. These struggles change the importance and role of certain geographical scales, reassert the importance of others, and sometimes create entirely new significant scales, but – most importantly – these scale redefinitions alter and express changes in the geometry of social power by strengthening power and control by some while disempowering others. (Swyngedouw 1997, 169)

Swyngedouw’s distributed notion of power is consistent with a second line of analysis that developed in the scale literature, namely the loosening of strict scalar boundaries (e.g., urban, nation state, global) and the broader integration of vertical scalar productions with horizontally conceived social networks. Neil Smith, for example, continued his elaboration of malleable scales, coining the terms “scale jumping” to describe how political power established at one scale can be expanded to another, and “scale bending,” the process by which “entrenched assumptions about what kinds of social activities fit properly at which scales are being systematically challenged and upset” (Smith 2004, 193). Less rigid forms of scalar thinking also emerged as geographers came to see that scales and networks together might provide a more potent descriptive and explanatory framework. For example, Kevin Cox (1998) proposed that scales are contingent on the “networks of association” upon which different capitals and local states depend. As networks become more global in reach, they begin to stretch across scales. The necessity of relaxing otherwise rigid understandings of scale was, for Neil Brenner, a result of globalization, which he defined in terms of scale: “a reconfiguration and re-territorialization of superimposed spatial scales, and not as a mono-directional implosion of global forces into sub-global realms” (Brenner 1997, 159). He explicitly links scales and networks, offering that:

Scales evolve relationally within tangled hierarchies and dispersed interscalar networks. The meaning, function, history and dynamics of any one geographical scale can only be grasped relationally, in terms of upwards, downwards and sideways links to other geographical scales situated within tangled scalar hierarchies and dispersed interscalar networks. ... Each geographical scale is constituted through its historically evolving positionality within a larger relations grid of vertically “stretched” and horizontally “dispersed” sociospatial processes, relations and interdependencies. (Brenner 2001, 605–606, emphasis in original)

Helga Leitner is another theorist of scale who responds to globalization – particularly of the political variety – by integrating vertical scales with horizontal networks. She writes:

transnational networks represent new modes of coordination and governance, a new politics of horizontal relations that also has a distinct spatiality. Whereas the spatiality of a politics of scale is associated with vertical relations among nested territorially defined political entities, by contrast, networks span space rather than covering it, transgressing the boundaries that separate and define these political entities. (Leitner 2004, 237)

A third development in the scale literature comes from glances downward – downward even from the urban scale – to the scale of the home, the street, and the body. In what remains the most cited paper on scale, Sallie Marston (2000) deploys the concept of social reproduction to illustrate how most scale theory has been: “largely unresponsive to questions of difference in human agents and how power relations outside the relations of capital and labor might also influence scale-making” (Marston 2000, 238). In response, she situates the home as the scale at which the
everyday relations of patriarchy, racism, and citizenship connect to wider scales. Marston demonstrates her argument through a description of the expanding consciousness and political roles of US women in the nineteenth and early twentieth centuries:

greater political empowerment proceeded from the reconstitution and reclamation of the social geography of daily life. A discourse about women as “female citizens” operated among and between scales from the household out to the globe and provided these subjects with a consciousness that enabled a particular negotiation of patriarchal subordination and began a gender transformation of the public sphere through a reconstitution of the private sphere of the home. In short, the home was utilized as a scale of social and political identity formation that eventually enabled American middle-class urban women to extend their influence beyond the home to other scales of social life. (Marston 2000, 235)

In what might be said to be geography’s first skirmish over scale, Neil Brenner reacted to Marston’s expansive theorization. His aim in responding was to:

contribute to the development of an approach to sociospatial theory in which the specifically scalar dimensions of social spatiality – in contradistinction to its many other dimensions, such as localization, place-making, territorialization, spatial distanciation, the formation of spatial networks, the production of environment/nature and so forth – may be adequately recognized and theorized. (Brenner 2001, 593)

In arguing for “a more precise and hence analytically narrower conception of geographical scale” (Brenner 2001, 593), Brenner’s reply – which includes eleven methodological hypotheses – was only strategically directed at Marston, for, as elaborated above, since its initial tracing by Taylor and Smith, the concept of scale has been progressively widened through a series of theoretical interventions. These have made the concept of scale both more processually inclusive (e.g., through a focus on the politics of scale and the inclusion of social reproduction and environmental processes in scale theory) and, relatedly, more spatially complex (e.g., by including horizontal networks and households). In offering that scale should be tied to “an explicit causal argument linking the substantive social content of the spatial unit in question to its embeddedness or positionality within a broader scalar hierarchy” (Brenner 2001, 600, emphasis in original), Brenner sought to limit scale to “relations of hierarchization and rehierarchization among vertically differentiated spatial units”, such that they can be distinguished “from other forms of sociospatial structuration” (Brenner 2001, 603).

Marston’s reply to Brenner, co-authored with Smith (Marston and Smith 2001), concedes the importance of more analytic precision around scale, but concludes that Brenner will not find the tools for it by maintaining boundaries between scalar production and the wider social production of space (à la Lefebvre):

scale is a produced societal metric that differentiates space; it is not space per se. Yet “geographical scale” is not simply a “hierarchically ordered system” placed over pre-existing space, however much that hierarchical ordering may itself be fluid. Rather the production of scale is integral to the production of space, all the way down. Scaled social processes pupate specific productions of space while the production of space generates distinct structures of geographical scale. The process is highly fluid and dynamic, its social authorship broad-based, and the scale of the household (or the home) is integral to this process. So too, we contend, is the scale of the body. (Marston and Smith 2001, 615–616)

In addition to their theoretical response – which is centrally pointed to the question of what kind
of space scale is—Marston and Smith also criticize Brenner for an “inability to see the theoretical relevance of the social reproduction argument” (Marston and Smith 2001, 617); they maintain that it is “arbitrary that the home is relegated to a ‘place’ or ‘arena,’ while the state gets to be a multifaceted ‘scale’” (Marston and Smith 2001, 618). “Future historical research may yet reveal the household to be a ‘stable background structure’ in all of this,” they reply, “but the smart money will be wagered elsewhere” (Marston and Smith 2001, 618).

Anti-scale theorizing

As suggested above, scale might not merit a simplistic oppositional trope—“anti-scale”—for it has long proved to be a multifaceted, evolving, and contested concept, even among its proponents. Nonetheless, it is clear that some time near the end of the century geographers began to reflect more critically on the analytics of scale—as witnessed in the debate between Brenner and Marston and Smith—but also, and more fundamentally, on the very question of whether scale adds value to the geographic lexicon. For example, in addition to her questioning of the primacy of capital, labor, and the state in the social construction of scale, Marston’s seminal intervention presaged her and others’ later work under the anti-scale label when she openly entertained the “the rejection of scale as an ontologically given category” (Marston 2000, 220). This point echoes an earlier but less widely-known essay by Katherine Jones (1998, 28), who may have been the first to sharpen the ontological and epistemological distinctions of scale when she wrote: “[W]e may be best served by approaching scale not as an ontological structure which ‘exists’, but as an epistemological one—a way of knowing or apprehending.” Writing in response to Kevin Cox (1998), who, like Brenner (2001), was concerned to distinguish between scales and areas, such as localities, Jones suggested that the politics of scale may be little more than a special case of the politics of representation:

If scale is a representational practice deployed by participants in struggles, a practice situated within a community of producers and readers who actively negotiate and construct it, then what is its ontological status? Does scale exist beyond that community as a fundamental structure of the world, or is it a mode for apprehending the world that is tied to a particular historical/geographical context? Furthermore, does it make any difference whether we see scale as a fundamental ontological category, or as an epistemology, and if it does make a difference, then what is that difference? I would argue that scale is an epistemological category, rather than an ontological one, and that the difference is an important one. (Jones 1998, 27)

The most extensive critique of scale to date came in a 2005 article by Sallie Marston, John Paul Jones III, and Keith Woodward (2005). Unlike Brenner (2001), Marston and her colleagues saw no possibility of achieving analytic specificity in the concept, which they claimed was ontologically and, hence, causally deficient. They illustrated their point by claiming that the primary difference between the horizontal

geographies of networks and the vertical geographies of scales is the reflexive position (i.e., epistemology) of researchers’ spatial imaginaries (Table 1), and not scale’s ontological – and therefore casually grounded – foundation. The resulting confusion leads, they argue, to conceptual gymnastics that are increasingly detached from the concrete social spaces of everyday practice: “[O]ne encounters … ‘structures’ not at some level once removed, ‘up there’ in a vertical imaginary, but on the ground, in practice, the result of marking territories horizontally through boundaries and enclosures, documents and rules, enforcing agents and their authoritative resources” (Marston, Jones, and Woodward 2005, 420). Scale theorizing, they continue, has so infiltrated – and been affected by – discourses of globalization that “over the past twenty years, political and economic geographers have tended toward macro pronouncements that assigned the global more causal force, assumed it to be more orderly … and, by implication, relegated [the local] to the status of the case study” (Marston, Jones, and Woodward 2005, 421). Such “globe talk” cordons off, if not eviscerates, agency and resistance relative to detached, but somehow powerful forces such as “global capitalism,” “national social formations,” and the like. These conceptual apparatuses diminish the epistemological, methodological, and political insights of feminists and other theorists of the everyday (Gibson-Graham 2002). Critically for them, these problems will not be solved by replacing one transcendent account of spatiality (scale) with another (networks):

Network-based horizontality does avoid some of the problems [of scale], but in reviewing this literature we see significant evidence of ‘flowsterism’: the idea that people, phenomena and processes somehow fly above the stickiness of space in an atmosphere of frictionless fluidity. We find, moreover, the same tendency to spatial abstraction in the horizontal view that we also criticize in the vertical one, with scattering lines of flows now standing as transcendental counterparts to layers of nested territories. (Jones, Woodward, and Marston 2007, 265)

In their 2005 and later articles, these anti-scale critics draw on various conceptual resources, including Deleuze and Guattari, Latour, Spinoza, and philosopher Theodore Schatzki, to construct a spatial ontology that replaces both scalar and network theorizing with a “flat,” or “site,” ontology, which they propose to consist of:

immanent (self-organizing) event-spaces dynamically composed of bodies, doings and sayings. Sites are differentiated and differentiating, unfolding singularities that are not only dynamic, but also “hang together” through the congealments and blockages of force relations. The “actuality” of any site is always poised for compositional variation – subject to reorganizations and disorganizations—as its inexhaustible “virtuality” or potential continually rearticulates itself. (Jones, Woodward, and Marston 2007, 265)

Site ontology thus stands as an alternative to the structural imperatives of scalar spatiality, avoiding the latter’s transcendent logics, predetermined spatial frames, and axiomatic strategies that, Marston and her colleagues maintain, identify research problems such that they can be “solved for scale” (Marston, Jones, and Woodward 2005, 426).

Conclusion

In 2006 and 2007 the journal Transactions of the Institute of British Geographers published a handful of replies – some spiritedly critical, others sympathetic – to “Human Geography without Scale” (Marston, Jones, and Woodward 2005), and the authors penned a lengthy rejoinder (Jones, Woodward, and Marston 2007).
SCALE AND ANTI-SCALE

The exchange has become known as the discipline’s “scale debates.” Since then, a number of other commentators have offered additional perspectives, leaving the current thinking on scale falling into two camps: (i) those who have reaffirmed scale’s ontological status (sometimes in combination with network theories), and as part of this view, continue to champion it as a foundational component of social space (Jessop, Brenner, and Jones 2008; Leitner, Sheppard, and Sziarto 2008); and (ii) those in geography and elsewhere who have criticized not only structuralist approaches to social relations, but also the attendant and conformant structuralisms of hierarchical spatiality, and who are thus supportive of developing ontological alternatives to scalar thought (Escobar 2007; Isin 2007).

Regardless of their position with respect to scale’s ontological status, both groups are generally united in their agreement on a third position, namely, that the scalar imaginary – that is, scale as epistemology – plays a significant role in social determination (Moore 2008; Kaiser and Nikiforova 2008). Perhaps here it bears emphasizing that no scale critic ever discounted the fact that people’s geographic imaginaries are often socially constructed in scalar terms. This is especially so in the Western tradition, where spatial order remains a powerful legacy of Cartesian thought. Likewise, no scale critic ever dismissed the fact that scale talk – that is, scale deployed as a discourse – is political, and thus regularly fought over by social actors. In this sense, anti-scale theorists continue the project of elaborating the “politics of scale,” even while they resolve to replace the concept with others more consistent with a poststructuralist ontology, such as the assemblage or the site. And so it might be said that the singularly important and as yet unanswered question about scale is a larger, disciplinary one: What is this thing we call “space,” and what added value does scale provide in our efforts to define it?

The concepts

As widely understood, geographic information is georeferenced information (GI) about spatial entities (e.g., buildings and rivers) and distributions (e.g., terrain elevation and land cover), and is becoming increasingly important for modern society. The increasing sophistication of spatial information technology, proliferation of spatial data and information products, and the development of geographic information science have prompted greater research efforts on some of the fundamental issues surrounding consumption of GI, including that of scale. Indeed, as an essential dimension of geospatial research and applications, scale is becoming increasingly acute as an issue due to accumulation of spatial data (with inconsistencies in geometry, attributes, and semantics), the ease of processing datasets of different scales in a computerized environment, and a lack of readily available tools to handle multiple scales and the associated challenges for interoperability (Zhang, Atkinson, and Goodchild 2014).

Definitions of scale include geographic scale, operational scale, measurement scale, and cartographic scale. As reviewed by Lam and Quattrochi (1992) and Zhang, Atkinson, and Goodchild (2014), geographic scale is also called observational scale, referring to the size or spatial extent of the study. The operational scale refers to the spatial (or temporal) extent at which certain processes operate in the environment and is also known as process scale or intrinsic scale (Blöschl and Sivapalan 1995). The measurement scale is commonly called (spatial) resolution and is commonly indicated by the sampling intervals or pixel sizes in remote sensing images. The process scale of a geographic phenomenon needs to be quantified to determine both the geographic scale and the measurement scale of observed patterns resulting from the underlying process. Cartographic scale refers to the ratio between the length measurements on a map and the actual measurements on the ground; it is also known as map scale. It refers to data representation, unlike geographic scale, process scale, and measurement scale, which refer to data characteristics (Lam and Quattrochi 1992).

An important concept related to (measurement) scale is data support. Data supports generally refer to the shapes and geometric dimensions (i.e., length, area or volume) associated with individual data. While certain entities or variables can be measured or evaluated at point-like locations (e.g., bench marks in land surveying), many others are sampled over units of positive finite geometric dimensions (e.g., sample plots in forest surveys and pixels in images). Data and geoprocessing over finite supports are common in geography, such as areal (polygonal) data of land use and demography, analysis over areal units, or inference about one set of areal units from another, as is the case for lattice data (Saveliev, Mukharamova, and Zuur 2007).

Discussion about data support may also be framed in relation to geospatial conceptualization or data modeling, for which there are two complementary models: entity models and fields. In the former, the real world is conceived
of as populated by discrete entities or objects \( ID(x, \ attr) \), in which position is indicated by \( x \) and attributes (both qualitative and quantitative) by \( attr \), while, for the latter, the real world consists of layers of single-valued functions (either continuous variables \( Z(x) \) or discrete variables \( C(x) \)) defined over space. In both object- and field-based representations, \( x \) should be viewed as data support rather than a mere notion of position, thus indicating the multiplicity of scales, as \( x \) can be different-sized units implying different spatial resolution.

Although scales of geographic phenomena, measurement, and analyses are required to be commensurate, there are often scale discrepancies among them due to the complexity of scale dependencies of geographic phenomena and differences in their data support. This indicates the importance of relating and communicating information across scales, which is facilitated by change of scale (i.e., scaling). For example, scaling is involved when predictions need to be made at a scale that is different from the scale at which data are acquired. There are two kinds of scaling in terms of the relationships between the scale of the existing data (or analysis) and the required scale: (i) scaling up or upscaling, which is information translation from finer resolution (smaller supports) to coarser resolution (larger supports), and (ii) scaling down or downscaling, which is to translate information from coarser to finer resolution, as discussed by Meentemeyer (1989), and Blöschl and Sivapalan (1995). Changing the support (or scale) of a variable creates a new variable, related to the original one, but with different statistical and spatial properties. This is a key idea in research on change of scale, as elaborated later.

In summary, scale is an essential metric for understanding information mechanisms in geographic information gathering, processing, and dissemination. Research on scale issues should focus on models for characterizing scale in spatial data and the underlying geographic patterns and processes, and methods for changing scale. Equally important are related tool developments to assist consumers of geographic information.

**Modeling scale**

There are various techniques to measure scale in a given dataset and to model scale in the underlying data-generating processes. Below, some of the scale descriptors and models will be reviewed, including fractals, local variance, spectral analysis, and wavelets, with spatial statistics (i.e., geostatistics and spatial autocorrelation analysis) being introduced as the framework for scale modeling in the second and third subsections. Such scale descriptors are useful for determination of appropriate scales for data collection, information extraction, and spatial analysis.

**Various scale descriptors**

Many linear features with complex detail (e.g., coastlines) are said to be statistically *self-similar*, because they appear to possess the same statistical properties over a range of scales. Statistical self-similarity is a well-known manifestation of fractals (Mandelbrot 1967), which have long been studied for their applicability in geography (Lam and Quattrochi 1992). For a curve that is not recursively generated, its fractal dimension can be estimated by measuring the length of the curve using a series of step sizes and performing a linear regression. Suppose the measured lengths \( L(\Delta) \) of such geographic curves are related to the measurement scale \( \Delta \) via a function of the form \( L(\Delta) = k\Delta^{1-D_{fractal}} \). We can see the linearity of a plot of the quantity \( L(\Delta) \)
versus scale $\Delta$ on a log-log graph: $\log L(\Delta) = \log k + (1 - D_{fractal}) \log \Delta$, where the slope of the regression line is $1 - D_{fractal}$, while $D_{fractal}$ indicates the fractal dimension (Mandelbrot 1967). A relatively smooth (irregular) curve should have a fractal dimension close to 1 (2). Fractal analysis can be performed not only with vector data but also raster data, such as digital elevation models (DEMs) and remotely sensed images.

For analysis of scales in remote sensing images, Woodcock and Strahler (1987) propose the local variance method, which can be used for quantifying the relationship between the size of objects in a scene and the spatial resolution of sensors, and thus useful for determining a suitable measurement scale for surveys. By this method, the mean value of the variance of a moving window (say 3 by 3 pixels) over the entire image is computed and plotted as a function of spatial resolution. Generally, the peak appears when the pixel size (i.e., spatial resolution) approximately matches the size of the objects, with multiple local-variance peaks indicating multiple scales of variation in the scene (Woodcock and Strahler 1987; Zhang, Atkinson, and Goodchild 2014). It is important to note that interpretability of scale in the underlying scene based on local variance is dependent on the image’s global variance. The local variance method has been used widely for multiscale analysis in various applications.

There are also spectral analysis methods that may be explored for analysis of scale. By (discrete) Fourier transforms, a signal (e.g., a terrain profile (1-D) or an imaged scene (2-D)) can be transformed into its equivalent in frequency space, and expressed as a linear combination of oscillating functions with different frequencies via inverse transforms. Fourier transform can be used to construct a Fourier spectrum indicating magnitudes and phases of the components at different frequencies in a signal. Pike and Rozema (1975) derived the spectral density function via the discrete Fourier transform of an autocovariance function estimated for a terrain profile, with the resulting spectrum depicting the functional relation between the variance associated with different-sized terrain undulations and topographic wavelengths.

As reviewed by Dale and Mah (1998), the wavelet transform method uses a localized function in time or space (to adjust and shift the wavelet’s size and location) for signal analysis at multiple resolutions. The wavelet variance can be calculated on the basis of the wavelet transforms and used as an indicator to quantify the spatial scale and as a suitable tool to study multiscale characteristics of spatial data and the underlying processes.

Theoretically, scale is related to the structure, extent, and strength of spatial dependence inherent in many spatial processes and patterns. A statistical measure of the similarity of properties over space is called spatial autocorrelation, as reviewed by Goodchild (1986). In the next two subsections, geostatistics and spatial autocorrelation are discussed for scale modeling in geostatistical and lattice data, respectively.

Geostatistical models of scale

Geostatistics is the mathematics for quantifying and utilizing spatial dependence in spatial analysis based on the theory of regionalized variables, which states that the spatial variation for $Z$ at $x$ can be viewed as a regionalized variable $Z(x)$, and is the sum of a deterministic mean, a spatially correlated residual, and uncorrelated noise (Journel and Huijbregts 1978; Webster and Oliver 2007). A related concept is the so-called random field (RF), which refers to a set of regionalized variables $\{Z(x), x \in D\}$ over a problem domain $D$ (which is discretized by $x$ as in the notion $\{Z(x), x \in D\}$). In geostatistics,
covariance functions and variograms are used as tools to quantify spatial dependence, in terms of correlation and dissimilarity, respectively, in regionalized variables, say $Z$, which exhibit both deterministic and stochastic characteristics as mentioned above. For a RF $Z$, its variogram is defined as half of the variance of the difference between $Z$ values at two locations, $x$ and $x+h$, which are separated by lag $h$ (the distance and direction of separation), in the domain $D$ (under the intrinsic hypothesis):

$$
\gamma(h) = \frac{1}{2}E[(Z(x+h) - Z(x))^2]
$$

A variogram model is shown in Figure 1.

There are three named parameters of a typical variogram model: nugget, sill, and range, which are represented by $c_0$, $c_0 + c_1$, and $a$, respectively, (Figure 1). These parameters can be used to characterize spatial dependence and, based on this, the scale. The nugget is the discontinuity of the variogram at the origin, due to uncorrelated noise (measurement error) and/or spatial structures operating at scales finer than the spacing of observations. The sill (if one exists, as in the case of bounded variability) is the value that the variogram reaches (asymptotically sometimes) as the lag distance increases, equaling the variance of the underlying RF. The range (if one exists, corresponding to the existence of a sill) is the lag distance at which the variogram reaches a sill, indicating the process scale over the domain, as also described by Zhang, Atkinson, and Goodchild (2014).

The scale model (e.g., a variogram model) of a geographic distribution is usually derived from sample data. As these sample data are often of finite support themselves, the resultant experimental or sample variograms are, thus, regularized versions of the underlying point-support variograms. These point-support variogram models are prerequisite for calculation of regularized versions over any finite supports and cross-scale data analyses. For this, variogram deconvolution or deregularization, as an inverse of variogram regularization, is required to estimate point-support variograms from finite-support variograms (Goovaerts 2008).

In addition to spatial dependence (as a general pattern), spatial heterogeneity is also characteristic of geographic distributions and entities. Spatial heterogeneity implies nonstationarity in spatial structure of an underlying RF (Sampson and Guttorp 1992), necessitating use of local models of scale to accommodate nonstationary structural pattern in the RF. For local modeling of scales, first-order (i.e., mean) and second-order (covariance) moments can be dealt with separately or in combination. Nonstationarity of the mean may be handled by the intrinsic assumption, by decomposing the RF into a local mean and a residual, or by partitioning a domain into homogeneous subdomains and modeling locally varying means within these subdomains. To handle local variation in other statistics (e.g., variance, spatial covariance, and spatial cross-covariance), it is sensible to adopt such a partitioning and local modeling strategy. It
amounts to restricting the stationarity in second order moments of the RF locally, thus resulting in local variogram models, for instance. There is another approach to nonstationary structural modeling, which works directly over the entire problem domain without partitioning it at the first place. An example for this approach is a spatial deformation approach (Sampson and Guttorp 1992): the coordinate space is transformed so that the covariance structure becomes stationary and isotropic in the transformed space.

In principle, many of the methods for variogram modeling can be applied, with proper modification, to categorical variables. This is often done through indicator transforms, resulting in indicator auto- and cross-variograms for quantifying spatial dependence in area-class occurrences and distributions. Methods for modeling spatial structure in area classes can be usefully addressed on the basis of phase space (Goodchild, Zhang, and Kyriakidis 2009), which is characterized by the process covariates that are believed to have shaped the area-class distribution observed. Also, to analyze multiple RFs involved in a problem domain, it is important to extend models of univariate regionalization to those of co-regionalization.

Lattice data and scale models

As reviewed above, variograms are versatile in being able to characterize RFs of both continuous and categorical variables, and flexible for global and local quantification of scale. In the literature, geostatistical modeling has implicitly assumed continuous indexing of locations over space. In addition to this kind of “geostatistical data,” there is another type of data known as lattice data, that is, data that are aggregated over finite areal units. For this kind of data, alternative modeling approaches are necessary and complement the geostatistical ones, as explained below.

In terms of data support, spatial data sampled from fields (of both continuous and categorical variables) can be called geostatistical data (over point or quasi-point support) and lattice data (over finite areal support). Geostatistical data result from sampling a field over a continuous domain $D$, where sample locations can be continuously indexed. A variogram quantifies the degree and range of spatial dependence in a particular dataset (and the underlying RF, say $\{Z(x), x \in D\}$ if the variogram is point–supported) and can be used as a model of scale, as reviewed in the preceding subsection. Unlike geostatistical data, lattice data result from aggregation of RF $Z$ over finite areal units (with prescribed tessellation schemes). This subsection discusses lattice data and their scale models, based on measures of spatial autocorrelation, for which neighborhood relationships (Goodchild 1986) play a central role in data analysis and scale characterization.

For lattice data, the number of lattice units imposed on a domain is countable (and usually finite), as the lattice units are themselves of finite areal extents. Census data and forest inventory over different mapping units are examples of lattice data (see Saveliev, Mukharamova, and Zuur (2007) for further examples). Lattice data can be regular or irregular in terms of tessellation (as exemplified by remotely sensed images and county-level cropland inventories, respectively), discrete or continuous in terms of scale of measurement (e.g., land use and population data), as in the case of geostatistical data.

Spatial autocorrelation in lattice data provides the basis for describing their scales. A key element in measuring and understanding spatial autocorrelation is to describe the relationship between the similarity of values of a field variable and the distance separating them, as described by Goodchild (1986). Quantification of spatial
autocorrelation in lattice data is usually based on Moran’s $I$ and Geary’s $c$, which can be used to create correlograms as models of spatial autocorrelation. In lattice data analysis and scale modeling, neighborhood relationships (spatial adjacency) rather than Euclidean distance alone are important for the prediction of relevant quantities over space.

As for geostatistical data, local measures of spatial autocorrelation, such as those proposed by Anselin (1995), may be explored for lattice data, resulting in local models of spatial autocorrelation and those of scale. Such local models are more useful and valuable than global ones in being able to capture spatial variability (i.e., nonstationarity) of scales over the extent of a problem domain $D$. Local indicators of spatial autocorrelation can be built upon both Moran’s $I$ and Geary’s $c$ (Anselin 1995), to accommodate spatial heterogeneity in the strength of spatial autocorrelation in $D$, and thus constructing local models of scales for lattice data.

Lattice data can be sensibly classified in terms of their suitability for geostatistical descriptions. There are lattice data, such as remotely sensed data (regularly shaped) and areal data sampled or aggregated over naturally regionalized zones (with bona fide boundaries). Such data can be analyzed with respect to spatial dependence by using geostatistics through use of finite blocks (as opposed to points), and are called Type I lattice data. On the other hand, lattice data not directly amenable to geostatistical handling are called Type II lattice data, such as those collected over arbitrarily demarcated reporting zones (with fiat boundaries). This is because, in Type II lattice data, lags over which spatial autocorrelation is quantified are not based on the Euclidean metric but on spatial adjacency, which is often not conformal to Euclidean distance. Therefore, for Type II lattice data, spatial statistics, such as Moran’s $I$ and Geary’s $c$ indices, become particularly useful for analyzing the spatial autocorrelation and spatial scale inherent in the underlying fields, as discussed also by Zhang, Atkinson, and Goodchild (2014).

In the light of the classification of lattice data above, regularization and its inverse, deregularization, of spatial statistics relevant to scale modeling can be discussed accordingly. As mentioned in the previous subsection, variogram regularization is the process of quantifying variograms over finite support from point-support ones, while deregularization is the inverse process. For Type I lattice data, because their scale description can be based on geostatistics as reasoned above, methods for regularization and deregularization of variograms can be applied straightforwardly. For Type II lattice data, regularization of spatial statistics should be based on proper weighting of spatial weight matrices in the aggregation of the underlying $Z$ fields, leading to regularized correlograms. However, the process of deregularization is far more complicated due to the difficulty in deconvoluting lower-order spatial adjacency from its higher-order version (Zhang, Atkinson, and Goodchild 2014), requiring further research in this regard.

Both global and local measures of spatial autocorrelation have been used for describing spatial variability of lattice-sampled fields. Proper use of correlograms provides valuable information about the ranges and strengths of spatial autocorrelation in the underlying fields and can thus be used to elucidate models of scale concerning the lattice processes and the data drawn from them.

### Scaling up and down

As already mentioned, there exists scale discrepancy in multisourced spatial data, geoprocessing algorithms, spatial models, and applications, necessitating change of scale to enable cross-scale information communication. In remote sensing,
for instance, it is often necessary to upscale finer resolution data (e.g., RapidEye image-based reference data with 5 m by 5 m support) to coarser resolution data (e.g., Landsat TM images with 30 m by 30 m pixels) for comparison or validation purposes.

Different methods have been developed to transfer data and model outputs from a finer to a coarser scale (upscaling or aggregation) or from a coarser to a finer scale (downscaling or disaggregation). Fractal methods may be used to extend the statistical properties (i.e., moments) of a variable from one scale to another. Area-based weighting (e.g., for deriving coarse-resolution data from fine-resolution data based on the area extents of different land cover types within the coarse-resolution pixels) is based on the law of conservation of energy or matter, and often applied for scale changes in remote sensing.

Variograms and autocorrelation functions are designed for modeling scales in geostatistical and lattice data, respectively, as discussed in the preceding section. Accordingly, the next two subsections will describe methods for scaling of geostatistical data and lattice data, respectively. For the latter, the focus will be on regularly gridded regions, such as various images or raster data.

Geostatistical methods for scaling

We consider upscaling first. Upscaling is increasing the size of data support or coarsening the corresponding spatial resolution. The choice of method to use for upscaling depends on the characteristics of the finer resolution data. When the smaller-support data are sparsely (and usually irregularly) distributed, certain interpolation approaches may be performed to predict the values of a variable $Z$ over larger supports (denoted $Z_v$) within which the data of smaller support fall. For this, block kriging may be applied, because it is optimal in the sense of minimum prediction variance and unbiasedness (relative to the spatial statistical models assumed for the underlying RF) and because it enables prediction over the larger supports automatically as a result of linear kriging equation systems. In addition to kriging prediction itself, location-specific kriging variance can be obtained, providing useful information on prediction uncertainty (Journel and Huijbregts 1978). When finer resolution data are on regular supports (i.e., regular lattice data, such as remote sensing images) and abundant, upscaling may be performed by: (i) averaging approaches (i.e., averaging finer resolution data falling within coarser resolution cells); (ii) other statistics, such as median, minimum, and maximum, as averaging is equivalent to taking mean values; or (iii) some more sophisticated procedures that handle sensor properties (e.g., point-spread functions) (Justice et al. 1989). This is further discussed in the context of gridded lattice data in the next subsection.

For downscaling (i.e., to refine the spatial resolution of an existing dataset), block-to-point kriging (or area-to-point kriging in 2-D cases where source data and locations being predicted are defined on area and point supports, respectively) may be employed (Kyriakidis 2004), providing a potential solution to downscaling in both geostatistical and lattice data. It is helpful to conceptualize downscaling as larger blocks-to-smaller blocks interpolation, because the source data and prediction locations are often defined on finite supports (larger and smaller, respectively). Thus, area-to-point kriging mentioned above can be seen as a special case of larger blocks-to-smaller blocks interpolation.

Geostatistical inverse modeling is another option for downscaling (Kitanidis and Vomvoris 1983). As a Bayesian approach, it is based on the principle of combining prior information with
information latent in measurements (or observational data), where the prior information concerns spatial structure (i.e., mean and spatial (or temporal) correlation) prescribed for an underlying distribution say $Z$ (Kitanidis and Vomvoris 1983). Clearly, geostatistical inverse modeling provides links to the data-generation processes, and will be a useful extension to kriging-based downscaling mentioned previously.

Methods for scaling gridded lattice data

As discussed previously, geostatistical scaling is particularly useful where the data to be scaled are sparse with respect to the density of locations to be predicted, because it makes use of spatial structural information in addition to the measurements themselves for accuracy in scaling. Besides, uncertainty related to spatial interpolation (downscaling) and averaging (upsampling) can be quantified and used as valuable information for balancing between accuracy and resolution in down- or upscaled data products. This subsection addresses the issue of scaling of lattice data, in particular, those of regular supports.

Consider upscaling first. Although the geostatistical methods can be employed for scaling lattice data, in particular, Type I lattice data that include regularly gridded data and areal data partitioned with bona fide boundaries, other methods may be explored for scaling gridded data (i.e., images). For upscaling, statistical approaches can be used to aggregate fine-grained data into coarse-grained data through certain statistical operators, such as mean, median, mode, maximum, and minimum; mode can be used for aggregating categorical data. In addition to statistical aggregation mentioned above that proceeds as a kind of sampling from smaller-support cell values within the bounds of larger-support cells, there are mechanistic approaches that are based on the imaging mechanisms pertaining to image acquisition and thus better suited for coarser-resolution image or sensor simulations. For this, convolution kernels, based on proper parameterization of sensor point spread functions (Justice et al. 1989), need to be prescribed.

For downscaling, deconvolution may be used. Deconvolution aims to reverse the effects of convolution on data (e.g., blurring and noise in imaging), although it may or may not refine the spatial resolution of the input datasets. For resolution refinement, super-resolution mapping may be explored through various techniques, such as the combined use of multiple observed images of coarser spatial resolution. Mechanistic downscaling of gridded data may be developed from the geostatistical inverse modeling approaches described previously. Both statistical and mechanistic approaches to downscaling of gridded data are useful and should be explored in combination.

It can be asserted that further developments are likely to be seen in the integration of sensor/imaging models, statistical image analysis, and geostatistics. Thus, on one hand, the physical models of imaging and sensor parameters can be used for geostatistical scaling of gridded data, as in geostatistical inverse modeling. On the other hand, the characteristics of image data (and other gridded data) should be utilized in geostatistical scaling and to enhance the efficiency of computing with gridded data (Zhang, Atkinson, and Goodchild 2014).

As shown above, for Type I lattice data, geostatistical scaling (both up and down) may be implemented. For Type II lattice data, however, methods oriented to geostatistical data and gridded data are seldom applicable in a straightforward manner. There may be merits in enriching the semantics of Type II lattice data by use of covariates that are regionalized and correlated with the variable being studied (Zhang,
Atkinson, and Goodchild 2014). Hierarchical models may also be used for scaling Type II lattice data, especially those hierarchically structured.

Process-pattern strategies and information-theoretic perspectives

This section highlights the importance of process-pattern strategies for addressing scale issues not only in categorical fields but also in objects. The process-pattern strategies will be shown as useful extensions of spatial statistical approaches to modeling scale and scaling. This is followed by some discussions about information-theoretic perspectives in spatial data, analysis, and scale-related research.

Undoubtedly, geostatistical and spatial autocorrelation models are valuable tools for characterizing scales. Local models can accommodate nonstationarity in spatial structures and, hence, scales. Cross-variable correlation should also be incorporated in scale modeling, in particular, that concerning multivariate distributions. In addition to these general modeling approaches, alternatives that are suited specifically for certain geographic distributions are worth exploring. For example, representative elementary areas (reviewed by Blöschl and Sivapalan (1995)) and various ruggedness indices, which are indicative of spatial scale, can be used for modeling scales in terrain variables.

The process-pattern paradigms are valuable for investigating scales in area classes. Area-class maps depict distributions of land cover, soil types, ecoregions (Bailey 2014), and other thematic classes. For modeling scales, there are various landscape spatial pattern indices (Gustafson 1998), which can be seen as a manifestation of the scales of the underlying controlling factors (Bailey 2014). Conventional methods for scaling area-class maps are statistically based: for upscaling, statistical operators, such as majority rule, averaging, and random selection, may be used; for downscaling, the methods include estimating, at fine resolution, areal extents of individual classes based on coarse-resolution data (either discrete classification or class proportions) and fine-resolution prediction of class labels from coarse-resolution data and covariates. Discriminant space (a renaming of phase space) (Goodchild, Zhang, and Kyriakidis 2009) was proposed as a conceptual framework for area-class mapping. It provides the basis to construct a process-pattern (environmental-species) strategy, which should be exploited for both upscaling and downscaling of area-class information: the scaling of categorical information is accomplished through scaling of class-controlling covariates, which span the discriminant space whereby area classes are defined.

The process-based strategy can be sensibly extended to investigate how scales in objects (in particular, the bona fide type) should be described and how their scaling may be more effectively implemented than otherwise. For instance, some terrain derivatives, such as flow paths, can be studied with respect to scale and scaling in the light of the process-pattern paradigm elaborated here.

As discussed above, the process view is valuable as to how terrain properties are derived from elevation data, how land cover information is extracted from class-controlling factors or covariates, and how objects are delineated from fields. The integration of spatial statistics and process models then provides a coherent framework for scale modeling and scale change.

Information theory offers yet another language for addressing scale-related issues. Entropy is a measure of the uncertainty associated with a random variable (RV), and quantifies the amount of information (number of bits) required on average to describe the RV. Let $S$ be a discrete RV
with probability mass function \( p(s) = \Pr\{S = s\} \), 
\( x \in \mathbb{S} \), \( \mathbb{S} \) being the set of states \( S \) can take. The entropy \( H(S) \) of \( S \) is defined by:

\[
H(S) = E[I(s)] = E \left[ \log_2 \frac{1}{p(s)} \right] = -\sum_{i=1}^{n} p(s_i) \log_2 p(s_i)
\]  

(2)

where \( I(s) \) denotes the entropy contribution of an individual message \( s \) (also known as the self-information of \( s \)), and \( E \) indicates expectation, with \( n \) being the number of states for \( S \) in the set \( \mathbb{S} \) (Cover and Thomas 2006). We also define the conditional entropy of a RV, say \( S \), given another, say \( Z \), as the expected value of the entropies of the conditional distributions: \( H(S|Z) \). Joint entropy \( H(S, Z) \) can also defined for a pair of discrete RVs \( (S, Z) \) with a joint distribution \( p(s, z) \). Joint entropy can be seen as an extension to univariate entropy and can be extended to modeling the entropy, measured by the so-called entropy rate, of sequences of RVs (i.e., stochastic processes). Mutual information is a measure of the amount of information that one RV contains about another, and can quantify the actual amount of information conveyed by a measured or estimated value (say spot height) about the true value. The mutual information between two RVs, say \( S \) and \( Z \), is often denoted as \( I(S, Z) \), and can be calculated as the reduction in the uncertainty of \( S \) due to the knowledge of \( Z \), i.e., \( I(S, Z) = H(S) - H(S|Z) \) (Cover and Thomas 2006).

Consider an image \( \text{IMG} \) of \( m \times n \) pixels, with each taking on one of the \( K \) discrete values (indicating the image’s radiometric resolution). If we view \( \text{IMG} \) as a noiseless communication channel, there will be \( K^{mn} \) distinguishable images that can be encoded and transmitted, with the amount of information conveyed by \( \text{IMG} \) being \( \log K^{mn} = mn \log K \). It is easy to see that, for an image acquired over a given study area, the finer its spatial resolution, the more pixels there will be in it, thus increasing its information capacity. However, inter-pixel spatial dependence in the image suggests that there exist informational redundancy among its \( m \times n \) pixels \( Z = \{Z_1, Z_2, \ldots, Z_{mn}\} \) and that the relationships between information content and resolution are rarely linear or simple (Zhang, Atkinson, and Goodchild 2014). Spatial statistics will be useful for accounting for effect of spatial dependence on entropy, say through entropic modeling of coarsened or refined pixel sequences \( H(Z_1', Z_2', \ldots) \). We can also examine the effect of image spatial resolution upon the mutual information conveyed by pixel measurements about the underlying spatial distributions.

Information content in images and maps should be quantified as part of performance analysis and map design. This may be done by taking an image as a whole or, more sensibly, locally, just as statistical quantities related to scale are often modeled locally due to nonstationarity in spatial distributions and their spatial dependence strengths and ranges. This indicates that spatial variation of information granularity, as often observed, should be accommodated in representations. We can accomplish this by using differently sized rasters depending on the density of local information in the dataset. Hierarchical data models are valuable constructs for geographic representations adaptive to local variability (information amount) in the underlying forms and processes.

As hinted at previously, spatial dependence will have complex effects upon the informational aspects of the processes underlying image acquisition and analysis. As process scale is inherently related to the characteristics of spatial dependence, it is possible to look into the relations between informational and scale indices. Journel and Deutsch (1993) described
a measure of spatial entropy based on bivariate probabilities quantified over lags. It is basically the joint entropy associated with a set of joint probabilities corresponding to pairs of intervals of values discretizing the joint distribution of the underlying RF $Z$ at two locations separated by a lag $h$. This bivariate joint entropy can be standardized as relative entropy, which ranges between 0 and 1. When a particular class of $z$ values persists over larger (shorter) distance $h$, relative entropy will be increasing at a slower (faster) rate, implying a stronger (weaker) spatial order for prediction at unsampled locations (Journel and Deutsch 1993). The similarity between standardized variograms (to sills) and relative spatial entropy suggests that we may well be able to use informational measures to model and interpret scale in spatial processes and forms.

Despite ever-increasing computing speed and storage capacity, data compression remains important for efficiency in spatial information gathering and processing, especially in this so-called big data era. Research on information granularity (not merely data amount) and its scale dependence suggests that optimality in spatial sampling and geoprocessing can be achieved in the light of (classic) information theory and, more importantly, the recent developments in compressed sensing (or compressive sampling, shortly known as CS) (Candès, Romberg, and Tao 2006). CS capitalizes on the sparsity of the signals being sensed and utilizes the informational efficiency of CS sampling matrices and signal reconstruction based on convex optimization, which provides the solution to an underdetermined system of linear equations even if it is sampled at a rate lower than the Nyquist sampling rate (Candès, Romberg, and Tao 2006). Information theory will be useful for exploring scene sparsity and determining optimal sampling rates in CS applications.

Prospects

This section summarizes methodology regarding scale and scaling. For this, some prospective views are offered on how scale-related research may be integrated in data collection (e.g., spatial sampling), data conflation, and uncertainty characterization.

Measurement scales are determined by the sampling framework. The sampling framework can itself be divided into the spatial coverage of the sample (defined by the sampling scheme, sampling density, and sample size) and support of each individual observation (Skøien and Blöschl 2006). As sampling can be uniform or non-uniform, the discussion about sampling density can be organized accordingly. For uniform sampling, the Shannon sampling theorem states that a sampling rate twice the maximum frequency of a band-limited signal (i.e., a spatial distribution and entity) is sufficient for exact recovery of the signal being sampled. The optimum sampling density for remote sensing (typically seen as a uniform sampling technique) should be determined based on the spectra of the underlying signals, although this is seldom pursued in practice. For spatial sampling undertaken at irregular nodes or on non-uniform grids, the literature on non-uniform sampling is growing and may shed light on how optimality in spatial sampling should be defined and what are the major factors in sampling implementation. For the classic sampling (either uniform or not) theorems, infinite sample support in space and time is assumed. However, spatial variation in sampling density and local definition of effective data supports are commonly encountered in practice. Further research must account for the interactions between sampling rate (density) and finite data support in determining the optimum sampling protocols for spatial applications. Moreover, determination of measurement scale over a
nonstationary domain is challenging. Obviously, there will be no single optimal measurement scale for such a domain, but measurement scales can be made to adapt to the nonstationarity in process scale therein. Webster and Oliver (2007) discussed how to design a network of sample sites (data support) so that multiple scales in the underlying RF are captured in a variogram. As mentioned in the preceding section, the CS paradigm should also be explored for optimum accuracy and efficiency in spatial sampling and mapping.

Sophistication of spatial information technology has led to spatial data proliferation. Remote sensors are providing unprecedented amounts of geographic data at increasingly fine spatial, spectral, and temporal resolutions, while various surveys are collecting data at finer spatial detail. However, despite these, our ability to maximize information potentials from multisource data lags behind, as it is hardly easy to analyze and integrate multisource data (often implying different accuracies, resolutions, semantics, or classification schemes). Techniques for data conflation must be developed that can handle scale mismatch and semantic inhomogeneity in multisource geospatial data effectively and efficiently, facilitating information fusion. Conflation of heterogeneous spatial information sources will also benefit from information-theoretic perspectives for modeling and assessing the sources and the fusion products.

Uncertainty is inherent in spatial information and analysis, and should thus be characterized properly. Components of uncertainty-related research include error description (accuracy assessment), error propagation, and management, with the former two being the focus here. Error description can take advantage of validation procedures, which are becoming increasingly integrated in operational remote sensing and spatial information production. It is also important to assess the impacts of errors upon spatial analysis and applications. This is known as error propagation. While analytical approaches based on variance and covariance propagation implicitly assume homogenized scale for model inputs and, if required, model parameters, geostatistical simulation is more robust to scale discrepancies, and should be explored in any scale-dependent modeling of uncertainty and applications. In addition to the conventional methods in which realizations are generated over grid nodes of supports conformal to those of the conditional data (implicitly, points or quasi-points), cross-scale simulation methods are particularly useful in the context of multiscale data and applications, as translating information about error margins is important.

Further reading

Scarcity poses a paradox. If, according to the Merriam-Webster Dictionary, scarcity means “the quality or state of being scarce; especially: want of provisions for the support of life,” then presumably actual scarcity has grown ever less common over the past 200 years, as industrial capitalism has expanded global supplies of food and other material goods to unprecedented levels in both absolute and per capita terms. But, during the same period, the idea of scarcity has grown increasingly pervasive in both obvious and obscure ways. Modern economics takes scarcity as its fundamental theoretical premise and raison d'être, and major strands of environmentalism likewise find motivation in the idea that natural resources are not only finite but also increasingly scarce. The prospect of imminent scarcities of food, energy, water, or other key resources has been a leitmotif of modernity, and chronic economic inequality and poverty have left significant numbers of people lacking basic necessities, apparent victims of scarcity. It is as though society cannot produce abundance without constantly thinking about—and in some places producing—its opposite.

Although the English word dates back to the fourteenth century, scarcity’s prominence as a modern concept coincides with the ascendance of market economies in northwestern Europe in the latter half of the 1700s. Scarcity was associated first and foremost with food, and especially with the political threats that high food prices could pose to the old and declining feudal regimes of the time. Occasional food shortages and famines were, of course, much older phenomena; what was new was the extensive mediation of the food supply by intra- and interstate commerce and the dynamics of supply and demand that this entailed. High prices could no longer so easily be blamed on climatic vagaries or divine misfortune if hoarding, speculation, monopoly, and trade were potential alternative culprits.

In the 10 years beginning with 1795, a series of spikes in the price of grains in United Kingdom prompted a flurry of polemical speeches, pamphlets, and treatises dedicated expressly to the topic of scarcity. Some viewed the deficiency of grain as a natural result of unfavorable weather, basing their arguments on personal observations of harvests in various parts of the kingdom. Others blamed farming methods and the quality of various soils, or referred to data on imports and exports and pointed to disruptions in interstate trade caused by the Napoleonic Wars. But, in the absence of comprehensive agricultural statistics—both for the United Kingdom and for countries whence grain was imported—actual supplies of food were difficult to judge, and the causes of price increases were subject to speculation and debate. Merchants and middlemen were widely accused of hoarding, monopoly, and speculation to create the appearance of (and to profit from) scarcity, regardless of real supplies. Some extended this criticism to landowners who were consolidating their holdings into fewer and larger farms, which critics viewed as more prone to monopoly and more vulnerable to unfavorable weather than smaller farms.

While nominally about scarce food supplies, the debates were more fundamentally concerned...
SCARCITY

with how government should relate to the market economy. Two other pressing issues lent great urgency to this question: the specter of the French Revolution and the emergence of widespread poverty among commoners, many of them recently displaced into urban centers by the Enclosure Acts. In a time of growing national and imperial prosperity, the masses of impoverished laborers were a paradoxical and ominous novelty, and elites feared that high prices – whatever their cause – might result in riots, rebellion, or revolution. In Karl Polanyi’s (1957/1944, 111) words, “When the significance of poverty was realized, the stage was set for the nineteenth century.”

Adam Smith’s Wealth of Nations provided the intellectual ammunition for those, such as Edmund Burke, who argued that free trade and private property were the best – indeed, the only – way to solve imbalances between producers and consumers of food. “Labour is a commodity like every other, and rises or falls according to the demand. This is in the nature of things,” Burke (1800/1795, 6) insisted. Middlemen “are to be left to their free course; and the more they make, and the richer they are, and the more largely they deal, the better for both the farmer and the consumer” (Burke 1800/1795, 24). By this logic, government measures to cap prices or ban hoarding would only make the problem worse by preventing market signals from operating effectively. “Of all things, an indiscreet tampering with the trade of provisions is the most dangerous, and it is always worst in the time when men are most disposed to it: – that is, in the time of scarcity” (Burke 1800/1795, 1).

Thomas Malthus weighed in with An Investigation of the Cause of the Present High Price of Provisions (1800), echoing many of Burke’s positions in defense of landowners and middlemen and in opposition to government intervention. Malthus saw bad weather as responsible for short-term declines in agricultural output, but he argued that the price increases were out of proportion to these shortfalls. Monopoly was not the cause of this disparity, however: in Malthus’s view, the market for food was too large and had too many players for anyone to monopolize it. Rather, he diagnosed the problem as stemming from the Poor Laws, which since 1795 had guaranteed supplements to wages at levels pegged to the price of bread (Polanyi 1957):

the attempt in most parts of the kingdom to increase the parish allowances in proportion to the price of corn … is, comparatively speaking, the sole cause, which has occasioned the price of provisions to rise so much higher than the degree of scarcity would seem to warrant. (Malthus 1800, 4–5)

Giving the poor money simply added to the effective demand for food without increasing supply, further raising prices, even if it did also help diminish suffering by spreading the impact across a larger number of people. The only real solutions were increased production and imports, both of which would come about in response to higher prices; in the shorter term, large farmers and middlemen were to be thanked for raising “the corn to that price which excluded a sufficient number from their usual consumption, to enable the supply to last throughout the year” (Malthus 1800, 15).

At the end of his pamphlet, Malthus shifted the question from food prices to the growing dependence of United Kingdom on food imports. Asserting (without evidence) that domestic agricultural production could not have “gone backwards” in the preceding 20 years, he deduced that “the present inability of the country to support its inhabitants” could only be due “to the increase of population” (Malthus 1800, 27). He referred readers to his Essay on the Principle of Population, originally published in 1798, which he was in the process of almost completely rewriting for the more famous second edition of 1803.
Two points about Malthus’s *Essay* are key to understanding its outsized influence on subsequent thinking about scarcity. The first is that it was fundamentally a moral argument about the nature of good and evil, virtue and vice – what LeMahieu (1979) termed a “theology of scarcity.” Although Malthus dampened his theological claims in the second (and subsequent) editions, he continued to view humans as naturally “inert, sluggish, and averse from labour” (Malthus 2004/1798, 115–116), and he considered moral and physical deprivation to be necessary, divinely sanctioned spurs to virtuous activity. High food prices were therefore actually a good thing, or at least served as a kind of medicine whose effectiveness required an unregulated market economy:

There are some disorders, which, though they scarcely admit of a cure, or even of any considerable mitigation, are still capable of being made greatly worse. In such misfortunes it is of great importance to know the desperate nature of the disease. The next step to the alleviation of pain, is the bearing it with composure, and not aggravating it by impatience and irritation. (Malthus 1800, 1)

LeMahieu (1979, 474) concludes: “Here at last was the Protestant ethic and the spirit of capitalism.”

The *Essay*’s second key contribution was interpreting scarcity as ultimately a function of human population – this was the underlying “disease.” Malthus defined his principle in terms of food: “the power of population is indefinitely greater than the power of the Earth to produce subsistence for man” (Malthus 2004/1798, 19). But neither the reductive circularity of his logic (Engels famously pointed out that even two people would constitute overpopulation by Malthus’s argument), nor the empirical fact that food production has indeed increased more rapidly than population since he wrote, has prevented Malthus’s followers from seeing virtually any environmental or natural resources-related problem as a function of population. Neo-Malthusianism can be understood as a body of thought that ignores the moralism and political context of Malthus’s arguments in order to take – and mistake – his principle of population as a “scientific” insight based on “natural” laws.

By the end of the nineteenth century, the meaning of scarcity had shifted from anomalous and transient episodes of shortage (people spoke of “a scarcity” as a period of time) to a normal, universal condition of human life and activity. The leading proponents of this shift were economists such as William Stanley Jevons, Leon Walras, and Carl Menger, who developed marginal utility theory on the basis of “what has come to be known as the scarcity postulate, an assumption of the universality of the condition of scarcity that at once gives neoclassical economics its focus and provides the legitimacy of its claim to science” (Xenos 1989, 68). (In his study *The Coal Question*, Jevons also developed the famous paradox that bears his name: When per unit costs are reduced, gains in the efficiency of use of a resource will increase, not reduce, its overall use. Scarcity thus becomes self-reinforcing.) Lionel Robbins (1984/1932, 15) summarized the postulate succinctly: “Scarcity of means to satisfy ends of varying importance is an almost ubiquitous condition of human behaviour. Here, then, is the unity of subject of Economic Science, the forms assumed by human behaviour in disposing of scarce means.”

In contrast to the political economy of Smith, Marx, and Mill, neoclassical economics was unconcerned with wealth and value. The new science understood human needs as “constructed solely out of the individual’s preferences, without any trace of social determination” (Xenos 1989, 70), expressed through individual calculations
of economizing self-interest. In one sense this reduced economics to the narrow world of commodity exchange, with scarcity as its fundamental premise. Anything that was abundantly available to all was not worth economizing, and therefore irrelevant to the discipline:

Economics is the science which studies human behaviour as a relationship between ends and scarce means which have alternative uses … It does not attempt to pick out certain kinds of behaviour, but focuses attention on a particular aspect of behaviour, the form imposed by the influence of scarcity. (Robbins 1984/1932, 16–17)

But this formalism also contained the potential for almost infinite expansion as scarcity came to characterize – or could be understood to characterize – a proliferating diversity of phenomena. “Economics is entirely neutral between ends … in so far as the achievement of any end is dependent on scarce means, it is germane to the preoccupations of the economist” (Robbins 1984/1932, 24; emphasis in the original). Even exchange was “subsidiary to the main fact of scarcity” (Robbins 1984/1932, 20): an individual’s time, for example, could be economized in choices about how to “spend” it, provided time were made or perceived to be scarce. Modern macroeconomics also rests on the scarcity postulate, applied at the scale of aggregate output, which is constrained by diminishing returns to capital and labor (Cobb and Douglas 1928; Solow 1956).

Scarcity in neoclassical economics naturalizes more than just a particular model of rationality: “It also universalizes a particular set of institutions – property and markets – which are deemed to be natural results of scarcity” (Xenos 1989, 72). Focusing on exchange-value (price) to the exclusion of use-value affords neoclassical economics the apparent objectivity of quantitative methods based on the universal abstraction of Homo economicus, but this very tractability presupposes that individuals always already appropriate property through markets. The question that preoccupied Burke and Malthus – the extent and legitimacy of a free market, with minimal government interference – vanishes by conceptual fiat under the postulated universal condition of scarcity.

The realization and extension of markets – and therefore the applicability of economic science understood in this way – is of course a historically and geographically specific process attended by contentious political struggles. Markets are not pregiven by nature but must be produced, and the state necessarily plays a major role in that production. It is in this role that Michel Foucault (2007) identified the origins of modern governmental power – government based on an “apparatus of security” rather than on a juridical-disciplinary system – which he traced to debates about food scarcity in eighteenth-century France. There, as in United Kingdom, older measures to keep food prices low began to backfire by inhibiting production and trade; what was needed was policies to foster and manage circulation. According to Foucault (2007, 41–42), a profound shift in the meaning of government pivoted on scarcity:

It means allowing prices to rise where their tendency is to rise. We allow the phenomenon of dearness-scarcity to be produced and develop on such and such a market, on a whole series of markets, and this phenomenon, this reality which we have allowed to develop, will itself entail precisely its own self-curbing and self-regulation. So there will no longer be any scarcity in general, on condition that for a whole series of people, in a whole series of markets, there was some scarcity, some dearness, some difficulty in buying wheat, and consequently some hunger, and it may well be that some people die of hunger after all. But by letting these people die of hunger one will be able to make scarcity a chimera and prevent it occurring in this massive
scarcity operates as a principle of rule and of personal conduct. Indeed, one might say that scarcity represents a sort of precondition for the modern, an epistemological principle on which our lives are built. It operates as part of a powerful discursive formation of the modern world. (Watts 2005, 99)

The Enclosure Acts are the most famous instance of what Marx termed “primitive” or original accumulation, which can be understood as the making scarce of the means of production (including land) and subsistence (including food) through commodification (including the commodification of labor, which brings scarcity to bear on time itself). But as Foucault suggests, the realization of scarcity encompasses much more. Scholars have shown that primitive accumulation is an ongoing process by which the commodity form is imposed on an ever-growing array of inputs and outputs. As Kloppenburg (1988) shows in the case of seeds, scarcity need not be based on actual physical dearth: all that is required is that private property claims be established to some good, and that others be compelled by law, technology, or other circumstance to recognize those claims and purchase that good in the market.

Actual physical dearth can also be produced by the very market processes that benefit from it, and the neoclassical economists’ narrow focus on price plays an instrumental role in this dynamic. Resources that are abundant or freely available, and therefore not economized, can nonetheless be brought into production for exchange, directly as raw materials or indirectly as conditions of production (e.g., sinks for pollution), and these actions can cumulatively degrade or reduce the resources in question to the point that they become scarce at local or larger scales. Or, short of actual scarcity, such actions can prompt measures to enclose the resources and assign property rights to them, effectively turning them into economic goods subject to the logic of scarcity. Such measures are often taken under the sign of the “tragedy of the commons” thesis, according to which the absence of property rights, rather than the market forces that motivate overexploitation, is the cause of environmental degradation.

Neoclassical economic theorizing about market effects on unenclosed (uneconomized) resources has often employed fisheries (Gordon 1954) and pastures (Coase 1960) as exemplars and touchstones from which to draw conclusions for broader application. In a more recent variant, economists understand free or nonpriced “ecosystem services” as “externalities” that should be “internalized” into market signals through the assignment of prices. Costanza et al. (2014), for example, calculate that the value of the world’s ecosystem services...
SCARCITY

dwarfs official global economic output, and the Millennium Ecosystem Assessment prescribes internalization as the solution to addressing global environmental problems (even though it attributes most of those problems to industrialization and globalization). The related concept of “natural capital” equates the ecological with the economic: nature becomes capital, and vice versa, and the conservation of one becomes identical with the conservation of the other. But as Robertson (2006) has shown, the practices of measurement and abstraction necessary to commodify nature are riddled with weaknesses and may well make matters worse.

Neo-Malthusianism arose in parallel to, but distinct from, the consolidation of neoclassical economics in the mid-twentieth century. Broadly speaking, neo-Malthusians focused on the use-values of the natural world, beginning from the axiomatic observation that the Earth is finite, and deducing that a growing human population must inevitably run up against the limits thereof. Progressive era conservation and the emerging science of ecology, coupled with the catastrophic spectacle of the Dust Bowl, provided intellectual and political traction for these views, often expounded (then and now) in the rubric of carrying capacity (Sayre 2008). In Road to Survival, William Vogt (1948) defined carrying capacity as the ratio of “biotic potential” to “environmental resistance” – more encompassing, but otherwise analogous to Malthus’s pairing of population growth and agricultural production. Early neo-Malthusians were also strongly influenced by eugenics, which subsequent proponents euphemized and transmuted into theories of modernization and development. During the Cold War, fears that population growth and resulting food shortages would favor communism in the developing world helped motivate both the Green Revolution (to modernize agriculture and raise yields) and international family planning programs (including coercive sterilization campaigns in places like India). Paul Ehrlich’s famous book The Population Bomb (1968), commissioned and published by the Sierra Club, helped consolidate population as a defining concern of emergent environmentalism. Economists countered with studies that showed declining real costs for natural resources based on technological innovation and substitution; Barnett and Morse (1963), for example, could not find evidence of increasing scarcity in US natural resources except in the case of forestry.

In the 1970s, neo-Malthusians turned to systems analysis and computer-based modeling to assess the prospects for continued economic growth at a global scale. The most famous result was The Limits to Growth (Meadows et al. 1972), which predicted the collapse of the modern world economy within a century. Although more sophisticated than Malthus’s principle of population, the Limits model ultimately reflected the same mathematical disparity between arithmetic and geometric (or exponential) growth. The book provoked raging debates, in which mainstream economists attacked the model on technical grounds while insisting that economic progress would solve environmental problems and extend the limits of available natural resources. Growing prosperity, they argued, would also lead to growing concern about environmental quality and political momentum to protect it – the so-called environmental Kuznets curve. In response, the original Limits authors twice refined and updated their model, reaching broadly similar conclusions as before. Others have built similar models to calculate the “ecological footprint” of human activities, calibrated by the number of planets identical to Earth that would be needed to support those activities indefinitely; values over 1.0 were reached, they claim, in the late twentieth century (Wackernagel and Rees 1996) – a conclusion that critics
might understandably see as proof that the model must be wrong.

The dominant debates about scarcity today cleave along the same lines as they did circa 1970: *either* economic growth has already exceeded (or will inevitably exceed) the limits of a finite Earth, *or* human ingenuity, motivated by market competition and opportunity, will extend those limits indefinitely. What both sides of the debate share, perhaps unwittingly, is an obsession with scarcity as the unquestioned lens through which to examine modern society. Lost are the voices of those who have challenged scarcity itself, whether as a flawed basis for economic reasoning and policy (e.g., Leon Keyserling, who helped design the New Deal) or as an anachronism rendered obsolete by the miracles of modern technology (e.g., ecological anarchist Murray Bookchin). Equally invisible are the views of the man who designed the original *Limits to Growth* model, pioneer systems analyst Jay Forrester (1971) of Massachusetts Institute of Technology, who concluded in a separate monograph that industrialization was the root cause of both population growth and environmental problems, and that restraining economic development might therefore be the best solution. Demographers have concluded that there is no fixed carrying capacity of Earth for humans; their projections indicate, with significant confidence, that the human population will stabilize this century for reasons unrelated to food supplies. Yet mainstream debates continue to focus on “feeding 9 billion by 2050,” as though alleviating hunger were a matter of increased production rather than more equitable distribution.

In this light, it is supremely ironic that the emerging field of behavioral economics, conducted squarely within the neoclassical tradition, has produced clinical evidence that the perception of scarcity can interfere with rational thought. A large body of research indicates that, whether real or imagined, scarcity makes people “less insightful, less forward-thinking, less controlled” (Mullainathan and Shafir 2013, 14). The idea of scarcity causes people to misapprehend their interests and misallocate their attention and resources, leading to self-perpetuating “scarcity traps”: the poor become poorer, the busy become busier, and so on. This is presented not as a threat to the fundamental premise of neoclassical economics, however, nor as a critique of the society that scarcity thinking has helped to produce, but as a useful insight that “sheds new light on how we might go about managing our scarcity” (Mullainathan and Shafir 2013, 15). Scarcity is taken not as a postulate, but as an unavoidable, ubiquitous, universal reality of the modern world.

The most prominent challenge to scarcity thinking was mounted by Karl Marx, who insisted that any shortage – whether of food, land, income, or jobs – could only be understood in relational terms, and that the root cause of imbalances in capitalist society was not scarcity but overabundance or surplus. If there were too many people relative to available jobs, it was not due to any “natural” human propensity to breed, but to excessive amounts of capital that had been amassed and transformed into machinery that displaced laborers. The resulting oversupply of laborers – the industrial reserve army of the unemployed – depressed wages, rendering the poor vulnerable to high prices for food and other necessities. Even for capitalists, the threat of overproduction – which can cause prices to collapse and profits to evaporate – has been a greater threat than scarcity in the history of capitalist natural resources extraction, as Huber (2011) has shown for the case of oil. Perhaps the path to addressing modern scarcity begins by thinking about its opposite.

Science and technology parks

Susan M. Walcott
University of North Carolina at Greensboro, USA

Definition and context

Science and technology parks (STPs) occupy a piece of land configured to promote economic activities of integrated firms, infrastructure, and amenities supporting technology-intensive production and commercialization in innovative enterprises, technology-based start-ups, research institutes, and universities (Bellavista and Sanz 2009). The key geographical feature of these developments lies in their combination of territoriality and functionality, which is targeted to promote a particular type of technology-based economic activity (Asheim 2000). Firms are attracted to these clusters due to their supply of a sufficiently skilled and abundant labor pool, and access to input, output, and assembly infrastructure, along with spaces organized to promote information exchange. The latter can take place in food and drink areas designed to mix workers informally, and/or more formally in lectures and events providing training and networking opportunities. Advanced and developing countries utilize STPs’ spatial agglomeration for a “catch up” technology leap, creating technopole “learning regions” to build local and global knowledge relationships while efficiently concentrating scarce fiscal and human capital in discrete places (Castells and Hall 1994). University “spill-overs” of research and personnel increase the absorptive capacity of companies, promoting codified and tacit knowledge transfer by increasing their proximity.

Physically, STPs appear similar to research centers. Glass buildings and landscaped campuses usually sprout in outlying rather than central city urban locations due to their relative newness and the amount of land assembled for amenities as well as core business functions. The “synergy of amenities, accessibility and agglomeration factors found in large urban regions” (Malecki 1997, 270) indicates that metropolitan scale urbanization as well as localization economies come into play. These characteristics hold whether in advanced countries in North America and Western Europe or in rapidly developing, relatively advanced regions such as East Asia and India. Regional economic development motivated creation of the first STP – North Carolina’s still flourishing and growing Research Triangle Park – in 1959 as a joint government-university-private enterprise. This motivation and underlying triad of contributing interests continues to fuel the spread of STPs around the world where the incentives and supports are strong enough to feed the needs of this particular type of development geared to generate innovation-based profits for corporate and territorial interests.

Unlike endogenously generated regions that loosely include related clusters of high technology companies such as in northern California’s “Silicon Valley” or Boston’s “Route 128,” STPs comprise territorially distinct and specifically configured real estate. High technology-based companies and business incubators (BIs) constitute the core components. Due to the relative inexperience of their occupants, BIs
Science and Technology Parks

rely particularly closely on cooperative networks for training and support. Although research and development (R&D) personnel frequently feel that they are intelligent enough to manage the business end of their innovative spin-offs, STP personnel feel it greatly beneficial to include training in business best practices and encourage teamwork along with other specialized skills for building long-term successful companies.

Particularly in developing countries where attractive amenities such as housing, transportation, retail, entertainment, and education facilities tailored to a globally competitive “knowledge worker” labor pool are in short supply, the STP can include them within its boundaries or cooperate with other interested parties to construct them nearby. Amenities include low-density settings near to prestige research facilities, thus promoting intellectual interaction. More amenities may be introduced in areas where they less frequently occur, such as country clubs, tennis courts, and international schools. This variety of elements and levels of regional development provides some flexibility in definition, but several attributes remain constant. The following sections will consider the aspects and impacts of territorial boundaries, regional development (at various scales), public–private partnership, university technology transfer, birth and growth of innovative companies, and global linkages.

Industrial parks and their STP variant inspired a number of terms as part of post-Fordist (postmanufacturing-focused) “new industrial spaces” forming new “high-tech locations” as an “innovative milieu” on the high-value-adding end of a production chain network (Park 1996). More simply, Henry Ford’s model of a large factory complex where all supplies entered and a finished product exited became eclipsed by a model prioritizing greater variety of products for a market demanding faster and more customized production. This model combined with increased technological sophistication of production tools and methods, drawing on computer-aided elements for both design and manufacturing. The large corporation dissolved into a more “horizontal” organization utilizing several competing but allied suppliers that were often small and medium-sized enterprises (SMEs). Locally clustered concentrations enhanced communication and inspection that increased accuracy and speed while decreasing the “friction of distance.” However, local specializations and widespread telecommunication technologies have enabled global extension of production networks, so STPs draw from local research strengths at nearby institutions as well as featuring multinational companies (MNCs) drawn by these specialties and a perceived desirability of being in or associated with that geographic location. MNCs coordinate basic and applied research with long-distance product development and production, marketing, distribution, service, and financial functions in multiple locations, with the former frequently taking place in an STP and related activities at nearby or headquarter locations.

Castells and Hall (1994) listed three motivations for establishing science parks: reinstitutionalization based on greater infusions of science and technology (S&T), regional development, and synergy creation through promotion of technology transfer to businesses from research institutions. The conscious creation of spatial proximity among these players in the vicinity of an STP is designed to promote communication interaction among humans to create an atmosphere and structural framework conducive to promoting and sustaining constant innovation (Scott and Storper 1987; Castells and Hall 1994). This virtuous cycle requires a suitable physical
infrastructure, institutional development, systemic actor networks, and universities with specific research linked to product in order to foster and embed social relations in a particular place.

Networks and the embeddedness of human and corporate participants are key features in the success of an STP’s economic development mission (Park 1996). These networks consist of multiple dimensions. On the human level, trust-building connections are key attributes for information sharing. In both developed and developing countries, STP managers need to be well connected to government representatives because of the nature and extent of government ties regarding funding and regulations. The first major business in the first American STP, for example, was a major government contractor. The need for ties to multiple government levels became evident, for example, in the case of one Chinese STP that was a product of two national governments but was undercut by the local and provincial government, which did not have a stake in the STPs’ success and started their own rival STP zone. On the micro level, companies benefit best from proximity to similar companies within an STP when managers have good relations with other company managers, and when workers circulate among companies and transmit information that improves their employer’s performance. The density of employment opportunities helps to attract mobile “kangaroo” knowledge workers whose job-hopping corporate cross-fertilization tends to raise the level of innovation within the region.

National governments play an indispensable role in the initial establishment of an STP due to the amount of capital required to assemble the land, physical and intellectual infrastructure, and amenity inducements necessary. Local authorities and finally businesses established within the STP become more important over time. Complex collaboration networks develop to coordinate research, development, production, financing, and other services needed at various stages for businesses in the STP. Corporate or government funds, for example, can be provided to research university laboratories, professors, and graduate students to work on projects targeted for development or commercialization. University technology transfer offices frequently provide assistance with expensive and time-consuming patent applications filed by their employees. The degree of expertise in sophisticated institutions such as Stanford, Massachusetts Institute of Technology, and UK Oxbridge universities supports the success of their related regional STPs. The more cooperative and interlinked the participants, the “fuzzier” the institutional boundaries and the greater the likelihood of successful ventures.

Major universities in more advanced developing countries such as China often have allied STPs supported by their employees and alumni, with students given time off to develop their ideas in special arrangements outside of academic requirements. STPs supply savings in sunk costs by offering occupants otherwise expensive components and services such as computers and printers, telecommunications linkages, training sessions, and opportunities for information exchange with others in the same facility and/or mentors who may come from successful companies related to their area. As Park (1996) observes, “Collaboration among small innovative firms – as well as between large and small firms – can change the local industrial culture and may be the means for regaining regional competitive advantage” (486).

The idea was, and still is, to provide a technical, logistical, administrative, and financial infrastructure to nurture new enterprises so they can eventually survive in an increasingly competitive market. STP funding generally comes from five
sources: universities (including bank borrowing), local authorities, government development agencies, private-sector institutions, and the tenant enterprises themselves. Governments devote considerable resources to science parks as policy instruments aimed at promoting research based on industrial and innovative activity. Proximity promotes the ability to fund, staff, and share resources with outside information sources such as higher education institutes. Science parks provide a nurturing cluster of elements acting as innovation enclaves, populated by groups of related enterprises located in one geographical region or centered at a nation’s science-based park. The clustering and interchange process among industries in the cluster works best when the industries involved are geographically concentrated.

Changes over time

Early observers of STP processes varied from skeptical to enthusiastic adopters (Castells and Hall 1994; Park 1996; Malecki 1997). Examinations of individual STPs and of the underlying concept are far from unanimous in their assessments of success or desirability. Massey, Quintas, and Wield (1992) see STPs largely as land speculation built on wishful “high-tech fantasies”: build it, they will come — then what? Contemporary observers in developing countries are more universally sanguine about the STP strategy favored by economically interventionist governments. At present the strategy of creating a science park to concentrate companies involved in high-technology ventures is globally utilized in developed and higher-level developing countries. Established examples of major parks from East Asia (Japan, Taiwan, Korea, and China) to North America, throughout Western Europe, and in developing regions in Malaysia and Iran have all been studied for their relative successes, strategies, and possible policy applications. Studies indicate that the success of university-linked science parks in the United States and Europe provided global models for next-tier developing countries such as Kuwait, Brazil, Russia, Israel, India, Taiwan, and China seeking to derive economic benefits by building their own. STPs spurring significant growth in newly developed Asian countries include Japan’s Tsukuba, Korea’s Daedeok, Taiwan’s Hsinchu Science Park, and several in China, most notably Zhongguancun in Beijing and Zhangjiang in the newly developed Pudong district of Shanghai, with a high linkage to public policy and governmental support. In several of these cases new urban areas grew up to support the growth of the STP on the outskirts of older cities.

Korea initially established science parks in Taejeon and Kwangju, urban centers that were products of government industrial and regional policies encouraging population density away from the capital city of Seoul in the 1970s and 1980s. Highly educated citizens were particularly targeted to move to developments such as Daedeok Innopolis. These areas acted as an export generator, with R&D centers in the science park drawing largely on global linkages. National government incentives included tax exemptions, desirable infrastructure, cheap land, and financing. These bore fruit as spin-off firms related to research institutions appeared since the 1990s in Daeduck Science Town and nearby Taejeon city. Signs of STP success also lay in increasing linkages and firms of various sizes, resulting from a mixture of post-Fordist corporate deverticalization and national government policy (Park 1996).

Japan created the technopolis complex of Tsukuba as part of a government policy to promote business links between industries and universities. Under the auspices of the national
government’s ministry of international trade and industry, R&D infrastructure along with lifestyle amenities created a landscaped oasis in a mountain setting for high-tech industries employing young graduates from across the country. Planning started in the 1960s for a new city that began to rise in the 1970s and flourished in the next decade with research laboratories, universities, housing, and related civic functions. Tsukuba in turn served as a model for and fed employees to Taiwan’s first successful STP in Hsinchu, on former rural rice paddy land lying several hours outside the capital city of Taipei.

Built by the government in the early 1980s, Hsinchu picked up unemployed Japanese R&D talent to staff numerous high-tech companies including semiconductor manufacturers (Taiwan Semiconductor Manufacturing Company Ltd., United Microelectronics Corporation), and computer, telecommunication, and optoelectronics firms. Hsinchu combined science-themed cultural amenities, proximity to powerhouse universities, and links to Silicon Valley in the United States through alumni and personal networks, reversing previous “brain drain” activity by luring Taiwanese back to rebuild their country of birth in settings similar to those they were accustomed to overseas. Science parks in Taiwan have incubated six major industrial clusters: integrated circuits, computers and peripherals, telecommunications, optoelectronics industry, precision machinery, and biotechnology. As key actuators, science parks play an important role in stimulating high-technology industry by Taiwanese companies, both in Taiwan and in mainland Chinese STPs and special “cross-Straits” parks.

Special areas that in China are variously called “pioneer,” “gazelle,” or “returnee” parks within larger STPs provide incubators, office space, and related facilities for high-technology firms started by Chinese who formerly studied abroad and now seek to utilize local employees for ventures based on lessons learned abroad. Due to the level and nature of skills involved, these returnee entrepreneurs often particularly seek to employ others like themselves who studied at overseas universities. This development is clearly a valuable return on the investment of basic training in the home country, in some cases, and increasingly, including state scholarships to study abroad. The reversal of “brain drain” seen in the past provides valuable new talent with managerial and technology knowledge. Employment advantages of the overseas educated are decreasing as domestic universities raise their level of training, but STPs remain key sites for high-tech economic activity. They are now linked in a national organization so they can share mutually reinforcing strategies and experiences.

Future directions in theory, research, and methodology

A third-generation science park (3GSP) structure is detected as having evolved from a first stage focused on pushing innovative technology with a beneficial regional economic impact. The second stage followed market-led directions and contributed at a national level of economic benefit. The focus of a 3GSP was seen to be at a global level of innovation generation and diffusion along with new management processes that are more sustainable and human-oriented (Kakko and Inkinen 2009). In line with this emphasis, questionnaire and interview methodologies continue to be extensively utilized as in earlier studies for assessing the workings and impact of STPs.

Major challenges shaping the elements of a particular STP include creating sufficiently attractive elements to draw in the type of creative, innovative idea-generating talent desired. Social network analysis, focusing on the particular
structure of human networks involved in information creation and exchange, is increasingly applied to examine the workings of STPs in their role of promoting collaboration among corporate, public-sector, and research entities (Kakko and Inkinen 2009). A new research thrust increasingly focuses on policies promoting these creative/innovative interactions leading to development of ideas and commercialized products. Analysis utilizes approaches from organizational studies, economic development, social geography, urban theories, and educational and human resource studies to account for variables such as culture, climate, systems, resources, skills, and leadership. This focuses particularly on the actions of skilled human actors facilitating flows of knowledge exchange through STP structures (Bellavista and Sanz 2009).

Sea ice formation

Freshwater typically freezes at 0°C; however, because seawater contains a high concentration of salt (seawater with a salinity of 34 contains 34 g of salt per kilogram of water) it does not freeze at the surface until the water temperature falls below −1.86°C. Once it starts to freeze, ice crystals form (called frazil ice) and rise to the ocean surface to form slicks of accumulated crystals that are termed “grease ice.” In turbulent waters the ice crystals accumulate to form loosely aggregated discs, “ice pancakes,” 5–10 cm in diameter. These grow larger becoming pancakes 20–50 cm thick that can eventually reach several meters in diameter. They freeze together and eventually a closed ice cover forms. Under quiescent conditions, the ice pancakes do not form but instead the ice crystals consolidate into uniform sheets of ice, called “nilas ice.” As temperatures decrease further, both consolidated pancake ice and nilas ice thicken by the accumulation of more frazil ice crystals, but also by the growth of “columnar” ice. This is ice that is made up of vertically elongated crystals that can reach lengths of tens of centimeters.

Other mechanisms by which pack ice thickens include winds and/or water currents causing ice floes to converge. When ice floes collide under great pressure the edges break into boulders of ice and the rubble collects in ridges of ice called “pressure ridges.” These jumbled up blocks of ice can, in extreme cases, extend down to 50 m under the water (keels) and tens of meters into the air (sails). Such substantial sails and keels clearly are important in determining the effects of currents and wind on the subsequent movement and transport of an ice field. Conversely, winds are a very effective force for breaking open fields of pack ice. As the ice is forced apart, the water underneath is exposed forming a “lead.” Depending on the speed of the wind, and the strength of the ice floes, leads can be anything from a few meters wide to several kilometers.

As ice crystals form, the dissolved salts in the seawater are expelled and collect as brines between the ice crystals in a network of pores and “brine channels” that permeate the ice matrix. The brine channels vary from a few micrometers to several millimeters in diameter, the size of which is determined by temperature: the amount of ice in relation to the pore/channel volume increases proportionally with decreasing temperature. Additionally, as temperatures decrease, the salinity of the brines will also increase; for example, for ice made from water of a salinity of 34, at −6°C the corresponding salinity of the brine will be 100 and at −10°C it
will be 145. As ice gets older, drainage of brines by gravity gradually results in salt being lost from the ice. This is one of the main mechanisms by which cold, high-salinity water masses are formed, which subsequently sink to the ocean depths and partly drive large-scale global ocean exchange.

Sea ice and Arctic Ocean oceanography

Arctic oceanography and the role that sea ice plays in setting the structure and transforming the water have their formal origins in the nineteenth century. It was the Norwegian explorer and scientist Fridtjof Nansen, during the arctic drift of the *Fram* (1893–1896), who described the characteristic layers of water with different physical properties in the ocean, and the possible interactions between the ocean and the ice. Access to the central Arctic Ocean by ship has historically been extremely challenging and so the sea ice itself has been exploited as an ideal platform for trans-arctic sampling as the icedrifts across the Arctic Basin. The first of these manned scientific stations drifted 2850 km between May 21, 1937, and February 19, 1938. Since then there have been around 40 such drift stations established, the most recent ending in June 2013. During the course of the drift, a program of sampling for oceanographic and meteorological parameters has been conducted which has significantly added to our understanding of arctic oceanography. Ice drift stations have also been set up to tackle particular research challenges, an example being the Surface Heat Budget of the Arctic Ice Station experiment (SHEBA), which aimed to measure the rate at which heat is exchanged between the ocean, the sea ice, and the atmosphere throughout the polar year. The year-long study was supported by the Canadian Coast Guard vessel *Des Groseilliers* which drifted over 2000 km between October 2, 1997, and October 11, 1998.

Sea ice is also used to support autonomous technologies for sampling the seasonally changing oceanic conditions of the Arctic. The current generation of ice-tethered platforms (ITPs) are able to make measurements in the upper 750 m of the ocean using a package of sensors that are able to move up and down a fixed line suspended underneath the ice. Typically, measurements of temperature, salinity, and depth are made at a resolution of 25 cm and the data are sent through satellite links back to the shore in near real time whilst the profiler drifts in the ice for up to three years.

The Arctic Ocean is essentially landlocked with rather limited routes for exchange and communication with the rest of the global oceans. The deepest connection is Fram Strait, which is greater than 3000 m; there is also a shallow entrance at the Bering Straits and further connection through the network of straits and sounds that is formed by the Canadian archipelago. The surface circulation patterns in the Arctic Ocean are dominated by two wind-driven currents: the Beaufort Gyre over the Canada Basin and the Transpolar Drift, which flows from the Siberian coast across the North Pole and exits through the western Fram Strait (Figure 1a). The major inflow to the Arctic is warm and saline Atlantic Water entering via the Barents Sea or through the eastern Fram Strait forming a warm boundary current that encircles the Arctic Basin. There is also a warm and fresh inflow to the Arctic Ocean from the Pacific that brings a third of the freshwater into the Arctic and is a significant source of inorganic nutrients.

The surface of the Arctic Ocean is covered with a seasonal sea ice cover that forms each winter, reaching its maximum extent in March before diminishing through melt and
Figure 1  (a) The Arctic. Blue arrows represent cold currents and red arrows the inflowing Atlantic Water. BG, the Beaufort Gyre; TD, the Transpolar Drift; AW, Atlantic Water. The drift of Fridtjof Nansen’s ship the *Fram* is shown in Green. Darker gray shows the mean maximum winter ice extent from 1979 to 2007 (February) and the lighter gray the minimum summer ice extent (September). (b) The average seasonal cycle of arctic sea ice extent against date calculated from the satellite record from 1981 to 2010; the gray shading either side of the line is the standard deviation.
export to reach a minimum extent in September. The winter maximum extent is typically 15 million km$^2$ whilst the summer minimum is around 5 million km$^2$ (Figure 1b) with a currently observed record minimum in 2012 of 3.4 million km$^2$. The extent of arctic summer sea ice cover is undergoing a rapid decline, decreasing at an average rate of around 14% per decade and some commentators have predicted an ice-free summer Arctic Ocean within a few decades.

The impact of sea ice on arctic oceanography is essentially through three principal mechanisms: (i) the release of dense, salt-enriched brine during ice formation, (ii) the export or release of freshwater during melt, and (iii) the insulating effect of the ice between the atmosphere and the ocean. Other impacts include enhanced stirring and mixing of the water when the ice and ocean move relative to each other. It is important to stress that the structure and properties of the ocean also impact on the formation and retention of sea ice. Consequently, they must be considered as a closely coupled system with multiple feedbacks.

One of the most important oceanic structures in the Arctic Ocean that is intimately related to sea ice is found at depths between 50 and 200 m and is the boundary between cold and fresh polar surface waters and the warm and saline Atlantic Water. It is characterized by a rapid increase in ocean salinity (a halocline) whilst the water temperature remains close to the freezing point. As noted above, it was Fridtjof Nansen who observed that beneath the halocline “this warmer and more strongly saline water must clearly originate from the warmer current of the Atlantic Ocean,” so the halocline is a steep gradient in water density and acts as a barrier preventing the warm Atlantic Water from mixing up into the surface water and causing enhanced sea ice melt.

The formation of the halocline has been linked to the presence of extensive shallow shelves around the Arctic Ocean. Sea ice formation in these areas can produce large volumes of cold and dense brine that flow across the shelf and enter the Arctic Ocean below the polar surface waters and replenish the cold saline waters of the halocline. Another, arguably more likely mechanism is that of sea ice formation inducing brine release and initiating convection in the surface waters. The cold and rather saline water produced sits on top of the Atlantic Water which is then further capped in the summer through sea ice melt. As this seasonal cycle continues the halocline layer becomes fully formed.

A critical measure for the stability of the remaining sea ice cover is the strength of the halocline, measured by the salinity gradient between the surface and the Atlantic waters. This strength of the halocline has been observed to vary between years and geographically. Weakening of the halocline has been linked with the way that fresh water is distributed across the shelves. Any weakening has the potential to allow Atlantic Water to mix more effectively into the surface waters and this enhanced ocean heat flux can reduce the winter growth rates of sea ice and thus the total ice formation during a growth season. Therefore, the formation and presence of the arctic halocline are intimately linked to the formation and retention of sea ice.

One process by which the sea ice can strongly impact the ocean is the formation of polynyas, which in Russian means “ice hole.” They can vary in area from tens to thousands of square kilometers and usually reoccur at specific geographic locations, implying that the mechanism of their formation is related to regional factors. Whilst polynyas can be formed through enhanced ocean heat fluxes causing thinning and melting of the ice cover (termed a sensible heat
Sea ice, ice drift, and oceanic circulation

Polynyas (or latent heat polynyas) can also be formed through a highly dynamic wind-drive process. Often these polynyas are located near the coast with offshore winds pushing ice away from the coast to maintain a region of open water, and there are many such localized polynyas along the arctic coastline. The surface of the water is maintained at freezing point, and as latent heat is lost to the atmosphere ice begins to reform only to be advected away from the coast by the wind. As this process continues, the release of brine from the forming sea ice causes the salinity of the shallow coastal waters to increase while the ocean-to-atmosphere heat fluxes can be many orders of magnitude greater than elsewhere in the polar ocean. The high salt fluxes to the ocean created in these so-called ice factories can ultimately lead to the formation of dense waters that can feed the halocline layer of the Arctic Ocean.

Sea ice in the Arctic goes through an extensive melt phase in the summer when it is warmed from the surface and from beneath. Energy balances at the interface between the atmosphere and the ocean determine when melting will commence, but once started it can establish very effective feedback mechanisms that enhance the melt rates. Surface melting of arctic sea ice creates relatively dark melt ponds which absorb solar energy, greatly increasing the melt rates. As ice becomes mechanically weaker and breaks up, the exposed ocean absorbs significant solar energy at the surface causing melting from the bottom of the ice such that sea ice thickness has been observed to decrease by over 2 m in a summer season. Freshwater from melting sea ice can be exported through the Fram Strait and Canadian Archipelago or retained within the biggest store of freshwater in the Arctic – the Beaufort Gyre.

As summer sea ice continues to retreat, the area of open water and the duration for which there is open water will increase. This will change the way in which ice can impact the Arctic Ocean. The loss of summer sea ice removes the insulating properties of the ice such that there will be increasing heat content of the surface waters by autumn. The effect is a delay in the onset of freezing as ocean heat is removed to the atmosphere. Once freezing starts, there is now a greater area of open water for ice formation and thus the generation of brine enriched waters is occurring over a much more extensive area both over the shelves and over the deep ocean. The delay in onset of freezing leads to a shorter freezing period and thus the ice at the end of the following winter is thinner and more susceptible to breaking up, exposing the ocean surface to solar heating. Therefore the fate of sea ice is inextricably linked to its relationship with the oceanography of the Arctic Ocean.

Sea ice and Southern Ocean oceanography

The Antarctic has been relatively isolated from the rest of the planet since the continent first separated from South America about 23 million years ago. At this point a circum-continent ocean current called the Antarctic Circumpolar Current (ACC) was established and the temperatures on the continent fell until it soon became ice covered – both on land, and with a very large seasonal sea ice cover. In complete contrast to the Arctic, there has never been an indigenous population such as the Inuit learning to live with and exploit the sea ice environment. As a consequence, the region was untouched until recorded history tells us Captain Cook discovered the Southern Ocean sea ice at 66.5°S in January 1773. During the next 100 years many sealing and whaling ships had visited the region, although it took until the late twentieth
SEA ICE, ICE DRIFT, AND OCEANIC CIRCULATION

century for even the continent’s coastline to be comprehensively mapped. It remains a fact that the Southern Ocean is extremely under-sampled in both oceanography and sea ice when compared with the work conducted in the Arctic Ocean. Furthermore, there are still large regions devoid of any data. In this section we will discuss the background oceanography of the Southern Ocean before considering the sea ice and its impact on the underlying waters.

The Antarctic is a central continental land mass surrounded by deep oceans, and Figure 2a shows a schematic diagram of the ocean circulation and extremes of the summer and winter sea ice extent. The isolation of Antarctica and the global wind field formed the Antarctic Circumpolar Current (ACC), and it is the largest continuous ocean current on the planet, circulating clockwise around the continent. The ACC is delineated by four circum-Antarctic full-depth ocean fronts (boundaries that can be clearly identified in temperature and salinity). The northern boundary of the ACC that is most pronounced in temperature and salinity of the surface waters is called the Sub-Antarctic Front (shown in Figure 2a and labeled SAF). The surface temperatures of waters to the south of this front are typically in the range 5 to 7°C. Further south is the Polar Front (PF) which has been historically termed “the Antarctic Convergence,” and surface temperatures again fall, this time to approximately 2 to 3°C. The SAF and PF can sometimes be relatively close, particularly when passing through the constriction between South America and the Antarctic Peninsula, which is called Drake Passage. The other two fronts are much further to the south. They are the Southern Antarctic Circumpolar Current Front (SACCF) and finally the southern boundary of the Antarctic Circumpolar Current (SBACC). Whilst there is much evidence to connect the SACCF with biological processes, it is the SBACC which is the easier to identify and its mean location is shown in Figure 2a as a dashed line. The flow of the ACC is large and in Drake Passage is typically around $100 \times 10^6$ m³ s⁻¹ between the SAF and SBACC.

South of the ACC there are two large closed circulations called gyres (marked on Figure 2a). These are the Weddell Gyre and the Ross Gyre, and both circulate in a clockwise sense. There is no equivalent to the arctic halocline in the Antarctic such that there is less restriction on vertical exchanges of water. Consequently, the gyres are globally important for the production of some of the densest waters in the global ocean – the so-called bottom waters. Finally, south of the ACC and the gyres there is evidence of an anti-clockwise coastal current close to the continent through for example the drift of icebergs breaking from the land ice of the continent. But as data are so lacking close to the continent we cannot say whether this current is continuous all the way around the continent.

The sea ice in the Southern Ocean, as in the Arctic, has a strong relationship with the underlying ocean circulation. The light gray shading in Figure 2a shows the mean minimum sea ice extent in February and at the height of summer, and the dark gray in Figure 2a shows the maximum sea ice extent in September. Overarching all of these general features of the sea ice, we are severely constrained by the lack of data. This is particularly striking when contrasted with the historical data from the Arctic collected from the drifting ice stations, ships, and many tens of thousands of kilometers of sea ice thickness data collected by nuclear submarines since 1958. In the context of sea ice extent, this has not been too much of an issue since the satellite record has produced high quality data since 1981. But for sea ice thickness the only data sources going back any period of time have been field experiments,
Figure 2  (a) The Southern Ocean. The location of the two ocean fronts that delineate the Antarctic Circumpolar Current (ACC) are labeled SAF for the Sub-Antarctic Front and SBACC for the Southern Boundary of the ACC. Arrows represent the schematic circulation direction. The darker gray shows the mean maximum winter ice extent from 1979 to 2007 (September), and the lighter gray the minimum summer ice extent (February). (b) The average seasonal cycle of Antarctic sea ice extent against date calculated from the satellite record from 1981 to 2010; the gray shading either side of the line is the standard deviation.
SEA ICE, ICE DRIFT, AND OCEANIC CIRCULATION

observations by ship collated through the Antarctic Sea Ice Processes and Climate (ASPeCt) program, and a few under-sea moorings equipped with upward looking sonar. The only drifting ice station comparable to the arctic efforts was Ice Station Weddell in 1992 (ISW-1) which followed a track through the Weddell Sea similar to that of Shackleton’s doomed Endurance in 1915.

Figure 2b shows the annual cycle of the mean Antarctic sea ice extent based on daily data from the period 1981–2010, and the gray shading either side of the line is ±1 standard deviation. The incredible range shown in the extent is striking. The minimum sea ice extent is in late February and is approximately $2.9 \times 10^6$ km$^2$; at this time one can see in Figure 2a that the ice is limited to relatively close to the continent and in the Ross and Weddell Seas. In September the extent has increased to approximately $18.6 \times 10^6$ km$^2$ and the northern limit in many locations around Antarctica is close to the SBACC. Where the northern limit of the sea ice extent diverges widely from the SBACC may be due to a relatively poor determination of the mean location of the SBACC due to data limitations, and it is likely not well fixed. The range of sea ice extent over the course of a year is approximately $15.7 \times 10^6$ km$^2$ and the sea ice expands by more than five times the minimum extent between summer and winter. At its maximum, sea ice in the Southern Ocean covers an area larger than the size of the Antarctic continent. This has enormous implications for the thickness of the sea ice: clearly most of it is going to be less than a year old and the only multi-year sea ice (as a consequence much thicker when unrafted) would be close to the coast and the gyres. It is also clear that there is an asymmetry in the seasonal cycle of Antarctic ice extent. Figure 2b shows that the sea ice grows at a steady rate from February through to July, then a much slower rate from July through to the beginning of September, followed by a very rapid sea ice retreat from the middle of September through to February.

Satellite images show that the steady sea growth due to the changing seasons extends outward from the continent. There is relatively high snowfall compared with the Arctic, and surface flooding of the sea ice and formation of snow ice (where sea water permeates into snow and freezes) has been widely observed. In contrast, as the sun returns the ice decays in much of the dark gray region in Figure 2a. The effect of this slow sustained growth versus rapid and distributed retreat is seen in the ocean. The slow growth and continued salinity input increase the density of the surface waters, which, through currently not well-defined processes in the gyres and on the continental shelves, creates water dense enough to sink and form bottom water, which then contributes to the global ocean circulation. The retreat causes a considerable input of low salinity water into the surface waters that are then mixed into the surface layers by wind activity.

Although there have been many regional changes in the distribution of sea ice extent over the length of the satellite record, there is a particularly significant retreat to the west of the Antarctic Peninsula. However, over the duration of the satellite record there has been a slight positive trend in Antarctic sea ice extent. Our understanding of the exact processes by which water density is increased due to sea ice formation is currently limited by a lack of data on water properties, but we expect this to be addressed in the coming decade through innovative techniques such as deploying hydrographic sensors on different species of Antarctic seals. The lack of comprehensive sea ice thickness data will be partially addressed by altimeter-equipped satellites such as ICESat and CryoSat.
Sea ice as a biome

When ice forms, the accumulation of ice crystals is effectively inoculated by a diverse group of organisms commonly found in the smallest size classes of the plankton in the waters from which the ice is formed. Most notably, these include bacteria, unicellular algae, ciliates, small species of copepods, flatworms, and nematodes. Many of these organisms have highly adaptable physiologies that enable them to survive in the brine channels in the ice and/or on the ice surfaces on the undersides of ice floes. In the open oceans these organisms experience rather buffered abiotic conditions in terms of temperature and salinity. In contrast, within the ice they experience vastly changing salinities in the brines and highly variable temperatures that can fall to $-20^\circ$C. Despite the extreme habitat, these ice dwelling organisms can thrive to such an extent that the ice, rather than being colorless, is frequently seen to be strikingly coffee-colored. This is due to the photosynthetic pigments contained within the unicellular diatoms that frequently dominate the sea ice communities in all ice-covered oceans and seas.

In turn, the biology contained within the sea ice is a key source of food for other marine organisms at times when food in the water column is scarce. One of the best examples is the Southern Ocean krill (*Euphausia superba*), a voracious grazer that normally eats plankton. In ice-covered periods the sea ice organisms provide the only food for many populations of krill that have been observed harvesting the algal-rich diet from the undersides of ice floes. The importance of this for the overall Southern Ocean ecosystem is highlighted by the fact that krill is in turn the major food source for squid, fish, seals, birds, and whales in these waters.

Although the study of how organisms are able to survive in the ice and their ecology continues to be an engrossing area of research, in recent years the role of ice in influencing the biogeochemistry of the surface waters of oceans and seas has emerged as a distinctive discipline. For many years it was presumed that a solid cover of ice on the surface of the ocean would effectively seal off the water from the atmosphere. It is now clear that this is not the case and during the process of ice formation, consolidation, and melt there is considerable exchange of gases such as CO$_2$ between the ice and atmosphere and the ice and water. Partly, this is a result of the biological processes in the ice (photosynthesis and respiration), although more recently the influence of cryogenically induced chemical processes has received increased attention.

On ice melt, some of the biology contained within the ice has been shown to inoculate extensive blooms of phytoplankton at the ice edges. Naturally, these are important for the overall biological productivity of these seasonally ice-covered ecosystems. However, a large percentage of the ice production is thought to simply sink to the ocean depths and if it reaches the ocean floor it provides a valuable food source for the organisms living there.

Although scientists have been venturing to the frozen oceans and collecting data for several hundred years now, it is only in the past 50 years or so, with the advent of specialized research platforms, that there have been the internationally coordinated expeditions that have had the resources and opportunities to elucidate the profound implications of sea ice formation, not just for the oceanography of polar oceans and seas, but also for the seasonal dynamics of the biology living in these waters and underlying sediments.

Sea level rise

Stephen P. Leatherman
Stephen B. Leatherman
Florida International University, USA

Coastal zones have been the wellspring of civilization since early times because of the ease of water-based transportation. About 50% of the world’s population lives in this critical interface between land and water, and 13 of the world’s 20 largest cities are located on the coast. Increasing populations and development are placing significant stresses on coastal resources; rising sea level is already causing land loss, putting humanity on a collision course (Figure 1).

Changing sea levels have been the driver of shorelines over geologic time. Tens of millions of years ago, the seas had advanced several hundred kilometers farther inland than today along the US East Coast. These ancient shorelines are marked by the “falls” in the river systems, and many of the major cities and state capitals are located there (e.g., Washington, DC, Baltimore, Maryland, Richmond, Virginia, and Raleigh, North Carolina). This fall line is the furthest upstream position for navigable waters and delimits the inland edge of the coastal plain.

If all the water tied up in the world’s glaciers and ice caps were to melt, sea levels would rise about 70 m, which would be devastating on a global basis. Consider that the Mall in Washington, DC, is little more than 3 m above today’s sea level and the Potomac River there is tidally driven.

Sea levels have also been much lower in the “recent” geologic past, approaching 100 m below present levels approximately 18 000 years ago. Coastal resorts, such as Atlantic City, New Jersey, and Virginia Beach, Virginia, would have been located several hundred kilometers landward of the shoreline at that time as the seas receded to the shelf edge, exposing the wide continental shelf. The Chesapeake Bay and associated salt marshes did not exist during the last Ice Age, and the Susquehanna River was a rapidly flowing river that reached all the way to the shelf edge.

Unlike many other manifestations of climate change, sea level rise is already a problem. While global sea level has only risen about 20 cm in the past century (Douglas 1991; Church et al. 2010), there is clear physical evidence of impacts manifested by coastal land loss on a worldwide basis. Erosion is the physical removal of material at a shore due to wave action. Leatherman, Zhang, and Douglas (2000) showed that beaches on the US Atlantic Coast, not affected by inlets or engineering modifications, erode at about 100 times the rate of sea level rise on average. They analyzed a large database of historical shoreline positions and long-term sea level change data obtained from tide gauges.

Over 70% of the world’s sandy beaches are presently eroding (Bird 1985), and the percentage increases to 80–90% for the better-studied and documented US sandy coasts. While many factors contribute to shoreline recession, sea level rise is considered the underlying factor accounting for nearly ubiquitous coastal retreat (Leatherman, Zhang, and Douglas 2000). Erosion of beaches and bluffs is a major worldwide problem. This land loss has enormous economic impacts; for example, some of the most expensive real estate in the United States is beachfront properties. Examples include Atlantic
City, New Jersey, Ocean City, Maryland, Myrtle Beach, South Carolina, Miami Beach, Florida, and Galveston, Texas, to name just a few of the cities on the beach.

Sea level rise also affects low-lying areas through inundation. Inundation is the permanent submersion of land as the sea level rises. This is not to be confused with erosion, which is the physical removal of sediment from the shore. The combination of inundation and erosion together is termed “coastal retreat.” Inundation is evident in many low-lying marshy areas, which can cause the marshes to die and disintegrate.

Sea level rise is the most certain consequence of global warming and has many adverse effects on the world’s coastal zone. Rising sea levels erode shores by increasing offshore and longshore loss of sediment, directly inundating (or submerging) marshes and other low-lying lands, increasing the salinity of estuaries and aquifers, raising coastal water tables, and exacerbating coastal flooding and storm damage. Beach erosion along developed coasts is the most obvious problem of rising sea level. However, sea level rise causes extreme disruption to humans living on small islands and river deltas. Millions of people will be displaced when large river deltas such as in Bangladesh become inundated; people living on small islands have no place to retreat, and this is especially true of island nations. While the potential impacts of sea level rise itself may not always be the largest threat to coastal environments and human habitability, in conjunction with other stresses they can become a serious problem for coastal
societies where the resilience of natural coastal systems has been reduced.

In addition to problems of erosion and inundation, hurricanes may become more intense due to global warming. Greater losses would occur from stronger storms because damage is proportional to wind speed cubed. In northern climates such as that of Alaska, retreat of sea ice is further amplifying coastal damage by allowing winter storms to pound and erode the land that has served as the home of Inuit and other indigenous groups for many millennia; so much erosion is occurring that villages have to be relocated inland (Arctic Climate Impact Assessment 2004).

Global (eustatic) sea level rise during the past century of about 2 mm annually is partly attributed to thermal expansion of the oceans and melting of small glaciers. About 25% remains unaccounted for, but the most likely candidates are the Antarctic and Greenland ice sheets (IPCC 2013).

The International Panel on Climate Change (IPCC) is the leading international body for the assessment of climate change; the organization was established by the United Nations Environmental Program and the World Meteorological Organization. The IPCC Fifth Assessment Report (IPCC 2013) projects that the global sea level will rise by 26–63 cm by the end of the twenty-first century (Figure 2). While unlikely, a sea level rise of greater than 1 m by 2100 is possible based on several IPCC models.

Sea level rise, which is supported by good historical data, is the primary climate indicator and provides constraints on global climate models. Sea level rise can be considered the “dipstick” of global warming. It is a much better indicator of climate than weather patterns, which are constantly changing. Sea level rise is derived from the long records of tide gauges, some of which extend back more than a century. Tide gauges are available at many of the major ports in the Northern Hemisphere and sporadically elsewhere.

Tide gauges provide the longest historical records of sea level rise and are therefore the best data sources available to determine a trend. The longest continuous tide gauge record in the United States is located in San Francisco and began in 1854, but the vast majority of tide gauge records are much shorter (Douglas 1991). Variability, both interannually and over longer periods, as well as vertical land movements, can severely distort a trend calculation.

In recent decades satellite altimeters have been used to measure sea level rise. Church and White (2006) utilized such data to show an acceleration of sea level rise by as much as 50% since 1930. Other authors (e.g., Ray and Douglas 2011) did not find this acceleration; therefore, more study is required. While tide gauges have a high noise-to-signal ratio, satellite altimetry data, which are nearly global in coverage, can provide more accurate measurements of global sea level rise and hence sooner detect any acceleration of the rate.

In addition to inundation of low-lying areas and the erosion of beaches and bluffs, sea level rise also impacts the coastal zone through saltwater intrusion and higher water tables. Saltwater intrusion occurs when saltwater is pushed into a freshwater aquifer due to a higher water head, and can drastically decrease the amount of available fresh drinking water. This problem is greatly intensified when over-pumping of aquifers occurs.

The Marshall Islands in the Pacific Ocean has a drinking water problem. This is true for many small island states such as the Maldives in the Indian Ocean. The Marshall Islands only has 1–2 m of relief. As the sea level rises, the prism of freshwater under the island is drastically reduced by saltwater intrusion. In fact, the residents of some small coral reef atolls in the Marshall
Islands have to scoop the top 5 cm of the fresh water head or else they will encounter salty water (Leatherman 1997).

Higher water tables are also a problem for reasons other than saltwater intrusion. Higher water tables cause issues with drainage in low-lying coastal cities as there is not enough freeboard for the hydraulic head to cause rapid runoff. This effect is evident in cities, such as South Beach in Miami, Florida. During king tides (e.g., extreme spring high tides), Alton Road, which is the major throughway on the bay side of South Beach, experiences saltwater flooding. In fact, South Beach is undertaking a multimillion dollar project to replumb its drainage system to prevent nuisance occurrences of intrusion of salty water on roadways. Other areas affected by higher water tables include Charleston, South Carolina, and the Galveston Bay area of Texas.

Subsidence causes higher sea level rise relative to surrounding areas. This lowering of the land elevation is due to compaction of underground sediments or the collapse of the forebulge area in response to glacial activity (Douglas, Kearney, and Leatherman 2001). In order for subsidence to occur, the sediments need to be compactible.
such as clay or organic matter. Subsidence can occur from natural or anthropogenic causes, and is a major problem in deltaic areas.

Anthropogenic subsidence is due to the extraction of subsurface fluids such as oil, water, and natural gas. Such activities, especially over-pumping of groundwater, have resulted in inundation of parts of San Jacinto National Monument in Houston, Texas. This monument is an important historical area—it was the famous battleground where General Sam Houston defeated Antonio López de Santa Anna’s Mexican army for control of Texas. Due to the severe inundation experienced here, the Houston–Galveston Subsidence Control District has banned groundwater mining, and residents are now required to obtain water from rivers, which is purified through treatment to make it potable.

Deltas are one of the world’s most vulnerable areas to sea level rise in terms of endangering vast numbers of people, especially during the advent of coastal storms. There are millions of people living on deltas who are vulnerable to natural and human-induced subsidence, global sea level rise, and large coastal storms, especially hurricanes, cyclones, and typhoons.

Deltas are made of rich deposits of sediment forming flat, low-lying land. Human settlements are easily built on these flat lands and are prime agricultural areas. Salt marshes also abound. Deltas are prone to erosion and inundation in response to rising sea level. New Orleans is the only major US city located on a delta, which has been built over the last few thousand years next to the Mississippi River that drains the mid-section of the country. The original city was built on the natural levee of the delta, but further expansion with increasing population led to the draining of wetlands and development of areas below sea level. Hurricane Katrina in 2005 graphically demonstrated their vulnerability when the levees were breached, flooding 80% of New Orleans. Nearly 600 people drowned in the flood waters, making it one of the worst natural disasters in US history.

Breaching of the New Orleans levees is not a rare event; in fact, it has happened more than 20 times in the past (Colten 2005). Hurricane Betsy in 1965 also flooded 80% of New Orleans, and the US Army Corps of Engineers constructed much stronger fortifications following this devastating event and pledged that the levees would never fail again. It has been said that there are two kinds of levees—those that have failed and those that will fail in the future.

New Orleans exhibits the highest relative rate of sea level rise in the United States—it amounts to 1 cm per year. Eighty percent of this rise is due to natural and anthropogenic subsidence with the remaining 20% being the result of global sea level rise. New Orleans is also in the track of major hurricanes from the Gulf of Mexico, and Louisiana is the US erosion “hot spot” with beach erosion rates of up to 15 m per year.

Tokyo is another vulnerable city built on a delta, and almost half of this capital city has been built below sea level (termed a “below zero city” by the Japanese). In addition to vulnerability from typhoons, Japan also has the additional coastal hazard of tsunamis. Another Japanese city that is partly below sea level is Yokohama, which has the same vulnerabilities as Tokyo. The devastating effects of the 2011 earthquake and resulting tsunami that struck Japan demonstrate the vulnerability of all low-lying areas, especially cities near or below sea level.

Venice, Italy, is built on the Po River delta and is experiencing major issues with sea level rise, both from local subsidence due to oil and gas withdrawal and from global sea level rise. Venice was originally built on a marsh during medieval times and was once the world’s largest trading port. It is a major tourist attraction, with the famous Piazza San Marco dominated by the great
church of St Mark. The problem is that Venice is experiencing a high level of relative sea level rise and is frequently flooded during winter storm events termed “acqua alta” or “high water” (Figure 3). This salt water flooding is destroying the wooden doors and even the mortar of the brick and stone buildings of the famous churches and monuments such as the bell tower.

One proposed solution to prevent flooding in Venice is called the MOSE (Modulo Sperimentale Elettromeccanico, Experimental Electromechanical Module) project, modeled after the Thames Barrier that protects London from North Sea storm surges. This coastal engineering approach involves sealing off the three inlets to Venice lagoon using a retractable dam system. These massive structures would be able to rise out of the water and close the inlets during acqua alta events to prevent flooding of the city, but remain open at all other times to allow flushing of the lagoon. This tidal flushing is critical as Venice has no sewage treatment system and relies upon water movement to remove pollutants from the lagoon enclosing the city.

Figure 3 An “acqua alta” event at Venice, Italy, causing saltwater flooding during winter storms of residences that is also damaging iconic landmarks and historical buildings. Photo ZioNicco, courtesy of Wikimedia Commons.
Implementation of the MOSE plan has proceeded slowly largely because of the high cost of construction. Also, the moveable dams would have to be in the “up” position and hence the inlets closed at all times to prevent flooding if sea level were to rise just 30 cm, which would prevent flushing of the bay. Venice is considered one of the most romantic cities in the world and a popular tourist destination, but this would not remain true if the canals were grossly polluted.

There are many ramifications of rising sea level, and the Chesapeake Bay can serve as a microcosm of sea level rise impacts. This area experiences a wide range of impacts from sea level rise. The long shoreline (e.g., nearly 10,000 km) encompassing the Chesapeake Bay is subject to coastal erosion. Local tide gauges indicate local sea level has risen 0.35 m in the past century, which is about double the global rate during this time period.

One of the consequences of slowly rising sea level has been the diminution and loss of small islands in Chesapeake Bay due to long-term erosion and submergence (Leatherman et al. 1995). These vanishing lands, such as Smith Island, named after the great British explorer Captain John Smith, are also experiencing saltwater intrusion and higher water tables. The cause of this high relative sea level rise is a global sea level rise of 20 cm from the melting of glaciers and thermal expansion of water (e.g., eustatic sea level rise), plus local subsidence from geologic factors (e.g., collapse of the glacially induced forebulge) and probably also the withdrawal of groundwater for agricultural purposes (Douglas, Kearney, and Leatherman 2001).

The western shore of Maryland is a cliff shoreline composed primarily of sand, silt, and dewatered clay termed “marl.” This shoreline is experiencing land loss, albeit at a fairly slow rate, at only centimeters per year, because of the erosion-resistant nature of the marine marl. The cliff erodes in chunks from wave action at its base, exposing a plethora of fossils and making it one of the best places to find sharks teeth in the world. Many houses and even roads have fallen over the 20 to 30 m-high cliff into the water as erosion has progressed over the past century. Point Lookout, located where the Potomac River meets the main stem of the Chesapeake Bay, is one of the most scenic spots on the bay. This area has lost 50% of its land in the past century (Leatherman et al. 1995).

The bluffs of the eastern shore contrast sharply with the flat and low-lying western shore. Erosion does occur on the bay edge, but the primary response to rising sea level is the submergence (e.g., inundation) of land and drowning of salt marshes. Between 1938 and 1988, one third of the salt marshes on the eastern shore have been lost due to sea level rise (Leatherman et al. 1995). These salt marshes are very important for the ecology of the Chesapeake Bay, being a base of the food chain and primary source of nourishment for many organisms, including economically important oysters and blue crabs.

Coastal marshes can sustain themselves during a slow rate of sea level rise. These marshes accrete vertically through sediment input and/or biomass production. However, when sea level rise reaches a certain threshold value, these marshes can no longer sustain themselves and become inundated, resulting in massive land loss. These land loss events can occur over wide areas within a few decades as the individual plants become waterlogged and sulfates build up in the soil layer beyond their tolerance levels (Stevenson, Ward, and Kearney 1986).

Island communities in the Chesapeake Bay have been dramatically affected by rising sea level. These islands have been depopulating because of severe erosion and inundation that leaves less room to live and farm as well as bringing...
SEA LEVEL RISE

the problem of saltwater intrusion. The highest points on these bay islands rarely exceed 2 m.

Poplar Island in the Chesapeake Bay is an example of a bay island community that is rapidly disappearing. The first recorded sale of Poplar Island in the late 1670s indicated an area of 560 ha (Leatherman et al. 1995). In 1848, the island was accurately mapped by the US Coastal Survey at 300 ha. In the early 1900s, the town on the island had a general store, post office, school, church, and sawmill. Erosion was becoming such a major problem that the island was completely deserted in the 1930s. Poplar Island, at an erosion rate of 4 m per year, was expected to completely disappear by the year 2000. However, the US Army Corps of Engineers saved the island through implementation of a restoration project to help protect endangered black ducks.

Perhaps of all coastal areas the most vulnerable to global climate change and sea level rise are small island nations (Leatherman 1997). These areas have limited resources and little to no means of preventing the impacts of sea level rise. Small island nations are characterized by their size, limited range of natural resources, susceptibility to natural hazards, limited biological diversity, great distance from other markets, extensive land/sea interface per unit area, extreme openness of economies, low resilience of a subsistence economy, and narrow range of skills and lack of educated specialists (UN General Assembly 1992). These characteristics make island nations very vulnerable to external stresses, particularly sea level rise impacts.

Coral reef atolls are oceanic islands that are volcanic in origin. A coral reef atoll begins as an extinct, subsiding volcano. As the volcano subsides, coral growth forms a fringing reef. These coral reef atolls are very low-lying and susceptible to sea level rise. The Maldives is an island nation in the Indian Ocean that consists of 26 coral reef atolls. Sea level rise is already causing extreme problems in the Maldives. Erosion of sandy beaches is impacting the tourism industry, and therefore the Maldives economy. Additionally, sea level rise is resulting in saltwater intrusion and loss of fresh drinking water.

There are two responses to sea level rise: mitigation and adaptation. Mitigation must be undertaken on a global scale to reduce the rate of sea level rise, while adaptation can be accomplished on a local or national level. Mitigation can slow the rate of sea level rise, which would reduce the impacts. The goal of mitigation is to reduce the sea level rise to a rate at which the impacts can be reasonably accommodated through adaptation.

Hurricanes are historically known to force retreat because a catastrophe is sometimes necessary to convince coastal inhabitants to abandon the area. It would be wiser to anticipate a certain rate of beach loss and prohibit construction within a designated distance from the shore. Adaptation to sea level rise can be one of three approaches: planned retreat, accommodation, or protection. Planned retreat (Figure 4) involves moving development and infrastructure landward as coastal erosion encroaches. This is the best method along little-developed coasts, but in highly developed areas, such as Miami Beach, retreat is not economically or politically viable.

Accommodation is another method to respond to sea level rise. Accommodation consists of building elevated homes to adjust to projected future water levels. Houses built on strong pilings and elevated high enough can survive coastal storms; the surge will flow underneath the structure, causing little damage during these episodic events. This response method is best combined with retreat or else the structure will still be vulnerable to coastal erosion on sandy beaches.

Protection is the method of using soft or hard engineering approaches to protect the land from a rising sea. Stabilizing the shoreline with seawalls was once a common method of
responding to sea level rise, storms, and coastal erosion. Seawalls are massive concrete structures built to protect upland areas that are developed with houses and infrastructure. Seawalls are costly, and eventually they need to be replaced or protected with rock riprap or concrete tetrapods in response to progressive beach erosion. A concrete seawall can successfully protect the land behind the seawall, but the beach will erode. The seawall constructed on Galveston Island, Texas, following the Great Hurricane of 1900, prevented erosional loss of urban development and stopped overtopping of storm surges, but the recreational beach was lost long ago.

Beach nourishment is now considered a much better solution than hard stabilization, but it can be more expensive. Nourishment through the introduction of new sand to build wide beaches protects buildings and infrastructure by serving as a buffer to storm waves and surge. In addition, the recreational beach is maintained for both residents and tourists to enjoy. However, beach nourishment only sets back the erosion clock, and additional sand is required over time as it only treats the symptoms (e.g., erosion) and does not cure the disease (e.g., rising sea level).

Sea level rise is clearly affecting the world’s coast, and the impacts will be exacerbated in response to accelerated sea level rise. The most vulnerable landforms are deltas and small island nations. Millions of people reside on low-lying river deltas, some of which are in the poorest countries in the world, such as Bangladesh, Egypt, and Nigeria. These countries, with large populations and few resources, do not have the

Figure 4  A house on the Outer Banks of North Carolina in the process of being moved inland due to coastal erosion. Photo Jimmy Luby. Reproduced by permission.
SEA LEVEL RISE

ability to undertake large-scale projects to mitigate sea level rise impacts. However, sea level rise affects all coasts and is a large economic burden even in developed countries. For example, the Chesapeake Bay in the United States has more than 10,000 km of developed shoreline. The cost of shore protection for this area as a whole is prohibitive so that only highly developed areas such as Annapolis, Maryland, can achieve a high enough cost-to-benefit ratio to merit major stabilization efforts.

Unfortunately, there is no ultimate answer to prevent sea level rise. Reduced greenhouse gas emissions can help slow down the rate, but the sea level is still rising. A global agreement to reduce emissions does not seem possible as China, India, and other major developing countries are emitting more carbon dioxide each year. Sea level rise is a very slow process, and the best solution is to plan ahead for its consequences. Unfortunately, the public does not typically plan for sea level rise until it is too late, and politicians are much better at responding to a sudden crisis (e.g., hurricane landfall) than to a slow one (e.g., rising water level).

Security

Ian Klinke
University of Oxford, UK

In its most basic form, security is the absence of threat, whether real or perceived. Throughout history, different issues, objects, and polities have been perceived as threatening and it is therefore difficult if not impossible to uncover a transhistorical and transcultural essence to security. Security has become a ubiquitous term in modern societies, governing highly different social contexts from national defense to cyberspace, and from airports to suburban crime statistics. Security is often invoked by states and their elites to foster support for exceptional measures, such as the restriction of basic human rights, targeted killings, or military invasions. Any call for such measures depends upon a certain level of insecurity or fear in society to seem pertinent and legitimate. The shaping and sometimes manipulation of this threat perception is key to the functioning of security discourses. Yet, despite its omnipresence and omnipotence, security is also elusive as a concept and a practice. It has become so interwoven with the social fabric that it is often difficult to locate or define.

Debates on security have traditionally been situated in security studies, a subdiscipline of international relations. Human geographers and those working on the margins of the discipline have made a number of important interventions into these debates, particularly by rethinking the question of security in an explicitly spatial register. Inspired by the end of the Cold War and the new security architectures that emerged with it, much of this work has challenged security as an expert-level realm of military knowledge. These transformations initially saw the emergence of critical geopolitics, an approach that investigates the role of problematic mental and cartographic maps in global security and human security, a paradigm that has placed the individual at the center of debates on international security. In the late 1990s, geographers started to discuss the displacement of security practices by a deterritorialized logic of risk. More recent research has tried to understand the development of security practices in a biopolitical age, tracing how they transform when states seek to govern populations through the attributes of life itself. In doing so, they have drawn attention to security dynamics in a number of areas that have received less attention in security studies: borders and territory, urban counter-terrorism and resilience, energy and climate change, and finally biosecurity.

Approaching security

Research in critical geopolitics emerged in the late 1980s and early 1990s to understand the role geopolitical knowledge had played in mediating between political elites, the military-industrial complex, and the wider public during the Cold War. It has approached geopolitics as a security discourse that surfaced in imperial Britain and traveled through Nazi ideology and Cold War strategy and into the unipolar world order and the “global war on terror.” Written by and for the state, geopolitical discourse naturalizes insecurity, conflict, and war as part of the human condition and suggests that balance of power considerations rather than ethical
SECURITY

concerns should be a guide to the pursuit of (national) security. Drawing on postcolonial theory, poststructuralism and feminism, critical geopolitics has helped to unearth the often banal and gendered identity dimensions involved in security discourses (Dalby 1990). In doing so, it has investigated the ways in which threats are constructed as emerging from far away, supposedly exotic and dangerous spaces, like the Soviet Union or the Middle East. Key to this endeavor is the insight that the constant articulation of insecurity is in fact the precondition for the state’s very existence. It follows that states should be understood not as security providers in a straightforward way, but as sources of global instability. Critical geopolitics has remained a vibrant field that continues to produce research on a wide array of security issues, including terrorism, humanitarianism, and global health.

Human security is a politically explicit approach to security that has tried to shift the referent object (that which is to be secured) from the nation-state to the scale of the individual. Drawing on a wide variety of ideological sources, including liberalism and feminism, human security was enshrined in the 1994 United Nations Human Development Report and has remained a powerful paradigm both inside and outside of academia. Part of its success has followed from the broadness if not the vagueness of human security, a syntagm that has variously included the freedom from poverty, hunger, diseases, pollution, torture, and forms of political oppression. Feminist geographers have stressed that human security makes visible vulnerable groups that do not pop up on the radar of narrowly state-centric and military conceptions of security. It is through human security that the politics of the family and of the gendered body can emerge to challenge hegemonic and gendered constructions of global security. More recently, there has been concern among geographers that the concept of human security is losing its emancipatory edge by increasingly speaking truth for rather than to power. Indeed, human security has the potential to be conscripted to power as a legitimation for humanitarian interventions into sovereign states that are deemed particularly hazardous to human security, as happened in the 1999 NATO bombing campaign on Yugoslavia.

By the end of the Cold War a number of incidents, including the Chernobyl disaster, had made it apparent that the world was facing new and human-made threats, which were neither of a military nature, nor could they be countered at a territorial level, but which were nevertheless commonly framed as security issues. In the mid-to late 1990s, these transformations prompted work around the concept of securitization. Securitization tries to capture the dynamic process by which previously merely political issues are turned into security issues (Buzan, Wæver, and De Wilde 1998). Securitization occurs when agents utter “security” and successfully move an issue from the realm of normal politics into that of panic politics in order to authorize exceptional measures that were previously legally or ethically impossible. In order for a securitization to be successful, these agents (elites, bureaucracies, scientists, companies, NGOs) make a case that although the survival of some vital referent object (the state, the environment, the economy, an identity) is threatened and a point of no return is about to approach, the issue is also resolvable. They will call for exceptional measures to be implemented at global, regional, national, or local scales, depending on the way a threat is framed as a security issue. Securitization has remained a useful tool for geographical research, even though critics have held that the concept lacks an explicitly political agenda and remains too analytically static to capture the complex interplay of twenty-first-century globalization and geopolitics.
At the same time as the concept of securitization started to gain academic impetus, other researchers suggested that the broadening of the security agenda to encompass nonmilitary threats should best be read as a new paradigm—risk (Ó Tuathail 1998). They proposed that as an industrial society organized around scarcity was making way for a wealthy society geared toward the management of hazards, the logic of security was slowly being replaced by one of risk. The government of risk, which is seen to have taken a foothold in Anglo-American societies in particular, challenges the logic of security in a number of ways. First, threats such as environmental disasters and terrorist attacks are now seen as deterritorialized and therefore no longer constrained by a particular territorial state. Moreover, rather than emanating from a foreign and threatening external space, they emerge from the midst of modern society. Second, such hazards are no longer immediate but long term, constituting threats to survival only in the distant future. Finally and most importantly, a state that operates in a modality of risk tries to manage hazards rather than removing them. It construes threats as being of such a nature that they cannot simply be eliminated but must instead be controlled and minimized through a complex set of precautionary governmental practices. In sum, this calculation of risk is not so much targeted at the causes of insecurity but at governing the future through predictive modeling. While earlier security discourses strove to eliminate insecurity, the logic of risk tolerates low levels of insecurity while trying to improve the resilience of modern society at a distance. As deterritorialized threats are unlikely to disappear in the foreseeable future, policy can only aim to reduce their frequency and impact. Under the government of risk, previously exceptional measures are made permanent and unexceptional, thus becoming normalized, everyday, and often unnoticeable.

This invisibility of security links up the literature on risk with that of securitization. Arguably, the calculation of risk becomes the dominant governmental rationality in a society that is already saturated with the logic of securitization. While the defenders of the concept of securitization understand security as a cycle in which issues become both securitized and desecuritized (moved off the security agenda), others have been more skeptical, arguing that security is a logic that subsumes democratic life through the progressive normalization of exceptional measures. This becomes clearest in a biopolitical age, which can be seen to emerge when the modern state starts to intervene in its population’s life, its health, welfare, productivity, and even sexuality. This biopolitical mode of power is closely connected to the rise of the welfare state and the idea of social security. As theorists of biopolitics point out, however, there is a dark side to a form of power in which the preservation of life may legitimate death. This often happens when states establish legally exceptional spaces through emergency laws that allow violence to be inflicted on bodies that have their rights as political subjects removed from them, as witnessed in the global war on terror (Gregory 2007). Geographers have been particularly visible in tracing these transformations in five areas: border, urban, energy, environmental security, and biosecurity.

Security issues

The border is often seen to have originated with modern territoriality and the creation of sharp outer boundaries that distinguish one sovereign state from another. Borders have been
securitized for a number of reasons, including military conflicts, but only in the cause of the twentieth century have they become governed through technologies such as fences, watchtowers, passports, and computers. Today the main purpose of borders is to mediate between two of society’s fundamental desires: mobility and security. Borders increasingly function as membranes that filter wanted mobility (tourism, business) from the unwanted (“illegal,” criminal, or terrorist migration). In the biopolitical age this is done through techniques of racial profiling, biometric data surveying, and the import of military technology at border crossings (Amoore 2006). There is a clear identity dimension to border security in its materialization and expression of anti-immigrant discourses that are home to the most advanced capitalist societies. The terrorist attacks of 9/11 led to an upsurge of border securitization, most visibly at airports. Although these were initially met by public outrage, they were subsequently normalized and increasingly seen as a necessary part of travel.

Another and closely related issue that geographers have explored is the securitization of urban space. In response to a perceived vulnerability to global terrorism, modern cities have seen a number of profound changes to their socio-material fabric, including gated communities, mobile checkpoints, and the explosion of CCTV technology. In the same way as the biopolitical border tries to filter wanted from unwanted migration, the resilient city tries to separate out “good” from “bad” urban circulation. The reconfiguration of the built environment according to principles of counterterrorism is no recent trend and many of its policies were previously tried out in urban warzones and divided cities. Although they are fueled by discourses of insecurity that rely on traditional inside/outside binaries, these transformations of urban space are also integrated into the calculation of risk and the way cities market themselves to investors as being secure. In the mid- to late 2000s, cities in the Global North increasingly became the target of policies that tried to create defensible space in ways that were inconspicuous. Working at the design stage, this invisible fortress urbanism introduced discreet but permanent fortifications into urban life, from concrete flower pots to collapsible pavements, all of which tried to provide security without a climate of fear (Coaffee, O’Hare, and Hawkesworth 2009). These debates have drawn attention to the way in which new security architectures manifest themselves materially in the urban landscape.

In recent years, journalists, scholars, and policymakers have self-evidently treated energy as a security issue. Yet, despite the prominent place that energy has had within twentieth-century geopolitical writing, military strategy, and logistics, it is especially since the 1970s and even more so since the 2000s that energy supply has become framed as a core matter of national security in many states of the Global North. This is due to a perceived scarcity of hydrocarbons, a concentration of the remaining fuels in states that are typically thought of as unstable or undemocratic, and the fear of piracy along key sea routes. Human geography has done much to interrogate the imaginative geographies behind this concern with natural resources and to problematize deterministic readings of global energy politics as a “scramble for resources.” Whether energy is securitized is very much a question of the local context. The 2003 US-led invasion of Iraq was not justified by a securitization of Iraqi oil but had to rely on other sources of public legitimacy. Nevertheless, despite this absence, the securitization of energy was very visible at the level of everyday practices, as research on the sport utility vehicle in the United States has shown (Campbell 2005).
Debates on the environment in the 1990s asked whether it qualified as a security issue and in what ways. While in the early 2000s insights from critical security studies and critical geopolitics were imported into the debate to unsettle some of its underlying assumptions (Dalby 2002), discussions in the late 2000s turned to questions of causality, calculation, and prediction as well as to the ethics of framing the environment as a security issue. In doing so, these discussions focused less on nuclear hazards and increasingly on the issue of human-induced global warming. Environmental security therefore tends to deal with the impact that drought, flooding, storms, and the melting of Arctic sea ice have begun to have on the security of humans and nonhumans. Particular emphasis has been placed on resilient infrastructure, which often determines whether natural disasters turn catastrophic. Similarly to energy security, much of the media and policy debate on climate change has focused on whether global warming will increase the likelihood of armed conflict in the future. Scholarly research has cautioned against overly deterministic arguments that do not take into consideration the complex ways in which climate change impacts on conflict landscapes. Crucially, it has shown the analytical limits of the concept of securitization in accounting for environmental politics, questioning whether the environment is best served by securitization and the logic of national security, geopolitics, and militarization that tends to accompany it.

The final and perhaps most recent area of concern is biosecurity. Biosecurity deals with the protection of human from nonhuman life, particularly pandemics, which have in the past included the plague, HIV/AIDS or the H1N1 virus. Human geographers have paid particular attention to the way in which global health security has operated in an unequal neoliberal political economy and tends to be scripted by the states of the Global North. Debate has focused on international nodes like airports and seaports at which governments seek to prevent the spread of diseases through emergency measures. It has also interrogated the (often racist) geographical imaginations that operate behind these policies. Pandemics are often constructed in similar ways to terrorism. On the one hand, they are framed geopolitically as emerging from far away and threatening places in the Global South or the Far East that need to be contained, controlled, or disciplined. On the other hand, they are treated as externalities of modern global mobility that emerge from the very target of biopolitical governance – the population. This split is particularly visible in debates around bioterrorism. Crucially, biosecurity is a governing rationality that seeks to anticipate the evolution of biological forms that are yet to emerge (Hinchcliffe and Bingham 2008). It therefore treats these organisms as dynamic threats that cannot be eliminated but only managed in the way that other risks are. While this governing of the future is long term, the outbreak of pandemics can be sudden and therefore potentially rather easy to securitize. The geographical literature is undecided as to how successful the securitization of pandemics like HIV/AIDS has been in the past, and skeptical as to whether it is ethically desirable.

SECURITY

Sensor networks, the sensor web, and the Internet of Things

Steve H.L. Liang
University of Calgary, Canada

Neil Gross’s article, “The Earth Will Don an Electronic Skin,” provides a compelling explanation of the sensor networks and sensor web vision: “In the next century, planet Earth will don an electronic skin. It will use the Internet as a scaffold to support and transmit sensations. This skin is already being stitched together. It consists of millions of embedded electronic measuring devices: thermostats, pressure gauges, pollution detectors, cameras, microphones, glucose sensors, EKGs, electroencephalographs. These will probe and monitor cities, endangered species, the atmosphere, our ships, highway traffic, fleets of trucks, our conversations, our bodies–even our dreams.” Figure 1 illustrates the concept of the sensor web as an electronic skin of planet Earth.

The scope of this entry is to provide an architectural overview and research challenges of the sensor networks and sensor web. As sensor networks and sensor web technology become more widely available, they are becoming essential tools for all GIScientists and geographers to collect, analyze, and share observation data. This entry presents the architectural components involved in an end-to-end sensor web system, from the sensor nodes in the field to the interoperable sensor web services on the web. Design tradeoffs and research challenges are also introduced.

The remainder of the entry is organized as follows: In the section “Sensors,” an overview is first given of the sensor network technologies, with a focus on the wireless sensor networks (WSN). At the end of the section, the sensor networks long tail issue is introduced leading to a discussion of the need for a sensor web infrastructure to capture the sensor networks long tail. In the section “Sensor web,” the OGC sensor web architecture is described and the open problems from a big sensor data management perspective are presented. The next section presents the next generation sensor web: the Internet of Things. This is followed by a conclusion.

Sensor networks

Sensors

A sensor is a device that is capable of observing a phenomenon and returning an observed value. A sensor detects and responds to physical stimuli, such as movement, light, heat, and so on. Today various physical, chemical, and biological properties can be measured and monitored by in situ sensors or remote sensors. Sensors are everywhere and include satellite-based sensors providing multispectral information about the Earth’s surface (imagery, land cover, vegetation indices), airborne sensors for detailed imagery but also for laser scans of physical or human-constructed structures (LiDAR), and sensors near, on, or under the Earth’s surface measuring anything from physical characteristics (pressure, temperature, humidity) and phenomena (wind, rain, earthquakes), to the tracking of animals, vehicles, and people.
Technical advances are allowing sensors to be smaller, lighter, and more energy efficient.

**Sensor networks or networked sensors**

A sensor network (SN) is a computer network consisting of spatially distributed sensors with the purpose of cooperatively monitoring physical and environmental conditions. In addition to being comprised of one or more sensors, each node in a sensor network is typically equipped with a communication device which incorporates means of transmitting data, from wires to cellular phones to microwave radios. Figure 2 shows a spectrum of sensor network devices, from large, expensive satellites, to tiny, cheap RFID (radio-frequency identification) tags.

Today, it is feasible and economically viable to deploy a large number of sensor networks to continuously monitor our environment. In fact, many sensor networks, including both in situ and remote, have been built and deployed over the past decade. The combination of these heterogeneous sensing systems can provide enormous amounts of timely, comprehensive, continuous, and multiresolution observations for applications, including environmental monitoring, underwater monitoring, habitat monitoring, and battlefield and disaster management. Examples of large-scale operational sensor networks include the regional-scale NEPTUNE (North-East Pacific Time-series Undersea Networked Experiments) ocean observatory network monitoring long-term changes at water depths ranging from 17 to 2660 m and the global-scale Argos network of buoys measuring temperature and salinity of the world’s oceans.

Sensor networks can also be mounted on mobile platforms including, for example, aerial tramways, robots, unmanned aerial systems, and satellites.

**Wireless sensor networks**

Recently, a new breed of sensor networks, called wireless sensor networks (WSN), is seamlessly immersing itself into our daily lives. A WSN is a network of sensors, each with an embedded processing unit and a wireless communication device. Each sensor is placed into the physical world and interacts with its environment. New technologies, such as microelectromechanical systems (MEMS), allow the WSN nodes to be constructed at the micro- or even nano-scale, which results in greater portability and flexibility than is otherwise possible.

Worthy of note, not all sensor networks are wireless sensor networks and many references do not differentiate between the two. This entry considers any sensor network that consists of sensors with networking capabilities, and they can use wire, wireless, or even underwater acoustic communication protocols. Wireless sensor networks means the WSN nodes that are described in this section.

A WSN node consists of four basic components as shown in Figure 3: a sensing unit, a processing unit, a transceiver unit, and a power unit. Many applications require additional
modules such as a location-finding unit and a power generator.

Sensor units usually have two subunits: sensors and analog-to-digital converters (ADCs). The analog signals produced by the sensors based on the observed physical phenomenon need to be converted to digital signals by the ADC, and then sent to the processing unit. The processing unit is programmable and provides computation, storage, and bidirectional communication with other nodes in the system. The processing unit interfaces with the sensing unit, performs basic signal processing (e.g., simple translations based on a sensor’s calibration curve), and disseminates the data according to the objective of the sensing task. Individual WSN nodes use the transceiver unit to communicate and coordinate with one another, as it is not feasible to bring direct Internet connectivity to each WSN node—the Internet communication module is too costly and it consumes too much power. The WSN nodes form a multihop network by forwarding each other’s messages, which can greatly extend the coverage of the monitoring system.

Through the exchange of messages, the WSN network can also perform in-network processing, for example, reporting the average temperature across a region or monitoring spatial change over time (Duckham 2012). This flexible communication structure allows us to
produce a network that performs decentralized sensing and computing tasks. Such in-network processing capability is a key differentiator between traditional data logger–based monitoring systems and WSN–based systems. Interested readers should refer to Duckham (2012), which provides an in-depth foundation of the methodologies and algorithms of such decentralized computing in a geospatial context.

Each WSN node needs a WSN operation system (OS) to manage the above hardware components. Subject to the resource constraints of typical WSN nodes, these nodes cannot use traditional OSs, such as embedded Linux. They require very specific operation system designs on architecture, programming model, scheduling, memory management and protection, communication protocols, resource sharing, and support for real-time applications. Existing WSN OSs include TinyOS, Contiki, MANTIS, and so on. Farooq and Kunz (2011) provide a comprehensive survey on the current state of the art in WSN OSs.

When considering deploying a WSN for applications, it is important to know the necessary components in the system. Figure 4 shows a typical tiered architecture of a WSN–based monitoring system, and this architecture has been widely deployed in field applications (Mainwaring et al. 2002).

The lowest level consists of the WSN nodes that are able to perform general purpose computing and networking in addition to sensing tasks. These small, battery–powered nodes are placed in areas of interest and embedded in the environment. Because they are placed very close to the observed phenomenon, these nodes can often use small and inexpensive off–the–shelf sensors. These WSN nodes as a whole can achieve high spatial resolution through dense deployment. Compared with traditional data–logger approaches, which use a few high–quality sensors with sophisticated signal processing, a WSN–based monitoring system provides high fault–tolerance against occlusions and component failures.

![Figure 4](image-url) A tiered architecture of a WSN–based monitoring system.
Ultimately, data from each WSN node needs to be propagated to the Internet. Each local wireless sensor network has at least a gateway, which often has more computing, storage, and energy capability (e.g., more storage space for caching the historical data from the WSN nodes and larger battery and solar panels). The gateway can communicate with the local wireless sensor network and provides connectivity to the transit network. Depending on the environmental constraints, each transit network design may have different characteristics with respect to expected fault-tolerance, energy efficiency, cost, real-time requirements, and manageability. For example, the transit network may use a single-hop wireless communication protocol to reach a long range or adopt a series of WSN nodes in a path from the gateway to a base station. Finally, the base station connects to sensor web service servers to place the sensor measurements in interoperable, reusable, and machine-readable web service interfaces and data formats.

When choosing a wireless sensor network for field deployment, the following list of performance metrics needs to be considered (Tilak, Abu-Ghazaleh, and Heinzelman 2002). In fact, these performance metrics are also the main research challenges in developing and deploying wireless sensor networks.

- **Energy efficiency/system lifetime.** Nodes in wireless sensor networks are powered by batteries and in some cases with rechargeable batteries and solar panels. As a result, these nodes must be energy efficient to maximize system lifetime. The lifetime of a single WSN node is in fact not the measure of the system lifetime, as a WSN is a cooperative sensor network. A WSN’s system lifetime can be measured by generic parameters, such as the time until half of the nodes in the system die, or by application-directed metrics, such as when the network stops providing the application with the desired information about the phenomena.

- **Latency.** Latency is defined as the time duration between the time instant when the observation happens and the time instant when the observation result is delivered to the interested user or application. Due to the high energy costs of the wireless communications between the nodes, there is a tradeoff between latency and energy efficiency.

- **Sampling frequency.** Obtaining accurate information is the primary objective of a sensing task. Higher sampling frequency can improve the accuracy because it reduces the need for interpolations between discrete data points. However, there is a tradeoff between sampling frequency, latency, and energy efficiency. A WSN should be adaptive so that the intended application obtains the desired accuracy with acceptable delay and with minimal energy consumption. For example, a sensing task can achieve the same objective by either requesting more frequent data dissemination from the same sensor nodes or distributing data dissemination from more sensor nodes with a lower sampling rate.

- **Fault-tolerance.** A WSN node may fail due to surrounding physical conditions (e.g., in a wildfire scenario) or when its batteries run out. It may be difficult or not economically feasible to replace existing nodes. A WSN must be fault-tolerant such that noncatastrophic failures can be hidden from the sensing task. Fault tolerance can be defined as the ability to sustain sensor network functionalities without any interruption due to sensor node failures. One effective strategy to achieve fault-tolerance is data replication. However, replicating data in different nodes...
requires energy. There is again a tradeoff between data replication and energy efficiency. A data replication strategy should be sensing-task-specific. For example, WSN nodes can only share and replicate higher priority data and neglect other data.

- **Scalability.** Depending on the application, the number of WSN nodes may reach an extreme value of millions. When the number of nodes in the network grows, the communication frequency between the nodes may also grow, thus consuming more energy and reducing system lifetime. For large-scale networks, it is likely that localizing interactions through a structured topology and aggregation will improve scalability.

Eventually, the observations collected by the sensor networks need to be sent to a data repository via the Internet so that they can be used by applications. However, from a data management perspective, we find that the so-called long tail phenomenon exists in sensor networks. A long tail distribution means a large number of occurrences are far from the “head” or the central part of the distribution (hence the long tail). Anderson (2006) popularized the concept of the long tail in his book *The Long Tail: Why the Future of Business Is Selling Less of More*, in which he mentioned Amazon.com as an example of a business applying this strategy in the online bookstore business. For example, before the establishment of online bookstores customers could only purchase books from physical bookstores. However, physical stores tend to concentrate on offering popular book titles, that is, focusing only on the head of the long tail. Less popular books are commonly unavailable from physical bookstores. Customers may not be aware of books that they might be interested in because they cannot see them on the shelves in their local bookstores. Such a long tail has been found in a variety of businesses. Similarly, sensor networks also exhibit such long tail properties.

Today most researchers rely on the sensor data portals hosted by a few large-scale government and research institutes (e.g., World Meteorological Organization (WMO), Global Earth Observation System of Systems (GEOSS), National Oceanic and Atmospheric Administration (NOAA), National Aeronautics and Space Administration (NASA), and Environment Canada) to search for and download sensor measurement data. The number of these portals is relatively small, but these portals provide substantial amounts of continuous and long-term sensor measurements. These sensor data are quality controlled, calibrated, indexed, stored, and published through the web. We can call these sensors and their data the “head” in a sensor networks long tail graph, and the head of sensor networks is currently accessible to the researchers. However, the number of local-scale sensor networks, such as the WSN nodes deployed and operated by individual scientists, has grown exponentially in recent years. These sensors/data are not accessible to most researchers. Heidorn (2008), in his article “Shedding Light on the Dark Data in the Long Tail of Science,” described this particular troublesome class of “Dark Data.” They are not indexed nor stored at the centralized sensor data portal, so they become nearly invisible to most scientists and other potential users. These sensors and data are more difficult to find and less frequently reused than those in the head of sensor networks. As a result, they are more likely to remain underutilized and eventually become lost. Consequently, there is a strong need to integrate these heterogeneous sensor networks into a coherent and interoperable global observation system, and such a system is termed the “sensor web.”
Sensor web

While sensor networks are primarily concerned with interconnecting the physical sensor nodes (e.g., the networking and in-network processing aspects of a monitoring system), the sensor web is mainly concerned with interconnecting the observation data and applications (e.g., interoperability and innovation-in-assembly). However, integrating diverse sensors into a coherent and interoperable observation system is complicated. Sensor network nodes are computers in the field. The design and deployment of the sensor networks are constrained by the application and the physical environment. Different environmental conditions in the field represent different challenges (e.g., remote location of the sensors, power constraints, extreme weather conditions, etc.). Different challenges lead to different designs and tradeoffs. As a result, these specialized sensor network systems have become islands of information systems. A coherent information infrastructure is needed to treat sensors in an interoperable, platform-independent, and uniform way.

The concept of the sensor web reflects such a kind of infrastructure for sharing, finding, and accessing sensors and their data across different applications. It hides the heterogeneous sensor hardware and communication protocols from the applications built on top of it. Similar to the World Wide Web (WWW), which acts essentially as a worldwide computer, the sensor web can be considered as a worldwide sensor. In the sensor web, users, applications, and sensors can access, as a single unit, vast amounts of data and processing power from a large number of widely distributed, heterogeneous WSNs or individual networked sensors.

Some references refer to this system as the worldwide sensor web, because the connection among these sensor networks is typically achieved via the WWW. It is worth noting that the concept of the sensor web is evolving, as evidenced by the wide range of sensor web definitions (Gibbons et al. 2003; Liang, Croitoru, and Tao 2005), and some references do not differentiate between the sensor networks and the sensor web. The key differentiator between the two is that while sensor networks research is mainly concerned with the networking and in-network processing aspects of sensing systems, sensor web research is mainly concerned with the data management and data interoperability aspects of sensing systems.

Open Geospatial Consortium Sensor Web Enablement (OGC SWE)

Similar to many global-scale information infrastructures, such as the WWW based on the World Wide Web Consortium (W3C) open standards, the sensor web also requires open standards to fulfill the sensor web vision. The Open Geospatial Consortium (OGC) Sensor Web Enablement (SWE) standards are the fundamental building blocks for the worldwide sensor web. The first version of the SWE specifications was approved as standards between 2006 and 2007 and the second version was approved between 2012 and 2013. They offer the following functionalities.

- Description of the observations collected by sensors to enable further processing.
- Description of sensor metadata including properties and behavior of sensors, as well as correlating reliability and accuracy of collected measurements.
- Access to observations and sensor metadata based on standardized data encodings and appropriate query and filter mechanisms.
- Tasking of sensors for the acquisition of observations.
To provide the above-mentioned functionalities, OGC SWE consists of two layers of standards. Each layer of standards deals with a “level of interoperability” issue. The two layers are: (i) SWE information models, and (ii) SWE service interfaces. The SWE service interfaces provide a standard way for sensor networks to access and exchange resources over the web, while the SWE information models provide a standard way to describe the information exchanged between the sensor networks. The two layers of the SWE framework are detailed below.

The purpose of the SWE information model is to allow applications to understand and use sensor networks data.

In SWE information models, the sensor web consists of three elements: (i) Observation, (ii) Sensor, and (iii) Phenomenon. It seems obvious that these are three different things; however, people often tend to use them interchangeably. The concepts underlying these entities are defined by OGC as follows:

1. **Observation**: an act of observing a phenomenon, with the goal of producing an estimate of the value of the phenomenon.
2. **Sensor**: an entity capable of observing a phenomenon and returning an estimated property value of the phenomenon.
3. **Phenomenon**: an event or physical property that can be observed or measured.

The relationship between these can be described using the following description: **Observations Use Sensors to Observe Phenomena**. Figure 5 illustrates the relationship between the three basic entities of SWE information models.

With the major entities and relationships identified, OGC then defines corresponding standard information models and encodings for the above three major sensor web entities.

The ISO/OGC observation and measurement (O&M) is the core of the sensor web, and it provides a conceptual model to represent data of spatiotemporal observations. Moreover, Sensor Model Language (SensorML) provides a generic model and XML encodings to describe both in situ and remote sensors and related processes. Regarding phenomenon-based models, since there exist ontological definitions for phenomena in different domains, SWE leverages the existing standard efforts, such as the SWEET ontologies for earth sciences (https://sweet.jpl.nasa.gov/) or the IOOS ontologies for marine sciences (https://ioos.noaa.gov/).

In addition to O&M and SensorML, there is the SWE Common standard describing common and basic data types used throughout the SWE framework. As SWE Common is primarily an implementation standard describing syntaxes and encodings, interested readers can refer to the OGC SWE Common 2.0 standard specification.

In the OGC O&M standard an observation is defined as an event of observing a phenomenon, with the goal of producing an estimate of the value of the phenomenon. O&M is a standard conceptual model and physical encoding for observations and measurements.

One misconception about the sensor web is that we tend to think “sensors” are the major interest of the sensor web. The name “sensor” web easily misleads us to view it from a...
sensor-oriented perspective. However, here it is argued that it is in fact the “observations” that are the major focus of the sensor web. Most of the sensor web applications are more concerned with observations than with the sensors that make the observations. Therefore, a standard model for the observations, such as O&M, is in fact the core of the sensor web. Figure 6 shows the basic observation model of O&M.

In the O&M model, an observation should at least have the following six mandatory properties. Each property is necessary in order to make an observation useful.

1 **Feature of interest.** Feature of interest is an identifiable object that is associated with the observed phenomenon. An observation results in a value being assigned to a phenomenon. The phenomenon is a property of a feature, the latter being the feature of interest of the observation. Feature of interest is a critical concept that allows O&M to be a generic model accommodating observations made by both in situ and remote sensors.

2 **Phenomenon/observed property.** Phenomenon is the observable property of the physical entities measured and quantified by the observation. Examples of a phenomenon can be temperature, humidity, or chemical concentration.

3 **Procedure.** The observation uses a procedure, which is often a sensor but may be a computing model or a simulator. For example, a thermometer can be the procedure for performing a temperature observation.

4 **Results.** An observation result is an estimate of the value of a phenomenon. This is the goal of an observation. A result is not only a value. It consists of two parts: (i) result value, and (ii) unit of measure. For example, 15°C

---

**Figure 6** Basic observation model of O&M. Bröring et al. 2011. Reproduced from MDPI.
is an instance of an observation result, while 15 is the result value and °C is the unit of measure.

5 Time. There are three temporal attributes for observations. An observation has a result time referring to the time when the observation’s result became available. Then an observation has a phenomenon time referring to the time instant or period when the result applies to the property of the feature of interest. For some observations, their result time is identical to the phenomenon time. However, there are important cases where they differ. Take water quality monitoring as an example. Where a measurement is made on a water sample in a laboratory, the phenomenon time is the time the water sample was retrieved from a river or a lake, while the result time is the time the laboratory procedure was applied. In some cases, an observation may have a valid time describing the time period during which the result is intended to be used. Valid time is commonly used in forecasting applications.

6 Location. An observation does not have an inherent location property. An observation’s principal location of interest is usually associated with the ultimate feature of interest but sometimes is associated with the observation procedure, according to the specific scenario.

The object-based model (or the ISO OGC feature model) and the field-based model (or the ISO OGC coverage model) are two common models of geographical information. O&M provides an additional view, an observation-based view of the geographical information. It is worth explaining the relationships and differences between these models or views.

ISO 19109 describes the term “feature” as a “fundamental unit of geographic information,” and in many GIScience literatures, features are called objects. The general feature model (GFM) presented in ISO 19101 and ISO 19109 defines a feature type in terms of its characteristic set of properties, including attributes, association roles, and behaviors, as well as generalization and specialization relationships, and constraints. The feature model presents a viewpoint of the world in terms of the set of discrete identifiable objects that occupy it.

ISO 19123 describes the coverage model as a principal alternative model for geographic information, and in much GIScience literature coverages are referenced to as fields. This viewpoint presents a perspective of the world that is property focused, highlighting the variation of a property within the (spatiotemporal) domain of interest. These viewpoints are not exclusive, and both are used in analysis and modeling.

ISO 19156 describes observations concerned with the data collection event. The purpose of an observation event is to assign a value to a property of a feature. The results of a collection of observations of the different properties on a feature can provide a complete description of the feature (or object) instance. Alternatively, the results of a collection of observations of a specific property on a collection of different features provide a discrete coverage (or field). The other properties of the observation are the important metadata (such as time, unit of measurement, quality, etc.) concerning the estimation of the value(s) of a property on a feature of interest.

In particular, observations are concerned with properties (e.g., temperature, humidity, status of on/off) whose values are determined with an identifiable procedure (e.g., a sensor), in which there is an uncertainty in the estimated result. The metadata provided by the observation instance are necessary in order to use the observation result for further analysis.

In addition, we can use the example data table of Figure 7 to illustrate the relationships among
the three models or viewpoints. The table is a dataset comprising values of a set of properties (e.g., Value\textsubscript{n}m) at a set of locations (e.g., x\textsubscript{n}, y\textsubscript{n}). A row of the table offers the properties of a single location and this row can be considered as a representation of a feature (or an object). A column of the table provides the variation of a specific property across the set of locations and this column can be considered as a representation of a coverage (or a field). A single cell in the table provides the value of a single property on a single feature. In the case that the value is the result of an observation event, this cell and the associated metadata form an observation of the O&M model.

A sensor is capable of observing a phenomenon and returning an estimated value of the phenomenon. SensorML is both a conceptual model and a physical encoding for sensors. SensorML provides a framework within which the geometric, dynamic, and observational characteristics of sensors and sensor systems can be defined.

There is a great variety of sensor types, and SensorML established a common framework to accommodate these different types of sensors. The key concept of the framework is the abstract model of processes as the atomic unit for modeling different types of sensors. SensorML provides the following functionalities:

1. Supporting the discovery of sensors by providing a means for encoding sensor metadata.
2. Providing information that can be used to interpret and analyze data produced by the sensor (e.g., the parameters of the sensor calibration).
3. Allowing the description of post-processing steps applied to sensor data for data reconstruction in an a priori process of data creation.

In the SensorML model, a process (a sensor is a special case of process) comprises the following components.

1. **Inputs, outputs, and parameters.** A process takes one or more inputs and, based on parameters of a methodology, generates one or more outputs. Inputs and outputs represent “ports” where outside processes exchange data with this process. Parameters can be considered as a special type of input, which is specifically required by the methodology of the process.

2. **Position.** Positions provide the location and orientation of a process at some discrete moment in time. Positional information is critical for the use of sensor observations. Positional information includes not only location but also orientation. Orientation is especially important for remote sensors. For example, knowing in what direction a traffic camera sensor is facing is vital in order to make use of the images taken by the camera. For mobile sensors, positional information is temporal in nature because positional information changes over time when the sensor moves.

3. **Metadata group.** The purposes of the metadata group are (i) to support discovery of resources, (ii) to qualify process results, and (iii) to assist human understanding. These metadata include identifiers, classifiers, constraints, capabilities, properties, contacts, documentation sources, and history.
The OGC Sensor Observation Service (SOS) provides standardized access to observations and sensor metadata of all sensor systems. Sensors can be characterized in at least three different ways: (i) proximity to the phenomenon being sensed: that is, remote versus in situ; (ii) mobility: that is, fixed versus mobile; and (iii) duration/lifetime of the sensor: that is, temporary/disposable versus permanent. SOS's extensible interface is able to hide the heterogeneity of the different sensors above. SOS provides two major functionalities: (i) it fetches observations according to spatiotemporal queries, and (ii) it describes the sensor according to spatiotemporal queries. SOS is not just a web service for users to download observations. SOS can filter out observations according to constrained queries. The query for observations or sensors can include one or many of the following constraints: (i) a specific sensor that reports the observations; (ii) specific time period(s) for which observations may be requested (can be real-time, historical, or even forecasting data); (iii) a specific phenomenon that is being observed by the sensor; (iv) a specific geographical region that contains the sensor; and (v) a specific geographical region that covers the feature of interest of the observations. Detailed operations and schemas can be found in the OGC SOS specification. Bröring et al. (2011) offer a comprehensive review of the second version of the OGC SWE specification (including SOS 2.0) with a focus on the improvements from version 1.0 to version 2.0.

The difference between SOS and WFS (Web Feature Service) needs further clarification because the two share several similarities and there are existing implementations that use WFS to serve sensor observations. The major difference between the two is that while WFS uses a very flexible modeling approach to encompass a real-world entity, SOS defines a focused common model for sensors, observations, and phenomena. WFS uses Geography Markup Language (GML) application schemas to define the specific properties of each type of feature. Clients of WFS in a particular domain must have a priori knowledge of the application schemas used in that domain. In contrast, SOS models are not domain-specific, and the client does not need a priori knowledge of domain-specific application schemas. For applications concerned with sensor observations, using SOS improves the applications' interoperability.

The purpose of Sensor Planning Service (SPS) is to provide a standard web service interface for collection assets and for the support system that surrounds them. A collection asset is an available means of collecting information. Collection assets include, but are not limited to, sensors or actuators. It can also be a simulation system, or any other information-gathering asset. SPS provides three major functionalities: (i) to assist in making task feasibility plans, (ii) to execute feasible task requests for collection assets, such as a sensor or sensor networks, and (iii) to query where the measured data can be accessible after the completion of the task. A typical use case for an SPS is updating a sensor's sampling frequency or the flight path of an unmanned aerial vehicle.

Organizations and research projects around the world are building the worldwide sensor web by establishing large-scale sensing systems with the SWE standards. The number of successful deployments demonstrates the maturity and suitability of the SWE standards in real-world applications. In 2013, the UK Ministry of Defence (MoD) funded an assessment of the maturity of implementations of OGC SWE standards (Percivall 2013). Bröring et al. (2011) and Percivall (2013) both offer a nonexhaustive list of the SWE applications and research projects around the world.
Sensor web research challenges

The following discussion highlights some open challenges and future work in the area of the sensor web. Corcho and García-Castro (2010) offer their view on the research challenges from a semantic sensor web perspective. Bröring et al. (2011) discuss some open research challenges from an interoperability perspective. Below, this entry will focus on some open problems in this research field from a big sensor data point of view.

The term “big data” is used to describe datasets that are too large or too complex to manage and process with traditional database management systems (DBMS) and data processing applications. The most widely recognized model for big data is the 3Vs model. The 3Vs model defines big data as data that are large in volume, velocity, and variety. And each “V” would pose different data management challenges. Sensor data in fact are considered a typical big data source with all of the 3Vs data challenges. Below the 3Vs model is used as a framework to discuss the sensor web research challenges.

**Volume:** One characteristic of big data is the large data volume, which can mean large size or large number of data records. While the data volume in social media is enormous, some even predict the size of sensor data will be 10–20 times that of social media. As the number of sensors and the size of the sensor data grow exponentially, how to store, transmit, process, analyze, and visualize sensor web data in large volumes is one of the major challenges. New big data architectures have been proposed and developed, including the MapReduce framework, Apache Hadoop and related projects (Shvachko et al. 2010), the Lambda architecture, and Storm (Marz and Warren 2015), and so on. However, these new frameworks are not specifically designed for spatiotemporal datasets. As the “spatial is special” argument is especially valid in the sensor web context, specialized spatial algorithms and architectures need to be proposed and developed.

**Velocity:** The velocity characteristic refers to the rate at which data are produced. Unlike the human participants in social media, the sensors in the sensor web can produce data in very high frequencies as long as they have a sufficient power supply. For example, Boeing jet engines produce 10 terabytes of sensor data every 30 minutes during flight. As a result, efficiently processing the high-velocity sensor data streams becomes very challenging, especially if we consider the geospatial nature of the sensor data. Many existing geospatial algorithms and architectures need to be updated in order to deal with the high volume combined with the velocity of the spatiotemporal sensor data streams. For example, the traditional request/response client-server architecture and DBMS may not be suitable for handling the high-velocity sensor streams. The publish/subscribe architecture and data stream management system (DSMS) is an alternative emerging data processing solution worth further investigations. Huang (2014) proposed GeoPubSubHub, a publish/subscribe architecture for the sensor web. The core of the GeoPubSubHub is the aggregated hierarchical spatial model (AHS) model, which is a new algorithm based on the DE-9IM designed specifically to efficiently determine topological relationships between continuous incoming sensor data streams and a large number of predefined queries (i.e., subscriptions). Huang scaled up the AHS model by developing the distributed AHS model based on MapReduce, a typical big data management methodology. The AHS model and the distributed AHS model are
examples of updating existing geospatial algorithms and architectures to handle the big data volume and velocity challenges.

**Variety:** The variety challenge includes non-aligned data structures, inconsistent data semantics, and incompatible data formats. In general, the variety characteristic refers to the differences between data records. In the context of the sensor web, the OGC SWE interoperability framework has been demonstrated to be useful and practical for addressing the sensor web variety issues, especially on observation exchange. However, while SWE provides a high-level semantic and syntactic interoperability framework, additional semantic annotations and domain-focus models are still required in order to improve the interoperability further. For example, Sheth, Henson, and Sahoo (2008) proposed that the semantic sensor web investigate the role of semantic annotation, ontologies, and reasoning to improve sensor discovery and sensor integration. The global hydrology communities demonstrated a great example by working collaboratively and defining domain-focus models for groundwater, surface water, and water quality observations based on the SWE framework. The result of the collaboration is the OGC WaterML standard and the OGC SOS hydrology profile (Valentine, Taylor, and Zaslavsky 2012). WaterML 2.0 was accepted as an official OGC standard in September 2012, then endorsed by the US Federal Geographic Data Committee (FGDC), and has been recommended for adoption as a joint WMO and ISO standard. Once officially adopted by WMO Commission for Hydrology, the hydrology communities around the world will have a truly global and interoperable framework on which to build a worldwide hydrology sensor web. More similar efforts are required in order to fulfill the worldwide sensor web vision.

For any large-scale distributed system (e.g., the WWW), both communication and data management fall back to the problem of resource discovery. Similarly, the sensor web needs an efficient and effective discovery mechanism, such as a registry, a search engine, or a recommendation engine, specifically for the sensor web. Jirka, Bröring, and Stasch (2009) developed a discovery mechanism in the sensor web, proposing two components, namely Sensor Instance Registry (SIR) and Sensor Observable Registry (SOR), offering mechanisms to search for sensors, exploit basic semantic relationships, harvest sensor metadata, and integrate sensor discovery into already existing catalogs. While the traditional centralized registry approach may be suitable for relatively static geospatial datasets and sensor networks, it may not be suitable for the always changing sensor networks and their data. New approaches need to be explored in order to address the dynamic and transient nature of sensor networks. For example, Liang and Huang (2013) proposed a hybrid peer-to-peer (P2P) architecture for sensor web research discovery, in which every sensor web service also serves as part of the sensor web service discovery infrastructure (i.e., a peer node). These nodes operate on a cooperative model, where each peer leverages the others’ available resources (i.e., central processing unit, storage, bandwidth, etc.) for mutual benefits. The decentralized design enhances the scalability of the sensor web to accommodate a very large number of sensors and users because it is more reliable due to the fact that it has no single point of failure and it achieves better load balancing by distributing the system load.

In contrast to the traditional top-down taxonomy-based registry approach, crowd-sourced folksonomy-based recommendation engines
recently emerged as an innovative approach to address the resource discovery issues in large networks. Some real-world examples include Netflix recommending movies, Delicious recommending URL bookmarks, and Flickr recommending images. A recommendation engine’s collaborative filtering framework can aid users to deal with the petabytes of data that are generated by the sensor networks. For example Rezel and Liang (2011) developed SWE-FE (folksonomy extension), a folksonomy-based recommendation system for the sensor web. SWE-FE is a collaborative tagging system that exploits the geospatial information associated with three key components: tags, resources, and users. SWE-FE is able to recommend new sensor networks and datasets according to the similarity of a user to the rest of the users in the sensor web system. In order for sensor web users to find relevant, fresh, and complete search results about their sensors and data of interest, new approaches that differ from traditional registries are needed.

The Internet of Things – the next-generation sensor web

In the past 50 years, information technology (IT) has twice radically reshaped every organization and business. During the 1960s and 1970s, the advent of computers brought the first wave of IT-driven transformation which automated individual activities in the value chain, from order processing and bill paying to computer-aided design and manufacturing resource planning. The birth of geographical information systems (GIS) is a typical result of the first wave of IT-driven transformation. In the 1980s and 1990s, the rise of the ubiquitous and inexpensive Internet unleashed the second wave of IT-driven transformation. The second wave broke the barrier of geography and enabled coordination and integration of the individual activities automated in the first wave. In a GIS context, web-based GIS, virtual globes, spatial data infrastructure (SDI), location-based services (LBS), and location-based social networks are some examples of the results of the second wave of IT-driven transformation. Following the advent of computers and Internet, the Internet of Things (IoT) is projected to be the third wave that will radically transform the world again (Porter and Heppelmann 2014).

In the near future, millions to billions of small sensors and actuators will be embedded in real-world objects and connected to the Internet forming the IoT. The basic premise of the IoT is that everyday objects or devices will be able to sense their environment, collect information, and communicate and interact with each other. By capturing this collective observation data, it will be possible for sensor-gathered IoT information to be accessed by multiple applications on multiple devices from any physical location. By embedding real-world sensor-based devices in our environment, the IoT is opening the door to limitless exciting possibilities.

Although the IoT is a new term, it shares a similar vision with the sensor web. Gubbi et al. (2013) provide comprehensive surveys and reviews of the IoT. As the IoT can be seen as an evolution of sensor networks and the sensor web, the IoT and the sensor web architecture stacks are very similar, if not identical. While OGC SWE has been demonstrated to be very effective for complicated sensor web applications, its complexity and the computational overhead may not be suitable for resource-constrained IoT devices. For example, Jazayeri, Huang, and Liang (2012) provide a comprehensive study and identify that the OGC SWE standards are too heavyweight and complicated for the resource-constrained IoT devices.

In June 2012, a new OGC Standards Working Group (SWG) was formed called the Sensor
Web Interface for Internet of Things (SWE-IoT) SWG; later the name was changed to the SensorThings API (application program interface) Standards Working Group. The OGC SensorThings API (Liang, Huang, and Khalafbeigi 2015) provides an open and unified way to interconnect IoT devices, observation data, and applications over the web. The SensorThings API is based on the comprehensive OGC SWE standards. The core of the SensorThings API is the ISO O&M model. The SensorThings API sensing profile is based on the OGC SOS and the tasking profile is based on the OGC SPS. The main difference between the SensorThings API and the existing SWE standards is that the SensorThings API is designed specifically for the resource-constrained IoT devices and the IoT application developers. As a result, the SensorThings API adopts the REST (representational state transfer) principle, the efficient JSON (JavaScript Object Notation) encoding, and the flexible OASIS (Open Artwork System Interchange Standard) OData (Open Data) protocol and URL conventions.

Conclusion

In 1991, Mark Weiser described his vision of ubiquitous computing: “The most profound technologies are those that disappear. They weave themselves into the fabric of everyday life until they are indistinguishable from it.” The author believes this vision is also applicable to describing the sensor networks, sensor web, and IoT. Today, we give little thought to the modern electrical grid and what our lives would be like without it. Tomorrow we will give little thought to the IoT, which will have grown to impact every aspect of our lives. Sensor networks will weave themselves into everyday life until they are indistinguishable from it.

Internet of Things and wireless sensor network

The Internet of Things (IoT) was built on the concept of ubiquitous computing (Weiser 1993; Sakamura 1987; Abowd and Mynatt 2000; Hightower and Borriello 2001), or pervasive computing, that has been proposed for more than 30 years. IoT refers to the interconnection of a uniquely identifiable embedded computing device within the current or next generation Internet infrastructure (Atzori, Iera, and Morabito 2010; McFarlane et al. 2003; Abdelwahab et al. 2014). The Internet of Everything (IoE), proposed in 2013 (Cisco 2013), refers to bringing together networked connections of people, processes, data, and things. Figure 1 shows the architecture of a ubiquitous system.

Sensing and wireless communication are two important components of the IoT. A variety of mechanical, thermal, biological, chemical, optical, and magnetic sensors may be applied to measure properties of the environment. These sensors could work together for specific applications (Figure 2).

Wireless communications include wireless WAN (wide area network), wireless MAN (metropolitan area network), wireless LAN (local area network), wireless PAN (personal area network), and wireless BAN (body area network). Wireless communication standards are developed and maintained by the Institute of Electrical and Electronic Engineers (IEEE) 802 LAN/MAN Standards Committee (http://ieee802.org/).

As an important part of the IoT, wireless sensor networks (WSNs) have gained worldwide attention since the 1990s (Akyildiz et al. 2002; Yick, Mukherjee, and Ghosal 2008; Sohrabi et al. 2000; Akyildiz and Kasimoglu 2004; Shiro 2006). With the advancement of micro-electro-mechanical systems (MEMS) and wireless communication, low-power, low-cost WSN nodes equipped with multifunctional sensors, a processor, memory, power supply, radio, and actuators can be developed. Figure 3 shows the components of a WSN node.

Research on WSNs includes (i) the network platform, (ii) communication protocol, and (iii) network services, as discussed in the next section. The design of a WSN is highly dependent on the application; it must consider such factors as the environment, objectives, cost, hardware, and system constraints. WSN applications are discussed in a later section.

Sensor network platform

A WSN platform includes sensor node software, hardware, interface, and sensors (Figure 4). It is important to integrate multifunctional sensors on a WSN platform and process raw data with limited resources. The operating system and protocol stack are designed to support...
these platforms. Figure 5 shows the component of a WSN platform, which was applied in Great Duck Island, Maine, USA, for habitat monitoring (Polastre et al. 2004).

WSN standards define the functions and protocols for sensor nodes to interface with a variety of networks including IEEE 802.15.4 (IEEE 2004), ZigBee (www.zigbee.org/), WirelessHART (Chen, Nixon, and Mok 2010), ISA100.11 (www.isa100wci.org/), 6LoWPAN (Hui and Culler 2008), and Z-wave (www.z-wave.com/).

Communication protocol
A reliable and energy-efficient protocol stack is important for various WSN applications. The relationship among applications, services, communication protocols, and platforms, is shown in Figure 6. The functions of each layer are shown in Table 1 (Yick, Mukherjee, and Ghosal 2008). Zigbee is a representative and widely used
Network services

Network services of WSNs include localization, synchronization, coverage, compression and aggregation, and security (Yick, Mukherjee, and Ghosal 2008). They enhance the performance of the network in terms of power, task distribution, and resource usage.

For localization, a global positioning system (GPS), beacon or anchor nodes, and proximity-based localization methods could be deployed for the sensor nodes. Time synchronization is important for routing and power conservation. The time synchronization protocols aim to accurately estimate time uncertainty and synchronize each node’s local clock in the network. Determining sensor coverage is important for evaluating its effectiveness. The quality of monitoring in a WSN is dependent on the application. Data compression techniques involve compressing the size of the data before transmission. Decompression of the data occurs at the base station. For data aggregation, data are collected from multiple sensors and combined together to transmit to the base station. The techniques address the issue of energy, robustness, scalability, accuracy, and efficiency, aiming to reduce communication cost and increase reliability of data transmission. Wireless nodes broadcast their messages to the medium, so the security issue must be addressed in WSN.

WSN applications

As an important part of the IoT, WSNs have many applications for environment/Earth sensing, health-care monitoring, target tracking, and so on. A WSN application system includes a server, sensor nodes, network protocols, and a database.

IoT architectures and applications in the world

In the United States, in 1993, the Defense Advanced Research Projects Agency (DARPA) supported a WINS (wireless integrated network sensors) project (Vardhan et al. 2000) at the University of California Los Angeles (UCLA). In 1998, DARPA supported the SensIT project (Kumar and Shepherd 2001) in more than 20 research institutes, to develop software for distributed WSNs. In 1999, the University of California Berkeley started the “Smart Dust” research project (Kahn, Katz, and Pister 1999).

Key research groups in the United States include the WEBS (wireless embedded system) laboratory at Berkeley (http://smote.cs.berkeley.edu/motescpelescope/), the Center for Embedded Networked Sensing at UCLA (http://research.cens.ucla.edu/), and the Ubicomp laboratory at the University of Washington (http://ubicomplab.cs.washington.edu/).

In the past 10 years, SmartGrid (http://www.nist.gov/smartgrid/), using information technology (IT) to deliver electricity in efficient, reliable, and secure ways, has become an important IT strategy. IBM outlined a new agenda for building a “Smarter Planet” in 2008 (www.ibm.com/smarterplanet/).

EPCglobal proposes a structure and worldwide standard for electronic product code (EPC) technology (www.gs1.org/epcglobal). Auto-ID laboratories under EPCGlobal is the leading IoT research network of academic laboratories (http://autoidlabs.org/).

A number of companies are working on IoT, including MEAS, Honeywell, Zebra, Symbol, Magellan GPS, HP, IBM, Cisco, AT&T, Oracle, Microsoft, and Intel. Representative WSN companies include Dust networks (acquired by Linear Technology in 2011), Archrock (acquired by Cisco in 2010), and Crossbow (acquired by Moog in 2011).

The main IoT application areas include smart grids, health-care monitoring, smart homes, environment monitoring, intelligent transportation systems (ITS), and the military.

In the European Union (EU), the eEurope strategy (eEurope: an information society for all) was proposed in 2000 (EUR-Lex 2005), followed by the i2010 strategy (i2010: information society and the media working towards growth and jobs) in 2005 (EUR-Lex 2009).

IoT projects supported by the EU Seventh Framework Programme (FP7) include IOT-A (Internet of Things-Architecture) (www.iot-a.eu/), SENSEI (integrating the physical with the digital world of the network of the future) (www.ict-sensei.org/), CASAGRAS (coordination and
support action for global RFID-related activities and standardization) and BRIDGE (building radio frequency identification solutions for the global environment) (www.bridge-project.eu/).

Many standardization organizations are working on IoT, including ITU-T, ETSI M2M TC, ISO/IEC JTC1 WG7/SC27, ISO TC104 SC4 WG2, and CEN/CENELEC/ETSI ITSTC.

A number of companies are working on IoT in the EU, including Ericsson, Nokia Siemens Networks, Alcatel-Lucent, and Vodafone. A representative WSN company is Libelium. The main IoT application areas include smart grids, smart homes, ITS, health-care monitoring, environment monitoring, industrial monitoring, and logistics.

In Asia, Japan proposed strategies including e-Japan (Electronic Japan 2001), u-Japan (MIC 2004), and i-Japan 2015 (i-Japan 2009). A number of research projects have been developed including CUBIQ (cross ubiquitous platform) (Dempo and Yoshida 2010), TRON (the real time operating-system nucleus) (www.tron.org/), Live-E! (live earth) (www.live-e.org/), WIDE (widely integrated distributed environment) (www.wide.ad.jp/), and GUTP (Green University of Tokyo) (www.gutp.jp/).

A number of companies and institutes are working on IoT in Japan, such as Hitachi, NEC, NTT DoCoMo, KDDI, NICT, and NRI. The main IoT application areas include smart grids, smart homes, ITS, health-care monitoring, environment monitoring, and earthquake prediction.

Korea proposed the u-Korea Master Plan strategy and the u-IT839 strategy in 2006, to promote the development of Internet Protocol version 6 (IPv6), ubiquitous sensor networks (USN), and radio frequency identification (RFID), aiming to achieve the first ubiquitous society. Four u-IT plans – u-City, telematics services, u-IT cluster, and u-Home – are proposed. A number of companies and institutes are working on IoT in Korea, such as ETRI, Samsung Electronics, LG Electronics, and KT.

China proposed a sensing China strategy in 2009, and a Smart City strategy in 2012. A number of companies and institutes are working on IoT in China, including the Chinese Academy of Sciences, China Mobile, China Telecom, China Unicom, Huawei, and ZTE. The main IoT application areas include smart city, ITS, smart homes, smart agriculture, health care, and environment monitoring.

Canada, India, Russia, Brazil, South Africa, Australia, Singapore, Malaysia, and other countries have started IoT projects in the application areas of smart city, ITS, smart agriculture, smart grid, health care, and oil exploration.

Field observation research network

Field observation research refers to monitoring and indicator measurement in the field for scientific research across many disciplines, including ecology, earth and atmospheric sciences, and ocean sciences. Through long-term observation, valuable raw data can be accumulated for original scientific discovery, new technology development, experiments, and demonstrations. Field stations are usually far from human settlements, so it is necessary to build field observation research networks for data acquisition and transmission.

Currently, there are many ecological research networks, such as the international long-term ecological research network (ILTER) (Aronova, Baker, and Oreskes 2010), national ecological observatory network (NEON) (Hobbie et al. 2003; Johnson et al. 2010), and Chinese ecosystem research network (CERN) (Fu et al. 2010). The system infrastructure includes components such as data acquisition, data transmission, data management, and application.
SENSOR NETWORKS, WIRELESS

(Figure 7). The Open Geospatial Consortium (OGC) sensor web enablement (SWE) (Botts et al. 2008) defined a suite of web service interfaces and communication protocols for the heterogeneity of sensor communications.

Exemplar environment monitoring applications

Environment and habitat monitoring are important application areas of sensor networks (Mainwaring et al. 2002).

Volcanic monitoring (Allen et al. 2006) provides a science-centric evaluation by a 19-day sensor network deployment at an active volcano on Volcan Reventador in northern Ecuador. The system used 16 sensors to continuously collect seismic and acoustic data and transmit reliable data to the base station.

GreenOrbs (Liu et al. 2013) is a consistently operating sensor network system deployed for forest surveillance. With up to 330 nodes deployed in the wild, GreenOrbs provides various data, including temperature, humidity, illumination, and carbon dioxide titer, for forest observation applications.

The Live E! project (Esaki and Sunahara 2006) is an open research consortium founded by the WIDE project and the IPv6 Promotion Council, Japan. This project is aimed at exploring the platform to share digital information related to the Earth and the living environment for disaster monitoring, reduction, and recovery. Live E! has accommodated more than 100 stations using a low-cost weather sensor network.

The ZebraNet (Zhang et al. 2004) system is a mobile WSN for tracking animal migration. It is composed of sensor nodes built into the zebra’s collar. GPS data are sent in multiple hops across zebras to the base station. Six to ten zebras were collared during the test in central Kenya. A dataset was collected to understand their migration pattern.

VigilNet (He et al. 2009) is designed to support long-term military surveillance using a sensor network consisting of 200 nodes in an outdoor environment. The complete system is designed to scale to at least 1000 XSM motes and cover a minimum of \(100 \times 1000 \text{m}^2\) to ensure operational applicability.

There are many research projects using WSN for environmental monitoring and target tracking. SenseScope (Barrenetxea et al. 2008) is a real-world deployment for environmental monitoring that took place on a glacier in Switzerland, consisting of about 100 sensor nodes. Trio (Dutta et al. 2006) is a sensor network deployment consisting of 557 solar-powered motes for multitarget tracking. MacroScope (Tolle et al. 2005) is a sensor network for monitoring the microclimate of a redwood tree. The experiment recorded 44 days in the life of a 70-meter-tall redwood tree, at a density of every five minutes in time and every two meters in space. ExScal (Arora, Ramnath, and Ertin 2005) is an attempt to deploy a sensor network at extreme scales. The system consists of about 1000 sensor nodes and 200 backbone nodes in a 13 km \(\times\) 300 m remote area in Florida, USA. An underwater WSN (Detweiler et al. 2010) has been used to understand water dynamics and their impact on the global environment.

Sensor network and integrated Earth observation network

Geospatial information science and technology (geomatics, geoinformatics) is the discipline of gathering, storing, processing, and delivering geographic information. This discipline includes tools and techniques used for land surveying, remote sensing, cartography, geographic information systems (GIS), global navigation satellite
Figure 7  Field observation research network.

systems (GPS, GLONASS, Galileo, BeiDou), photogrammetry, geography, and other fields involving mapping the Earth. Google Earth is changing the way the world is seen.

The integrated Earth observation system is the frontier research area of geomatics; it comprises the measurement of air, water, and land based on a network of sensors stationed on the ground, in the air, or in space, to improve the understanding of the changing Earth and interactions among various components on Earth. The global earth observation system of systems (GEOSS) (www.epa.gov/geoss/), promoted by the group on earth observations (GEO), connects the producers of environmental data and decision-support tools with the end users to enhance the relevance of Earth observations to global issues.

With the development of IT and communication technologies, the integration of Earth observation networks includes smart sensor networks, intelligent data-processing systems based on cloud computing, grid GIS, and intelligent geoservice agents (Li and Shao 2009).
SENSOR NETWORKS, WIRELESS

IoT is becoming the most important information technology that connects distributed, embedded microsystems in the physical world with the cyber world through networks. As an important part of IoT, core WSN information technologies include sensing, computing, and communication. WSNs will have more real-world applications in the IoT and IoE fields in the future.

SENSOR NETWORKS, WIRELESS

Unlike many terms and concepts in geography, “sequent occupance” has a clear genealogy. Derwent Whittlesey (1929) coined the term and proposed the methodology.

He declared that human occupance of an area, similar to biota, carries the seeds of its own transformation. Given this, it would be the task of geographers to discern the various stages of occupance, and thereby to provide regional or chorographic studies with a structure amenable to generalization. Although cast as an approach to historical geography, the concept was adopted and adapted mostly by cultural and regional geographers. Whittlesey’s initial training at Beloit College and the University of Chicago was in history, punctuated by service in World War I. Returning from the war, he completed his PhD in geography at Chicago and joined the geography faculty there, before moving to Harvard in 1928. Like Carl Sauer’s (1925) “The Morphology of Landscape,” published soon after Sauer’s arrival at Berkeley, Whittlesey’s “Sequent Occupance” might be seen as a “habilitation” exercise – providing a programmatic statement and a preview of his epistemological orientation. He failed, however, to demonstrate its utility with directed studies of his own. That task was left to other geographers and a generation or two of graduate students for which the concept and method offered an attractive and tractable approach to geographical change in bounded places or regions over time. Marvin Mikesell (1976), in his essay “The Rise and Decline of ‘Sequent Occupance’,” suggests that the concept enjoyed a decade or two of popularity and patronage before sliding into senescence by the 1950s coincident with the eclipse of regionalism as geography’s key paradigm and with Richard Hartshorne’s earlier advocacy of an ahistorical chorology. Pace Mikesell’s somewhat ironic title (see References), the concept’s own occupancy in geography and neighboring fields has had a longer if not stronger presence than is often assumed.

Whittlesey’s move from Chicago to Harvard meant a shift from a human geography-oriented department to one where Davison physiography and ontography still held sway. In proposing a model that held that human occupance of an area, similar to biotic phenomena, carries within itself the seed of its own transformation, Whittlesey appeared to many to be following the logic and logistics of Davis’s stage-managed erosion cycle. Further he held that the succession of stages of human occupance establishes the genetics of each stage in terms of its predecessor. Thus it followed that the life history of each discloses the inevitability of the transformation from stage to stage. He did, however, suggest that change could come from exogenous as well as endogenous causes, whether from the inherent character of a particular mode of occupance, or from extreme physical events (earthquakes, windstorms, tidal waves, floods, volcanic eruptions, landslides, insect or other biological pests, pestilence, and so on) or human agency (boundary shifts, political upheavals, legal changes, population movements, communication innovations). But rather than narrowly viewing sequent occupance as a variant of the Davison model, or an opportunistic entrée into his new milieu, one might look to
SEQUENT OCCUPANCE

his Midwestern schooling for inspiration or at least incubation. Most commentaries on sequent occupancy point to similarities with Frederick Jackson Turner’s Frontier Thesis. Whittlesey and Turner not only shared middle-class small-town Midwestern origins and careers capped at Harvard, but Turner’s historical vision was among the optics with which Whittlesey focused his earlier historical studies. While their stage models of historical change invite comparison, the pioneering work of the Chicago biological ecologists probably had the larger influence. Human ecology as formulated by Chicago geographers J. Paul Goode and Harlan Barrows, or the derivative and lateral development of the urban theories by the Chicago sociologists Robert Park and Ernest Burgess, owe initial impetus to their cross-campus colleagues studying ecological plant succession. Whittlesey himself notes that the analogy between sequent occupancy in chorology and plant succession in botany should be apparent to all. But he goes on to say that human occupancy involves greater complexity, as the botanist is dealing with a single subject – plant associations, and the main agents of transformation are limited to three factors – climate, soils, and human disturbance. With human occupancy, the successional history is not only mediated by changes wrought by biophysical factors, but also by those stemming from correspondingly complex cultural forms.

Sauer’s “Morphology of Landscape” (1925) was a resounding repudiation of the environmental or geographical determinist current in geography that had flowed through the discipline’s history since its inceptions in Classical Antiquity, but had welled up in the late nineteenth century and first two decades of the twentieth. Sauer’s “Morphology” also provided an opening or avenue for historically directed chorology or regional studies, but this was not to be its principal legacy. Whittlesey’s aim at offering chorology conceptual and methodological underpinnings was more direct, and more realized. With the discrediting of the environmental determinist conceit, geography was deprived of its reigning nomothetic or generalizing approach. Whittlesey recognized that chorology, left to its own logic, would be endlessly idiographic – rendering regional descriptions at any and all scales. No matter how artful or erudite these constructions might turn out to be, in aggregate, the summation would be simply that. Instead, Whittlesey proposed that his scheme could coax an order out of chorology that would lend itself to generalization. By identifying the sequential occupation stages evident in different regional histories, geographers could then begin to build a quasi-science of chorology.

To illustrate the concept and method, Whittlesey chose a small district in northern New England rather than his native Midwest, no doubt a nod to his recent relocation to New England. He does not specify its precise location, but does give its areal extent – 15 square miles, thus at the scale of a “micro-region.” While in graduate school at Chicago, Whittlesey participated in the Midwestern geographical summer field schools directed by Robert S. Platt, advocate of microgeographical research. Work at this scale was deemed manageable for either teams or individual researchers. Whittlesey’s sample district’s features was described as having a massif of high hills, mantled by bouldery podsols, with deep winter snow and well watered by frequent summer rains. The climate consisted of long, cold winters and cool summers with only occasional hot days. The vegetation cover was a tangle of pioneer, mixed deciduous and coniferous second-growth forest. A few grassy lanes penetrated the plot, allowing cattle grazing. Whittlesey suggests that finer microgeographical discrimination was possible, but would not alter its exclusively descriptive character. To
go beyond, posing the description in sequence with preceding modes of human occupance and positing the probable subsequent mode(s) would allow for genetic correlations. Whittlesey detected three distinct stages and predicted a fourth. The prior stage had featured farming and associated land use: plowed fields on gentle slopes, pasture land on steeper slopes, sugar maple selection on rougher terrain and soils, and wood lots in remaining spaces. Evidence for this regime could be found in both field and archive in the form of relic walls, paths, and roads, house foundations, and written accounts. Prior to European agriculture, Whittlesey posited virgin mixed forest with only a few migrant Indians pursuing a hunting and gathering existence. Whittlesey foresaw a future reoccupation of the district by nonresident owners cutting it periodically for pulpwood or possibly lumber. From this example of sequential occupancy, Whittlesey drew a confident conclusion as to its internal logic and by extension its seemingly universal applicability. He asserted that each generation of human occupance is linked to its forbearer and to its offspring, with individuality expressed through mutations in some elements of its natural and cultural characteristics.

The reception by geographers was far from universal acceptance, but it did attract adherents, especially among geography students writing theses and dissertations within the larger regionalist or chorological framework. Perhaps the most widely cited example was Preston James’s (1929) Blackstone Valley study. This publication actually preceded Whittlesey’s paper, but it has been drafted as exemplar. Afterward, the center of gravity of these studies moved west. Darrell Davis (1930) published on the succession of human activities in the Kentucky Mountains, and Stanley Dodge (1931) the following year on sequent occupance of an Illinois prairie. Perhaps the doyen of this genre was Alfred Meyer (1934), who wrote his dissertation under Dodge on the Kankakee Marsh in northern Indiana and Illinois. Meyer spent the next two decades publishing a series of studies on this region using the sequent occupancy approach. Whittlesey mentee Edward Ackerman (1941) demonstrated sequent occupance’s potential in the urban sphere. Subsequently, a somewhat independent current developed in urban studies and the planning arena. To date, there has been no complete accounting of the number of studies that Whittlesey’s paper inspired, nor of their locational distribution. But in the spirit of Whittlesey’s concept, there seem to have been three distinct stages: (i) a scattering of geographical studies prior to 1929 (sans the precise terminology) that anticipated Whittlesey’s directives, (ii) a collection of studies during the 1930s and 1940s spawned by his manifesto, tailing off in the 1950s, and (iii) residual studies to the present day that may or may not be directly derivative of Whittlesey’s proposal.

SEQUENT OCCUPANCE

Serbia: Geografski institut “Jovan Cvijić” Srpske akademije nauka i umetnosti (Geographical Institute “Jovan Cvijić” of the Serbian Academy of Science and Arts)

Founded: 1947
Location of headquarters: Belgrade
Website: www.gi.sanu.ac.rs
Membership: 58 (as of December 31, 2013)
Executive director: Milan Radovanović
Contact: m.radovanovic@gi.sanu.ac.rs

Description and purpose

The institute is a unit of the Serbian Academy of Sciences and Arts in Belgrade. Its mission is to organize systematic scientific research in geography, including the study of landscape phenomena, objects, forms, relationships, conditions, and processes within the geographical environment. The institute focuses on the landscapes of Serbia as well as the broader territories of the Balkan Peninsula, south and central Europe, and the world.

Journals or major publication series

Other editions and joint publications. www.gi.sanu.ac.rs/en/publications/other_editions/other_editions.html

Current activities or projects

The scientific research of the institute is performed by way of engaging, individually as well as collectively, the services of all the collaborators of the institute with a view to realizing scientific projects. The results of this scientific work are published in institute, academy, national, and international periodic and special publications. Research results are presented at scientific conferences, congresses, symposia, seminars, expeditions, and other gatherings that contribute to scientific advances.

Brief history

The institute was founded on May 31, 1947, within the framework of the Serbian Academy of Sciences and Arts. One of the founders was the world-renowned scientist Milutin Milanković. It has been operating since 1961 under the name of the Geographical Institute “Jovan Cvijić” of the Serbian Academy of Sciences and Arts. Jovan Cvijić was one of the greatest Serbian scientists, the leading geographer, a founder of modern Serbian and Yugoslav geography, an influential intellectual, and a great national figure in Serbia and Yugoslavia at the beginning of the twentieth century. The first director of the Institute was Petar S. Jovanović, a member of the Academy of Sciences and Arts.

The institute’s fundamental interest is in basic, applied, and developing scientific research in
SERBIA

physical geography, the geography of population and settlements, social geography, regional geography, and cartography. To support its scientific programs, the institute is organized into departments that are subdivided into separate divisions.

In addition, the institute has an administrative organization which offers professional services.

Submitted by Milan Radovanović
Serbia: Srpskog Geografsko Društvo (SGD) (Serbian Geographical Society)

Founded: 1910  
Location of headquarters: Belgrade

Description and purpose

The Serbian Geographical Society is a professional organization whose mission is to bring together scientific, professional, and educational activities of geographers, scientists, university professors and assistants, and professors of secondary and primary schools in Serbia. The main objective is to develop field and theoretical research in geography, study events and processes in all geographic disciplines and develop subjects at different levels of education, improve methodological and didactic principles of teaching at all levels of education, publish textbooks, manuals, scientific, professional, popular, and methodical-pedagogical works, organize scientific gatherings, congresses of Serbian geographers, regular annual seminars (10–12 lectures), and regular monthly meetings of the teaching department and the scientific department. Organization of competitions in geography for pupils in the final grades of primary school, collaboration with corresponding organizations and popularization of geographical knowledge in a variety of media on different occasions are also relevant.

Journals or major publication series

Special issue of the Serbian Geographical Society (in Serbian)  

Current activities or projects

The SGD organizes 10–20 expert and scientific lectures for its members every year. It carries out 4–7 excursions in Serbia and abroad where geographical issues of the visited areas are discussed. Once a year accredited seminars for teachers of geography of secondary and elementary schools are organized. On that occasion, eight to twelve lectures are presented and discussions follow. Members of the society are encouraged to prepare papers on a regular basis for publishing in journals for which financial support is provided by the Ministry of Education, Science and Technological Development of the Republic of Serbia. Organization of regional and state competitions for students in grades 7 and 8 of primary schools is of utmost importance. More than 1300 participants take part and many of them continue to the highest state-level competitions depending on their success. Every year, on Jovan Cvijić’s birthday (the founder of modern geography in Serbia and a world-renowned scientist), the Serbian Geographical Society organizes a exhibition, The Days of Cvijić, when representatives of 13 participating schools from Serbia and the
Republic of Srpska with the name of Jovan Cvijić take part. The event includes expert lectures, experience sharing, socializing, and field work.

Brief history

The SGD was founded in 1910 on the initiative of Jovan Cvijić and his associates, and was associated with the Faculty of Geography at the University of Belgrade. It was on this occasion that the rules of the society were established and the publication of the journal started. It is the oldest geographical publication in the Balkans, which is still regularly published in four volumes per year. During both world wars, due to the bombardment, destruction, and burning of the existing archives, the assets, library, and unsold copies of the books were destroyed. The main task of SGD is the scientific and professional work and popularization of geographical knowledge in all geographic disciplines and teaching subjects. The society has established successful cooperation with institutions in Serbia and abroad. Through the exchange of publications it has created a rich library. In 1935, it established the Medal of Jovan Cvijić as the most important recognition to individuals and institutions in Serbia and abroad for their outstanding contribution to the development of geography. The society has a board comprised of 11 members. The head of the board is the president who has assistants for teaching and research. Activities take place through the work of the teaching department and the scientific department. The SGD has branches in several major cities in Serbia. In 2010 the SGD celebrated a century of existence and operation by publishing a commemorative issue.

Submitted by Stevan M. Stanković
The first geographic information systems were built as tightly coupled whole systems. This coupled and closed system architecture made it easy to develop relatively simple domain-focused applications. But when more functions were added to these systems, and especially with the widespread proliferation of computer networks, it became necessary to decouple the monolithic system architecture into a componentized framework to improve the management of system design and development functions. At that stage, system architectures started to evolve into structure-oriented, object-oriented, and component-oriented frameworks. For example, to further improve software componentization and make it correspond more closely to our conceptual recognition of the world, object-oriented system architectures were proposed and became popular for a few decades. Since the beginning of the 1990s, numerous software components have been developed and put into operation to provide valuable data-processing capabilities. These operational components are of value when they can be integrated and used to build new computer systems. Even more value can be added when components are further built into interoperable services based on standards defined by user communities as well as by national and international standard bodies. Service-oriented architecture (SOA) has emerged and has served as an important model for system design and development since the mid-2000s (Erl 2005). SOA has been advanced as a set of methodologies and principles that guide the design and development of new computer systems by leveraging existing computing services and managing their development for future reuse in an interoperable fashion.

The geographic information science (GIScience) community recognized the importance of SOA for information system integration, and it was initially adopted to build the National Spatial Data Infrastructure (NSDI) by the Federal Geographic Data Committee (FGDC) and to support the reuse of geographic information assets by adopting a set of geospatial standards defined by the Open Geospatial Consortium (OGC), such as the OGC suite of web services for sharing geospatial information assets. Many recent developments in GIScience have benefited from this service-oriented approach of reusing and interoperating existing geographic information systems. For example, the Google Map and Google Earth systems can be easily integrated into new geographic information system (GIS) applications through the use of relatively simple scripting programs. This service-oriented design enables developers to leverage the vast amount of geographic data and mature functionalities of Google (such as geocoding, routing, IP-to-address conversion, and geographic pattern visualization) in a rapid fashion, thus reducing the system–development life cycle from years to weeks or days, with high reliability and scalability.

This entry introduces SOA from the aspects of key supporting technologies, popular examples, and future developments in the GIScience domain.
Key technologies

The reuse and interoperability of information systems has been an elusive goal of system designers for several decades. This goal became achievable with the development of SOA. SOA evolution has been enabled by several technological developments since the mid-1990s, including software design technology, computer networks, standardization, and services.

Software design technologies

The first computers were created to carry out numerical calculations to meet complex production requirements. This focused capability was supported using sequential software design and engineering processes. In the 1960s computers began to be used for many business functions, and these general-purpose information systems required much more complex functionalities. To deal with the complexity of software development, multiple software design approaches were proposed in the 1960s and 1970s; the most notable ones (Shaw and Garlan 1996) are structure-oriented (SO), object-oriented (OO), and component-oriented (CO).

The SO software design approach was adopted to improve code clarity and quality, and to reduce development time by using subroutines and block structures as well as for and while loops. This structured approach to system design and development was very useful when software assets were limited, and the approach was used for several decades, achieving particularly widespread use in the 1980s to design business systems.

Seeing the need for modeling software components that would correspond to real-world objects and to design software in a more “natural” fashion, OO design and development emerged in the late 1960s and became popular in the 1990s for the design and development of software systems. Because it is close to human perceptions of problem domains, the OO approach remains a very popular approach for software design and development.

The CO software design and development approach was also developed in 1960s when general purpose, and thus complex, software systems became common. The CO approach divides an information system into different functional components and ensures that each component is fully documented and tested; complexity is hidden from end users in this approach (Heineman and Councill 2001). The CO approach is popular for software development because of several important characteristics: (i) single modules can be developed and used multiple times; (ii) noncontext-specific development maximizes reuse; (iii) modules can be combined with other components to form complex systems; (iv) complexity is encapsulated, thereby leaving external interfaces open to current and future users; and (v) independent units can be flexibly deployed and tested. These characteristics were eventually developed into the service-oriented software design and development approach.

Computer networks

Computer networks were introduced in the late 1950s and early 1960s to share data between computers and facilities, though they operated initially at a very low speed (at the rate of kilobits per second or kbps). In the 1980s the speed was improved to megabits per second (mbps) with Ethernet. In the 1990s the speed was increased to 100 Mbps, and at the end of 1990s the network speed was increased to gigabits per second (Gbps) with new fiber optic cables and fast switches. This development is best represented by the Internet, the global interconnected Internet protocol (IP) system.
In 1960s the US Department of Defense sponsored the ARPANET to connect computing facilities across different organizations in the 48 US continental states using interconnecting transmission control protocol (TCP)/IP networks. In 1982 the TCP/IP protocols were standardized, and it then became much easier to connect to the Internet. In the 1980s and early 1990s the Internet expanded quickly to Europe, Asia, and other continents. The late 1990s and the first decade of the 2000s saw enormous increases in content delivered through the Internet. This fast-growing use of content exchange was especially accelerated with the World Wide Web (WWW).

WWW refers to the system of interlinked hypertext documents accessed via the Internet; it has its origins in the late 1980s at CERN, the European Organization for Nuclear Research. In the WWW, a web browser (the end-user application) can universally display all web pages provided by different web servers by following the Hypertext Transfer Protocol (HTTP) and the Hypertext Markup Language (HTML) standards. This seamless integration of web content made it extremely easy to publish documents in a worldwide environment.

The original format of serving static web pages through HTTP and HTML was termed Web 1.0. After the success of static content delivery, developers began to share multimedia through the web, including animations, videos, and others. Web 2.0 emerged in 2004 for end users of the web to contribute content through tools such as wiki, Twitter, Facebook, and blogs. The emerging Web 3.0 is envisioned to have intelligent capabilities, such as the ability to understand the meaning of text and to use that meaning to conduct searches and access information and other resources available on the Internet.

The continuous evolution of computer networks has provided convenient channels for end users to freely share information and processing capabilities through web services. The broadening of web capability from desktops and laptops to portable devices such as smartphones and tablet computers has made it easy for people to access and contribute content through web services.

**Standardization**

The rapid development of software technology and computer networks has been enabled by the standardization of system interfaces, from hardware switches and plugs (such as RS-232 and HDMI) to software and information coding (such as HTTP and HTML). These standards are developed by professional organizations, such as the Institute of Electrical and Electronics Engineers (IEEE), in collaboration with the International Organization for Standardization (ISO). In the GIScience domain, many GIS application successes have benefited from the standards developed by organizations such as the FGDC, OGC, and ISO (Alameh 2002).

In the early 1990s the FGDC was established to build the NSDI for the United States. Soon, it was recognized that standards and interoperability are the core enabling technology for sharing both information content held across different agencies and services built and operated by different organizations. OGC was established at a similar time to look at how to standardize geospatial information systems. During its first few years of operation, OGC laid out a framework for various aspects of standardization, from projections, geographic coordinate systems, data content, and data encoding, to data and information services. In the early 2000s, the focus of OGC has shifted to standardizing the format of information encoding (such as Geography Markup Language (GML)) and system interfaces as service contracts.
among different services (such as the OGC Web Services).

OGC Web Services include the well-known Web Map Service (WMS), Web Feature Service (WFS), Web Coverage Service (WCS), Catalog Service for the Web (CSW), Web Processing Service (WPS), and Sensor Web Services, among others. With these services standardized and approved by the American National Standardization Institute (ANSI) as national standards and by ISO as international standards, OGC is focusing now on how standards could facilitate the sharing of geographic information services to support the integration of new applications to address challenges ranging from global climate change and natural hazards to emergency response. A primary focus is placed on its well-known OGC Web Services (OWS) Initiatives and by leveraging the latest technologies such as cloud computing.

Services

Based on advances in software technologies, computer networks, and standards, a variety of services are being developed to provide content or functional capabilities to a wide variety of end users. These services (Erl 2005) are:

- platform-independent: based on a set of standards to enable the interoperability between different services across different platforms and languages;
- loosely coupled: minimum amount of interdependencies between services;
- autonomous: service owns its own implementation logic;
- abstract: services hide their internal logic except through the interfaces that are defined by the service contract;
- service contractual: the interface between services is based on communication and documented agreements or standards;
- reusable: the abstraction and autonomy minimizes interactions among services, thereby improving reuse;
- composable: services can be assembled from other existing services;
- stateless: a minimum amount of activity-specific information is stored;
- discoverable: services can be discovered by their users through a registry or its interface.

These characteristics make it easy to compose new applications by using existing assets of data, information, and processing services. The next section provides examples of how SOA is utilized in the cutting-edge development of geoportals, mashups, and geoplatforms to facilitate the sharing of services across distributed environments.

Examples

Recent developments in GIScience have benefited from the evolution of OGC Web Services and the SOA approach in developing applications. SOA is made up of the three parts of service, catalog, and application (Yang and Tao 2006): services are different types of systems operated by different organizations; catalogs are where organizations register their services so that others can search and find them; applications are where the services are bound to support a specific end-user function. Figure 1 shows a typical OGC SOA for the services publish, find, and bind (OGC, 2003). The bottom of the figure shows different types of data, portrayal, and processing services that can be published into a catalog service. The catalog can be searched by applications to find specific services. Then the services can be bound to form new applications, such as data discovery, map viewing, and others.
The OGC web service architecture adopts SOA concepts, including service, catalog, and application, in the functions of publish, find, and bind. Publish, find, and bind are supported using different types of encodings (adapted from OGC 2003).

Spatial web portal

A spatial web portal (SWP), also known as a geoportal, is based on SOA to build integrated geospatial information applications for data discovery, access, and integration. Figure 2 shows the architecture of the NASA Earth Science Gateway (ESG), which is a typical SWP and was one of the milestones of NSDI, along with the Geospatial One Stop (GOS) portal. The figure shows that many services are built and operated at the bottom with facilitating services, spatial web services, and maintenance services. These services are easily accessed by the spatial web portal through SOA, and the spatial web portals interact with each other to support different types of applications with publish, search, view, and visualization services. The interoperable services can be leveraged easily without much centralized development.

Mashups

Mashups have become a major application development approach for GIS in the mid-2000s because SOA enables rapid and reliable leveraging of existing GIS services (Batty et al. 2010). For example, homesdatabase.com easily integrates Microsoft Bing Maps as a background map with a minimal level of scripting development. In a similar vein, Google Maps easily integrates
Figure 2 The spatial web portal, supporting the Geospatial One Stop, geoportals, and many other portals in the past decade, adopted the SOA approach to leverage existing GIS services.

near real-time traffic and Global Positioning System (GPS) information to show driving conditions through scripting to ingest services from relevant systems. Figure 3 shows the architecture for the development of an emergency response system using existing services for the Loma Linda University Medical Center (LLUMC) Advanced Emergency GIS (AEGIS).

GeoPlatform

GeoPlatform (www.geoplatform.gov) is the latest development of the NSDI. The initiative is targeted to be a collaborative environment that leverages SOA and the latest advancement of Web 2.0 to facilitate community application building by combining existing geospatial assets from different agencies, companies, academia, and other organizations. The system is built on top of a cloud computing infrastructure and is linked to existing geospatial information services through interoperable interfaces. This SOA approach can easily piece together data and services from different resources to form an application that addresses a specific problem. For example, Figure 4 shows a map that integrates different types of natural hazards information from different organizations such as the National Oceanic and Atmospheric Administration (NOAA). Microsoft Bing was adopted as the background map and Esri’s GIS services were used through the SOA architecture. With this final product in hand, decision-makers are able to understand what natural hazards are present across the country without needing to care about system integration details. Most important of all, this functionality can be quickly achieved in GeoPlatform, and live feeds from operational services would be able to keep the system up to date.
Figure 3  Leveraging SOA, GIServices (represented by all the boxes) can be accessed through standardized protocols including HTTP/SOAP, TCP/IP, XML, and other scripting-level development techniques to easily integrate data from a variety of resources in a relatively fast fashion to support the emergency response of the Loma Linda University Medical Center.

New developments

Cloud computing

Cloud computing is a new computing paradigm that is being used to provide computing resources (virtualized hardware, platform, software, functional components, and others) as a service. This new computing paradigm continues to benefit from SOA service standardization. Cloud computing provides five valuable computing characteristics – on-demand self-service; elastic; pooled computing; measured services; and broadband access – which have helped to popularize the use of SOA. However, it should be noted that cloud computing is focused on sharing computing capabilities and SOA is focused on sharing services; they benefit each other. Spatial cloud computing is proposed to address how the GIScience domain could benefit from and help to shape cloud computing (Yang and Huang 2013).

Big data

Big data are emerging as a new opportunity and challenge for scientific discovery. Historical and new datasets are accumulating at geographically distributed locations. The processing capabilities, as well as the information demands for mining big data, are also distributed. It is very
likely that SOA will play a driving role in the development of solutions to convert big data into information and knowledge by improving the discoverability, accessibility, and usability of massive data streams.

VGI or social media
Volunteered geographic information (VGI) has become a popular way to amass user-contributed content which can be used to support decision-making and provide information that was heretofore unavailable. The collection, management, processing, and serving of VGI have also benefited from SOA; the general public can freely and easily contribute information and data through publicly accessible services.

Crowdsourcing or volunteered computing
Many traditional computing problems are shipped out to the general public to use idle computing cycles (Anderson et al. 2002). The support for this type of computing and the collection of computing results are provided in an SOA environment. The evolution of this approach has also helped in the development of popular worldwide service systems such as Google Maps and Microsoft Bing Maps.
Citizen as sensors and the Internet of Things

The popularity of SOA and the ability to connect anything to the Internet make it very convenient for users (people, devices, sensors) to contribute information in an automated fashion. This makes it possible for citizens and things to easily serve as sensors by contributing their situational awareness and information to the overall computing infrastructure. The infrastructure in turn can be mined to support better decision-making with new information and knowledge.

Discussion and conclusion

SOA as an architecture and methodology for developing GIS applications has been firmly established during the past decades. An increasing number of applications are being built using SOA practices. The SOA approach is also being driven by the demand for agile and scalable information and solution developments, such as for NSDI, geopertals, the GeoPlatform, and the NSDI Clearinghouse, as well as mashups. The development life cycle for integrating different services and applications has been reduced from years to months, weeks, even days and hours. Systems ranging from GIScience infrastructure to emergency response can rely on an unprecedented availability of information and computing infrastructure.

The SOA evolution has supported major GIScience advances across several GIS frontiers, such as spatial cloud computing (Yang and Huang 2013), big data, VGI, crowdsourcing (Goodchild and Glennon 2010), volunteered computing (Anderson et al. 2002), citizens as sensors, and the Internet of Things. Given its maturity and verified efficiency for GIS application development, it is expected that SOA will continue to play a significant role in GIScience and geography in the coming decades.

SERVICE-ORIENTED ARCHITECTURE

During the past several decades, geographers have begun to consider seriously how human sexualities are both shaped by and expressed through the places in which they live and encounter others. Prior to the 1980s, human geography had typically treated human sexuality as innate, fixed, and presumably heterosexual. Despite some early attention to sexuality in psychoanalytic strands of the social sciences, a mid-twentieth-century quantitative revolution favoring measurable phenomena had made Western geographers more concerned with, for example, fertility patterns in countries rather than the gendered and sexualized experiences or family formations that produced those patterns. Progress toward more critical, flexible understandings of sexualities has since been somewhat gradual and uneven. Geographers’ understandings of sexuality now encompass lesbian, gay, bisexual, transgender, queer, and intersex (LGBTQI) populations, and often emphasize a “queer” politics that blurs the lines between sexual and other social categories. At the same time, much of their work remains uneven both geographically and socially, focusing mostly on gay and lesbian sexualities in the cities of the Global North, and for many geographers around the world it remains a nonsubject.

Many of the first interventions into geographies of non-normative sexualities in the late 1970s and 1980s simply described uses of urban space among sexual identity “groups” (e.g., gay men) and still treated sexuality as a fixed characteristic. Many of these studies were also urban economic in orientation, identifying how spatial concentrations of residences and businesses among gay men in cities such as New Orleans formed the basis of political voting blocs and complementarities within a gay consumer market. More recent work has focused on how these areas in North American and European cities have been developed, branded, and visibly marketed to attract a broadening based of consumers, including heterosexual people, while excluding others such as gays and lesbians who are working-class or transgender individuals. Meanwhile, work on lesbian communities has revealed a more diffuse, socially networked (as opposed to spatially concentrated) form of kinship (Peake 1993). Work on younger gay men and lesbians has also examined the role of more specific processes (e.g., migrating away from the family home to the “big city”) in sexualized life transitions, such as coming out or developing a gay or lesbian identity. Over time, research on sexuality and space became influenced increasingly by feminist and critical approaches in Euro-American geography that acknowledged sexualities as one of the multiple, overlapping forms of social subjectivity that mediate how individuals experience the places they inhabit.

The narrower body of work on urban-focused “gay and lesbian geography” is now joined by work on sexual identities in a wider variety of populations (including heterosexual people) and on the inscription of sexuality in places through ongoing processes of performance, evaluation, and regulation. Performativity refers to the ways in which individual representations of sexualities
SEXUALITIES

(e.g., dress, corporeal movements, and speech) are shaped by dominant, often repetitive, discourses. While performances that align with these scripts might elicit positive responses such as love, affection, and social affirmation, those that do not might be met with violence or exclusion. In this way, individuals become the actors that perform “acceptable” discourses to make them a lived reality. Since sexualities – at least as they are interpreted societally – are characterized by particular sets of gendered norms (e.g., “masculine” confidence and aggression vs “feminine” fragility) that can be altered or concealed, they may be performed differently in different areas: a gay-identified man might walk more “butch” in certain areas where he expects to be threatened or harassed for being perceived as gay. Similarly, research on urban nightlife has shown that codes of behavior (e.g., self-segregation of men and women into different spaces of bars, perceived conventions that men must approach women or buy drinks for them) are reinforced by expectations that those behaviors are given in those spaces. Consequently, they may disempower some individuals (heterosexual women) by casting them as sexualized objects that are meant to be sought out or solicited by others (heterosexual men).

Research on the regulation of sexuality has also been fruitful in outlining how sexualities are inscribed in particular places. Some work has looked at the regulation of female sexualities, which were historically thought of as needing to be “cocooned” in domestic, procreative heterosexual relationships. Historical work on British imperialism, for example, demonstrates how control over sexuality, through dress codes and curfews for single women, was used to create “proper” female subjects (and prevent prostitution by “fallen women”) within a colonial empire. More recently, the study of how women’s sexualities are regulated has somewhat shifted to the city scale, again with particular emphasis on their location in public versus private spheres. Some work on female sex work has shown that local and national governments’ attempts to regulate it, positioning the sex worker as harmful or morally corrupted, may push it further underground and into more geographically marginal areas, threatening the safety of workers. Conversely, attempts to bring sex work into the public sphere through legalization and containment (e.g., in urban red light districts) can encourage a sense of public ownership over individuals’ sex work, leading to moral panic over “powerless” sex workers being trafficked and, in turn, police interventions that may leave sex workers without economic livelihoods. In these ways, sexualities also became understood as fundamental to how individuals and the state relate to one another. Through a process of sexual citizenship, individuals are granted moral and social recognition for acting in a way that underpins the values that states use to construct themselves (e.g., as economically viable, safe, and family-oriented). Sexualized bodies therefore make places by providing the basis for social norms and policies, but also solidify (or resist) those norms by enacting (or rejecting) them.

For gay men and lesbians, regulation stemmed from the categorization of same-sex attraction into a single population category (i.e., homosexuals) at the turn of the nineteenth century, the subsequent classification of homosexuality as a mental illness as outlined (until 1978) in the American Psychiatric Association’s Diagnostic and Statistical Manual of Mental Disorders, and a criminal offense (until 2003 in many US states). The classification and regulation of same-sex attraction as “deviant” was evident in a number of historical campaigns. The US and Canadian governments, for example, sought to root out sexual non-normativity from the civil service by expelling thousands of gay-identified or
gay-suspected employees in the 1950s and 1960s, often on the premise that homosexuality was tantamount to other deviant affiliations, such as communism. In the 1970s and 1980s police raids and subsequent closures of urban bath houses, carried out in the name of public decency and public health, removed sexual and social spaces that were crucial to many in the community amid otherwise heteronormative and heterosexist environments. More recently, some urban gay communities have experienced the “de-gaying” of historically established gay space through gentrification and residential development intended for straight, middle-class inhabitants.

The study of geographies of sexualities has also been extended into a wider range of places and scales beyond the urban center. Work on sexuality and space has often positioned metropolitan areas as the socially progressive places in which sexual and gender norms are challenged, and from which important notions of “gay culture” and “queer culture” diffuse (Knopp and Brown 2003). Rural and suburban areas, in contrast, have often been assumed to be profoundly heteronormative places where coupled relationships and gendered work/home divides most in line with the Euro-American state are valued and sexual non-normativity – in the form of being queer, or even heterosexual and single – is excluded. Since the 1990s, however, many geographers of sexualities have challenged these notions. Some have looked explicitly at events (e.g., gay- and lesbian-friendly festivals and retreats) or processes (e.g., return migrations of gay men and lesbians) that temporarily or permanently transform rural areas. Others have examined more intimate spaces (e.g., gay men’s suburban homes) that act as community spaces and are marked as visibly gay or queer through subtle uses of art and design referencing places and events relevant to the gay experience. Still other work, however, has suggested that rurality is not necessarily something to be transformed or overcome but a consciously chosen milieu that facilitates its own forms of kinship among sexual “others.”

More theoretical strands of sexuality and space, particularly those concerned with queer theory, call into question the concepts of “abnormal” and “other” themselves. Queer theory offers a challenge to heteronormativity (the norms that make heterosexuality right in the first place) and the associated systems of patriarchy and of othering of those who do not conform. It not only imagines sexuality as a flexible continuum rather than a set of categories, but posits queerness as both a sexual non-normative identity and a political disposition that actively rejects the normalization of certain sexual identities and the notion of fixed identities themselves. Part of this work is concerned with critiquing the ways in which some sexual identities have become accepted and even co-opted into heteronormative “mainstream” society. The concept of homonormativity, for example, suggests that gay and lesbian citizens, as long as they engage in coupledom, monogamy, full-time work, homeownership, and consumption habits that build the economy, can transcend their previous position at the margins of society. Figures such as the white, middle-class lesbian couple and the well-traveled “global gay” become assimilated while other less acceptable sexualities (e.g., nonmonogamous, working-class, and trans sexualities) are pushed to the margins in the same way that gays and lesbian had been within heteronormative society (Duggan 2002). These so-called homonormative subjects have also been described as complicit in the systems traditionally used to oppress them. Since they now partake in recently granted marriage and adoption rights, and other practices regarded by the state and society as “responsible” (e.g., homeownership), their actions are thought to marginalize those...
queer people who are unable to participate in these practices as a result of laws, discrimination, or financial limitations.

Other work influenced by queer theory asks why certain sexualities are considered normal in the first place. Recent work on polyamory, for example, has suggested that, rather than combating portrayals of polyamory as personal underdevelopment, immaturity, or self-absorption, scholars should question why “traditional” romantic love and monogamy were ever considered morally or ethically superior. Even framing polyamory as an acceptable, private personal choice, then, prevents it from being understood as another way of loving that need not be valued differently. Yet other work rejects treating sexualities as categories or stand-alone attributes. Recent work on intersectionality has suggested that sexualities cannot truly be separated from other individual identities and characteristics such as “race,” and the term “intersection” erroneously assumes that they are separate to begin with. Although more traditional streams of the social sciences suggest that discrimination experienced by queer individuals who are also working-class and/or nonwhite is additive (e.g., “double discrimination”), others have suggested that discrimination can only be understood through lived experience and encounters with different places (Valentine 2007). In these encounters, one subjectivity may be favored over another to negotiate a new place or scenario. In others, a more privileged subjectivity (maleness) can undo a more marginalized one (gay sexuality).

In the past decade, work on global sexualities has further destabilized ideas about Euro-American categories of sexualities. Many scholars have noted that the ideas animating much of sexuality and space studies, such as urbanity, rurality, liberalism, conservatism, and “coming out,” are profoundly Western and white. In addition, the places and events (e.g., San Francisco’s Castro, the Stonewall Rebellion in New York City) discussed in so-called gay and lesbian history tend to be located in North America and Europe. Work on South and East Asia, in contrast, shows that same-sex attracted communities are constructed flexibly alongside – or even as part of – religious, nonurban, and deeply familial communities that would be described as “traditional” in the West. By the same token, work on countries such as Brazil and Thailand has shown acceptance for same-sex affinities involving drag queens and other gender-bending performers, but less so for men that present as typically male (in Western countries, the opposite is often true). The study of global sexualities has broadened not only in its geographic scope but also in its scale: increasing mobility of individuals and information means that sexualities are also informed by cross-cultural encounters. A gay Filipino man who moves to the United States, for example, may find that the more effeminate performance of a bakla identity that would be accepted or even celebrated in the Philippines is marginalized and excluded in New York City. In contrast, Filipina domestic workers working in Hong Kong who have heterosexual identities at home may find that it is common within their specific community to have masculine female lesbian partners while working away.

The globalization of sexuality is now also increasingly seen in concepts of development and nation-building that have gained transnational popularity. There is, for example, an increasing association of sexual diversity with cosmopolitanism and the “creative city” notion popularized by Richard Florida. In this model, cities that are welcoming to sexually non-normative individuals are thought to also support artistic enterprise, innovation, and diversity in general, making them viable centers of tourism and capital.
accumulation. Consequently, countries such as Singapore have overturned strict antigay policies and begun holding pride festivals, even though the lived experience of being gay or lesbian is still subject to less strenuous but equally present regulation. Despite welcoming sexual diversity in theory, many jurisdictions have also tried to suppress the sexualization of urban space. The Giuliani administration in 1990s New York City, for example, removed sex work, sex shops, cinemas, and other visibly sexualized spaces from Times Square to secure the city’s place as a global tourist destination. At the national scale, non-normative sexualities have been employed in what Puar (2007) calls “homonationalist” discourses of nationalism, terrorism, and counterterrorism. In these scripts, governments and media outlets in countries such as Israel and the United States may portray national acceptance for non-normative sexualities as evidence of their own political liberalism even as they pursue aggressive military actions in Muslim countries. In European countries, such as the Netherlands and France, similar scripts have been used as justification for assimilationist integration policies that presume homophobia and intolerance among new, often Muslim, immigrants.

Some have argued that the recent emphases on sexual identity, the state, and its regulatory capabilities have obscured some of the practices and emotions associated with sexualities. At the same time, work in several areas is both returning to the particularities of sexualized everyday lives and extending sexualities work beyond the realm of cultural geography. Work on love within emotional geography, for example, has shown that – despite its status as an ideal in the eyes of the state – it can actually be a competitive and pressure-filled endeavor for single people, especially living in certain settings. Similarly, work in migration and population geography has shown how mobilities for gay men and lesbians are influenced by distinct historical contexts, institutions, and personal transitions they encounter across the life course (Lewis 2014). Geographers working on health and sexuality, a field long dominated by psychology, epidemiology, and other quantitative health sciences, have sought more to engage with the actual contexts (e.g., the clinic, the “gay scene”) in which elements of sexualities – including sex itself – might influence health outcomes (see Del Casino 2007). Sexualities therefore retain solid (and growing) intellectual purchase within geography into the second decade of the new millennium.

Further reading

Congressional districts, changing urban form, geomorphologic processes, and ecological fragmentation are geographic topics that draw from the conceptualization of shape. Shape is broadly defined as the geometric outline or boundary of an object that, internally, is typically homogeneous in nature. Some shape definitions regard only the outside outline as the shape while others recognize that interior variations modify shape. For example, some regard a solid object and a hollow object as having the same shape, and others do not. Mathematicians formally define shape as what is left after the properties of translation, rotation, and scale are removed (Kendall 1984). With this basic principle, shape measures describe or define an object’s shape qualitatively or quantitatively to assess whether two objects are the same or similar in shape. Qualitative descriptions use nominal values to describe shape. This works effectively with simple regular shapes such as circles, squares, and triangles. Objects with irregular and complex shapes are more challenging to assign to a specific name. Quantitative methods for both simple and complex shapes rely on assigning a number or an equation to describe an object’s shape. The field of statistics has a structured research program to quantify shape with methods relevant to fields including medical research, image analysis, and geography.

These conceptual and formal definitions of shape flow intuitively into geographical definitions of shape. Geographic objects are those regions on the surface of the Earth that are conceptually homogeneous, such as political, municipal, and property boundaries, geology type delineations, or clusters of events such as crime or disease instances. As in the formal mathematical definition of shape, two geographic objects are the same shape even when they are in two different locations, when they are rotated by any amount, and when they are a different size (Figure 1). With some exceptions, geographic objects tend to have complex shapes rather than simple mathematical shapes such as circles, squares, and triangles. Shape plays a fundamental role in geography through map projections, geographic representation, shape analysis, and several application areas.

Map projections

Shape is one of the fundamental properties either preserved or distorted in a map projection. A map projection is the transformation of the three-dimensional spherical coordinates of the Earth’s surface (e.g., latitude and longitude) to two-dimensional Euclidean coordinates on a flat plane. This process that creates representations of the Earth’s surface features results in distortion or preservation of one or more geometric properties such as area, shape, or direction. A map that preserves shape is known as a conformal map; it preserves the angles between intersecting lines in two-dimensional
SHAPE

space. By preserving angles, the shape of surface features (e.g., boundaries of land masses) look basically the same as they do on a globe with distortion increasing away from the standard point or line.

Common conformal map projections include the well-known Mercator projection and the Lambert conformal conic projection (Figure 2). By examining the Tissot circles, Figure 2 shows that shape is preserved but area is distorted in both projections. The types of maps best suited for a conformal projection, important even in a digital age, include navigational charts, meteorological maps, and cadastral or parcel maps.

Geographic representation

Thematic maps, which display the spatial distribution of a specific subject matter, use point, line, and area symbols to represent the type or quantity of features. Area-based thematic maps, including area-class maps, categorical maps, nominal maps, and dasymetric maps, all use fill symbols within the boundary of a geographic object or line symbols along the boundary to represent the variations in the theme of the map. In other words, the shape of the geographic object influences the way the map is displayed. One distinction between the different types of area-based thematic maps is how the boundaries are derived (Chrisman 2002). In area-class maps, for example, the themes (or attributes) are controlled and the geographic boundaries are measured. Land-use maps fall into this category because the land-use categories – the attributes – are defined in advance and the boundaries are derived to maximize homogeneity within the boundaries. Choropleth maps, however, are different because in these types of maps the geographic boundaries are controlled and the attributes are measured. In census-based mapping, for example, census tract boundaries are predefined and the statistical data (e.g., population density or income levels) are measured.

Regardless of whether the attributes or boundaries are controlled or measured, the object’s shape depends on measurement scale. Measurement scale on the attributes refers to the level of detail and the number of categories represented. A finer measurement scale results in a classification system with more categories, affecting the shape, size, and number of geographic objects. Similarly, measurement scale on the boundaries also impacts geographic objects. A larger scale map will have more detail in the geographic object’s boundary and, more than likely, more geographic objects in the mapped
Figure 2  Mercator (top) and Lambert conformal conic (bottom) projections showing the preservation of shape through Tissot’s indicatrix.
SHAPE

region. So while comparing shape remains invariant under scale, how real-world entities become geographic objects (thus becoming a shape) depends on both attribute and spatial scale.

Geographic shape analysis

Geographic shape analysis is a systematic process that uses the qualities of a geographic object’s boundary or outline to gain insight into spatial and temporal processes. The qualities of shape are described qualitatively and quantitatively. Qualitatively, an object such as Italy could be described as having a “boot-like” shape. Perhaps the most pervasive use of nominal terminology in geography is geomorphic forms such as deltas (e.g., bird-foot delta) and drainage systems (e.g., dendritic). However, the shape of geographic objects is often difficult to describe qualitatively so quantitative measures are used when greater precision is needed, the comparison of similar shapes is needed, or there are reasons to believe that shape reflects important underlying processes.

Quantitative shape descriptors involve a mathematical metric or equation to characterize geographic objects with a simple or complex reproducible representation. Simple metrics, such as most compactness measures, are often indices, with results between 1.0 and 0. Shapes closer to 1.0 are more compact and closer to a circle (the most compact shape). Figure 3 illustrates the results of two such measures, the iso-perimeter quotient (IPQ) and the normalized moment of inertia (NMI), on three different shapes (Li, Goodchild, and Church 2013). IPQ uses an object’s perimeter as a parameter in the compactness measure, and so the results are much influenced by the convolution of an object’s boundary. Therefore, although the left and center objects in Figure 3 appear similar in shape, their compactness indices are quite different. The far right object has a convoluted shape and therefore receives a very low score by IPQ. The NMI, on the other hand, relies on the variability of the boundary’s distance from a central point rather than area-to-perimeter ratio to determine compactness. In addition to compactness measures, other simple shape measures include elongation.

![Figure 3](image-url) Comparison of IPQ and NMI compactness shape measures for three different shapes.
measures, direct comparison with a standard shape, and dispersion methods (Wentz 2000).

Complex shape measures result in an equation or set of numerical indices to describe an object’s shape. Fractals for example, widely used for simulation and analysis across many fields, use the principles of self-similarity to examine the relationship between scale and geographic boundaries. The resulting index indicates the complexity of the boundary at a given scale. Fractals have been used to quantify the dynamics of urban form, coastline processes, and boundaries between ecological zones (see Xu et al. 2014; Frost et al. 2005). Fourier harmonic analysis, which also focuses on the complexity of the outside boundary of a geographic object, provides a method for quantifying shape that is reversible. That is, the shape of the object can be reconstructed from the mathematical harmonic analysis (Moellerling and Rayner 1981; Akamatsu, Takayama, and Ikeda 2012). The method uses the eigenvalues and eigenvectors from a discrete Fourier transformation as indices to quantify spatial form.

Shape is conceptually and empirically incorporated into geographic studies and analysis to support spatial pattern analysis, to support image classification, and to correlate geographic form and process. Spatial patterns emerge through the composition and configuration of shapes on the landscape, which gives rise to questions on how and why these patterns occurred where they did and how they change over time (Williams and Wentz 2008). Recognizing the regularity of shapes in the landscape, algorithms to classify satellite images use shape metrics to improve classification results by extracting features with known shape parameters (Jiao, Liu, and Li 2012). Finally, geographic theory suggests that human and physical landscapes contain structures and forms that are strongly influenced by the underlying processes that gave rise to those forms (Walsh, Butler, and Malanson 1998; Bunge 1966). Shape analysis provides a fundamental mechanism to correlate form and process.

In September 1956 a conference was held in Alba, Italy, that brought together avant-garde revolutionary groups from all over Europe. The conference created an accord between three of the attending groups, the Lettrist International (led by Guy Debord), the Scandinavian and German based Movement for an Imaginist Bauhaus, and the London Psychogeographical Association, to disband and reform as a single organization committed to the revolutionary critique and subversion of contemporary forms of alienation. This organization was called the Situationist International (hereafter SI). Although membership of the SI never rose above 70, through its journals (especially the Paris-based Internationale Situationniste) and agitational role within the French student revolts of the late 1960s, the group managed to attract a level of recognition and notoriety, particularly within the French far left, out of all proportion to its size.

The two theorists who dominated the movement were Guy Debord and, to a lesser extent, Raoul Vaneigem. Debord and Vaneigem’s most influential works, respectively, The Society of the Spectacle and The Revolution of Everyday Life, were both first published in 1967 and were intended to complement each other (the first English translations appeared in the early 1970s). Both texts express what can be seen as situationism’s unique theoretical contribution, a rebooting of Marxism for the late twentieth century; more specifically, the development of a critique of “the spectacle,” the term Debord and Vaneigem gave to the massively reified, appearance-based, nature of contemporary life. Debord describing the onset of spectacular society, suggested:

The first phase of the domination of the economy over social life brought into the definition of all human realisation the obvious degradation of being and having. The present phase of total occupation of social life by the accumulated results of the economy leads to a generalised sliding of having into appearing, from which all actual “having” must draw its immediate prestige and its ultimate function. (Debord 1977, thesis 17)

It is no coincidence that the favorite social metaphor employed by situationist authors was of that archetypal modern cultural product, the motion picture. It seemed to them that all society had turned into one giant movie spectacular, with a transfixed and willing audience. The situationists insisted that Marx’s (Marx and Engels 1970, 96) dictum that “men make their own history … but they do not make it under circumstances chosen by themselves” can only be understood in the second half of the twentieth century through an appreciation of the centrality and totality of the “image society.” “The spectacle,” wrote Debord (1977, thesis 34), “is capital to such a degree of accumulation that it becomes an image.”

After the events of May 1968 and a series of acrimonious expulsions, however, the SI lost momentum and dissolved itself in 1972. Although described by Berger (1975, 600) as “one of the most lucid and pure political
formulations of the 1960s,” until the 1980s the situationists tended to be dismissed both by orthodox radical opinion and by the mainstream press as fanatics whose extravagant rhetoric exceeded their political or intellectual significance. The situationists were brought back into fashion in the 1980s, in part because of the rise of postmodernism, a current that in both intellectual and artistic life encouraged an interest in the transgressive, playful, and everyday as forms of political activity (Bonnett 1989).

Situationism is unique among radical theories in placing geography at the center of its ideas and activities. Place and space were at the heart of their investigations. In part, this was a result of their suspicion of modern town planning, which they regarded as reactionary and politically pacifying. “The whole field of urban planning” suggested Vaneigem and Kotanyi (1981, 66) should be understood “as the organization of participation in something in which it is impossible to participate.” What is required, proposed the situationists, is a new form of geographical investigation that can enable the revolutionary reappropriation of the landscape. “Proletarian revolution is the critique of human geography through which individuals and communities have to create places and events suitable for the appropriation, no longer just of their labor, but of their total history. In this game’s changing space, and in the freely chosen variations in the game’s rules, the autonomy of place can be rediscovered” (Debord 1977, thesis 178).

The techniques involved in this form of reappropriation revolved around the idea that, through the instinctual exploration of the emotional contours of one’s environment, playful and anti-authoritarian places and journeys can be discovered or created. This process was supposed to enable the construction of revolutionary “situations,” hence the appellation “situationists.” What the SI called their “psychogeographical” investigations adopted the practice of the “dérive” (literally translated, “drift”) that involved an unstructured wandering through the landscape, allowing oneself to be drawn consciously and unconsciously toward those sites and movements that heighten one’s experience of place and disrupt the pacifying banality of everyday life as it is lived in “the society of the spectacle.”

The situationists proposed that new maps expressing psychogeographical possibilities and explorations should be drawn up and used as blueprints for a situationist town or “utopian center.” The visionary nature of these proposals was most fully articulated by Chcthegov (1981), who looked forward to the division of cities into zones of emotional intensity (for example, the Bizarre Quarter, Sinister Quarter, Noble Quarter) through which people would be in perpetual dérive. Other, slightly less extraordinary schemes suggested the setting up of sites of psychogeographical experimentation that could “function as bridgeheads for a new invasion of everyday life” (SI, quoted in Barrot 1987, 24).

As Marcus (1989, 170) notes in Lipstick Traces, a work that traces the creative links that stretch from Dada to the situationists to punk rock, for Debord and his coworkers, “to pursue the dérive” was “to give yourself up to the promises of the city, and then to find them wanting – to drift through the city, allowing its signs to divert, to ‘detourn’ your steps, and then to divert those signs yourself, forcing them to give up routes that never existed before.” The dérive, Marcus continues, was supposed to contribute to the development of a revolutionary “way of life that anyone could understand and anyone could use.”

The practical activity that emerged from the theories of the SI ranges from seemingly inconsequential rambles around European cities to
SITUATIONISTS/SITUATIONIST GEOGRAPHY

relatively rigorous and well-documented experimental activity. In either case, however, the primary intention was not to release the unconscious or to admire the delights of “chance,” as it had been for the surrealists, but to think about and engage physically with the possibilities of creating a new and radically stimulating kind of city.

Over the past three decades situationist geography has developed a scholarly following (see Bonnett 1989; Pinder 2005). Much of this attention is focused on the radical nature of “everyday space” and the “suppression of the street” augured by modern traffic and modern planning. Outside of the academy, the situationists have had an even greater influence. The early 1990s witnessed the birth of local psychogeography groups across the United States and Europe. From the late 1990s activity passed to the arts community and subsequently, to “urban explorers,” who investigated the hidden and exciting within the seemingly ordinary world of the everyday city.

Further reading

The concept of skill is important to many disciplinary fields in the social sciences including economics, sociology, urban studies, labor studies, and human geography. It has also been closely linked to some of the most significant debates in the social sciences over the past half-century including the “deskilling debates” of the 1970s and 1980s regarding the growing levels of income inequality and ideas emanating from human geography about creativity and innovation. An apparently simple idea, the concept of skill, on reflection, proves to be rather more complex and perhaps even controversial. Not only are there definitional ambiguities related to skill but the way in which the concept is used in academic and mainstream discourses has invited much confusion. In this entry, skill is treated mostly in relation to economic activities rather than social development or educational outcomes, though these latter issues are often closely linked to economic outcomes.

After a brief section detailing the definitional issues related to skill – much of this work having been carried out by human development scientists and psychologists – the first major section of this entry will examine how skill has been understood in economics and sociology. It has been in these two fields that the bulk of social scientific theorizing on skill has been undertaken. What is most interesting about connecting some of the definitional issues studied by scientists with the research carried out by social scientists is how the work of the former intimates or foreshadows the conclusions drawn by the latter. This is particularly the case with respect to the perceived scientific distinction between cognitive skills and motor skills, a distinction that has filtered into social science as a way of distinguishing “high-skilled” from “low-skilled” workers. One of the most prominent and elegant theories of skill has been provided by economists in the form of human capital theory as a way of explaining divergent labor market outcomes based on the skills and qualifications of individual workers. Many sociologists have been highly critical of human capital theory, arguing that notions of skill are often socially constructed to fulfill particular social and economic goals. This is most evident in the vast literature from within industrial and labor sociology which identifies the skill levels and attributes of workers in various occupations over time.

Following the description of the ways in which skill has been understood by economists and sociologists, the second major section focuses on how the concept of skill, and debates from other fields, have been translated into human geography. Since the 1970s, skill has been examined in a variety of different ways by geographers, mostly within the subdiscipline of economic geography. Since the political economist Adam Smith developed the idea of the “division of labor,” scholars have been interested in the ways in which workers of different skill levels are integrated together in the production process. In many ways, economic geographers and regional scientists have been particularly attentive to issues of skill because one of the key goals of these fields has been to map how divisions of labor are organized and managed across space.
This is related to perhaps the broadest question at the heart of economic geography: What explains why some regions succeed economically while others fail? Since the mid-1990s, renewed interest in this question has spawned important debates where skill – either explicitly or implicitly – is at the center of attention. Many urban and regional economies in OECD (Organisation for Economic Co-operation and Development) countries are increasingly being defined by the spatial and social polarization between “high-skilled” knowledge workers and “low-skilled” service workers in personal care, retail, and food services. Skill, creativity, innovation, and economic growth have never been distributed evenly across space. The questions which currently animate much of economic geography revolve around the study of exactly which factors explain the clustering of so-called skilled knowledge workers, whether such clustering provides a good model of urban economic growth, and whether cities can be designed to attract knowledge workers. Beneath the surface of these debates, however, reside foundational issues long studied by social scientists about what skill is, who is considered skilled, and what functions these definitions serve.

**Definitional issues and the science of skill development**

The dictionary definition of skill reveals some of the complexity and ambiguities of the concept. Each of the subdefinitions from the dictionary has at its core the notion of competence or expertise: “the ability to do something well,” according to the *Oxford English Dictionary*. Should these abilities, however, be considered natural gifts or as having been acquired through training? Do these abilities belong in the realm of physical dexterity and coordination or of knowledge and intellectual activity? In general use, “skill” often refers to both mental and physical processes and is understood as the result of both training and genetic predisposition. Scholars in the human sciences – especially those interested in child development – have studied the ways in which humans acquire skills, and their conclusions are very relevant to the study of skill by social scientists.

Scientists tend to distinguish between motor development, which governs physical skills, and cognitive development, which covers mental processing skills. The traditional view among scientists has been that there is an important distinction between these two forms of development, not only in the skills they produce but also in the processes which initiate such skill development. As prominent neuroscientist Adele Diamond has stated, “motor development and cognitive development have been studied separately” and “have generally been viewed as independent phenomena, although occurring in the same organism over the same time period” (Diamond 2000, 44). The scientific rationale for such a distinction has been based in the historical understanding of different locations of brain activity for motor and cognitive skills. Motor skills have been thought to originate in the cerebellum and to develop earlier in childhood. In contrast, cognitive skills have been linked to the prefrontal cortex, which does not fully develop until later in adolescence. This simple mind/body dichotomy has been incredibly impactful because it supports the view of motor skills as basic and cognitive skills as more advanced.

Yet new research using medical technologies such as functional neuroimaging is beginning to show the errors of this traditional view. Not only are motor and cognitive skills intimately related in terms of brain activity, but certain advanced (or “fine”) motor skills take equally long to develop in the human brain. Neither
As Diamond argues, “Motor development and cognitive development may be much more interrelated than has been previously appreciated. Indeed, they may be fundamentally intertwined” (2000, 44). Since the early 2000s, significant progress has been made in the scientific understanding of skill development and the neurological processes which support such development. The mind/body dichotomy is increasingly being supplanted by integrative understandings of how motor and cognitive development are mutually reinforcing. This type of thinking has not fully diffused into the social sciences where there is still a strong assumption of high skills being related to cognitive abilities and lower skills being related to physical or emotional tasks.

The economics and sociology of skill

In a classic article on the subject entitled “What Is Skill?” sociologist Paul Attewell (1990) details many of the challenges related to the study of skill in economies. Most importantly, he outlines four main approaches through which skill has been studied in the social sciences: positivism, ethnomethodology, Marxism, and Weberian social constructionism. The first, and perhaps most prominent, approach is the positivist view, which is most closely related to human capital theory in economics. Human capital theory was established by the economist Gary Becker to account for the knowledge and skills that an individual has gained through education, job training, or work experience. According to neoclassical economics, human capital can be considered either as an investment in training made by an individual or as skills that add value in the production process. The amount of human capital – or skill – that each worker has is seen as directly proportional to the amount of wages that can be earned: “Wages are seen either as a return on an individual’s investment in human capital or as determined by the marginal utility of the skill attained” (Attewell 1990, 425).

Given this elegant argument that an individual’s investment in their own skills will result in higher productivity and ought therefore to be rewarded with higher wages, the key question is how human capital should be measured by economists. Human capital is usually measured as the sum of years spent in formal education or job training, as well as years of job experience. This approach is beneficial in that it provides a clear and consistent way of measuring human capital across occupational segments. In general, economists have consistently shown that workers with greater levels of human capital are rewarded with higher wages and participate more fully in the labor market. Yet, many sociological theorists have been critical of human capital theory because of the rather tenuous links between educational achievement, skill acquisition, job performance, and income. As Attewell (1990, 426) remarks, human capital theory:

(a) … abstracts from such phenomena as credentialism (whether college degrees really provide job skills or function as a rationing device); (b) the impact of occupational monopolies (unions and professional and state certifications); (c) the relationship of sex-typing of occupations to their perceived skill; and (d) the effects of ongoing gluts of certain skills and shortages of others on the social and monetary valuation of those skills. From a sociological viewpoint, therefore, human capital represents a shortcut around studies of skill and income attainment by assuming a fairly direct equivalence between education, skill, and reward.

There are two other issues that arise in relation to human capital theory. First, a bias can clearly be detected between skills that are considered cognitive and those that are considered motor
development. That years of schooling are the key measure through which levels of human capital are determined suggests that cognitive skills are more valuable than motor skills, social skills, or emotional skills. Yet a growing body of research from various different academic disciplines is showing that work that has traditionally been considered “low-skill” in fact requires high levels of skill that are not visible in human capital measures.

One of the original lines of analysis of this sort came from sociologists in the field of ethnomethodology, the second approach detailed by Attewell (1990). For scholars such as Kusterer (1978), the level of skill of individuals was something that must be studied in extraordinary detail rather than something to be assumed from level of education. A core idea of ethnomethodology is that all human activity is rather complex and is oriented toward fitting into the existing social order. In the work sphere, this means that scholars would expect there to be high levels of skill in occupations that have traditionally been considered unskilled. Kusterer (1978) was at the forefront of this type of research which involved participant observation and in-depth interviews. Studying machine operators and store clerks, Kusterer found that most skill is invisible to outsiders. Such researchers argue that the most skilled workers are those that make their jobs look routine, irrespective of their levels of human capital, since they have mastered all the nuances of their work.

More recent research from within sociology and labor studies has extended these basic ideas to study the key skill capacities of so-called unskilled service workers, who are a growing part of many urban economies. Despite their relatively low levels of human capital, many service workers have important physical, social, and emotional skills that they utilize in their work (Hampson and Junor 2010). This point is related to the second major problematic with human capital theory. The view of work in human capital theory is one in which each individual can be effortlessly distinguished for the value that they have brought to the production process. As more types of work become team-oriented, however, it is possible that individual performance related to cognitive skills becomes less important than the social and emotional skills involved with teamwork. More fundamentally, we might ask whether skill is best treated as an attribute of a person or whether the ability to use certain types of skill are largely determined by the nature of the job itself (which is often not controlled by the worker).

This distinction becomes important when considering how Marxist scholars have thought about skill. Marx himself announced early in *Capital* that he would treat every type of labor as “simple unskilled labor.” This is representative not only of the rising importance of industrial labor at the time of writing, but, more crucially, of the importance Marx placed on the ownership over the means of production in a capitalist economy. Where Marx does discuss skilled labor, he argues that the higher cost of skilled labor is required to pay for investment in skills training. Marx, in some ways, prefigures human capital theory (Attewell 1990). Many later Marxist scholars would develop more sophisticated ways of thinking about skill. The most famous of these was Braverman (1974) who developed his deskill thesis in line with Marx’s notion of alienated labor. For Braverman, the imperatives of capitalist competition and the falling rate of profit necessitated the constant search on the part of the owners of capital for efficiencies in the production process.

According to this view, the related rise of Fordist mass production on the assembly line and Frederick Winslow Taylor’s techniques of “scientific management” were an attempt to wrest
control of the production process away from skilled workers and toward unskilled workers who could be paid less. Extending the division of labor may not essentially change the skilled character of workers but it does reduce the task complexity of jobs and therefore affords reductions in the cost of labor. In this sense, the job itself is first deskilled before the worker’s previously valuable skill becomes outdated. Any job in which technology and extended divisions of labor can be applied might be at risk of deskilling.

Braverman’s 1974 book *Labour and Monopoly Capital* spawned intense debate across the social sciences between those who reported deskilling occurring in workplaces and those who saw problems with both the theory and the empirics used in its support (Attewell 1990). This debate, which not coincidentally corresponded with an age of deindustrialization and stagnation in many Western economies, was never fully resolved. There was, however, a sense that with the emergence of the postindustrial and “knowledge-based” economy in the 1990s, the worry over deskilling had subsided. Some semiskilled industrial jobs had been lost to deskilling and offshoring but many new skilled jobs were emerging, sometimes in entirely new economic sectors.

In an interesting twist, recent research by labor economists is suggesting that job routinization (a process resembling deskilling) is becoming endemic with the ever greater use of information and communication technologies (Autor, Levy, and Murnane 2003). This push for routinized work has not stopped at the occupational level of unskilled and semiskilled workers but instead has rapidly breached so-called skilled job sectors, threatening the job security and wages of professional workers in law, accounting, engineering, science, and software development (Blinder 2006). The outcome of these processes is that many OECD countries are currently experiencing significant polarization in the skill requirements of jobs between low-wage service workers (some of whom are economic migrants) and those professional workers who still have the opportunity to fully utilize their knowledge and creativity (Autor 2010).

This final point about the declining protection of skilled professional workers from competition and routinization is related to the last approach to understanding skill as outlined by Attewell (1990). For those in the Weberian tradition of sociology, the real task is not to identify the best way of defining skill in the economic sphere once and for all, but rather to appreciate that human capital often has very little to do with economic standing. This approach has two interrelated branches. Some scholars focused on how market factors of supply and demand, rather than skill composition, determine wages to argue that there are moments when relatively low-skilled work can be paid handsomely. The other branch focused on ideological factors to argue that the idea of skill is a vehicle used by certain groups to promote or maintain their own power and prestige. This notion of the social construction of skill is related to the market factors approach because the ideology of skill is often used to improve supply and demand conditions in certain occupational segments. In Weber’s own writing, occupational groups are considered as another social group interested in securing its own goals (often at the expense of others). The clearest way in which they do this is by restricting access to the social group so as to reduce the number of competitors for supplying such skills in the labor market. Medieval guilds, craft unions, and modern-day credentials work on this basic principle, often sanctioned by state bodies.

If the income level and prestige of various jobs is mostly a product of social manipulation by those that fill the occupation, what does this suggest about the actual skills that are needed
to complete certain worker tasks? Among neo-Weberian sociologists some have taken a very strong stance that the social construction of skill has successfully created occupational power even in the evident absence of task complexity. Others have taken a weaker stance that some “real” skills are necessary to carry out work tasks but that these do not fully explain the different standing of occupational groupings. What we have seen, then, is that over the past half-century economists and sociologists have been engaged in serious debates about the meaning and significance of skill in economic activity.

Skill in economic geography

Economic geography has become an immensely diversified field of study since the 1980s, with a plethora of coexisting theoretical, methodological, and empirical approaches. This is a dynamic academic discipline which perhaps complements its topic of study: an ever-changing global economic system. Moreover, as economic geography has widened its scope of analysis, it has come into closer contact with related academic fields including economics, economic sociology, urban studies, labor studies and international political economy. Yet, despite the changing directions and orientation of economic geography, the main objective of the field has remained much the same: to trace in real time the changes that have been occurring in the spatial dynamics of economic activity.

The notion of skill has been central to these efforts. What is most interesting is the changing way in which skill has been studied and used in contemporary economic geography. Indeed, it is possible to track the real-time changes in global economic activity alongside the particular interests of key economic geography research. When this is done, it becomes clear that skill has been at the heart of some of the most important debates in the field while also being one of the key topics on which economic geographers remain divided and fragmented.

In the 1970s and 1980s many Western economies experienced plant closures, jobs losses, and a general decline in their industrial sectors. Economic geographers made key contributions to understanding these phenomena. Massey (1984) argued that growing international competition among jurisdictions for industrial activity – largely carried out by so-called unskilled and semiskilled workers – was leading companies to relocate production in search of cheaper labor costs. The labor arbitrage strategies of multinational firms were seen as a key element in explaining the deindustrialization of Western industrial regions during the 1980s. Relatedly, economic geographers developed theories of “uneven development” to show how the owners of capital leveraged their spatial mobility in order to find the most profitable locations for production (Smith 1984). Capital flight not only shaped levels of economic development across space but also disciplined workers through threats of plant relocation.

As a result of deindustrialization, the proportion of overall employment in manufacturing jobs declined considerably across most Western countries (Pilat et al. 2006). During this time, while many economic geographers focused their research on the challenges of economic restructuring, others began discussing the apparent rise of postindustrial or post-Fordist economies (Scott 1988). The basic argument was that newly industrializing countries in the Global South would have a comparative advantage in production that required unskilled or semiskilled workers, while Western economies had an advantage in the production of knowledge and information which was an increasingly important component of economic growth. Economic geographers
across various subfields have appreciated that the fundamental feature of the global economy is the way in which different places are interconnected through trade relations (Dicken 1998). It is not possible to have a place defined by knowledge production unless that place is connected to resource, agricultural, and industrial peripheries somewhere else. Indeed, this is precisely the shape that the global economy has taken.

Since the 1990s, as this postindustrial economy came to fruition to varying extents across space and time, much contemporary economic geography has been concerned with the nature and spatial dynamics of the “knowledge economy” or the “learning region” (Morgan 1997). Whether it is acknowledged or not, this is largely about skill. There is a strong assumption in much of this research that successful economic places – global cities, creative cities, and so on – are defined by their highly skilled workforces. A key area of interest has thus been about cities, since city-regions have been the main site through which knowledge economies defined by innovation, research and development, business services, and cultural production are organized. Economists have demonstrated that workers with high levels of cognitive skill – or human capital – generally earn higher incomes and are increasingly clustering in “skilled cities” (Glaeser and Saiz 2003). As a result, many economic geographers have studied the conditions under which such knowledge economies grow, though there has been an interest in labor migration and the challenges facing unskilled workers as well.

Most commentators agree that knowledge economies are defined by the agglomeration, or clustering, of innovative people and firms in a specific location. These agglomeration economies provide mutual benefits to firms and skilled workers. Firms benefit from reduced transactions costs, a larger labor pool, and the potential for knowledge spillovers that potentially generate innovation. At the same time, workers gain from access to a greater number of firms, as well as the opportunity to develop social networks that can yield employment or entrepreneurial opportunities. The unanswered question remains how these agglomeration economies are catalyzed and to what extent cities can themselves establish the conditions to achieve such firm clustering.

Within economic geography there has been a recent debate about the mechanism through which agglomeration is initiated. Richard Florida (2002) argues that workers are the instigators. Cities that offer the best and greatest number of amenities will attract the best and most talented workers, which will in turn draw innovative and profitable firms. In contrast, Michael Storper and Allen Scott (2009) suggest that firms come first. Talented workers are attracted to a city not because of its amenities but because of jobs that have been created by firms already there. While the exact mechanism remains somewhat unclear, what is evident is that so-called skilled and unskilled workers are increasingly residing in different types of cities (Glaeser and Saiz 2003).

This polarization of economic opportunities across space is leading to new geographies of uneven development. At the urban scale, the polarization of income groups within the city is increasingly problematic for social and economic reasons (Wilkinson and Pickett 2009). At the same time, however, not all successful regional economies in Western countries are knowledge-based and this perhaps provides some hope for regions not defined by knowledge activities. Likewise, not all cities that have aimed to transition to a knowledge economy have succeeded, and this reminds us that the same imperatives of competition which impacted unskilled workers in the 1980s may now be impacting skilled workers as newly developing countries such as China, India, and Brazil increasingly
prepare for their “knowledge economy” future. In both the United States and Canada, some of the fastest-growing regional economies, which are providing high wages, are defined by resource extraction activity. In Germany, manufacturing has remained an important part of employment and economic growth (Pilat et al. 2006). What economic geography tells us about skill, above all else, is that there is nothing static about how certain skills are valued over time and across space in a globalizing economy.

**Conclusion**

There are many ways to understand skill in the social sciences and it is a term that is mobilized in various ways to suit the interests of different social groups. Most scholars agree that skill represents an endowment of capabilities that enable an individual to contribute to the production of valuable goods and services. Where differences of opinion emerge are with how different sets of skills are defined, measured, and rewarded.

This entry began with a discussion of how skill as a human development trait is currently being understood by scientists. It appears that the scientific consensus is moving to a view of skill as a multifaceted and complex human development process instead of previous dichotomous conceptions of physical skills as rudimentary and cognitive skills as more advanced. This new orientation toward skill raises important questions about how the categories of “skilled” and “unskilled” workers have long been activated in the economic sphere. A scientific view of skill in the workplace would question why a marketing analyst with a university degree is seen to be more skilled than a personal care worker or a flight attendant. Indeed, as has been shown, this view is emerging across the academic social sciences through research by economists, sociologists, economic anthropologists, and geographers.

The more fundamental question remains, therefore, on what basis economic participation should be rewarded. Income inequality has been rising dramatically across most OECD countries since the 1980s (IMF 2014), puncturing the smooth Kuznets curve view that inequality declines as economies develop. This growing disparity in incomes and wealth is not only a threat to social cohesion (Wilkinson and Pickett 2009), but it very likely represents a significant dampener on economic growth as workers struggle to consume (IMF 2014).

Beyond academia, issues of skill in the workplace are increasingly becoming fodder for film and TV franchises. One of the most popular new shows on North American television over the past few years has been *Undercover Boss*. Each week, the CEO of a major company takes on the guise of a training employee to see how the business operates “on the ground.” The most memorable moments of each episode are reliably when the CEO cannot perform the task being taught to them by the employee mentor. The viewer is constantly asked to reconsider which one of these two people is the “skilled” worker. Yet, at the end of the show, the stunt is revealed, the CEO learns important lessons about how to improve their business, the employee-mentors are surprised with a substantial gift, and there is a lot of hugging and crying. Needless to say, the broader world of work does not reflect these understandings of how much skill the “unskilled” worker actually has.

As scientific evidence is increasingly suggesting, skill is not an exclusive cognitive category for those who have received a certain level of education. There are multiple forms of skill that workers perform during the process of production. Skills have been recognized and rewarded differently over time and space.
Geographers have made important and lasting contributions to social science debates by highlighting the locational dynamics surrounding economic skills. We can only assume that there is more research to be done as the nature and operation of skill shifts in a fast-changing economic world.

Description and purpose

The Institute of Geography is a scientific center of the Slovak Academy of Sciences involved with research in several branches of geography. The mission of the institute is to carry out basic research into spatial structures and linkages existing between the natural and socioeconomic systems with special regard for Slovakia. The institute accomplishes its goals through its journals, postgraduate educational programs, research grants and contracts with academic institutions and government agencies, and participation in numerous national and international conferences. Currently the institute consists of three scientific departments: Physical Geography, Geomorphology and Natural Hazards; Human and Regional Geography; and Geo-Information Sciences.

Journals or major publication series

Current activities or projects

The institute actively collaborates with partner universities and academic institutions in Slovakia and abroad. The institute participates in activities of numerous international organizations (e.g., IGU, ICA, IUCN, IALE, and MaB). The IG actively participated in preparation of the Regional Conference of the IGU (Prague 1994) and the 2nd EUGEO Congress (Bratislava 2009), and in the edition of Population Atlas of Slovakia (2006) along with the monograph Demo-Geographical Analysis of Slovakia presenting changes in Slovakia after 1989. Participation of the institute in the international projects financially supported by the EU: CORINE land cover 2006, PANet2010, INFRAREGTUR, and VITAL LANDSCAPES.

Brief history

The institute was founded in 1943 as the Geographical Institute of the Slovak Academy of Sciences and Arts. Apart from geographical
research, studies in sociology, ethnology, and demography were pursued in the institute as well. The second stage of the institute’s development (1953–1963) started with the founding of the Slovak Academy of Sciences (SAS). At the beginning the focus was in tasks dedicated to the physical-geographical themes, later the asymmetry was corrected as additional themes were added. The institute has used its present name since 1963. The third stage (1964–1989) involved tasks imposed by the governmental plan for the basic research, including work synthesizing research on landscape and environment. Results of the research were incorporated in the monumental work, the *Atlas of the SSR* (1980). The institute entered the fourth stage of its history after 1989 when the new political and socioeconomic situation were reflected in its different forms of organized research-scientific activities. Future opportunities are defined in four research clusters: structure and dynamics of natural landscape, hazards and risks; landscape changes explored by application of remote sensing data and the GIS; sustainability and quality of life in changing environments; society in flux, spatial disparities; and local and regional development.

Slovakia: Slovenská geografická spoločnosť pri Slovenskej akadémii vied (SGS) (Slovak Geographical Society at the Slovak Academy of Sciences)

Founded: 1955
Location of headquarters: Bratislava
Website: www.sgs.sav.sk
Membership: 290 (as of January 1, 2014)
President: René Matlovič
Contact: rene.matlovič@unipo.sk

Description and purpose

The SGS was founded to support geographic education and professionalization and the dissemination of geographic research and knowledge in Slovakia. The members are mostly scholars, teachers, researchers, and other professionals in Slovakia. It has six regional branches (Bratislava, Prešov, Nitra, Banská Bystrica, Košice, and Ružomberok) covering three areas of geography (theoretical geography, applied geography, and geographic education). The society organizes a congress every 4 years as well as various other events (conferences, field trips, workshops, lectures, exhibitions, and expeditions). SGS is a member of EUGEO (Association of Geographical Societies in Europe).

Description and purpose

The Geografski inštitut was founded in 1946 by the Slovenian Academy of Sciences and Arts. In 1976 it was named after Slovenia’s greatest geographer, academy member Dr Anton Melik (1890–1966), who served as the institute’s first director. Since 1981, the institute has been one of the members of the Scientific Research Center of the Slovenian Academy of Sciences and Arts. In 2002 the Institute for Geography (established in 1962) and the Geographical Museum of Slovenia (established in 1946) joined the institute.

Current activities or projects

The institute participates in numerous projects in Slovenia and abroad, organizes academic conferences, trains junior researchers, and participates in professional exchanges. In the past ten years, the institute’s research team has published over 3000 bibliographic units and made over 500 presentations at conferences in Slovenia and abroad.

Most of the institute’s research work derives from its long-term research program Geografija Slovenije (Geography of Slovenia). In 2013, the research work supplemented seven basic and seven applied national projects, mainly funded by the Slovenia Research Agency, as well as twelve international European projects.

Brief history

The institute’s main task has always been to conduct basic and applied geographical research on Slovenia and its landscapes as well as to prepare basic geographical texts on Slovenia. Since Slovenia gained independence the institute has prepared a large variety of basic geographical works on Slovenia, including national, world, school, and census atlases, a dictionary of geographical terminology, a lexicon of Slovenian places, and a regional and general monograph.

A slum is a squalid settlement of substandard housing and living conditions where inhabitants lack fundamental resources like shelter, job opportunities, water, and food. While conditions vary from place to place, most slums are heavily and densely populated, have a substandard housing stock, contain a large pool of underemployed and unemployed workers, and lack reliable utilities and services such as clean water, electricity, sewers, and waste collection. In addition to being underserviced, most slums do not contain or have easy access to public institutions such as hospitals and schools.

The first large slums originated during the rapid migration, industrialization, and urbanization processes that occurred during the Industrial Revolution in Europe and the United States. New York City is considered to have had the first slum in the late 1700s, Five Points, in what is today’s Little Italy in Manhattan. Five Points housed newly arrived freed slaves and immigrants of Irish, Italian, and Chinese origin who came to New York City for work opportunities and the prospects of a better life. Five Points was situated near the center of the urban area close to numerous large factories, and was known for its filthy, disease-ridden conditions caused by trash accumulation, a poor sanitation system, and polluting industries that occupied the city center. Slums in the twenty-first century are predominantly found in urban areas of underdeveloped and developing counties.

Today, slums and slum residents are widely stigmatized as being socially dysfunctional, carriers of antisocietal norms, and characterized by an absence of morals. News and media portrayals of slums disproportionately invoke realities of crime, gang violence, drug abuse, and individual social malaise. Yet, while such outside perspectives may see disorder and aberrance, life in slums is typically organized and replete with nourishing social networks, engaged leadership, and strong communication channels. Lost in the common caricaturing and stereotyping of people and place is the reality of people practicing superior survival skills, resourcefulness, and adaptability to the challenging circumstance of difficult everyday conditions.

Slums of the world

Slums exist across the world in developed, developing, and underdeveloped countries. UN–Habitat (2012) estimates that the proportion of urban people living in slums in developing countries decreased from 39% to 32% between 2000 and 2010. In 2012 the proportion of urban population living in slums was highest in sub-Saharan Africa (61.7%), followed by southern Asia (35%), Southeast Asia (31%), East Asia (28.2%), West Asia (24.6%), Oceania (24.1%), Latin America and the Caribbean (23.5%), and North Africa (13.3%). Compared to 1990, these regions tended to experience losses in proportion of urban dwellers living in slums, e.g., South Asia (−22.2 percentage points), North Africa (−21.1 percentage points), Southeast Asia (−18.5 percentage points), East Asia (−15.5 percentage points), Latin America and the Caribbean.
(-10.2 percentage points), and sub-Saharan Africa (-8.3 percentage points). Oceania saw no change between 1990 and 2012 and only West Asia saw an increase (2.1 percentage points).

**Migration and the reproduction of slums**

Migration from rural to urban environments for economic opportunities, better schools, and a higher quality of life has been a major force in sustaining slums. With populations in cities swelling, local labor markets have often been unable to provide decent-paying jobs and suitable shelter for those that desire them. Formal and informal mechanisms, such as realtor steering, zoning, and discriminatory house buying and renting practices have often systematically concentrated these populations in slums. Moreover, technological change displacing workers from agricultural settings has exacerbated rural to urban migration, visibly expressed as the increasing substitution of capital for labor in the agricultural process across the globe. Thus, many countries have had a declining share of agricultural contribution to GDP from 1961 to 2015, including Turkey (-44.8 percentage points), Bangladesh (-42.1 percentage points), Niger (-37.2 percentage points), Indonesia (-32.0 percentage points), China (-31.2 percentage points), Sudan (-26.8 percentage points), Malaysia (-26.6 percentage points), India (-24.8 percentage points), Ecuador (-23.6 percentage points), Ghana (-19.0 percentage points), Pakistan (-19.9 percentage points), and Brazil (-13.9 percentage points).

**Slum characteristics**

A slum is typically established at the urban edge of a city on undesirable public land. As urban boundaries expand over time, it is common to see slums that were once on the periphery of a city become integrated into its urban morphology. The exact location of a slum on the urban edge depends on a variety of factors, including locations of employment, availability of land, and layout of transportation systems. Slum settlements often begin with impermanent tents or shelters before slow investment associated with longer tenure creates more permanent settlements with more durable materials. The availability of water is of vital importance to sustain life and is strongly considered in settlement location. Accessibility to work outside of a slum causes settlers to locate on the edge of an urban area or near rail infrastructure. Settlers may choose to locate on land viewed as undesirable because it poses little threat of being seized by government. These considerations often mean that slums occupy environmentally dangerous areas such as floodplains and earthquake fault lines, making them susceptible to natural and human-made disasters (Wisner *et al*. 2003).

Migrants who settle on land that will become a slum seldom have the legal authority to occupy the land. The land may belong to another individual or the state, or may be nonparceled property with unidentified ownership. Even in cases where a government does not address the settlement of a land which the inhabitants do not own, the settlers do not obtain the property rights, making them susceptible to displacement (Agbola and Agunbiade, 2009). In the absence of formal land tenure and regulation of land use and building codes, an informal group may sell the informal right to establish residency in the slum and dictate where building construction can occur. Having paid to occupy a slum often gives residents a feeling of true community; however, this landownership is not legally binding or recognized by governments. Having legal land tenure
and recognition by government provides benefits such as an improved ability for residents to obtain financing, the willingness of government to establish or upgrade infrastructure within a slum, and integration into the larger urban fabric with roads and infrastructure. Governments may be reluctant to recognize slums because of the costs associated with providing basic services and assumptions that official recognition and service provision may cause further slum formation.

Housing structures in slums are often poorly built and structurally unsound to endure extreme climates or weather conditions. The materials used to build shelter increase the instability as the building materials used are inexpensive, lightweight and capable of being carried long distances, and are easily maneuverable for construction without the aid of heavy machinery. The structural soundness and quality of materials vary widely from place to place and are dependent on the expertise of builders and the availability of materials in the region. Construction materials include durable materials such as brick, concrete, wood, metal, and less durable materials such as straw, mud, and wood and metal scraps held together by ropes. Overcrowding is an issue in dwellings, as a single structure with one or two rooms may house a family and sometimes more inhabitants. Inadequate space requires inhabitants to utilize one room for sleeping, cooking, and recreation.

Slum dwellers participate in both the formal and informal economy both within and outside the confines of a slum. High unemployment rates persist in slums as a result of limited employment opportunities and a skills mismatch between slum residents and formal employment opportunities. The industries and occupations that comprise the informal economy may be remarkably similar to the formal economy, the only difference being that the informal enterprise is unregulated and untaxed by the government. Workers in this setting may be exploited as a result of the lack of legal oversight into employment conditions. Informal economies in cities of developing countries may be larger than the formal economy and encompass entire industries such as manufacturing. Dharavi in Mumbai, India, has a $1 billion a year informal economy which includes a recycling industry that processes 80% of Mumbai’s waste (Yardley 2011).

While slums are situated in different contexts within cities, UN-Habitat (2008) provides a typology for three distinct types of slums that can be seen in cities across the world. The first is a slum city or cities with high slum prevalence. These slums exist in cities and countries where poverty is endemic, and adequate shelter, infrastructure, and protection from environmental hazards are often nonexistent for much of the population. This type of slum is most prevalent in countries in sub-Saharan Africa. A second type is an isolated slum environment that exists in a city where there is a large nonslum area which is easily distinguishable from concentrated slum areas. Large capital cities in Latin America are clear examples of this form; economically prosperous areas are typically in close proximity, sometimes separated only by a wall. A third type of slum, representing poverty at the geographic margins, occurs in cities and countries with low slum prevalence. In these cities and countries, low-income households are often most visibly marginalized and denied the goods and resources that a city and region contains. These slums are most common sub-Saharan Africa, Latin America, and the Caribbean, and Asia.

Efforts to eliminate slums

Attempts to eliminate slums have focused on removal by demolition, guided relocation of
SLUM

residents, and upgrading with essential infrastructure. Slum removal has been justified by legal means in instances when slum residents do not have the legal right to occupy their land. This strategy is widely viewed as shortsighted as it does not address the causes or the likely perpetuation of slum conditions. This strategy forces slum residents, who need a place to live, to find similar affordable conditions elsewhere. Slum clearance is a common intervention strategy by governments, and is common when slums occupy valuable land near city centers.

Slum relocating typically seeks to guide residents to areas with improved living conditions. Housing in these areas, often rural or semirural settings, may be provided free or at low prices to encourage occupancy. While this strategy reduces slum occupancy, it often provides spatial disadvantages to former slum occupants who are displaced from job opportunities and not provided with transportation to cities centers. Opposition to relocation by slum residents may occur when residential improvements are not coupled with job accessibility and employment opportunities. Slum residents who sign up for housing relocation programs may not understand how suburban living conditions will affect them and, as a result, are worse off after relocation. This approach also ignores the fact that many very poor areas have viable community links that are disrupted by relocation.

Slum upgrading aims to provide infrastructure and physical improvements to address poor living standards, environmental hazards, and the disconnection of slums from surrounding urban areas. In addition to vitally important goods and services such as clean water, electricity, and waste collection, slum upgrading may establish schools, community centers, or paved roads, and may connect mass transit networks to slums, providing access to jobs and amenities outside of the slum. Upgrading may not involve the construction of new dwellings but may provide housing finance options for residents to obtain construction loans. Even in instances where no finance options are present, housing upgrades are believed to be encouraged by residents as a result of the supplementary infrastructure upgrades (Turner and Fichter 1972). Most importantly, residents are most likely to invest in housing when a deed is granted for legal occupancy. The amount a slum dweller is willing to pay toward legal housing typically exceeds what a government is willing to contribute and is seen as a less beneficial investment compared to infrastructure installation.

Snow and ice avalanches

Christophe Corona
Centre National de la Recherche Scientifique (CNRS), France

Markus Stoffel
University of Bern and University of Geneva, Switzerland

An avalanche is a rapid flow of snow and/or ice with a volume of more than 100 m$^3$ down a steep slope (30–45°) with a path length of more than 50 m. Snow and ice avalanches are natural processes occurring in many parts of the world, and they are a risk where their occurrence interferes with humans and their infrastructure. The term “avalanche” implies the whole process of movement, from release in the starting zone to displacement (flow) through the path and deposition in the runout zone (Rudolf-Miklau et al. 2015). According to the American Avalanche Association, the worldwide number of avalanches falling annually is on the order of 10$^6$. Throughout history, avalanches have endangered human life in mountainous areas, and thereby exerted major control on the development of settlements and infrastructure. Over the past century, the combination of urban sprawl in mountain ranges across Europe and North America with the growing demand for mobility and recreational activities has increased avalanche risk significantly (Rudolf-Miklau et al. 2015). The growth in winter sports, for example, has led to a significant increase in avalanche deaths over the past few decades, with an average of 250 ski tourers or free-riders being killed worldwide every year (Ancey 2006). In a society with ever-increasing avalanche risk and safety expectations, the risk acceptance of modern societies has been decreasing in equal measure over recent decades.

Substantial efforts have therefore been deployed over the past decades to enhance understanding of avalanche processes. This entry summarizes the key features of snow and ice avalanches, details the main approaches used to describe snow avalanche motion and related hazards, and summarizes recent findings on avalanche triggering, with a special emphasis on meteorological factors in the current context of global warming.

Classification and formation of ice and snow avalanches

Ice avalanches have frequently been responsible for large disasters in ice-covered mountains. According to McClung and Schärer (1993), they result from the calving (breaking off) of ice masses or seracs. Ice avalanches typically occur at positions where glacier ice flows over a steep slope or a cliff and/or as a result of the breakoff of a large piece of glacier (massive events), thus resulting in a tensile failure of the ice which is usually caused by a combination of internal flow (creep) and sliding of the glacier over its bed.

Most catastrophic snow avalanches, by contrast, follow a different basic principle where gravity at the top of the slope exceeds the binding force holding the snow together and thus results in a weakening within the snowpack. A solid slab of the surface layer of snow can then push its way across the underlying layer, and so result...
SNOW AND ICE AVALANCHES

in a snow avalanche (Ancey 2006). The triggering of an avalanche can occur as a result of (i) localized rapid near-surface loading by, for example, people or explosives (the latter being called artificial triggering), (ii) gradual uniform loading due to precipitation or other factors, or (iii) a no-loading situation that changes snowpack properties, for example, surface warming (called natural triggering or spontaneous release) (Schweizer 2003). Schematically, two types of release exist. Loose snow avalanches start from a point in a relatively cohesionless surface layer. They then spread out laterally by pushing and incorporating more snow. Snow of low cohesion may be either dry or wet, but the important point with respect to water content is that wet loose snow avalanches can be much more massive than dry avalanches. Snow slab avalanches, by contrast, involve the release of a cohesive slab over an extended plane of weakness. The failure usually develops first along a sliding surface, and then propagates throughout the upper layers across a crack perpendicular to the downward direction.

Avalanche motion and related hazards

The motion of ice avalanches has been described as analogous to rockfalls: ice chunks roll and bounce along the surface enveloped by a powder cloud. By contrast, and for practical reasons, the movement of snow avalanches has been characterized in more detail, taking into account the velocity, flow height, and mass density of the avalanche snow. In addition, the maximum runout distance, defined as the point of farthest reach of debris, and impact pressure, a relevant criterion of the avalanche movement in hazard mapping or planning of mitigation measures, have been quantified. Data from field experiments from various avalanche test sites as well as numerical modeling have exemplified that the total snow mass of an avalanche, mainly controlled by entrainment, clearly defines runout distance. Similarly, avalanche front velocity, a common measure to estimate avalanche intensity (as it can be linked with expected impact pressures), scales with the square root of the total fall height of the avalanche front (Schweizer 2014).

Schematically, three limiting cases of avalanche dynamics exist and they depend on the form of motion rather than the quality of the material. Within these three limited cases, discussed below, a wide variety of avalanches can be found; they are referred to as mixed-type avalanches.

Laminar type flow avalanches are characterized by a high-density core at the bottom where particle sizes are defined by the state of the snowpack. Fresh dry snow tends to form small granules (2–3 mm in diameter) whereas old snow which has undergone several cycles of metamorphosis consists of ice grains of typically 5–10 mm in diameter. Flow depth does not generally exceed a few meters, and trajectory of the flow is dictated by topography. The typical mean velocity of laminar type flows ranges from 5 to 25 m s⁻¹ but velocity profiles typically differ in each section of the avalanche. The highest velocities of the flow section can be observed at the avalanche front (head), whereas the velocity profile of the normal flow (i.e., the movement recorded perpendicular to the topography) will be disordered with heavily fluctuating velocities. The avalanche body, by contrast, is characterized by a typical shear velocity profile, whereby velocity increases with increasing height above the ground. The avalanche tail, however, is characterized in many cases by weak or missing shear in the flow, such that snow flows in a block on a very thin shear layer or glides directly on the substratum. On average, the density of laminar type flows is fairly high, generally ranging from 150 to 500 kg m⁻³. These avalanches can cause extensive damage because of the large
SNOW AND ICE AVALANCHES

Snow masses involved in the flow in spite of their comparably low speed.

Powder-snow avalanches are large-scale turbidity currents descending slopes at high velocities, in which most snow particles are suspended in the ambient air by turbulence. These clouds can reach 100 m in height and very high front velocities in the order of 100 m s⁻¹. They grow continuously but have fairly low average densities ranging from 4 to 25 kg m⁻³. The front velocities are smaller than core velocities due to air resistance. The mass coming from behind to hit the front is severely decelerated and therefore slower than the avalanche core. Relief has usually only a weak influence on aerial flow. Typically, for snow depth, mean velocity, and mean density, the orders of magnitude usually observed during events are 10–100 m, 50–100 m s⁻¹, and 5–50 kg m⁻³, respectively. These often spectacular avalanches occur only under certain meteorological conditions, namely after abundant fresh snowfalls, as well as in the presence of cold, dry, and weakly cohesive snow on strong slopes. The danger generated by the powder layer of an avalanche is comparable to squalls. They mainly result from powder pressure on the upwind side and suction forces of the aerosol. These devastating pressures (up to 10 bars) are able to uproot forest stands, to destroy buildings, to tear off roofs, to cross valley bottoms, and even to climb up the opposite slope during their propagation stage. The loads caused by powder avalanches are dependent on the density and velocity of the aerosol (Rudolf-Miklau et al. 2015).

Wet snow avalanches have a low flow velocity – with the exception of very steep avalanche paths – and a clear structure of clumps. While agreement exists that the high density of wet snow avalanches can develop very high pressures, appropriate tools to calculate pressures or runout distances are still largely lacking today (Rudolf-Miklau et al. 2015). This is partly due to the fact that wet snow avalanches show special deposit patterns with extremely long and unpredictable runout directions. Slush flows represent a special form of avalanche found especially at high latitudes; they occur as a result of the rapid onset of snowmelt in spring as the return of sunlight adds intense radiation to snowpacks that have been previously subjected to strong temperature gradients. Slush flows consist of a suspension of snow dissolved in water and their rheology has been described as a hybrid of a liquid and granular constitutive law (Rudolf-Miklau et al. 2015). Slush flows can occur on low-gradient slopes and have even been observed at terrain inclinations of 12° or less. Densities of slush-flow deposits can exceed 100 kg m⁻³ due to the combination of water, ice, snow, and entrained rock or earth material. Such densities imply high damage potentials and class them among the most destructive avalanche types (McClung and Schaeerer 1993).

Fixed triggering parameters

The avalanche release process still remains largely unknown, mainly because of complex interactions between terrain, snowpack, and meteorological conditions leading to avalanche release (Schweizer 2003). Yet, one can distinguish between fixed parameters related to the avalanche path and varying parameters which are generally related to weather conditions (Ancey 2006).

Terrain characteristics are the only constant factor in snow avalanche triggering over time, and slopes with an inclination of >30° are generally required for snow avalanches to form. It is also recognized that the starting zone is usually the steepest segment of the avalanche path, and that starting zones are often located above timberline, where avalanches break away, accelerate down the slope, and pick up additional material as they move. Avalanches tend to
SNOW AND ICE AVALANCHES

occur more frequently on surfaces with concave starting zones (both in terms of profile and in the longitudinal direction). From the starting zone, the avalanche moves into the track (20–30°) where velocity tends to remain more or less constant and little or no additional snow is added to the moving avalanche. The runout zone is an area with an average inclination of less than 10°, which is insufficient for further movement of snow. Two main path configurations are particularly prone to produce devastating avalanches: (i) large bowl-shaped starting zones in which the stress increases until these sections can no longer support themselves and break loose; (ii) paths consisting of several gullies that feed into a common track farther down.

Terrain roughness also influences avalanche formation by hindering the formation of continuous, weak snowpack layers (Schweizer 2003). A minimal snow depth, of 0.3–1 m, for example, is needed to smooth out most terrain roughness. Vegetation, by contrast, has mixed effects on avalanche release. Dense forest stands (>200 trees ha⁻¹) in the starting zone increase friction coefficients between the snowpack and the substratum, thus limiting the triggering of snow avalanches. In addition, the interception of snow — compared to nonwooded areas — can be between 30 and 70% greater on such slopes, depending on snowfall, snow volume, tree species, air temperature, and wind conditions. However, the protective effect of trees and forest stands usually decreases downslope and under extreme conditions. Forests cannot stop large avalanches that have released above the forest limit, as their braking effect remains insignificant. Conversely, unmanaged pasture land and the existence of shrubs have negative effects on the stability of snowpack since they form ideal surfaces for snow gliding (Rudolf-Miklau et al. 2015).

Finally, the orientation of slopes with respect to the sun and dominant winds has a strong influence on the day-to-day stability of the snowpack. For instance, in winter, shady slopes receive little incoming radiation and conversely lose heat through longwave radiation. It is generally observed that for these slopes, snowpack will be cold and will tend to develop weak layers (i.e., faceted crystals, depth hoar). In late winter and spring, temperature increase will enhance stability of the snowpack on shady slopes and, at the same time, instability on sunny slopes (Ancey 2006).

Meteorological triggers

The collapse of glacier seracs in icefalls and related ice avalanches are usually caused by glacier motion (or less usually earthquakes). As a consequence, actual occurrences of ice avalanches are not usually related to weather conditions even though meltwater has been demonstrated to often play a role in their release (McClung and Schaerer 1993). Yet, since glacier sliding is known to be faster in spring or summer when more basal water is available, more events have been shown to occur during these seasons.

By contrast, most of the factors contributing to snow avalanching are related either to the strength or to the load of snow and its variation over time. In addition to terrain, Schweizer (2003) describes four essential factors leading to the release of snow avalanches: precipitation (snowfall), wind, temperature, and snowpack stratigraphy.

Among the varying factors intervening in avalanche release, experience clearly shows that in most cases snow avalanches result from changes in weather conditions. Snowfall has been demonstrated to be one of the most important forecasting parameters for large snow avalanche events. In European mountain ranges, heavy snowfalls with a total precipitation exceeding 1 m within three days have been considered
critical for the initiation of extreme avalanches; about 30–50 cm is seen as a threshold for naturally released avalanches in general. However, even with large accumulations of new snow, the combined release probability of a group of avalanche paths is frequently <50%, underlining that the newly deposited snow depth alone is not sufficient to explain avalanche activity. The precipitation rate or loading rate can also strongly influence the critical balance between stress and strength. Snow within the snow cover behaves like an elastic, yet viscoplastic, material that can absorb slow load changes. However, under rapid load (2.5 cm h⁻¹), the weak layer below the storm snow layer might not gain strength sufficiently quickly. In such cases, the response of the snowpack becomes elastic and the snowpack is much more likely to break. In addition, rainfall plays a complex role in snow metamorphism. Generally, for dry snow, a small increase in the liquid water content does not significantly affect mechanical properties of snow. However, heavy rain induces a rapid and noticeable increase in liquid water content, which results in a drop in the shear stress strength. This situation leads to widespread avalanche activity (wet snow avalanches).

In addition, redistribution of snow by wind is a major feature of mountain snowpack and essential for avalanche formation. For loose, unbounded snow, the typical threshold wind speed is 5 m s⁻¹ at which snow is picked up from the surface by turbulent eddies. For a dense bounded snow cover, winds greater than 25 m s⁻¹ are necessary to produce blowing snow (McClung and Schaerer 1993). In mountain environments, snow redistribution by wind is uneven and can significantly influence snowpack stability. Variations in wind speed and subsequent snowdrift form layers of different density or hardness, thereby creating stress concentrations within the layered snowpack, accelerate snow metamorphism, and form cornices on the lee side of ridge crests, whose collapses may trigger snow avalanches as well. When discussing the role of snowdrift in avalanche formation, the influence of wind is very diverse, and can either consolidate snow (compacting and rounding snow crystals) or, by contrast, weaken it.

Apart from precipitation and wind loading, rapid increases in air temperature and/or solar radiation are commonly considered as additional meteorological factors contributing to avalanche formation, particularly in situations without loading. Wet loose snow avalanches are thus usually triggered by intense melting resulting from snowpack warming. The effects of temperature on slab avalanches are more complex, as the cohesion of wet snow causes changes in air temperature to primarily affect the top surface layers (20–30 cm). Since thermal conductivity of snow is low, the energy added to snowpack by sensible heat will only travel slowly from the snow surface to the layers beneath. With increasing temperature in the near-surface layers, stiffness will decrease – in other words, deformation will increase, both in the slope parallel and in the vertical direction (Schweizer 2003). Indeed, recent studies have shown that surface warming can increase the propensity for crack propagation, provided that pre-existing weaknesses exist and that considerable energy inputs are available (Schweizer 2014).

Finally, snowpack stratigraphy is recognized as a key contributing factor to avalanching as the complex structure of an individual snowpack will affect its stability, and therefore its propensity to fail catastrophically in an avalanche. Any snowpack will develop a layered structure during its formation, which will in turn evolve through time. Each layer is formed by the deposition of falling snow, the redistribution of windblown snow, or a combination of these two processes. The initial snowpack will subsequently be modified through compaction and thermal metamorphic processes, thus resulting
SNOW AND ICE AVALANCHES

in the gradual densification of the snowpack. Surface melting, percolation, and, under certain conditions, refreezing of meltwaters further modify snowpack. When comparing stable with unstable stratigraphy, the differences in grain size and hardness between the weak and the adjacent layers of unstable profiles are significantly larger than those of stable profiles. Temperature gradient within the snowpack has been found to be decisive for the metamorphosis processes and avalanche formation as well. If snowpack is subject to strong temperature gradients, the resulting movement of water vapor between grains at different temperatures will drive kinetic growth metamorphism (with grain growth rates in the order of 0.1 mm day$^{-1}$ for a 150 K m$^{-1}$ gradient), thereby producing characteristic faceted grains known as surface hoar and depth hoar. These are among the most critically weak layers. Together with their edgy shapes, formed at the beginning and then developing into jar-like depth hoar, they are at the origin of a majority of slab avalanche incidents.

Snow avalanches and climate change

Statistical relations between snow avalanche activity, snow, and weather drivers are often significant and may help forecasting in operational contexts. At larger spatiotemporal scales, links with atmospheric circulation patterns exist as well. Being phenomena controlled by climate, snow and ice avalanches are not only expected to be affected by changes in atmospheric conditions, but also by climatic change.

Several ground-based studies recently demonstrated a decrease in snow precipitation phase, snow depth, snow cover duration, or snow water equivalent in the Alpine space (e.g., Laternser and Schneebele 2003). On the other hand, however, only very few studies discussed the impacts of ongoing climatic change on actual avalanche activity. Over long timescales, records derived from lichenometry, lake sediments, tree rings, or pollen counts have shown an increase in avalanche frequency in northern and western Europe during the cold phases of the Little Ice Age (Corona et al. 2012). Yet, these studies relied on rather limited datasets of relatively low resolution and were limited to exceptional study sites where depositional sequences have been conserved. Over shorter timescales, based on continuous systematic records, Laternser and Schneebele (2002) did not, by contrast, observe any significant changes in avalanche activity between 1950 and 2000 across Switzerland. On the other hand, thanks to the exploitation of systematic regional avalanche records from the French Alps, Eckert et al. (2009) highlighted significant changes in avalanche activity since the 1950s, with a clear temporal trend toward changes in avalanche runout altitudes which were, in turn, well correlated with climatic variables. Owing to the lack of continuous and multicentennial avalanche chronicles, quantitative prognostics on the future evolution of avalanche activity (e.g., to the end of the twenty-first century) remain extremely scarce and often speculative. The current state of knowledge, still rather qualitative, predicts an ongoing increase in the proportion of wet loose snow avalanches compared to dry snow avalanches, as well as a shift in their respective timing, which is in good correlation with field observations of snow cover wetting at smaller scales.

Snow cover changes

Ross D. Brown  
*Environment and Climate Change Canada*

**Background**

Seasonal snow covers a large fraction of the Northern Hemisphere (NH) land area for periods ranging from several weeks at lower latitudes to eight to ten months in the Arctic. Snow has unique physical properties (high reflectivity, low thermal conductivity, and low surface roughness) that together with storage of water over the winter period play important roles in climate and hydrology. For example, snow insulates soils, modifies underlying ice growth rates (on lakes and sea ice), and modifies energy and water budgets. Snow also provides protected winter habitat for plants and animals and supports a wide range of human activities such as overland transportation in the Arctic, skiing, tourism, and water storage for hydroelectricity production and fresh water supply. The storage and release of water from winter snowpack are especially critical in semiarid regions of the world where mountain snowpacks are a major freshwater source. Global warming is a particular threat in these areas due to high and growing demands on the existing water supply and strong temperature sensitivity of the fraction of precipitation falling as snow.

The accumulation of snow on the ground (to form a seasonal snow cover) requires snowfall (precipitation forming at air temperatures below freezing) and a negative energy budget that precludes snow from melting. These conditions occur for various periods of time during winter over most of the NH land area north of about 40°N and in mountainous regions at lower latitudes, for example, Himalayas and Atlas Mountains (Figure 1a). Outside Antarctica, seasonal snow cover in the Southern Hemisphere is mainly confined to mountainous regions of South America and New Zealand with smaller localized areas of snow cover in South Africa and Australia. Seasonal snow cover over NH lands accounts for about 98% of the global terrestrial snow cover extent (Armstrong and Brun 2008) and exhibits a seasonal range of more than 40 million km² from the minimum in August to the maximum in January (Table 1). Interannual variability in snow cover extent (SCE) is largest in the snow cover onset (October–November) and melt (May–June) periods and over mid-latitudes and coastal mountain regions where winter air temperatures are relatively close to freezing (Figure 1b). Snow cover in these regions is particularly sensitive to warming air temperatures.

The duration of snow on the ground (SCD) is closely linked to air temperature which explains the strongly zonal character of SCD in Figure 1a and the longer SCD at higher elevations. How much snow accumulates on the ground is initially governed by geography. Latitude, elevation, proximity to storm tracks and moisture sources are key factors controlling snowfall amount and air temperature that together define the length of the snow cover season and the maximum amount of snow that accumulates. Once on the ground, local factors such as land cover, vegetation type, exposure, surface roughness, topography, and interactions with surface wind determine how much snowfall is lost to sublimation (from the...

Snow surface, from blowing snow, and from the vegetation canopy) and how much accumulates at a particular location. Local site characteristics also play a major role in snow melt processes (e.g., topography and vegetation cover influence local advection, shading, and longwave radiation fluxes). The reader is referred to Armstrong and Brun (2008) for a detailed discussion of snow processes and their physics.

The effect of geography on mean annual maximum snow accumulation over the NH is demonstrated in Figure 2a. The largest accumulations are found in maritime mountain regions with large snowfall amounts related to
proximity to storm tracks and moisture sources and orographic effects on precipitation and temperature. These same regions are also characterized by large interannual variability in snow accumulation linked to atmospheric variability in air temperature and precipitation (Figure 2b). The North Atlantic Oscillation is an important driver of annual variations of snow cover in Europe while snow cover variability over western North America is linked to various modes of Pacific-driven climate variability including El Niño–La Niña, the Pacific Decadal Oscillation and the Pacific-North America pattern. Accumulations are much lower over the relatively colder and drier continental interiors and Arctic regions, and also around the southern margins of the continental snow line where snow cover is ephemeral in nature. Moisture penetration into the Arctic via Baffin Bay and the Norwegian and Barents Sea results in higher snow accumulations in these regions of the Arctic.

Observed snow cover changes

While the average snow climate of a region is initially governed by the abovementioned geographical factors, the seasonal evolution of a snow cover and its physical properties (e.g., depth, density, snow water equivalent (SWE),
SNOW COVER CHANGES

albedo, stratigraphy, crystal structure, thermal conductivity, and liquid water content) are the result of a complex set of processes and landscape interactions driven by the local climate (incoming solar and longwave energy, wind, air temperature, humidity, cloud cover, and precipitation). Changes in any of these climate drivers, or changes in the landscape through enhanced shrub growth for example, will influence the snow cover. Atmospheric aerosols can also influence snow cover: the deposition of black carbon particles (“soot”) on the snow surface reduces the reflectivity of the snow and contributes to enhanced spring snowmelt. There are thus many potential drivers of snow cover change.

A number of surface and satellite sources of snow information are available for monitoring snow cover; these cover different periods of time and different spatial scales and have particular characteristics that need to be taken into account when interpreting observed trends (see Armstrong and Brun 2008, ch. 5, for a review of snow observing systems). Surface observations of daily snow depth are available over much of the NH from approximately 1950 but the observations are biased to lower elevations and lower latitudes with large data gaps in low populated regions such as northern Canada. Point measurements of snow depths are usually made at open sites which may not be representative of the prevailing snow cover (note that Russia takes depth measurements in open and vegetated areas). For example, measurement made in open locations in the Arctic will not register the effect of any Arctic green-up and increased shrubiness which increases the snow trapping potential of the landscape and modifies the spring melt energetics.

Major advances have been made in the ability to monitor snow cover from space over the period since approximately 2000 (see recent review by Frei et al. 2012) but this period is too short for establishing trends. The satellite-derived NOAA snow cover climate data record (CDR; Estilow and Robinson 2013) provides weekly snow cover extent information over the NH at approximately 200 km resolution since November 1966. This dataset is suitable for continental-scale monitoring of snow cover extent during the winter season but there are homogeneity issues related to changes in mapping methods and satellite resolution and coverage over time. Efforts have been made to mitigate these effects but there are known inconsistencies in mapping snow over mountain regions and in the snow cover onset period. In the past, attempts to monitor and map global SWE from space using passive microwave had limited success as the retrievals did not work well in many landscape areas (dense forest, complex terrain, and deeper snowpacks). The recent GlobSnow passive microwave SWE dataset (Takala et al. 2011) overcomes some of these limitations by incorporating surface observations in the satellite retrieval process. GlobSnow SWE data are available daily over the nonmountainous NH at a 25 km resolution from 1979.

Information on historical variability in snow cover can also be obtained from reanalysis datasets that are essentially reconstructions of past weather using an atmospheric circulation model and an ensemble of historical meteorological observations (e.g., surface observations, upper air soundings, satellite data) in a data assimilation framework. Snow cover information can be generated from data assimilation of available surface snow depth observations (e.g., ERA-interim reanalysis) or reconstructed using a land surface scheme coupled to the atmospheric model (e.g., MERRA reanalysis). Another approach is to use the output from a reanalysis to drive a detailed snowpack model. This approach was used by Liston and Hiemstra (2011) to reconstruct snow cover at a 10-km resolution over the Arctic for the period from 1979 to 2009. Great care
must be taken when using snow output from reanalyses as there can be discontinuities created from changing data streams (e.g., new sources of satellite data) as well as important biases in temperature and precipitation from the atmospheric model.

The spatial and temporal variability in NH monthly SCE and SWE over the period from 1972 and 1980 respectively are shown in Figures 3 and 4 from the NOAA CDR and GlobSnow datasets. The period prior to 1982 had above average snow cover over the Arctic.

**Figure 3** Evolution of NH monthly snow cover extent over the period 1972–2015 from the NOAA CDR dataset. Values are expressed as departures (%) from the 1971–2000 mean.

**Figure 4** Evolution of NH October to May monthly SWE over 1980–2014 from the GlobSnow V2 dataset. Values are expressed in units of standard deviation with respect to a 1981–2010 reference period; for example, a value of 2 for a month indicates the SWE was two standard deviations greater than the monthly average for 1981–2010. Note the different start periods in Figure 3 and Figure 4.

**Figure 5** (a) Projected change (%) in annual SCD from 8 CMIP5 models for the RCP8.5 emission scenario for the 2080 period (2070–2099 minus 1970–1999). (b) Same as top left panel for annual maximum monthly SWE from 11 CMIP5 models. (c) Mean expected year of significant change in annual SCD for the RCP8.5 emission scenario. (d) Same as bottom left panel for SWEmax.
Figure 5
while the period since approximately 2000 has been characterized by progressively earlier spring melt over northern latitudes. SWE was above average over most of the NH in the decade from 1988 to 1998 with below average values dominating since 2005. The recent marked reduction in high-latitude spring snow cover is consistent with enhanced snow albedo feedbacks at this time of year. Brown and Robinson (2011) were able to extend the NOAA NH spring SCE record back to the early 1920s with surface snow observations which showed that most of the twentieth century change in NH spring snow cover has occurred in the period since 1980. A synthesis of trends in snow cover from surface-based observations in the 5th IPCC Assessment (Vaughan et al. 2013) concluded that the majority of sites have experienced declining snow cover with the largest reductions at locations where winter temperatures were closer to freezing. In these regions, particularly those with high precipitation amounts like the coastal mountain ranges of North America and Norway, warmer temperature result in the combined impacts of a shorter snow season and less snowfall. Some regions of northern Russia show increases in maximum snow depth in spite of trends toward a shorter snow cover season (Callaghan et al. 2012). This apparent contradiction is consistent with climate model projections and is a response to increasing snowfall. Brown and Mote (2009) showed that the response of snow cover to concurrent trends of warming and increasing precipitation depends on the snow cover variable, climate region, and elevation. Start/end dates and snow cover duration are closely linked to air temperature and exhibit rapid reductions in response to warming. However, the response of annual maximum accumulation depends on the interplay between a decreasing length of the accumulation season and increasing snowfall. Winter warming also has implications for snowpack properties; winter thaw events and rain-on-snow events have the potential to generate a denser snowpack with ice layers that can hinder ungulate grazing. An increased frequency of ice layers within the snowpack has been observed in northern Sweden (Callaghan et al. 2012).

Projected changes in snow cover

Climate model projections of future changes in snow cover (Räisänen 2007; Brown and Mote 2009; Brutel-Vuilmet, Ménégoz, and Krinner 2013) provide a picture of widespread significant reductions in SCD and maximum SWE (SWE-max) over most of the NH mid-latitudes (Figure 5, top panels), with the largest changes around the southern margins of the continental snow line and the previously mentioned temperate mountain zones of North America and Europe. The models also project significant increases in maximum SWE over high latitudes although there is much greater model scatter in the models for SWE-max than SCD, particularly over Eurasia. Some idea of the spatial pattern in the timing of the projected changes can be obtained from the expected year of emergence (EYE) of the climate change signal following De Elía, Biner, and Frigon (2013) (Figure 5, bottom panels). On average, EYE is approximately 30 years earlier for annual SCD than annual SWE-max with the climate change signal emerging earliest over the western margins of each continent and latest over Siberia and the Tibetan Plateau. Between-model consistency in EYE is much lower over the last mentioned regions particularly for SWE-max. Large scatter in the strength of snow albedo feedbacks in climate models (Qu and Hall 2013) is likely contributing to this uncertainty, and recent evaluations (Derksen and Brown 2012; Brutel-Vuilmet,
SNOW COVER CHANGES

Ménégoz, and Krinner 2013) show that climate models underestimate the response of NH spring SCE to observed warming. There is evidence of improvements in the representation of snow cover in climate models but important sources of uncertainty remain related to snow albedo feedbacks, precipitation bias (models overestimate precipitation over high latitudes), and inadequate treatment of landscape-dependent snow processes such as blowing snow, snow–canopy interactions, and sub-grid scale advection of energy during snow melt.

Snow cover

David A. Robinson
Rutgers University, USA

Snow cover plays an important role in many of the processes within the Earth’s climate system (Barry 2002). The presence of a snow cover has been shown to affect boundary layer climate variables such as atmospheric temperature, moisture, sensible and latent heat fluxes, and radiative fluxes (Flanner et al. 2011). The amount of snow cover and its subsequent ablation is also important to the hydrology of a given region, including streamflow (Yang et al. 2003). The influence of snow cover on a continental scale is clearly linked to other geophysical and biophysical systems (Callaghan et al. 2011). In turn, the presence or state of snow is influenced by weather, climate, topography, proximity to water bodies, and humankind. Likewise, snow cover, or the lack thereof, is of considerable importance for decision-makers in transportation, recreation, utility, and other sectors of local to global economies.

Snow cover characteristics

Snow covers approximately 30% of the Earth’s land surface on a seasonal basis, with additional coverage over alpine glaciers, polar ice sheets, and sea ice. High reflectivity associated with fresh snow affects the energy balance of a region by increasing surface albedo and thermal emissivity, decreasing shortwave radiation absorbed and consequently increasing the amount of infrared radiation lost to the atmosphere, and reducing surface air temperature. Snow also acts as a thermal insulator due to its low thermal conductivity, resulting in decreased sensible heat flux from the ground into the lower atmosphere. Energy involved in the warming and melting of a snowpack serves as a sink for latent heat, thus making snow cover a major factor in modulating climate variability and change. Snow cover also plays a key role in the hydrologic cycle by acting as the frozen storage term in the water balance.

Snow ablation is a major contributor to streamflow, soil moisture, and groundwater supplies. Approximately one-sixth of the world’s population lives within snowmelt-dominated regions that encompass much of the industrialized world and account for approximately one-quarter of the global gross domestic product (Barnett, Adam, and Lettenmaier 2005). At locations where snow cover is ephemeral, the lack of a single seasonal melt, or lack of consistency in volume or timing, has made forecasting the release of water from the snowpack a formidable challenge, leading to harmful environmental and societal consequences. These consequences may be in the form of snowmelt-induced floods, lack of streamflow in snowmelt-fed rivers, or transport of pollutants or excess nutrients in rapid snowmelt events. These events are also a significant risk to human life. For instance, excluding flash flooding, snowmelt floods result in roughly one-third of all flood-related fatalities in the United States, despite the fact that large populations in the southern United States are not at risk from these floods.

A number of studies have shown that the distribution of snow cover has an influence on low-frequency atmospheric circulation patterns
SNOW COVER

(Rydzik and Desai 2014). Variations in snow cover may be associated with sea surface temperature patterns or involve the vertical propagation of stationary waves within the troposphere and lower stratosphere. This can result in zonal wind and subsequent latitudinal temperature shifts, changing sea level pressure patterns, and shifts in storm track activity. These influences apply to both above and below average snow cover extents, and of course extent changes are associated with these relationships that feed off one another. Determination of cause and effect is often elusive, but without question snow cover is not a passive participant.

The presence or absence of snow cover also plays a role in short-term weather anomalies, most notably departures of surface air temperatures. An anomalous covering of the ground with snow may result in temperatures far lower than might have been achieved (or forecast) in the absence of snow (or knowledge of the presence of snow in a forecast model). Likewise, anomalous warmth may be amplified at a given time and location where snow cover is expected climatologically but is absent. This may result in a positive feedback and greater warmth, much as an extensive cover may enhance cooling.

Monitoring snow cover

Recent years have seen the availability of more accurate and complete information on the spatial extent and physical state of snow. Mature and well-documented climate data records (CDR) of snow on regular grids are available for empirical and modeling studies. This is leading to a better understanding of the variability of snowfall and snow cover on annual to decadal scales, of cryosphere–climate interactions, and of the role snow may play in regional and global climate change. However, observing snowfall or snow cover continues to present a variety of challenges. Given the remoteness of much of the cryosphere, the small, scattered human populations in regions with extensive snow cover, and the logistical constraints associated with in situ sampling, satellite data provide the most comprehensive source of information to generate snow and sea ice data records.

Ground–based data on snow cover are not without worth. While relatively sparse outside of the lower elevations of the middle latitudes, they include daily station observations of snow depth made at a single point. Less frequent and far fewer measurements are taken along snow courses that may extend for multiple kilometers. Data on the amount of water in a snow pack (snow water equivalent (SWE)) are gathered at very few point sites, along snow courses, and by snow pillows that measure snow mass in some mountainous regions. In situ observations serve a useful role as ground truth for satellite-derived estimates of snow depth and SWE. They are critically important in alpine regions where the snowpack serves as a reservoir to fulfill water needs elsewhere and remote sensing cannot provide adequate SWE information. Of course, prior to the advent of the satellite era, in situ observations were the only means of identifying snow cover variability and change.

Visible and passive microwave sensors on geostationary and polar orbiting satellites record information used to monitor snow cover on regional to hemispheric scales. Snow cover extent (SCE) is best identified on visible imagery by recognizing characteristic textured surface features and brightness (Figure 1). Shortcomings include the inability to detect cover when solar illumination is low or when skies are cloudy. In the figure, characteristic cloud textures and a priori knowledge of what the landscape looks like under snow cover (e.g., the most often unfrozen New York Finger Lakes are not seen) assist in determining that the white shades in
the image toward the west (middle left) are thick clouds, while thin cirrus partially obscure snow-free ground at the southern end of the Delmarva Peninsula (lower center). In addition to clouds obscuring the surface, trees protruding through the snow pack may mask the presence of snow cover from the satellite vantage point. Once analysts determine that skies are clear,
they rely on characteristic patterns or the spatial texture of the snow-covered landscape to reach a determination of snow presence or absence. For instance, deciding whether the densely wooded Adirondacks of northern New York and the Pinelands of southern New Jersey are snow covered on February 12, 2010, relies in part on the brightly snow-covered lands surrounding them. The broad valley running generally from southwest to northeast in the lower left quarter of the image is largely forest free, thus bright snow cover is seen. To the northwest of the valley the wooded ridge tops and open valleys of the geologically folded Valley and Ridge province are quite apparent when snow covered. Utilizing a priori knowledge of snow-covered lands is important where the darker areas in the Hudson and Connecticut River valleys and in the Boston area suggest that snow cover is thin and patchy, as they are much brighter when deeply covered. However, at best, visible imagery only provides a qualitative estimate of pack depth.

The recognition of snow using microwave techniques results from differences in the emissivity of snow-covered and snow-free surfaces across several different frequency ranges. Information on water equivalent can be obtained, although not of the accuracy necessary for climatologic studies. Clouds and low solar illumination are not problems when using microwave data to chart snow cover; however, there are difficulties in identifying shallow or wet snow.

Weekly snow files of SCE produced from visual analyses of visible satellite imagery are available from late 1966 through May 1999. The 1972 to present data were mapped by National Oceanic and Atmospheric Administration (NOAA) meteorologists, while the 1966–1971 data were reanalyzed at the Rutgers Global Snow Lab. The maps are digitized in binary format to a 128×128 pixel grid over the entire Northern Hemisphere. In June 1999, the weekly map series was replaced with the daily NOAA/National Ice Center Interactive Multisensor Snow and Ice Mapping System (IMS) product. These maps are digitized to a 1024×1024 grid (even higher resolution products have been generated as the IMS system has recently been upgraded to a third version). A routine was developed to reduce these daily maps to a weekly product at the former lower resolution to facilitate multidecadal assessments. This data product has undergone several stages of reanalysis and recently efforts culminated in raising this environmental satellite data record to CDR status. This involved several steps to reduce inconsistencies over time and improve continuity between the historical weekly record and the more recent IMS-derived snow maps. Thus this CDR now constitutes the lengthiest satellite-derived dataset of any environmental variable (Estilow, Young, and Robinson 2015).

Another snow mapping effort employs MODIS (moderate-resolution imaging spectroradiometer) satellite visible data to recognize snow-covered continental surfaces. The snow product is generated in an automated manner, employing an algorithm to filter snow from clouds. Daily, eight-day, and monthly composite snow maps displaying fractional snow cover are available at 500 m and 0.05° resolution. For modelers, and others interested in a coarser-resolution product, a 0.25° resolution product is also available. A cloud-gap filled (CGF) snow cover fraction product provides daily cloud-free views of global snow cover (Hall et al. 2010). The CGF maps allow the user to select how many days they wish to look back in time to see a snow decision for each grid cell.

Satellite monitoring of snow cover using the microwave portion of the electromagnetic spectrum dates back to the late 1970s. While active radar or scatterometer approaches have
SNOW COVER

been developed, they do not have the tempo-
ral or spatial coverage of passive methods that
measure emitted radiation with a radiometer.
Microwave emission from a layer of snow over
a ground medium consists of emission by the
snow volume and emission by the underlying
ground. Both contributions are governed by
the transmission and reflection properties of the
air-snow and snow-ground interfaces and by the
absorption/emission and scattering properties of
the snow layer, as well as by a myriad of physical
parameters that affect the emission. As an elec-
tromagnetic wave emitted from the underlying
surface propagates through a snowpack, it is
scattered in all directions by the randomly spaced
snow particles. As the snowpack grows deeper,
there is more loss of radiation due to scattering,
and the emission of the snowpack is reduced.
The deeper the snow the more ice crystals
or grains are available to scatter the upwelling
microwave energy; because of this relationship
between microwave energy and number of snow
grains, it is possible to estimate the depth and
SWE from microwave emission.

Microwave measurements can be made through
darkness and can often be made through non-
convective clouds. While there is proven utility
of microwave data for snow cover studies, there
are significant limitations as well. If the snow
cover is thin it may not be detected as snow.
Wet snow is indistinguishable from snow-free
soil. Vegetation, especially forest cover, causes
further complications. SCE can be processed
using a land-cover decision tree that uses mul-
tiple frequencies or through empirically derived
multispectral algorithms. Algorithms also permit
estimates of SWE or depth (using empirical
algorithms based on estimates of snow density)
and snowmelt occurrence.

Snow frequently covers sea ice in the Arctic
and Southern Oceans. However, particularly in
the Arctic, snow melts atop sea ice, though in
some areas it remains well into the summer. The
onset of snowmelt over sea ice can be deter-
mined using multichannel satellite microwave
data. Algorithms can detect when liquid water
begins to be found within the snowpack, but
once the pack is wet, the signal emerging from
an empirically derived algorithm is no different
from that for snow-free ice, thus the actual
disappearance of snow over the ice cannot
be determined (Drobot and Anderson 2001).
To date, there has been no sustained effort to
monitor snow atop sea ice using visible imagery.
The condition of snow cover over the Green-
land ice sheet is monitored using microwave
satellite data using several methods. This includes
the approach of Mote (2007) that uses a radiative
transfer model to estimate the microwave bright-
ness temperatures (TBs) associated with a snow-
pack containing 1% liquid water by volume. The
modeled TBs are used as threshold values and
compared to observed radiances. Much as over
sea ice, only the presence of liquid water within
the snowpack can be determined. The limited
areas of the Greenland sheet that lose snow cover
during the summer are not mapped on a regular
basis. Liquid water within the snowpack over the
Antarctic ice sheet, let alone the complete loss
of snow cover, is exceedingly limited in area.

Continental snow extent

The considerable interannual variability of snow
makes long-term datasets a necessity when
investigating means, trends, low frequency
events, or interactions of snow with other
climatic elements. The standard 30-year climatic
normal used for variables such as temperature
and precipitation may not be of a sufficient
length for realistic cryospheric means. Unfortu-
nately, consistent decades-long data are scarce.
Satellite-derived snow maps for Northern Hemi-
sphere lands have been available since the late
SNOW COVER

1960s. Automated maps of SCE over Southern Hemisphere lands have recently begun to be generated using visible or microwave satellite data. With time, they will provide useful information for the development of climatologies. Station data exist for approximately the past century, though they are of limited scope early on and, as mentioned previously, even today there is limited coverage. Issues with the collection, quality control, archiving, and synthesis of snow data, be it in situ or satellite derived, must be considered before employing the data in long-term climatologic studies.

Utilizing observations from the NOAA snow product, the geographical extent of snow cover in the Northern Hemisphere is found to vary from a maximum of $46.8 \times 10^6$ km$^2$ in January and February, to a minimum of $3.6 \times 10^6$ km$^2$ in August. Between 60 and 65% of winter (December–February) snow cover is located in Eurasia (Figure 2). The vast majority of Russia and Canada are snow covered throughout at least 80% of the winter. A rather pronounced winter decline in SCE frequency occurs to the south of the Canadian-US border and across the middle latitudes of Eurasia. Areas further to the south, such as the Himalayas, Turkish mountains, European Alps and US Rockies, are also more frequently snow covered than nearby lands. The southern advance of snow cover in fall begins in northern Siberia and the Canadian Archipelago. Far less than half of the season is snow covered elsewhere. Spring melt progresses poleward, with extents averaging about 20% greater than fall in most regions. Summer cover is confined to lower elevations above the Arctic Circle and mountains further south in June and only on the Greenland ice sheet and mountain glaciers in July–August.

In the Southern Hemisphere, most of the seasonal snow cover is located in the Andes of South America and on occasion the higher-elevation grasslands toward the south of this continent. Elsewhere, snow cover is found in the New Zealand Alps and less commonly over higher elevations in Australia and even South Africa.

Over terrestrial surfaces, total spring and summer snow cover has been considerably less extensive since the late 1980s in comparison with the satellite era and likely with earlier twentieth-century conditions (Brown and Robinson 2011), but with regional variations, such as increased fall and winter snow cover in Siberia. Along with the recent decline of arctic sea ice, this loss of terrestrial snow cover is one of the better-known and more striking examples of global climate change.

Snow cover was more extensive in the first half of the satellite record than in the past decade (Figure 3). Between 1972 and 1985, annual means of snow extent fluctuated around a mean of 25.9 million km$^2$. An abrupt transition occurred in 1986 and 1987, and since then the mean annual extent has been 24.2 million km$^2$. Monthly anomalies from the long-term mean are most often less than 3 million km$^2$; however, on occasion they range to 4 and 5 million km$^2$, with October 1976 having a positive anomaly of over 8 million km$^2$.

Recent decreases in snow extent are large during the spring and summer, while winter and fall extents show no statistically significant change (Figure 4). The tendency toward less late-season cover in recent years begins in February. During seven of the first 15 years of record, February snow extent exceeded the January value. This has occurred only once in the past 12 years.

Station records for portions of the Northern Hemisphere continents suggest that spring and early summer snow extents in the past decade may be at their lowest values of the century. Otherwise, winter season extents in the latter portion of this century exceed those of earlier years. Annual and decadal fluctuations
are embedded in this upward trend, and, at least over portions of central North America, the variability of snow cover duration has also increased throughout the century. The increase in snow cover duration in this region is accompanied by statistically significant increases in seasonal snowfall. In recent decades, snowfall has also been heavier to the lee of the North American Great Lakes than earlier in the century. These findings are in line with observations from Canada and the former Soviet Union, with all areas appearing to be part of a trend towards increased winter precipitation over the middle latitudes lands in the Northern Hemisphere.

Figure 3 Twelve-month running mean departures (from 1981 to 2010 mean) of snow cover extent over Northern Hemisphere lands between 1967 and 2014. SCE is gleaned from NOAA snow maps and converted to a climate data record at the Rutgers Global Snow Lab. Source: Rutgers Global Snow Lab (GSL).

Modeling snow cover extent

General circulation models (GCM) simulate the seasonal timing and the relative spatial patterns of continental-scale snow cover extent fairly well. However, there is a tendency to overestimate the rate of ablation during spring, and significant between-model variability is found at various spatial scales (Frei et al. 2005). GCM predictions of future changes in snow and sea ice cover under different global warming scenarios show a continued overall decrease in snow and sea ice extent (Brutel-Vuilmet, Menegoz, and Krinner 2013). This is hardly surprising, as ultimately with temperatures more often climbing above the freezing point in many areas that presently experience snow, snowfall and SCE will be greatly diminished. However, before this occurs, and in some cold regions well after the planet has warmed considerably, winter snowfall and snow depth may increase. All of these changes are likely to have major impacts on humans and the environment, including amplifying global warming.

Conclusion

Snow plays a critical role in the climate system and will continue to be an important climate variable to monitor when assessing climate change. However, there remain many
unanswered questions regarding the variability of snow and the long-term representativeness of recent empirical studies of cryosphere–climate interactions, such as links between snow extent and monsoon strength. Additional information is needed over space and time, including better information regarding snow cover atop sea ice and ice sheets in both hemispheres. Historic station datasets of snowfall and snow cover remain to be collected and analyzed. Recent efforts to integrate visible and microwave satellite and station data must continue for past intervals and future years. Studies need to examine variations in snow water equivalent, and work begun recently to improve model simulations of snow must continue.

With increasing levels of greenhouse gases expected to result in warmer conditions over the coming decades, the coverage of snow across continental landmasses will likely decrease, which in turn should enhance the warming. Snow cover should become established later in the fall, and melt sooner in the spring. Areas where snow cover is ephemeral throughout the winter will see the ground covered less often. Likewise, it is possible that warming will be accompanied by an increased flux of moisture into the high latitudes, resulting in a deeper
SNOW COVER

winter snow pack in some regions, though probably in a shortened snow season.

Snow

Martin Schneebeli
WSL Institute for Snow and Avalanche Research
SLF, Switzerland

Snow is a unique matter in nature. It symbolizes coldness for humans, but is the only widespread high-temperature material on Earth. It modifies the landscape dramatically, has a huge effect on the biosphere and strong interactions with traditional and modern human culture, especially as a water resource. Snow crystals also became a symbol of natural uniqueness and beauty in the past century. At the same time, snow avalanches are an important natural hazard in mountainous areas. This makes “snow” a unique, complex phenomenon.

Snow is formed in the atmosphere by direct crystallization from supercooled water vapor and sub-micrometer sized water droplets. These minuscule droplets usually contain nuclei; foreign material, for example, as dust from soils, plants, and fires. Snow crystals can rarely homogenously nucleate, by spontaneous freezing at a temperature below about $-40^\circ$C, but typically by heterogeneous nucleation. Heterogeneous nucleation occurs at higher temperatures, and is mediated by nuclei. The immense variety of snow crystals stems from the fact that the growth rate of the basal and prism plane of the hexagonal ice crystal depends on temperature and excess vapor density (supersaturation). Several transitions between preferential growth of the prism plane ($a$-axis of the crystal) and basal plane ($c$-axis) occur over the temperature range 0 to $-40^\circ$C and a supersaturation between 0–0.3 g m$^{-3}$. As the individual snow crystal travels through the clouds, the crystal encounters continuously different conditions, creating the many different combinations of plates, dendrites, needles, and columns, until it is too heavy and falls to the ground. Typically, the formation of snow crystals in the atmosphere takes around half an hour. The size of the falling crystals is between about 10 μm and 10 mm. The very tiny crystals are called “diamond dust,” and are most often observed in inland Antarctica, the largest crystals appear in areas with optimal conditions for snow crystal formation, as on the south coast of the Great Lakes or in Hokkaido.

As soon as snow is on the ground, and often even before, diminution and sintering begin. Diminution of the original crystals is caused by wind action in the air or close to the ground. Under windy conditions, only a very small percentage of undamaged crystals survive until they settle on the ground. Fallen new snow is often redistributed again, especially in windy areas (Arctic, Siberia, Antarctica, alpine ridges), which causes further diminution to small particles. As soon as the snow is settled, the single ice particles, comparable to sand, start sintering. This process starts within seconds, even at low temperatures. Sintering causes the snowpack to stop being granular; instead a solid frozen bond connects all crystals (grains). Snow on the ground must be imaged as a fully connected three-dimensional structure of mostly monocrystalline ice particles.

Metamorphism is the process of recrystallization. Snow being a high-temperature material, very close to the melting point, recrystallizes easily. A high-temperature material is defined as the absolute temperature higher than 60% of

SNOW

the melting temperature, which is for snow at about $-110^\circ$ C. Metamorphism and compaction (settling) are the key processes acting on snow on the ground. Snow on the ground is a monomineralic rock. Snow as a rock is unusual with regard to that it exists at a high homologous temperature but at very low external pressure. The combination of high vapor pressure of water and ice and high homologous temperature causes a very rapid recrystallization. A typical arctic snowpack may completely recrystallize within a few days (Pinzer, Schneebeli, and Kaempfer 2012). Earlier held views suggested a relatively slow change of the structural evolution of the snowpack. The rapid structural changes directly affect the optical, mechanical, and other physical properties. Depositional and metamorphic processes lead to a complex stratigraphy. The complex stratigraphy is a key component in avalanche formation, especially the formation of the weak layer. The seasonal and annual patterns in the stratigraphy are important for ice core interpretation, as they can be recognized after hundreds and thousands of years. The structure of snow is described by the shape and size of the snow grains. The most basic snow types are new snow, rounded snow, faceted snow, and depth hoar (Fierz et al. 2009). All these snow types show transitions, and an objective determination is often difficult. Substantial effort is going into a more quantitative description of the snow structure as physical models are in need of a more precise quantification. The density of snow varies between 50–550 kg m$^{-3}$. The upper value is the threshold density to firn. A typical alpine snowpack has a density of about 250 kg m$^{-3}$, a tundra snowpack of about 350 kg m$^{-3}$, as wind packs snow particles denser. The specific surface area of snow is about 40 m$^2$ m$^{-3}$, and as low as 1 m$^2$ m$^{-3}$ for refrozen coarse-grained wet snow. Mechanical strength of snow is mainly determined by density, specific surface area, and time of sintering. Due to its high homologous temperature, mechanical properties can change within hours. This is important for the formation of avalanches, trafficability, and snow sports.

Snow on the ground has one of the highest albedo of all natural surfaces, up to 90% of solar radiation is reflected (other examples are dried salt lakes). Typically, snow increases the albedo by 30–50%. This property changes the radiation balance dramatically, and is the main reason that snow cover is relevant to climate. The high albedo of snow is caused by two physical properties. First, ice is one of the least light-adsorbing materials in the visible spectral region. Second, the small size of snow particles, which is commonly measured as specific surface area or optical diameter, causes multiple scattering. However, the influence of snow albedo is somewhat limited due to the polar night in the Arctic and, to lesser degree, in Antarctica. Snow albedo can be substantially reduced by impurities, most effectively by black carbon. Dust can have similar effects, although the radiative forcing is much smaller by mass, it is known to strongly influence snowmelt in mountains. Recent research shows that snow impurities affect snowmelt in many alpine mountains and in arctic regions.

The thermal conductivity of snow varies between almost air (0.026 W m$^{-1}$ K$^{-1}$) and 0.6 W m$^{-1}$ K$^{-1}$. A typical snowpack has a thermal conductivity of 0.2–0.3 W m$^{-1}$ K$^{-1}$. Snow is therefore in most cases not a very good thermal insulation, but thermally similar to dry soils. However, snow is a still a very important insulation for flora and fauna, as the ground heat flux often maintains a 0$^\circ$-boundary at the soil–snow interface. Snow is also very important to reduce temperature fluctuations, which is a very important effect. The large latent heat stored in snow causes a substantial delay in the warming of the soil during melt.
The snow cover in the Northern Hemisphere extends over about $45 \times 10^6$ km$^2$ during winter maximum, and is less than $1 \times 10^6$ km$^2$ during summer. Snow cover extent is measured by remote sensing. As there is no visible light during polar night, the emissivity in the microwave spectrum (brightness temperature) is used during winter. These microwave observations form one of the longest data series in remote sensing. On a global scale, the year-to-year variation of the maximal extent is about 10%, and there is a small trend of about 1% reduction per decade since the 1970s. In the western United States the duration of the snow cover decreases by 2–3 days per decade (Maurer 2007). The mass of snow deposited every winter is of immense importance for agriculture, human water consumption, and electric hydropower production. The mass of snow is usually expressed as snow water equivalent (SWE). It is defined as equivalent height of water stored as snow. The density of snow is highly variable, but can be estimated based on the snow climatology (Sturm et al. 2010). Remote sensing methods to reliably estimate SWE are still in development, and especially difficult over mountains. Recent advances are made using airborne laser scanning techniques, which are now routinely applied in some watersheds in the United States. Most of the snowpack in the Northern Hemisphere is seasonal, and only a very small fraction perennial, as on the Greenland ice sheet. The snow cover in the Southern Hemisphere is mostly perennial, and is concentrated in Antarctica. Perennial snowpacks can exist at densities below 550 kg m$^{-3}$ for up to about 20 years, undergoing long-term metamorphism.

Snow has a very strong effect on growth and hydrology of forests. Snow is easily intercepted on branches, temporarily stored, and released later. Interception and radiation can have very different effects on total water stored. In the northern boreal zone, sublimation of the intercepted snow leads in general to a smaller SWE than in open land. However, forests in Mediterranean mountains often store more snow on the ground compared to open area, due to the shading of the trees and reduced radiation. This complex relationship is of interest as the increasing demand of water resources by competing uses intensifies. Management practices can significantly contribute to the optimization of forest function. Forests are also the best and cheapest way to prevent and protect from snow avalanches. Forests prevent the formation of snow avalanches by stabilizing the snowpack. The main effects are the interruption of weak layers by unloading of intercepted snow, the reduced formation of weak layers by the higher snow surface temperature under trees compared to the open field and reduced redistribution by wind. Although forests cannot stop a fully developed avalanche, they are able to stop or reduce run-out of smaller avalanches.

Snow is the key element for winter tourism. Winter tourism is a multibillion economy, and in many mountainous areas the key income. The availability of sufficient snow for snow sport is crucial to attracting a large number of tourists. The increasing number of alternatives to winter tourism has made the guaranteed availability of ski slopes a necessity. Spurred by the development of technical snow making (“artificial snow”) in the United States, all snow resorts worldwide are now routinely equipped with sufficient snow making capabilities to guarantee snow. The snow making technology developed to more energy efficient systems, some even using only the available water pressure. Specific reservoirs for snowmaking lower the pressure on other water resources. Typically, 30 cm snow depth during 100 days is considered as the minimal natural snow depth to run a ski resort economically.

Social capital

Kenji Tsutsumi
Osaka University, Japan

What is social capital?

Social capital refers to the mutual trust, social norms, and supportive networks in a society or community. The idea stems from notions of reciprocity, and the concept has a strong relationship to several kinds of social matters. The ideas of trust and reciprocity are fundamental, and include a personal, strategic trust, which expects something to be returned by others (such as club goods), and a general, moral trust, in a wider or bigger society (such as public goods). According to Ronald Burt (Lin, Cook, and Burt 2008, 32), “[S]ocial structure is a kind of capital that can create for certain individuals or groups a competitive advantage in pursuing their ends. Better connected people enjoy higher returns.” A quantum leap from personalized trust up to a generalized trust may be vital for economic development. Though controversial, the concept is of particular interest to geographers, as it implies that it is necessary to look beyond a purely deterministic account of economic relations.

Geography and social capital

Under the current conditions of economic depression in advanced societies, various regional revitalization measures have been adopted for local implementation. Recently, some economic geographers have advocated that social regeneration, which can be achieved through the solution of social problems on a regional basis, will finally lead to regional economic regeneration, instead of giving subsidies from local government to the private sector. In such social regeneration schemes, various forms of private network or local social capital play important roles. Rather than offering “top-down” solutions, in this model the government should be a mediator to help enhance and capitalize on the underlying strengths in local neighborhoods.

Social capital is also of interest to health geographers; indeed, the relationship between well-being and social capital is a field that has aroused active discussion. For example, in some developed countries, a strong correlation is observed between a high elderly employment rate and low medical bill per capita for elderly people. Generally speaking, the higher the employment rate becomes, the more active citizens’ movements become, with more abundant social capital. Accordingly, in an aging society, social capital is of great significance when it comes to health policy and the cost of care. It has been seen not only to mobilize the power of the elderly, but also can have benefits when it comes to longevity and the quality of life afforded to people of the silver age.

Another important attribute that geographers bring to the study of social capital concerns the issue of scale. Societies and networks are formed across many different scales, spatial and temporal. Wide–narrow and long–short relationships offer a world of ontological settings. For geographers, social capital needs to be considered at multiple scales. Moreover, even in a virtual world, people can build networks with social capital. This
suggests a more spatially sensitive account of social capital, where it can be considered virtual or real, simple or complicated, wide or narrow. Social capital is formed, used, and activated in networks. One’s social capital may relate to several kinds of network: relationships among humans, resources, goods, information, and so on. John Urry’s concept of social scape is helpful when thinking about the problem. Social scape is a network that connects certain relationships with a spatial and temporal situation. It is a dynamic and structuralized entity, reconstructing dimensions of time and space (Urry 2000). In this spatial application, social capital may give shape to the social scape and generate change.

Histories of social capital

There is a long history of research into social capital. A number of writers see antecedents in the work of Aristotle, John Dewey, or Glen Loury, or in the excellent concept of public responsibility offered by Jane Jacobs in the 1960s. But few people directly defined or referred to social capital before Robert Putnam (2002), whose work is discussed in the following section.

In the nineteenth century, before the American Civil War, Alexis-Charles-Henri Clérel de Tocqueville, a French politician and philosopher, wrote that the democracy of America had been formed upon a social capital led by local community churches. Early in the twentieth century, Lyda Hanifan was perhaps one of the first people to suggest that a local school can be a center of local social capital in each community. Putnam has often cited Hanifan’s words as a simple and understandable definition of social capital. As for the “capital” of “social capital,” Hanifan did not refer to real estate, or to personal property, or to cold cash. Rather, he mentioned “goodwill, fellowship, mutual sympathy and social intercourse among a group of individuals and families who make up a social unit, the rural community, whose logical center is the school” (Hanifan 1916, 130).

Hanifan, a state supervisor of rural schools in West Virginia, would have liked to establish schools as public centers in communities. Thanks to the efforts of local teachers and neighbors, some schools acted as community centers, forming social capital through community surveys, community center meetings, agricultural fairs, school exhibitions, community histories, school attendance, evening classes, lecture courses, school libraries, and school athletics. This was a vision from the time of World War I, but even now social capital is said to have a strong influence on educational outcomes. For instance, it can be seen that in a region where the social capital index is high, rates of school violence and dropout are low.

In the early part of the twentieth century, particularly in the United States, modern capitalism developed on a drastically bigger scale, alongside social issues concerning to society and the economy. Some settings in American stories, such as An American Tragedy (1925), drew people’s attention to practical social phenomena, which form the basis of much of the famous works of the Chicago School of Sociology. The age of American pragmatism and practicalism was the embryonic stage of social capital, as captured by the sophisticated expression of Hanifan, Dewey, and others. Also, American sociology, rural or urban, had expanded into all the fields of community research, within which social ties and their changes became one of the central issues in the discipline.

Since the 1960s, Pierre Bourdieu, a French sociologist, addressed the concept of capital in a series of works on economic, social, cultural, and symbolic capital (Bourdieu 1983). Among these, social capital refers to a variety of kinds
of valued relations, some more important than others. In the United States, the sociologist James Samuel Coleman has referred to three forms of social capital: obligations and expectations, information channels, and social norms. He placed social capital as a resource of action and thought through which a rational action paradigm may be related to social structure, connecting a network of human capital with social capital (Coleman 1988).

In the twenty-first century, a few researchers have started to measure a part of social capital (Grootaert and van Bastelaer 2002). Some of them have belonged to the World Bank and have made much of measuring social capital to consult about regional development policy in developing countries. The Social Capital Thematic Group of the World Bank has developed two measurement tools: the social capital assessment tools (SOCAT) and the social capital integrated questionnaire (SOCAP IQ). There is some criticism of such measuring methods, because as a matter of course quantitative research limits treatment of qualitative data, but improvements have been made to these tools for use in the field in developing countries.

The revitalization of social capital

Since the late 1990s, the term social capital has increased in popularity. In his book Bowling Alone, Robert Putnam provides examples of research outcomes in the United States, claiming that in states with high social capital, schools work better, children watch less television, and violent crime is reduced (Putnam 2000, 299–310). Some scholars have criticized the vagueness of the definition, suggesting that social capital should be a social resource. In particular, it is important to distinguish between social capital, a social network, and social ties. But despite these shortcomings, the seed of social capital sown by Putnam has grown up and generated a lot of fruit for discussion and research. Putnam emphasizes that democracy should be sustained by the horizontal and spontaneous activities of citizens. Activating people towards more cooperative forms of behavior may contribute to social efficiency, as social capital. The concept can be a good platform to discuss life, intersubjectivity, and public utility in a society. For example, a sense of wellbeing, satisfaction, and altruistic behavior that cannot be explained by economic rules alone may be built upon the foundation of social capital.

Putnam has also referred to a distinction among types of social organizational activity. Bonding and bridging refer to relations of internal and external networks respectively. For example, although a little bit simplified, an organization in a premodern, traditional rural community (or in a Gemeinschaft) is a bonding network, and a bridging network is one among socially heterogeneous or inter-independent groups (or among Gesellschafts). In other words, groups with a high level of bonding capital tend to be self-reliant, with close links within their networks. In contrast, those with a high level of bridging capital have the potential to make links across networks and, therefore, have more extensive connections and are not wholly reliant upon a single node or community.

According to Putnam’s argument, recent decades have shown declining trends in the power of traditional groups such as unions, parties, and churches, to accumulate social capital. But some new groups have emerged, including sports groups, environmental groups, new social movements, and so on. Naturally, the attributes of actors of each group have changed. Social capital is mentioned constantly in relation to communities. In many works, a community is a matrix of social capital. Some of
SOCIAL CAPITAL

the essential points in the matrix are presented in Box 1. Regarding social capital in a community, attention should be paid to its membership, purpose, property, accessibility, connection, energy, and functioning. Activities that develop social capital would work in a very complicated structure, which can be dissected from several perspectives, scales, and levels. The basic unit for social capital is an individual. A group of people form social relations or networks with certain purposes, goals, or motivations. This bonding perhaps leads to further bonding, or bridging to another level. At each phase, or stage, of shaping social capital, important elements can be seen. After Lin, Cook, and Burt (2008), the utility of social capital also differs by setting.

The limits of social capital

A number of works have addressed relations between social capital and economic phenomena. For example, a large accumulation of social capital reduces transaction costs, resulting in a positive impact on economic growth. In economics, income inequality is due to differences in preferences for labor and differences in the abilities of individual persons. The variation among individuals is not a major problem discretely, but from the point of view of social capital, the expansion of economic disparity would lead to damage to social capital, which then generates further disparity. Inequality of endowments of social capital seems to lead to a widening of economic disparities.

Sometimes social capital is damaged by economic disparity, crime, or violence. And one form of social capital may itself sometimes resist other forms of social capital. Very strong social capital with tight inner ties in a bonding-type community will result in a restriction of the freedom of the members, and the group will be restrictive and exclude others. Social capital is, therefore, often considered in connection to external relations. Thus, the dark face of social capital can be seen: exclusiveness, external diseconomy, and so on.

Regarding disparity, developments in information technology are likely to create fewer winners and more losers, with social fragmentation and bipolarization among classes. If this occurs, young people tend to be NEETs (not in education, employment, or training). In EU countries, in addition, immigrants experience social exclusion, as a result of low social capital, and public policy should be developed to avoid the isolation of young or immigrant people, leading to social inclusion and social protection.

Social capital in a society has a major impact on the efficiency of the government. As government itself tends more and more to outsource its own work, the question arises as to what kinds of social capital and networks the government can construct. The government has an obligation not only to promote and maintain the external establishment of social capital, but to generate and capitalize new social capital by itself.

In today’s information society, some people believe that television and computer games have damaged social capital because they have deprived people of time and the chance to establish and maintain social relationships. But the Internet and SMS text messaging can also expand social networks, albeit in different ways. People can create virtual communities that are free from the bonds of place. They might also strengthen social capital of the bonding type, even among family members and good friends. In an enterprise, for example, an in-house local area network (LAN) and a cloud computer system are very efficient at bridging sections; therefore, in the information society bonding
SOCIAL CAPITAL

Box 1 Important elements of social capital in a community.

- Member or membership: Who is the member? (Age, sex, occupation, status, ability, consciousness, motivation, etc.) A hierarchy of members is also an essential factor.
- Purpose, goal or motivation: What is the logic behind establishing social relationships for social capital?
- Property of social capital: What are the resources, rules and norms of social capital?
- Boundary or range: How broad is the group to which social capital is extended?
- Accessibility: Is there a degree of freedom or exclusiveness to use the social capital, and how can people access it?
- Connection: How does one unit of social capital connect to others (further bonding, bridging, linking, etc.)?
- Energy: How does the social capital get energy, or how is it reinforced? (Adding budget, members, trustworthiness, etc.)
- Interscale or interlevel functioning: How does the social capital work on different scales or levels?

Source: Tsutsumi 2011, 136 (modified by the author)

and bridging are still possible, and are becoming more complex with globalization.

There is also a problem of government and research perspectives on social capital creating a dualism: “top down versus bottom up.” The roles of national and local institutions in restoring American community need to be complementary; neither can solve the problem alone (Putnam 2000, 413). But in some countries, such as Japan, at the beginning of the twenty-first century, most scholars who had introduced the concept of social capital were economists, with a strong top-down perspective, and a tendency to speak of the nation state, but not of local smaller communities. However, there were also regional sociologists who had been more accustomed to a bottom-up perspective, making much of social ties or social relations in a community. Furthermore, a traditional sociologist would say that social capital is not new at all and terms such as social ties and social relations have been around for more than 100 years, so they may avoid using the term “social capital.”

Conclusion

Although on first consideration Putnam’s definition of social capital is relatively simple, it is, in fact, more complex, and subsequent research has been broad and deep. Putnam’s definition is constructed from structural, collective, behavioral, and cognitive perspectives, because it is formed from functional and structural, or physiological and morphological, points of view.

Although social capital can be formed even in a virtual or cyber world, it is still a very convenient conceptual tool for the study of community, regional education, regional identity, regional welfare, social networks, and social relations in space. In other words, it is sometimes rooted in a place, so social capital has a certain geographical character. Hanifan (1916) saw a school or a church in a community as a center for social capital, and Putnam (2000) also made regional disparity clear on a scale of states. Social capital consists of several
kinds of function that are rooted in a place or a space within a regional scale system. And social capital can be researched or analyzed geographically in the context of such topics as regional living functions and regional differentiation (Tsutsumi 2011).

In shrinking societies, local social capital has the advantage of supporting the regional daily life of residents at varied points: education, medical service, welfare, shopping, housekeeping, security, and so on. Sometimes religion, sports and recreation help people form a network of social capital. On the other hand, in developing societies a network with vernacular social capital can act as a conduit for industrialization and modernization.

Social constructionism and its critique

Social constructionism – a trend of theoretical thinking about the social construction of reality, and synonymous with the “cultural turn” in the social sciences and humanities in the 1980s – became popular in human geography in the early 1990s. The roots of social constructionism lie in a number of philosophical movements re-examining what used to be regarded as “common sense” or “reality,” as well as the means by which we perceive it. Its precedents can be traced back to the nineteenth century, when criticism of teleology and metaphysical ontology by post-Kantian continental philosophers – from Hegel and Marx, to Sartre and Nietzsche – eventually contributed to the rise of poststructuralist scholarship in the late twentieth century; American pragmatism, pioneered by theorists such as John Dewey, also engendered constructivist philosophies aimed at critically reviewing traditional epistemology in regard to the foundation of knowledge, everyday experiences, meaning-making, and communication.

Social constructionism has developed into an umbrella concept over time, covering a wide range of philosophical trends spanning poststructuralism, postmodernism, hermeneutics, and phenomenology, and thus defies easy definition. Nonetheless, social constructionism has the goal of accentuating differences, situatedness, and positionality in knowledge construction; specifically, it refutes the universal theories and essentialist and foundationalist categories that engaged in stereotyping and social marginalization. It is now widely acknowledged, for instance, that there is no inherent “truth” to gender and the assigned social roles defined by it. Categories of race and ethnicity have also been deconstructed, with whiteness being unraveled as formed in opposition to the racial Other. The complex intersections between always multiple and situational identities have undergone critical examination as well. In geography, the ways in which place, landscape, and nature are socially constructed and contested have been extensively interrogated. This intellectual development of social constructionism has contributed to the emergence of identity politics, the politics of recognition, and the celebration of cultural diversity, which have been posited as politically emancipatory and progressive.

Despite its growing prevalence in the social sciences, social constructionism has aroused heated debate regarding its theoretical validity and its political and moral desirability. This is especially the case for the realist scholarship initiated by Roy Bhaskar. First, its nonessentialist ontology and its emphasis on language has been criticized for being haunted by philosophical idealism, for if everything is socially constructed, how can things independent of mind, such as rock, or sensations, such as bodily pain, be accounted for? However, criticism of this kind usually resorts to a binary reading of mind and matter, which itself is contentious. Second, social
constructionism is often considered theoretically flawed, for its inherent difficulty lies in identifying the causes of social change. The charge of relativism is also apt: if reality is entirely subject to construction from different social positions, it then becomes impossible to identify the victims of social oppression. Moreover, its associated identity politics may hint at hermeneutic emancipation without substantial political actions. Such apprehensions led the geographer Sayer (1997, 445) to contend that social constructionism is “unsatisfactory with regard to ontology, epistemology and its conceptualization of nature and society and is as open to reactionary interpretations as it is to progressive ones.”

Commenting from the position of critical realism, Sayer further distinguished a strong form of social constructionism from a weak one; the former deems reality and social life as nothing more than what we know about them, and is therefore more aligned with a postmodernist philosophical stance, while the latter posits that there is a reality that can be known but that there are different, always partial and often competing, ways of recognizing it. In this formulation, Sayer argues that critical realism and social constructionism are not incommensurable, for critical realism shares some common ground with weak social constructionism in its view of relational and constantly evolving essences, concerns for historical contingencies, and heedfulness to differences.

Discourse theories in social constructionism

The development and critiques of social constructionism have contributed to multifarious evaluations and contentions, mostly in relation to epistemological and ontological questions. Scholarship indebted to Foucault’s theoretical framework, or poststructuralism in general, addresses the critique of social constructionism by highlighting the notion of discourse and its roles in social processes. Instead of viewing language as a mere reflection of the “real world,” discourse theories emphasize how linguistic structures produce meaning for social practices and constitute “reality.” It is noted, however, that there are divergent approaches to discourse, ranging through critical discourse analysis proposed by critical realism scholarship, Laclau and Mouffe’s discourse theory, to Butler’s performativity theory. These discourse-focused approaches, while all rejecting a postmodern take on the world as constituted solely by free-floating symbols, diverge not only in their definition of discourse, but also in their understanding of power, the relation between discourse and materiality, the formation of subjectivity, and whether/where potential space for resistance can be identified. These differences have contributed to their distinct ways of addressing social constructionism.

Asserting the importance of incorporating a cultural dimension into the tradition of political economy scholarship, critical discourse analysis (CDA), developed by Fairclough, and cultural political economy (CPE), advocated by Jessop, among others, provide a theoretical supplement to social constructionism from within critical realism. While these approaches acknowledge the constitutive role of discourse and language in the processes of social change, they insist on the distinction between discourse and nondiscursive social realms – where institutional arrangements or economic forces belong – and on their dialectical interplay. As such, it is believed that only through scrutinizing the interrelation between discourse and extra-discourse can social causalities be accounted for, while at the same time avoiding the quagmire of political relativism inherent in social constructionism. Methodologically, both CDA’s and CPE’s take
on discourse emphasizes semiotics and regards the intersubjective production of meanings as their major site of analysis. The philosophical outlook of critical realism and the methodologies stemming from it have had great implications in economic geography, which is now in search of analytical approaches to the study of the discourses of economic imaginaries and the intersections between governance, identity, and the restructuring of political economic forces.

Grounded in Gramsci’s theory of hegemony, Laclau and Mouffe (2001) use discourse theory as a way to rework the Marxist framework of base–superstructure as well as subject–object relations. In contrast to critical realism’s preservation of the discourse/nondiscourse demarcation, Laclau and Mouffe assert that the totalizing nature of discourse includes all forms of social practices. In their theoretical framework, “reality” is constituted through endless discursive struggles until a fixed meaning system – so-called hegemony – is reached, which makes social constructionism a question of hegemonic construction. Since there is no pregiven reality that can be apprehended prior to discursive practices, and it is impossible to tell exactly where discourse stops and the nondiscursive realm starts, they contend that the line between discourse and nondiscourse should not be drawn analytically but empirically. It is because of the nonpredetermined nature of subject positions, existing in the non-eliminable gaps between ideas and materiality, that room for radical democratic politics opens up. This theoretical approach has been popular among political geographers in their inquiries into popular culture, popularism, social movements, and resistance in the face of hegemonic dominance operating on various scales and in various locales.

A counterargument against the critique of social constructionism as idealist and politically relativist is addressed by Butler. Resorting to Foucault’s notion of discourse as power effects, Butler’s approach delimits the role of human will in language and foregrounds the historicity of discourse. Moreover, Butler shows that the material/discourse dichotomy – a position underpinning the charge that social constructionism is overly idealist – is exactly the premise upon which power operates and is normalized. Butler posits construction as a constructive constraint that demarcates, differentiates, and renders certain matters real, yet unintelligible – the very logic that sees gender as socially constructed also insists on the existence of sex as nothing more than “real.” It is through the production of such pre-discursiveness prior to human thoughts, for example, that heteronormativity is naturalized. To resolve the structure/agency dichotomy, Butler further draws on the notion of performativity – a reiterative, yet unstable, process from which subject positions emerge and are constantly (re)formed (Butler 1993). Butler’s take on discourse and performativity seeks to overcome the mind–body divide and question the superiority of human will, themes which surface in much of the critique of social constructionism. Performativity has been taken up widely by geographers in relation to studies of gender, sexuality, ethnicity, race, place, and space. Nonetheless, the notion of performativity is also cautioned against by geographers for being unable to attend to the historical and geographical embeddedness of subject formation.

Social constructionism in geography

This critique has been furthered at both ontological and epistemological levels by the flourishing scholarship challenging human centrism through decentering discourse, reason, and the human being at large. Scholars have attempted to discard the residual Cartesianism that has haunted modern human knowledge, and have looked
SOCIAL CONSTRUCTIONISM

to philosophies such as phenomenology and Deleuze and Guattari’s theories as a way out of the deadlocked debate between realism and social constructionism. The emergence in geography of nonrepresentational theory (NRT) and the wide adoption of actor-network theory (ANT) are two ways in which the discipline has contributed to this critique.

Nonrepresentational theory, a project launched by the geographer Nigel Thrift (2007), among others, in the 1990s, marks a departure from a representation– (or discourse–) focused approach to social constructionism. Also known as “more-than-representation” theory, NRT focuses on the embodied and relational practices through which a performed subject arises – a concern shared with performativity scholarship. Yet, instead of chasing meaning–making practices (and the unavoidable accentuation of language and reason), NRT highlights unintentional, precognitive, or noncognitive affects and emotions generated from encounters between hybrid entities – be they bodies, things, or ideas – that bring forth the social. The tenets of NRT attend to the lifeworld as it exists in the interrelational actions between such entities, and thus is always “becoming,” “emerging,” and “destabilizing,” forming spaces of in-betweenness.

Likewise, drawing on the studies of laboratory practices and technology, sociologists led by John Law and Bruno Latour formulated ANT as a nonanthropocentric approach to debunk human mastery that sets up the one-dimensional “tug of war” between realism and social constructionism (Latour 1992). While stressing the socially constructed aspect of science, Latour refutes the ability to explain nature in terms of social construction. ANT is neither a return to the realist account for the “out-thereness” awaiting discovery nor a return to its interpretation by human agents. Instead, ANT rejects the human being as the only actor with the power to contribute to the formation of the social – either through discursive articulation or through material interaction. It holds to the ontology of emergence, where different entities (or so-called actants) – humans, animals, things, and discourses, for instance – are constantly enrolled into a heterogeneous network of assemblage. Although not exclusively a geographical theory, ANT is widely deployed within the discipline, resonating with many geographers’ concerns about spatiality, socio-nature, and connectivity.

Social construction of scale

The vibrant ontological and epistemological discussions surrounding social constructionism take place both within and outside of human geography scholarship, and have largely reshaped the ways in which the core concepts of the discipline – scale, for instance – are theorized. Scale, a way of looking at, thinking through, and acting upon variegated social, economic, and political processes, once regarded as fundamental to the discipline by many, since the 1990s has been questioned for its self-evident nature. Despite differences in conceptualizing the social production of scale, studies range through (re)scaling processes of capitalism to the scale-making and scale-jumping strategies deployed by various actors.

Nonetheless, the scale literature, as such, has been critiqued for being unable to eschew the limitations of a hierarchical ontology. Against this backdrop, Marston, Jones, and Woodward (2005) proposed a provocative alternative approach, calling for a “flat ontology” to replace any transcendental understanding of spatial organization. With the abandonment of scale, “site ontology” – always emergent and only existing in the interactive processes between humans and non-humans – is favored for its theoretical openness.
and political radicalness. Yet such a proclamation has received a diverse range of evaluations and criticism. While many wonder whether site ontology parallels the ontological ground of ANT or that of phenomenology, others are concerned with the political implications of such a theoretical practice, criticizing it for falling short of addressing concerns of power and politics.

While it is generally agreed that scale is socially constructed and therefore dynamic and relational in nature, it remains unresolved as to whether scale denotes a complex set of ontological structures through which social relations are organized and contested, or whether scale should be understood as a language of spatial politics that produces its own empirically determined “scale effect.” Viewpoints over which approach possesses more radical potentiality in opening up space for resistance are also in contention and resemble the ongoing struggle, straddling critical realism, poststructuralism, and much of the scholarly work deriving from, yet radically modifying, social constructionism.

Developing themes within and beyond social constructionism in geography

There has been a sea change in the research agenda of human geography, with a move towards unconventional themes triggered by the recent developments in social constructionist literature. The subfields of economic geography, political geography, and political ecology, among others, are undergoing considerable revision through approaches adapted from, but not limited to, those reviewed above.

In economic geography, the economy and the market have been widely viewed as having logics and spaces not only indifferent to culture, but also independent of how we understand or study them. This doctrine did not change much when economic geography shifted its attention from neoclassic economic theories to that of Marxist political economy; however, the ontological and epistemological premises of such a theoretical orientation have met with critical examination from social constructionism. The constructive ways in which economic imaginaries and discourses, such as “globalization” and “development,” contribute to the organization of material, institutional, and social relations is critically investigated by poststructuralist economic geographers. Unpacking capitalism, Gibson-Graham’s (1996) work presents a critical inquiry into the politics of knowing and urges us to recognize the real existing diverse economic practices discursively excluded from orthodox political economy’s theorization. Informed by both performativity theory and ANT, Barnes (2001) further delineates how the discipline of economic geography and its subject of study came into being in the situated messiness comprising a hybrid network of theories, textbooks, institutions, and professionals.

Social constructionism has also found an extensive influence in the recent development of political geography, whose traditional theoretical foundation – be it notions of states, sovereignty, borders, or territory – has been fundamentally reshaped. It has directly contributed to the burgeoning critical geopolitics literature aimed at unraveling the geopolitical reasoning and discursive practices of statecraft and the world politics associated with them. A critical interrogation of Cold War rhetoric demonstrated the importance of discourse in constituting the nature of war and military manipulation. Fruitful work on border studies has also revealed the socially constructed nature of modern state boundaries and the violence associated with border practices. Working with emotional geographers, recent work in political geography has begun to apply affect and NRT to scrutinize issues from a geopolitics
SOCIAL CONSTRUCTIONISM

of fear to nationalist aspirations, showing that the nature of politics is not restricted to discursive struggles, but also embodies feelings and emotions.

The reworking of social constructionism is also manifest in the realm of recapturing the nature−culture relationship, where the conventional wisdom of the social construction of nature is being critically revisited in distinctive ways. The poststructuralist approach not only challenges the dualisms between human and nature upon which the notion and the existence of “nature” are formed, but goes further to depict the mutual construction between the two. The development of posthuman scholarship further discards the anthropocentricity of a constructionist approach and turns to heed the hybrid practices of matters such as animals, water, and disease, manifesting the wide application of ANT in the subfields of animal studies, resource geography, and health geography. Another theoretical intervention into the social/nature question can be found in Haraway’s (1991) interrogation of technoscience and the very nature of life. Her construction of the “cyborg” as “a cybernetic organism, a hybrid of machine and organism, a creature of social reality as well as a creature of fiction” (149) breaks down the boundaries between animals and humans, animal-humans (organisms) and machines, and the physical and nonphysical, by which the inquiry of political ecology is fundamentally modified.

Social geography

Vincent J. Del Casino Jr
University of Arizona, USA

Social geography is a subdiscipline with its roots in a number of different intellectual traditions and places. It has developed into what it is today as a result of the institutional and theoretical contexts in which it emerged, flourishing in some national contexts and barely recognized in others. The question of what constitutes social geography is still debated, as scholars consider what it means to study social life geographically. Broadly speaking, social geography focuses on the relationship between society and space, with a particular emphasis on issues related to social identity, nature, relevance, and justice. Social geographic research also focuses on the spatialities of difference and inequality and has links to the question of “who gets what, where, and how” (Smith 1994). With diverse histories that stretch from European anarchist traditions in the early nineteenth century to the social relevancy debates and the quantitative revolution that took hold of geography in the 1960s, and later the feminist, postcolonial, antiracist, and Marxist geographies that emerged in the 1970s across the globe, social geography today is a mix that draws on a range of theoretical and methodological approaches to include more recent interventions from poststructuralism and postmodernism.

Historical origins of social geography

Social geography’s historical roots are challenging to trace. Some claim that sociologists in France were the first to use the term “social geography,” while others trace its origins specifically to the work of the French-born scholar and anarchist, Élisée Reclus, both in the late nineteenth century. In reality, social geography has its roots in French, German, and British geography and has developed different trajectories in the United States, Canada, New Zealand, and Australia. The history of social geography also parallels the development of the wider discipline across Asia, Latin America, and Africa, where social geography has a complex relationship with, for example, the system of apartheid in South Africa or international collaborations across Southeast Asia. Rob Kitchin’s (2007) project, Mapping Worlds, illustrates some of this breadth, even as he acknowledges the challenge of internationalizing social geographic thought in relation to the hegemony of Anglo-American traditions, a concern that John Eyles (1986) also noted in Social Geography in International Perspective. Instead of tracing the history of social geography through its own diverse geographies by country (see reports in Social & Cultural Geography), it is better to approach its history through a framework that highlights both the inclusions and the exclusions that mark its development over time.

Social geography in the early to mid-twentieth century

In the early twentieth century, geographers had to contend with a significant amount of theoretical and methodological change, as evolutionary thinking began to permeate not only the natural sciences but the social sciences as well. For some geographers, the integration of theories of natural selection and other components of
evolutionary thought led to environmental determinism and theories of social evolution whereby climate and other physical factors were said to determine social structures, the success of and hierarchy among groups of people in particular places, and the spatial organization and distribution of different ethnic groups, races, and societies. Some of these theories were applied to overtly racist understandings of social development, while others were picked up and appropriated by eugenics movements as well as used in late nineteenth-century anthropogeography and twentieth-century geopolitics. For geographers interested in explaining the spatial organization of societies and their distributions over time, the larger question was the relationship between nature and society, the natural and the social worlds. Ontologically speaking, Western thought had, in the nineteenth century, begun to develop a fairly clear delineation between nature and society – the natural world was out there and organized by societies to meet human needs. Environmental determinism inverted the relationship, regarding nature as a determining factor in social development and organization. Although the directional arrow was changed, the ontological division between nature and society remained.

Frederich Ratzel’s *Anthropogeographie*, which was integral to German geopolitical theory, was based on social evolutionary theories of human development and spatial organization. Ratzel’s influence extended to other parts of Europe and to the United States, where his student, Ellen Churchill Semple, applied his thinking in her famous *Influences of the Geographic Environment*. As Semple argues, “man is a product of the earth’s surface,” and, as such, geographers must understand “the dominance of different geographic factors at different periods” (1911, 1, 31). Semple’s theories took as a starting point a global environmental system, which was mediated by local physiographic factors. Her theorization was not simple or straightforward but suggested that the “geographical environment, through the persistence of its influence, acquires peculiar significance … in the shifting fate of races” (Semple 1911, 6). This environmental basis of racial difference emerged as a critical aspect of early environmental determinism, which is also found in the work of Ellsworth Huntington (1915), whose *Civilization and Climate* made direct linkages between the spatial organization of racial differences and climate. By 1930, C.C. Huntington and Fred Carlson had tempered the argument about environmental determinism in *Environmental Basis of Social Geography*, in which they outline two disciplinary subareas: physical geography and social geography. Huntington and Carlson suggest that “it must not be supposed … that environment alone can furnish all of this explanation of ‘social causation’” (1930, 44) even as they insist that “location is a geographical factor of fundamental importance. It largely discloses the nature of man’s environment, and profoundly influences the character of his activities” (Huntington and Carlson 1930, 63). This tension – between (different degrees of) sensitivity regarding the complex drivers of social organization and the determining position of the environment – informs the question “How do we describe and explain the spatial distribution and organization of social life?” Despite Huntington and Carlson’s attempts to elevate social geography to the human social science approach in geography, in the United States in particular, cultural geography and regional geography held much more import, as social geography remained marginal to the discipline. This was not the case in other countries, such as the United Kingdom, France, and Germany, where social geography built on environmental traditions and also expanded other social theoretical work to explore the spatial organization of societies.
Despite its marginal status in US geography, social geography changed throughout the early to mid-twentieth century, as questions of the spatial organization and distribution of societies animated social science in Europe and North America. European social geography was strongly influenced by the work of French geographers, including Paul Vidal de la Blache, whose “science of place” as deep regional description was picked up by French and British social geographers during the early twentieth century. Many social geographers borrowed from Vidal de la Blache’s approach, focusing on the material aspects of social life, although he acknowledged the importance of studying social networks and norms as well. By the mid-twentieth century, geographers in the United Kingdom and a growing group of urban geographers in the United States were beginning to draw more inspiration from the field of sociology and the work of scholars, such as Park, Burgess, and McKenzie (1967/1925) who famously employed ecological models to study the city and its social differentiation. Their text, *The City*, strongly influenced the development of urban geography and social geographies of the city more generally by focusing attention on issues of racial and ethnic segregation and criminal patterns, as well as how cities were spatially organized over time. Park, Burgess, and McKenzie also theorized models of change in the city, how neighborhoods developed new characters and populations. In the United States, these ideas found their way into quantitative urban analyses of cities and regional development. In fact, the development of social geography in a number of countries, such as Germany, relied on deepening conversations between sociology and geography.

At the same time that social geography began to grow in North American and European contexts, many nongeographical scholars, such as W.E.B. DuBois and Jane Addams, were asking social geographic questions. DuBois’s *The Philadelphia Negro* paralleled the scope of Park, Burgess, and McKenzie’s work, although those scholars never recognized DuBois’s contributions (Sibley 1995). As David Sibley (1995, 154, cited in Del Casino 2009, 39) argues, “DuBois eschewed Social Darwinism, recognizing that it provided a justification for the oppression of black people.” DuBois’s qualitative inquiry into the lived experiences of black people in Philadelphia was seen as marginal to the scientific work of other scholars at the time. And yet, DuBois’s scholarship has more affinity with the work of many current social geographers, who often use qualitative methodologies to study race and racism. Jane Addams’s scholarship has also been marginal to the broader cannon of social geography and sociology (Sibley 1995). But, her research, which was part of a larger Chicago project called Hull House, applied sociological and geographical methodologies to the study of urban housing discrimination. Like DuBois, Addams and her Hull House colleagues deployed their research toward applied, political ends, which included the reorganization of urban space to address poverty and racism. Their work did not fit neatly into the objectivist approach of Park, Burgess, and other urban sociologists and geographers.

From today’s perspective, the research of DuBois and Addams is easily recognizable as social geography, but it is not surprising that their work remained marginal to the historical writing of social geography as the twentieth century moved forward. The quantitative revolution further reinforced this marginalization, as geographers conceptualized their field as a social science similar to economics. The turn toward a spatial scientific geography, which included the incorporation of hypothetical and deductive approaches as well as statistical methodologies and the use of large datasets, was applied generously to social geographic questions in the
1960s and 1970s. Social geographers began to analyze the spatial organization of racial and ethnic groups, crime patterns, segregation, and access to services, for example, asking how distance from a certain place or the agglomeration of particular activities or people could be scientifically analyzed to explain how and why they appear as they do. The goal was to model and map the patterns of difference among groups and peoples, and to predict how those patterns change over time. Richard Morrill (1965) examined the US ghetto and how its spatial organization could be analyzed through a scientific approach, modeling the variables that have driven the growth and decline of these spaces. Morrill’s work attempts to model diffusion and suggests that the racist practices of white urban dwellers could partially explain how neighborhoods change in relation to their social organization. Put another way, Morrill’s research presupposes other urban social geographic work on “white flight” and the suburbanization of extra-urban areas in the 1960s. Morrill suggests that “a real reduction in ghettoization implies governmental, not a voluntary, regulation of the urban land and housing market” (1965, 361). In taking up the question of race – in this case black and white populations in Seattle – Morrill argues that social geographic research can and should be applied to address social problems which, he suggests, have a spatial dimension.

Social geographers in the mid-twentieth century also drew on other social theories, particularly those emerging from humanism, to think about the relationship between human lived experience and place. Humanistic philosophies recenter social geography on subjective experience and qualitative methodologies. David Ley pushed social geography to pick up on humanist approaches and examine the “taken-for-granted realm of experience” and the social realm of “shared meanings” ((1977, 509, 505). Ley theoretically positions places as sites of both shared meaning and lived experience, the latter differentiated by one’s subjective relationship to that place. These approaches demand a new type of fieldwork involving conversation, description, and deep connections between researchers and research subjects. The shift away from the distanced perspective of spatial science strongly influenced social geography moving forward, particularly as new social theories entered the scene and questions shifted toward explorations of different people’s lifeworlds. This research mapped onto critical social geography in the 1970s and 1980s, which sought to reimagine the relevancy of social geography to the world in which that scholarship was being produced.

Social geography’s critical turns

As social geography began to take up questions of social difference and inequality, social geographers turned their attention to the spatial organization of society and the ways in which that organization benefited some populations and not others. That work did not always take up deeper social issues, such as the history of racism, sexism, or classism that could explain the everyday social geographies of living in the city, for example. And, when social geographic work did take up those questions, the larger field of geography often ignored it. It was the turn to a more critical social geography informed by the wider social changes taking place at the time that brought social geographers into conversation with Marxism, feminism, cultural studies, and European continental philosophy as well as antiracist and postcolonial theory. Bill Bunge’s (2011/1971) Fitzgerald: Geography of a Revolution engaged presumptions about the spatial organization of difference and inequality through a focus on one neighborhood, Fitzgerald, in Detroit. Bunge’s analysis of how people grow
up in a ghetto demonstrates that the spatial organization of the city is quite fluid. As children turn into youth, spaces that were once available to them are closed off by racialized politics and violence, marginalizing male black youth in particular. A politics of racialized and class fear structures the spatial organization of Fitzgerald and the state response to the neighborhood, producing material barriers in the landscape that limited the social mobility of people living there. In many ways, Bunge’s *Fitzgerald* asked very different questions from Morrill’s study of the ghetto, even as both were rethinking how cities might be better organized to address inequalities. Bunge worked from the ground up to ask what it felt like to live in a ghetto, and what structural constraints were found in that space.

David Harvey’s (1973) *Social Justice and the City*, more than Bunge’s work at the time, marked a distinct break from a spatial scientific social geography, as he took up the question of the spatial inequalities that are part and parcel of capitalism. His class-based analysis suggested that social and spatial differences in the city are structurally embedded in capitalist social relations. Put another way, Harvey pointed out that a spatial science of the city, which focuses on social groups, activities, and places as points in space that can be analytically evaluated through a scientific model, fails to account for the fact that “the city has to be regarded as a functioning totality within which everything is related to everything else” (1973, 303). The social relations of capitalism are the ways through which people and places relate and are organized. The development of a more socially just social geography is paralleled by the question of social geography’s relevance to everyday social problems. Relevance thus emerges as a topic in parallel to the work of Harvey from social geographers in the discipline with interests in applied geography. However, the approach to relevance also prompts the question of for whom relevance was being measured and defined.

The Marxist turn in social geography also ushered in a retheorization of the relationship between space and society. Drawing from Henri Lefebvre, a French social theorist, geographers began to theorize space as a social relation, and the ontological distance between space and society collapsed. Edward Soja coined the term “sociospatial dialectic” and Derek Gregory developed the concept of spatiality to explain this new understanding of the space–society relation, suggesting that, for example, “all organized space will be seen as rooted in a social origin and filled with social meaning”; filled with social meaning, space “is a structure created by society” (Soja 1980, 210, cited in Del Casino 2009, 45). Space is an active agent in the structuring of social relations, as spaces produce and reinforce capitalism and by extension other oppressive forces, such as patriarchy or heterosexism. Theorized this way, space is not a backdrop to social relations. Rather, space is always already social, as it helps constitute difference and maintain inequalities (see Figure 1). Social geographers suggest that the organization of space reinforces the division between “races,” articulates the boundaries between classes, and maintains the historical marginalization of gendered and queer bodies. It is also through protesting such boundaries and divides that dominant forces are challenged. The application of this retheorization of space cannot be understated; space is also a social construction, constituted by the same relations that reinforce race, ethnicity, gender, sexuality, and class. Social geographers thus began to question the representational politics of power and authority that produce spatialities of difference. As geographers expanded their intellectual reach, the realm of the symbolic and the importance of symbolic spaces to the constitution of social life and sociality became more important. This is where
the boundaries between cultural geography and social geography became less clear, as culture was theorized as a social relation but also as a political process through which social categories and differences became sedimented in space.

The cultural revolution of the 1970s, which marked the world’s rapid period of decolonization and the feminist, queer, and antiracist movements in many parts of the world, affected the types of social geography being written. Feminist geographers criticized spatial science’s study of Homo economicus (economic man) as a clearly masculinized subject. Feminist geography developed the notion that...
geographers must analyze how gender relates to the experience of living in particular places. From there, feminist geography asked inherently social questions about the spatial organization of gendered lives and how those spaces both reinforced gendered roles and norms and offered opportunities to challenge patriarchy and sexism. Early feminist geographers focused attention most closely on women’s lives, while feminist theory began to push the question not only toward women’s roles and experiences but also to the broader sociospatial constitution of gendered relations. Drawing from a wide range of theories, feminist geography quickly engaged social questions related to women’s inequality, heterosexism, and the hegemony of masculinist models of the spatial organization of societies, as well as the gendered body. By the 1980s, the cultural revolutions taking place in many societies had infiltrated the discipline of geography, although feminist geography and the social geographies of gender remained rather marginal to a wider disciplinary canon. By the mid-1980s social geography had begun to take on a very different and more diverse sensibility, in large part based on the influence of feminist geography.

The expansion of postcolonialism, a function of the massive wave of decolonization that took place across the globe in the 1960s and 1970s, also raised questions and produced challenges for social geography. The postcolonial scholarship of Edward Said and Frantz Fanon illustrates how the colonial imagination extends well beyond the specific geographies of colonial occupation. Both argue that the binary logics of Western thought – for example, white/black, colonizer/colonized, West/East – are hierarchically structured and problematically reinforce relations of difference and inequality. This work has had a significant impact on geography, and the cultural production of the East as an object of Western desire and control has been taken up in critical social geography, particularly by those interested in the relationship between spatial practice, thought, and identity. Perhaps most interesting is Said’s theorization of an internalized Orientalism, whereby former colonized elites appropriate Western cultural representations of an idealized society, and deploy that within their own national contexts. Social geographers have built on this critique to suggest that modern-day oppression and violence are situated within much wider power relations that include the Orientalist thinking of hegemonic global authority and geopolitics. Postcolonial theories thus help social geographers explore how concepts of race and racialization are situated within global geographic imaginaries and colonial and neocolonial projects. Postcolonial work has also inspired social geographic scholarship as it is taken up directly in revolutions and in inspiring anticolonial efforts. Steve Pile (1997) draws on Fanon to re-examine French colonial occupation and the spatialities of conquest as an incomplete process. Indeed, as Pile suggests, women’s experiences of the Algerian revolution demonstrate that “relationships of confinement, passing, boundedness, unbinding, birth are profoundly spatial as much as they are also temporal. In occupying space, women changed that space” (1997, 22). In short, the social geographies of the city have been altered both by the oppressive occupation of French colonialism and by the everyday practices of Algerian women who “changed the rules governing gender and sexual relationships as well as those imposed by colonial administrators”; as a result, the French occupation was “never more than partial” (Pile 1997, 22, 23).

The emergence of subaltern studies in India also challenges the broader canon of Western social theoretical thought, affecting the ways in which social geographers imagine their research
and the relationship between researched and researcher. Indian postcolonial feminist scholars, such as Gayatri Chakravorty Spivak and Chandra Talpade Mohanty, have had a dramatic impact on how social geographers think about their work. Their challenges to Western feminism suggest that the constitution of “third world women” as an object of Western discourse is problematic, an issue that social geographers have taken up through research on the historical construction of the gendered subjects of colonialism as well as through more recent considerations of how racialized, postcolonial subjects are constituted through the practices of modern-day development work. That said the postcolonial turn within India had limited impact on Indian geography in the 1970s and 1980s, where much social geographic literature focused on South Asia as a region and not as a site of knowledge production in its own right.

The challenges to Western social theory have pushed many social geographers to rethink their own theorization of the relationships between race and space. The examination of race in geography has been further inspired by black feminism, particularly the work of bell hooks and (the novels of) Toni Morrison, both of whom build on the notion that the binary logics of black and white break down when one examines the constitutive nature of identity (McKittrick 2006). Put another way, social geographers should theorize racialized spaces as productive of social relations of difference, while also calling into question the project of racism as a partial one that fails to invest space fully with a totalizing narrative. Social geographic theories inform and are informed by theories developing from antiracist and queer philosophies, as geographers ask questions about the relationship between racial formations and segregation, as well as from other forms of difference around, for example, sexuality and space, in ways that take up the question of space as a social relation of power.

Social geographies in the twenty-first century

The development of social geography during the early twenty-first century has taken place along a multiplicity of trajectories informed by the histories discussed so far. Today, social geography is a theoretically and methodologically pluralistic subdiscipline that draws inspiration from spatial science and applied geography while focusing on the social geographies of inequality and building on the critical cultural revolutions that have demanded social geographic research focus on the constitution of radical difference. To offer an approximation of what social geography is today, it is important to recognize both its pluralism and its contextualization and also to appreciate how certain practices serve to delimit the subdiscipline, cutting off areas of difference (Peake 2011). The challenge of thinking about social geography this way is that it highlights that geography has its own colonial roots and has served as a vehicle through which empire has been justified. There is, however, a radical tradition to social geography that should not be underestimated, and even as social geography remains vested in certain traditions (spatial science) or places (UK-based social geography), it is also a subdiscipline with a core focus on inequality and difference, including areas such as children’s geographies, geographies of aging, and geographies of religion. This range suggests that social geography can be a site of radical alterity, and provides geographers with the space to interrogate relations of power and authority.
Spacing inequalities

Social geography has remained invested in the question (initially adopted by welfare geography) of “who gets what, how, and where” (Smith 1994) through a body of scholarship interested in investigating both the distributions of spatial inequalities and the factors that limit accessibility to needed resources, be those health care, food, or green spaces, to name a few. Much of this research is applied, and looks at addressing sociospatial problems. Drawing from both the critical and spatial scientific traditions of social geography, questions related to access and accessibility to services, the relationship between crime and violence, gentrification and the politics of difference, health and wellbeing, and food deserts remain important. In these areas, social geography overlaps with other subdisciplines, including urban geography, population geography, and health geography. In the application of geographic methodologies to the study of social problems tied to inequality, social geographers have taken up questions that challenge societies to recognize the relationship between where one lives and what resources one has to manage that life.

The study of homelessness, a core concern for social geography, investigates the complex relationships between housing availability, economic conditions, social exclusionary politics, and other spatial relationships that affect accessibility to needed resources. Marginalized from everyday political practice, homeless populations are rarely considered in policy relating to urban revitalization projects, which gentrify and marginalize homeless peoples. Nor are homeless populations considered when environmental mitigation strategies designed to protect populations from natural hazards are constructed.

Social geographers are interested in questions regarding the relationship between homelessness and public transportation accessibility. Challenging the geographical perception that homeless people are spatially bounded in particular parts of the city, social geographic research suggests that homeless peoples have a sophisticated pattern of mobility as they seek out services and opportunities. Neither is it only physical accessibility to public transportation that is a critical component for understanding how and in what ways homeless people move through the city. Discrimination and stigmatization are aggravating factors that limit the capacity of homeless people to take advantage of various transportation networks.

The notion that the sociospatial processes of inequality mediate the everyday landscapes of social services is an important point of analysis in social geographic research on inequality. This work is not only limited to traditional areas of social geographic inquiry, such as health care, but addresses new areas of inquiry, including Internet accessibility. Social geographers have long been interested in questions of “digital differentiation,” and the relationship between Internet resource accessibility and social inequality. In food desert research, social geographers map and analyze the relationship between high-quality food resources and the social organization of urban and rural space. In some places, which have seen declines in broadband speed availability, supermarkets serving diverse foods are also limited. Social geographers are particularly interested in interrogating how food deserts emerge out of the structures of inequality that are produced through racism and classism. This tradition is paralleled by the work of other social geographers that call into question how inequalities are tied to health disparities between different populations. This line of research is particularly pressing for the spread of both infectious diseases such as Ebola, HIV/AIDS, polio, and dengue, and chronic diseases such as diabetes, heart disease, and asthma. Social vulnerability
Social geography relies heavily on social geographic approaches to investigate the potentialities of population health, for example, in a wide range of contexts from natural disasters (e.g., the relationship between race and flooding in the wake of Hurricane Katrina in New Orleans) to the spread of HIV among commercial sex workers in Southeast Asia.

Social justice

With a focus on inequality and difference, it is not surprising that social geographers have also asked questions about social justice and equity. Articulating the contradictions inherent in the spatial logics of social differentiation, social geographers have pursued more socially just geographies through their scholarship and activism. David Smith's *Geography and Social Justice* (1994) mounts a case for the role that geography must play in building societies based on the principles of justice. Smith's analysis is quite complex, but at its core rests the notion that “People who have lost their place, for one reason or another, must be provided with or find another. There is no question about it. People need it. They just do” (1994, 152). A socially just geography must take into consideration not just the material elements of place but also the politics of inclusion and equity. This principle situates a much larger tradition in social geography, which takes up social justice by providing alternative models and theories for how to reorganize space to be more socially just. Smith is not the only geographer to take up this question, of course, as many have pursued the theoretical and practical implications of a socially just geography in the context of concerns about ethics, morality, economy, and politics.

Social geographers' interest in questions of social justice has been applied to many subjects, including rights to the city, rights to education, rights for green space, rights of transportation accessibility, and rights of equity regardless of disability, sexuality, gender, and race/ethnicity. Undergirding geographies of social justice is the question of how to constitute spaces that provide for difference and allocate resources in ways that are not based on the economic principles of capital. Such research is inherently activist in nature, as social geographers become aligned with struggles that push against the tendency to treat space as a neutral backdrop to social relations. Put more directly, social geographers have argued that quality housing, safe spaces, and resource accessibility, for example, must be mapped onto a broader ethics of care and hospitality. This raises ethical questions about how to create spaces of inclusion that match an ethical concern for a multisituated subject that is not based on the individual responsibility to care for one's self but on the sociospatial responsibility to build just and equitable societies. A social geography of activism is thus concerned with questions such as the right to public space and how we reimagine the spatial organization of societies to parallel our ethical and moral concerns for social justice. This is quite challenging, as public space is often constituted as a space of fear and thus as a site of necessary state control. What can and cannot happen in public space is a reflection of a much larger set of sociopolitical processes that social geographers have long been interested in interrogating. From the ways in which certain sexual minorities are marginalized through the practice of limiting spaces of social connectivity to the policies and practices that limit public speech and gathering, social geographers are concerned with how rights are limited by the spatial practices of state and corporate actors.

Methodologically, social geographers have taken up the question of social justice not only through the study of injustice but also through their own practices. Participatory action
research (PAR), for example, is a methodological approach that de-centers the researcher and situates the research process as a collaborative engagement, which includes the so-called research subject or research informant. As Mrs. C. Kinpaisby-Hill suggests, “spaces normally reserved for data collection are turned into arenas for learning and action, and the ethic that respondents should be left unaltered is replaced with an ethic that research can directly challenge injustice and facilitate social change” (2011, 220). PAR is not only a challenge to the question of what makes a socially just geography, but also to the very practice of social geographers, who tend to focus on the research process as much less dialogic. These practices also challenge the assumptions of institutions, which tend to privilege objectivist science and the publication of scholarly research in a narrowly defined set of academic journals. Thinking about research as a different sort of process, one in which academics and activists engage in challenging inequality through the research process, constitutes a new agenda for social geography: “Instead, the agenda for the ‘communiversity’ envisages a two-way interaction between scholars and communities, where communities (local and global) may define and conduct geographical research with academics, but based on their own priorities” (Mrs. C. Kinpaisby-Hill 2011, 221).

Social movements

Social geographers have also focused attention on the emergence of social movements, which are best understood as mobilizations of political action that challenge the hegemony of sociocultural and political-economic elites. Geographically, social movements not only take place somewhere, they are also always about the rights to space. From the Black Consciousness Movement, which began in South Africa in the 1960s to challenge apartheid, to the Chipko Movement in India from the 1970s, which gave rise to the practice of tree hugging to stop logging, to the protests in Seattle against the World Trade Organization in 1999, to the Arab Spring that began in 2010, to the Occupy Wall Street movement of 2011, all social movements are struggles over space and the right to use space in ways that provide the opportunity to reallocate resources or promote difference. Social geographers are interested both in how social movements work and in how they operate spatially through the development of social networks that facilitate flows of ideas and practices. Social movements scholarship within social geography has tended to focus on urban movements, although social movements research more broadly draws from a wide range of theoretical and empirical examples, particularly from movements located outside North American and European locations. Social geographers also focus on what some call new social movements, which have built on the traditions of earlier movements that emphasized resources and struggles against capital, to develop arguments for broader rights, related to sexuality, gender, race, or ethnicity. Social geographers investigate not only how these networks emerge and function, often through encompassing numerous localities into wider networks, but also how they are mediated through different spaces. How social movements play out is always tied to the spatial politics of the movement itself. Social movements scholarship also calls into question not only how movements are organized across and through different spatialities but also how they are organized in relation to spatial imaginaries. The challenge for social movements is tied to the politics that undergird them, which insists, at some level, that the movement articulate its goals and therefore its constituencies. This demand sometimes puts such movements into...
conflict with themselves, as a movement in one place might have to manage multiple goals and objectives. Routledge, Cumbers, and Nativel (2007) highlight these tensions in their analysis of global social movements, which are trying to produce horizontal connectivities that foster autonomous possibilities in various localities. At the same time, these movements often rely on “key organisers (those we term ‘imagineers’) and key events in producing the network” (Routledge, Cumbers, and Nativel 2007, 2577). These concerns point to the ways in which social movements function in relation to the complex networks of power that sometimes operate in and through them. What becomes clear through the study of social movements is that, like all sociospatial processes, social movements have the potential to sediment binary logics of inclusion and exclusion, insider and outsider, either through direct intention or through a reliance on a politics of verticality that limits the autonomous potential of various aspects of a movement. Barker (2012) powerfully argues that the Occupy Wall Street movement in North America excluded indigenous peoples through, on the one hand, a deployment of settler myths of indigenous peoples and their activism, and, on the other hand, a thorough dissociation of the movement from the long-term occupation of indigenous spaces. And yet, as Barker points out, “Indigenous peoples are willing to share the struggle, but only to the point that the ultimate goal of liberation from colonial power, expressed through state and capital, is achieved” (2012, 332).

Much social movements research focuses on left-leaning, liberal activism, eschewing the movements that are tied to right-leaning, conservative political agendas. And yet, such movements are powerful political forces within the modern-day landscape, as they create sociospatial networks that permeate everyday life. Carolyn Gallaher (2003) turns her attention to the emergence of the Patriot Movement in the United States to suggest that these movements have their basis in a complex set of identity and economic politics that should not be dismissed. Rather, through the study of such movements, it is possible to disentangle the complex geographical imaginations that animate such movements, with their interests in separatism and isolation, from others whom they see as degrading their own social, political, and economic positions.

Space, representation, and identity

Perhaps one of the biggest challenges to the integrity of social geography as a subdiscipline has been the alignment of the discipline with poststructuralism. Poststructuralism, at its simplest level, suggests that there is no predetermined structure (or hierarchy) to social relations or, for that matter, spatial relations. The earliest intersections of social geography and poststructuralist thought pushed the discipline toward the question of how, why, and in what ways space is represented. Put another way, geographers called into question some of its own core practices, including that of cartography, which was questioned for its authorial approach to representing the world. For social geographers, the question of what social life means spatially was reimagined to suggest that spatialities were only temporary formations enshrined through social practices and representations. To this end, social geographers turned heavily to textual analysis that they began to apply to a myriad number of geographic objects, including maps, landscapes, and film, to name a few. Thought this way, space as representation is also material in that it mediates the flows of people, ideas, and objects. Del Casino and Hanna (2000) suggest, for example, that spatial representations, such as maps, are possible only because of the performances that
people bring to them. Suggesting that map and space are not separate – one representing the other – Del Casino and Hanna argue for a theorization of

a map space [that] is not bound by the margins of the paper on which it is printed, but is inscribed with meaning through its intertextual linkages with other texts and spaces. In addition, map spaces are sites through which we can examine the processes of identity construction, and the historically and spatially contingent social relationships that constitute identity categories. (2000, 30)

This move, toward a much more performative sense of space and of identity, followed the work of scholars who suggested that categories of identity – gender, race, sexuality, class – were not embedded in a priori structures but were made real only through repeated performances of them. Identity thought this way is also a performance that demands certain practices to make real its meanings and organizations.

Following the work of Michel Foucault, social geographers also began to theorize power as a central object of analysis, and scholars began to ask how certain forms of authority are enacted through the organization and construction of space. Disciplinary logics, what one should and should not do in various spaces, were theorized as projects of the state and of social elites, who seek to reinforce and naturalize their power through people’s own acquiescence to various spatial forms of authority. Social geographers began to investigate this internalization of power through scholarship that reimagines space as epistemological. Thought of as such, spatial imaginaries – how we view the world as organized through discreet or relational categories of identity, for example – become a way of mapping difference (see Jones 1998). Spaces do not exist prior to our ways of knowing and understanding them but are socially constructed through our relationships with them. Foucault’s work has profoundly impacted on the discipline, as the categories of politics and geopolitics have been called into question as foundational concepts. Instead, Crampton and Elden (2007, 7) argue that, for Foucault, “the art of government is less about geopolitics (territorial gain and retention) and more deeply geographical … [The] population thus had to be known in its spatial dispersion, giving rise not only to statistics but to a new form of cartography.” Picking up this thread of analysis, social geographers have pushed the discipline to question its inherent assumptions around territory as fixed and naturalized and also have called into question the relationship between social and spatial categories, such as citizen and noncitizen. Crossing over with questions relevant to political geography, then, social geographers have analyzed the concept of citizenship through the lens of poststructuralist philosophy by interrogating the grounds on which the boundaries of the “citizen” are marked by the everyday politics of class, race, sexuality, and other forms of identity.

This poststructuralist turn was largely a critique based in epistemology in the sense that knowledge of the world cannot exist prior to human engagement of it. Rather, knowledge produces the ways through which we understand space and identity. This is why the focus on representation and representational politics became such a powerful question for social geographers, some of whom reimagined the ontological basis of their arguments about sociospatial structures of capitalism and power. Power operates not through predetermined core structures, but through relationalities – including economic systems – that are always constitutive of the so-called other that power seeks to disable. Core concepts in the discipline, such as scale and sovereignty, have also been called into question for the ways in which they are deployed to
produce difference and violently to mark out spaces of inclusion and exclusion.

Gender and sexuality

Social geographers have long been interested in questions of the spatialities of gender and sexuality, most recently investigating the assumptions that all human beings experience the world as if they are of one gender or sexuality. Asking to what extent spaces are differently constituted in relation to gender, for example, social geographers also challenged the hegemony of the adult subject as a totalizing narrative of lived experience, leading to the development of the subfield of children’s geographies. Research on gender and sexuality draws from the work on theories of social reproduction and finds commonality in the examination of home spaces as well as spaces of caring. Social reproduction theory suggests that the spaces of waged work are not the only ones that support the expansion of capitalist social relations or patriarchy, for example. In interrogating home spaces as sites of unwaged domestic labor, which is vital to the reinforcement of certain sociocultural and political-economic processes, social geographers have offered up analyses that demonstrate the complex relations of home and work and opened up questions related to how one’s experience of the life course is contingent on the sociospatial processes of not only age but also race, gender, sexuality, and class. This work thus builds on feminist geography’s interest in exploring the everyday gendered experiences of waged and unwaged labor.

In this way, feminist geography has much more in common with social geography than, say, cultural geography, which has often focused on social power and authority instead of the positionalities of women, queer subjects, and people of color. Gender is taken up in social geography to include the analysis of gender as more than a binary of men and women, but as an ongoing sociospatial process of gendering and constituting femininities and masculinities. Indeed, the scholarship on gender and geography includes not only the study of women’s experiences but also the gendered dynamics of relations that inculcate spaces of femininity and masculinity in ways that are sedimented in relations of power. That said, gender is not a constant force across space but is intimately interwoven in space. Put another way, the constitution of what is normalized as appropriate gendered performance is developed through the social geographies in which those performances are being enacted. The violence that structures “normal” gendered performance is thus always a social geographic process, one that can be investigated through an analysis of everyday practice. In interesting ways, this approach has opened up social geography to the broad study of masculinities as well, as social geographers investigate the spatial formations that reify certain forms of masculinity and privilege those forms over others.

All of this work has forced social geographers to think about the body and body politics as an integral component of their social geographies. Historically, social geographers studied the body not as an object unto itself, but rather as an external marker of social identity that could be mapped in and through space. But the body is a complex space as well; it is constituted through relations of power and authority in ways similar to other spaces. And, yet, the study of bodies and bodily processes has not always been the subject of social geography. It is queer geographies and the study of sexualities and geography that have expanded the study of bodies and body politics to the area of sexual politics, opening up questions as to how bodies and other spaces are heteronormatively constituted and possibly queered through the practices of radical sexual
alterity. While *Geographies of Sexualities* (Brown, Lim, and Brown 2007) built on the questions offered through sexuality studies in the discipline and provided concrete empirical examinations of queer bodies and spaces, other social geographers have extended these arguments, calling into question the construction of queer urban and rural bodies, spaces, and networks. The literature on/in queer geographies also challenges the notion that queer space is simply an alternative to heterosexual space, suggesting that the study of sexualities is much more than simply mapping out the spaces of queer collectivity, but rather includes the interrogation of sexualities and sexual politics more generally, including processes of the heterosexualisation and queering of space. This work has also pointed to the complex relationship between sexualities and other forms of bodily difference and has noted that the reorganization of queer studies of the city, in particular, has moved away from queer urban spaces as empirical objects of analysis to the examination of embodied queer experience.

Race and racialization

The study of race and racialization is also a key inquiry in the field of social geography, although these categories of scholarship have been differentially taken up across the subdiscipline. The development of critical race studies in the discipline, in particular, calls into question the historical lack of race studies in human geography writ large. Thus, despite the existence of a number of leading scholars in the discipline, including Audrey Kobayashi (2012) and Ruthie Gilmore (2007), who have long interrogated not only the discipline’s problematic racial imaginary but also the complex relationships between race, space, and everyday lived experience, there remains a problematic relationship between social geography and the study of race. As Minelle Mahtani (2014, 365) recently suggested, “Simply acknowledging the whiteness of the discipline does nothing to eradicate it.” In this regard, critical race scholars in the discipline have struggled with both racial geographies as a subject of analysis and the disciplinary context in which those racial geographies take place. For critical race scholars in geography, it is not possible to separate out the two. Following on from Katherine McKittrick’s (2006) powerful argument, Mahtani goes on to aver that far too often black bodies are simplified, related to occupying inevitably black spaces, resulting in dire and dour geographical determinism (what would Semple say?), or else reduced to a solely corporeal identity based on the colour of their skin, reflecting an almost obsessive focus on phenotype and flesh, where body is understood as the only useful black geographical scale. (Mahtani 2014, 362)

The study of race suggests that there are new ways to imagine a social geography of difference, which operates not from the social construction of so-called black or white bodies (Mahtani 2014) but, rather, through a more robust analysis of the everyday material violence that marks out spaces of difference for people of color. This includes a critical interrogation of whiteness as well as the intersections of race, racism, and other forms of subjectivity, including the postcolonial. This is where social geographers draw from the rich array of critical race studies scholarship (e.g., black feminism) and postcolonial theory (e.g., subaltern studies) to interrogate both the representational and the material violences that are associated with the processes of racialization, a historical-geographic process that is not produced merely through social constructions of categories, such as black, white, or brown, but through epistemic and material violences that are constituted through the deployment of racial difference.
SOCIAL GEOGRAPHY

One important argument that critical race scholars contribute to the work of social geography is the notion that representations are material; they do not simply circulate out there in the world but rather are inculcated in the real worlds of racialized bodies and spaces. This is an argument that Audrey Kobayashi (2012) makes in her recent review of the field of race studies in geography, suggesting that the concern within race studies is not whether representations have material effects, but rather that a postrepresentational world, which is suggested to be postracial, minimizes the ongoing racial violence (both material and representational) that marginalizes people of color. As Divya Tolia-Kelly (2010, 364) puts it: “Questions of race, identity and ‘other’ bodies fuel contemporary lived environments and world politics. When foregrounded, these questions can unravel a myriad of coordinates, yet to be visited.” These coordinates include the ways in which racialized processes and race as lived experience mediate the everyday lives of people of color. These concerns have been taken up in the study of immigration politics in the discipline, as social geographers investigate the relationships between racialization, for example, and anti-immigration politics. Helga Leitner (2012, 836), whose work on white residents’ relationships to new immigrant populations in the rural upper Midwest of the United States, suggests that “Cultural and racial differences were not only remarked on but evaluated as inferior.” Leitner also shows how whiteness is not a singular category but, rather, intimately related to class position. While almost all white participants in the study illustrated concern around immigration and degradation of white, rural (American) values, the ways in which racism appeared in their practice was differentiated along class lines, with upper middle-class professionals hiding their racialized politics in rhetoric reminiscent of postracial discourse. This suggests that the social geographies of race are complicated by the intersectionalities between race and other subject positions, including class, gender, ethnicity, and sexuality.

Posthuman social geographies

Social geography has changed and evolved over time to take up new questions and challenges, including ones related to a more-than-human social geography. What role, for example, do nonhuman subjects have in the study of social geographic processes? Is there a way to reimagine the nature/society binary in social geography in line with current theories of the nonhuman and questions of affect or emotion? Humans are, after all, embroiled in all sorts of relations with nonhuman subjects that have a real world impact on the organization of social geographies. The materiality of the urban environment, for example, has long been examined as a medium through which humans constitute their social worlds. But, the turn toward posthuman social geographies is more than simply a recognition of the nonhuman; it is about investigating the complex hybrid geographies through which humans and nonhumans interact. It is also about the affective moments in which humans co-create their worlds with, for example, animals, that social geography, as a purely human endeavor does not call into question. Indeed, the research in which human–animal relations are taken up provides an opportunity for social geographers to think about how humans are enrolled in a range of social relations through their interactions and affective relations with animals. Humans not only form relationships with their pets, but their pets call on them to form new relations with others – both human and nonhuman. Heidi Nast (2006, 304) takes up this question in her discussion of the evolution of “dominance–affection–love,” suggesting that
“post-industrial isolations and narcissisms have made pets into screens onto which all sorts of human needs, desires, and investments can be and are being projected, such projections [are] part and parcel with larger sociospatially uneven processes of wealth accumulation and investment.”

Recent theorizations of the posthuman in social geography, however, have extended the question of whether animals and other nonhuman subjects are reflections on which the human is presented, to ask how a more-than-human social geography is enacted through relationships between various subjects, both human and nonhuman. To this end, some social geographers have turned to actor-network theory (ANT) or nonrepresentational theory, two bodies of literature that, in different ways, ask how social geographies of the more-than-human are enacted through the enrollment of human subjects in different relations or forces. These philosophies, which argue for a rematerialization of social geography, are paralleled by the work of geographers interested in site ontology, which is best understood as a theoretical approach that “emphasizes the immanent, material connection between bodies and unfolding, situated practices” (Woodward, Jones, and Marston 2010, 273). Ian Graham Shaw (2012, 620) builds on this approach and picks up the philosophies of ANT and nonrepresentational theory, along with site ontologies, to suggest that “A world is a constellation of objects.” This constellation of objects is not evenly distributed but, rather, forms assemblages through geo-events. It is the unfolding possibilities that a more-than-human or posthuman social geography can interrogate that make this new line of inquiry particularly provocative for social geographers interested in how human sociospatialities are always already constituted through their broad range of relations with the nonhuman world. One way in which this inquiry is currently being investigated is through the concept of the Anthropocene.

Conclusion

Social geography is an incomplete project that has been built on through a wide range of theoretical and methodological approaches. Today’s social geography is itself an assemblage of multiple approaches and empirical subjects that stretch the expanse of the discipline. There are likely to be many future social geographies that pull on and push against the historical evolution of the subdiscipline. This suggests that it is difficult to clearly map a singular path for a set of traditions that is marked as much by its differences as it is by its conjunctures. What is clear, however, is that social geography as a subdiscipline will continue to mark out its intellectual trajectories that map relations of inequality and difference in provocative and important ways.

Social justice

Jenna M. Loyd
University of Wisconsin–Milwaukee, USA

The domain of social justice theorizing and practice is social, political, and economic institutions and processes. These institutions and processes structure the production and distribution of resources and create the conditions for individual and collective action. Thus, social justice theorizing and claims-making address issues of distribution, democracy and power, and procedures for decision-making. Social justice theorists also consider how these institutions and processes reproduce group oppression and domination materially and discursively, thereby maintaining unjust constraints on self-development and self-determination. Movements for social justice, thus, necessarily challenge dominant cultural norms and knowledge hierarchies.

Social justice has a central and deeply contested place in contemporary political theory, political mobilization, and social movement organizing. Conservative critics such as Hayek contest the concept of social justice, arguing that only individual action can be judged as just or unjust and that state action to redistribute social goods will inevitably impede individual freedom. Among proponents of the concept, debates center on questions of universality and human nature, and the interrelations among different forms of power and injustice. Some argue that universal norms of justice and humanity can be defined. Decolonial, feminist, and antiracist critiques of the apparent universality of concepts such as justice, liberty, and humanity have led others to abandon the pursuit of a normative definition of human well-being; however, recognizing a world of differences and distances among humans has not meant the end of social justice, but rather its pursuit through a range of ethical and political registers.

Social justice, moreover, is spatialized. Over the past 30 years, the discipline has shown that social and environmental goods and dangers are unevenly distributed across space, how socio-economic processes produce such unevenness and can create oppressive and violent places and spatial relations, and theorized how just geographies might be created. Geographers have contended that theorizing the production of unjust and oppressive geographies is necessarily related to collective efforts to transform their constituent spaces and power relations. For these reasons, social justice is at the center of debates over the relationship between theory and practice, the relevance of the discipline, responsibility, and caring.

Intellectual and historical context

Social justice – as a domain of political theory and organizing – emerged in the late eighteenth and early nineteenth centuries as part of revolutionary upheavals in the Caribbean, Europe, and North America against slavery, land enclosures, and monarchial rule. Abolitionist, organized labor, and socialist movements challenged existing terms of freedom, rights, and humanity. The development of different conceptualizations of social justice from this period onwards has been closely tied to the formation of, and contests over, state social and welfare institutions. Liberal political theories of justice emphasizing
individual rights have supported a limited state while communitarian principles of solidarity have been used to advocate a greater role for the state in society, which in principle, better fosters individual wellbeing. In the twentieth and twenty-first century, mobilizations for freedom among oppressed social groups have again fundamentally expanded terms of rights, sovereignty, belonging, citizenship, and humanity.

Liberation movements, relevance, and unjust geographies

Geography’s involvement with social justice can be traced to the late nineteenth century. Anarchist geographers Peter Kropotkin and Élisée Reclus developed theories for dismantling hierarchies of power and organizing more egalitarian ways of living. Kropotkin wrote against the dominant terms of free market individualism and social Darwinism, and sought to provide a scientific basis for mutual aid. Reclus developed a social and ecological ethics premised on reciprocity between humanity and the Earth. Arizona Baber, founder of the Chicago Geographical Society, was committed to anti-imperialism, environmental conservation, and actively supported women’s suffrage in Puerto Rico.

Despite these important early contributions, it was not until the late 1960s and early 1970s that social justice gained a prominent place within geography. The context was one of worldwide anti-colonial struggles; movements for freedom from racial oppression and for self-determination; and antiwar, environmental, gender, and sexual liberation movements. Humanist, radical, and critical geographers criticized the field’s inability to explain pressing social and political crises such as racial segregation, poverty, and ecological destruction. Radical geographers further questioned the positivist paradigm undergirding geographic knowledge production and the discipline’s tacit support for colonialism and international hierarchies. They argued instead that scholars should research and explain the roots of social problems and actively work to change them.

Marxist theory increasingly became central to many of the theoretical developments in radical geography, as evident in Antipode: A Journal of Radical Geography (established in 1969) and Harvey’s (1973) Social Justice and the City. Harvey built on Rawls’s (1971) A Theory of Justice, which remains a central text in contemporary debates over social justice. Rawls’s two-fold theory advances a universal principle of equal rights to basic goods and liberties and a “difference principle” whereby social and economic inequalities should be arranged to benefit the least advantaged. Harvey theorized “territorial social justice” as “a just distribution justly arrived at” (1973, 116–117), a conceptualization that remained closely tied to distributive models of social justice.

Radical and critical geographers in the 1970s also drew on and developed diverse threads of anarchism, feminism, and critical social theory. Theorizing domination and oppressive social relations was a main thread in this work. Blaut argued that the white, European claim to universal knowledge was better understood as an “ethnoscience” that erases other forms of knowledge and undergirds the violence of Western imperialism. Feminist geographers examined gendered geographies of everyday life, gendered class relationships, the gendered and capitalist division of public and private space, and gendered inequities in the discipline, launching various feminist groups within the professional organizations of geography, such as the Geographical Perspectives on Women (GPOW) group established in 1979 in the Association of American Geographers. Richard Peet, in the early pages of Antipode, proposed that Kropotkin’s
anarcho-communism should form the basis of radical geographic thought, and Myrna Breitbart moreover organized an issue of the journal dedicated to anarchism and the environment.

Social justice and difference

The dominance of modernist, Western teleologies of history and theorizations of society was undermined from organized challenges to structural racism, colonialism, and heterosexism. Into the mid-1980s to 1990s, these intellectual currents overlapped, and frequently were conflated, with developments of postmodern and poststructural theory. Some on the left dismissed new social movements for being concerned merely with superficial “identity politics” and not with broader social justice. For some, postmodern and poststructural emphases on fluidity, multiplicity, and social constructionism undermined the possibility for commonality or shared purpose. For others, multiple identities and identifications opened possibilities for coalition-building rather than assuming a common basis of interest (or community or nation), which easily could elide difference and power differentials within social movements. Antiracist, feminist, and queer theories sometimes engaged directly with each other, and other times not, but all would pose challenges to the whiteness, heteronormativity, and masculine dominance of the discipline.

Philosopher Iris Marion Young’s work pushed the focus of social justice beyond that of distribution to one that starts from the “concepts of domination and oppression” – exploitation, marginalization, powerlessness, cultural imperialism, and systematic violence – through which inequitable group differences are produced and maintained (Young 1990, 16). Young has been influential in human geography, in part because she insists on understanding social justice in specific historical and social contexts. Harvey engaged Young’s work to reconceptualize social justice as the “just production of just geographical differences” (Harvey 1996, 5).

But how has difference been theorized? Debates in geography in the 1980s over gender and class tended to ignore racism, and into the 1990s, studies of gender and sexuality also tended to analyze these categories separately from one another. Such debates often were tied with reconceptualizations of the “subject” of history (in Marxist terms: the proletariat, peasantry, and lumpenproletariat). There was, however, a growing appreciation for the co-construction of categories of difference. Concepts of intersectionality indebted to women of color feminists, the idea of articulation attributed to Stuart Hall, and poststructuralist ideas of assemblage of complex systems provided different ways of understanding the co-construction of difference. Together, they showed how the complex construction of identities and subjectivities is material and tied to political-economic processes. Race, for example, would come to be understood as specifically constructed through ideas of femininity, masculinity, and sexuality.

Far from being immaterial, unreal, or secondary to fundamental social change (commonly read as class and class struggle), theorists of race, gender, and sexuality have demonstrated how such relations of power and difference are intertwined or articulate with political-economic structures and processes. Space, not just identity and subjectivity, is also produced through multiple, interacting social relations. Differently positioned groups thus contest (and reproduce) dominant geographies in distinct, if interrelated, ways. The political implication is that conceptualizations of social justice that ignore how race, gender, or sexuality constitute class or citizenship will inevitably reproduce social and spatial injustices. This understanding changes
SOCIAL JUSTICE

both the subjects and spaces of social change. For example, feminist interventions into debates over capitalism showed how social reproduction is necessary work for capitalist accumulation, and therefore, identified spaces of the home, education, and collective care as fundamental sites of political emancipation.

Antiracist, feminist, postcolonial, and queer theorists have vividly demonstrated how challenging dominant epistemologies is an imperative aspect of liberatory struggles. Such challenges involve both deconstruction and ideological critique and the creation of transformative geographic imaginations and forms of political praxis through subaltern, queer, and insurgent epistemologies. The field of black geographies, for example, has been established through efforts to undermine the symbolic and structural violence of dominant white epistemologies to offer a fundamentally different way of thinking about freedom, space, and what it means to be human. Decolonization has also emerged as an important theoretical strand and practice that seeks to undermine ongoing colonial practices and epistemologies. Strategies of decolonial practice involve recognition and use of Indigenous epistememes as a way of unsettling Eurocentric claims to knowledge and sovereignty.

Postcolonial and feminist theories in particular have emphasized the principle that social change must be made by oppressed people with strategies informed by their experiences and analyses. Ruth Wilson Gilmore argues that “centering attention on those most vulnerable to the fatal couplings of power and difference signified by racism … will [enable geographers to] develop richer analyses of how it is that radical activism might most productively exploit crisis for liberatory ends” (2002, 22). This principle has significant implications for thinking about coalition-building, differential positions of power, and representation. Spivak, for example, argued that while categories of difference are socially constructed and not natural, sometimes it was necessary to deploy a strategic essentialism in the course of making political claims. This idea has been widely debated, perhaps most forcefully by women of color feminists who contend that such moves enforce rather than transform hierarchies within oppressed groups.

Environmental justice and the production of nature

A key contribution to thinking about social justice has come through theorizing not merely uneven distribution of goods across space, but the production of space. Neil Smith’s Uneven Development (2008/1984) offers a Marxist theorization of the production of nature wherein the capitalist production of space is a dialectical process that equalizes and differentiates space, creating unevenly developed geographies across spatial scales. The “abolition of uneven development,” he argues, “is one of the first conditions of communal life” (2008/1984, 204).

Marxist theorizations of human–nature relations were central to the development of explicit links between environmental and social justice concerns. The field of political ecology emerged in the 1980s and brought Marxist (and later poststructuralist and postcolonial) theories to questions of nature, society, and change. The field has focused on the historical, social, and institutional relationships shaping the environment and development projects primarily in the Global South. Rather than attributing issues such as environmental hazards, famine, or land degradation to premodern or uninformed practices, founding studies in the field showed how local agricultural and resource extraction practices are tied to specific histories of colonialism, state development projects, and the international
political economy. Feminist political ecology emerged in the 1990s to theorize gendered relations of knowledge production, development practices, and decision-making; and to advance feminist practices and strategies for change.

Environmental justice centrally concerns the distribution of societal harms across space, procedural justice, difference, and recognition. The term environmental justice emerged in the late 1980s in the United States out of a nationally networked movement to challenge environmental racism. The term, first defined in a 1987 United Church of Christ report, refers to the disproportionate exposure of nonwhite people to toxins and pollution (Pulido 2000). The centrality of questions of racism for the US movement for environmental justice has generated debates over the interrelations between race and class, the role of state regulation, and epistemology. Dominant understandings of racism tend to frame the distribution of environmental harms as the result of discrete acts. Yet such liberal individualist paradigms ignore histories of colonialism and racism that have produced uneven geographies of harm. Thus, Laura Pulido’s intervention reframes questions of distribution into the uneven production of goods and harms by conceptualizing racism “as a sociospatial relation” that links together “industrial zones, affluent suburbs, working-class suburbs, and downtown areas, all of which are racialized” spaces (2000, 13).

“Think globally, act locally”: debates over the scale and scope of justice

Anticolonial movements and the rapid restructuring of the global economy and nation-state provide the context for theorizing the scope and scale of justice. The politics of scale involves attention to how different kinds of political-economic spaces are produced and unevenly related, and the discursive strategies whereby different scales are constructed as “higher” or more powerful. Existing nation-state structures and forms of political affiliation (e.g., citizenship) often do not provide the means for political action. The traditional confinement of politics to the national scale or to formal citizenship in turn has led to a proliferation of political action, particularly since the late twentieth century, including the growth of the “global justice” movements and subaltern transnational political networks. It also has fueled theorizing on how to understand the relations between people and different places, including efforts to redefine terms of solidarity, responsibility, citizenship and political affiliation, and sovereignty at a range of geographic scales.

Harvey’s reconceptualization of international solidarity offers that “theoretical practice must be constructed as a continuous dialectic between the militant particularism of lived lives and a struggle to achieve sufficient critical distance and detachment to formulate global ambitions” (1996, 44, emphasis in original). Feminist theorists in particular have contended that this conceptualization of lived as local and global as abstract reproduces discourses of globalization as all-powerful and localities as weak. Doreen Massey, for example, contends that the global is also concrete. She theorizes places as relational constellations of power relations that actively reconstitute “localities” as well as “the global.” While different social groups and individuals are differentially situated in relation to socioeconomic processes, conceptualizing space as relational and continually being made opens the possibility for “a more configurational and outwardlooking stance” toward political responsibility (2006, 94).

From the early 1990s to mid-2000s, geographers engaged in a robust series of discussions over theorizing geographic scale. A principal
SOCIAL JUSTICE

question concerned how situated political actors organizing in one kind of place (e.g., in the household, in the city) can link their issues both to other places and across scales, and thereby foster avenues for broader political mobilization and policy change. Feminist interventions have been fundamental to the so-called scale debate, particularly by demonstrating how attention to the politics of the body and social reproduction transforms understandings of justice and politics. Geographers drawing on poststructuralist theory, however, have contended that vertical imaginations of scale may limit progressive political organizing and have turned to flat ontologies, horizontality, rhizomatic networks, and assemblages as alternative conceptualizations for complex political terrains.

The urban question, spatial justice, and right to the city

Lefebvre’s work on everyday life in capitalist society and the production of space offered a conceptualization of how class relations are built into cities, and in turn how class struggle is also about city life itself. The concept of spatial justice is a dialectical one wherein spatiality is understood as the contradictory outcome and object of social struggle. Thus, spatial analyses of injustice can link the economic and social conditions of different groups to interventions in the exploitative and oppressive production of space. This resolutely practice-oriented conceptualization of spatial justice has been developed most explicitly since the early 2000s, at the same time as the flourishing of political organizing (e.g., Shack/Slum Dwellers International and the US-based Right to the City Alliance) and theorizing under the banner of right to the city.

Principles of communitarianism, direct democracy, and deliberative communication converge on urban public space, as an ideal and material space. For Young, “because city life is a being together of strangers, diverse and overlapping neighbors, social justice cannot issue from the institution of an Enlightenment universal public” (1990, 240). Rather than ignoring group power differentials, she instead explores the “implications of a politics of difference by envisioning an ideal of city life as a being together of strangers in openness to group differences” (1990, 256). Marxist urban geographers have explored how in practice bourgeois private property relations underscore the constitution of public space as a site for public political debate. Feminist geographers, moreover, have illustrated how access to and the creation of public space are gendered. Feminist, queer, and anarchist scholarship has also shown how relations of power and difference intersect to structure public and private space, with state and state-sanctioned violence frequently deployed to create and sustain particular inclusions and exclusions. In drawing attention to these interrelations and to systemic violence, this scholarship works to theorize new possible forms of politics as alternatives to representative and deliberative democracy.

Questions of normativity and postfoundationalism

Debates over scale and difference have dovetailed with debates since the 2000s over the necessity and desirability of normative thinking and the development of postfoundational concepts of justice. These concepts have been elaborated in terms of ethics, morals, and emotion. In the wake of postmodern, postcolonial, and feminist critiques of universal truth claims and a common humanity, normative reasoning was also deeply in question. Yet given the widely shared view
that all knowledge construction is partial and political, many geographers with a social justice commitment have advocated that researchers make explicit the terms of their normative thinking. Among the sources for normative ethics are religion, animal–human ethics, and the capabilities approach to moral philosophy developed by Amartya Sen and Martha Nussbaum.

In contrast, Barnett argues that foundational definitions of values or justice do not necessarily provide the means for judging a situation as just or unjust. He suggests that analyses begin “not so much from a clear-sighted definition of justice but from widely shared intuitions of injustice” (2010, 248, emphasis in original). He further suggests that theorizing and political mobilization around concepts like right to the city, spatial justice, and environmental justice exemplify forms of practical reasoning through which “normative concepts of justice are worldly, emerging from situated conflicts” (Barnett 2010, 248). Geographers have drawn on postcolonial theory to develop non-Eurocentric ethics and alternative geographical imaginations of connection and responsibility. Barnett also observes that Massey’s conceptualization of geographies of responsibility resonates with Young’s idea of shared responsibility that is “distributed across complex networks of causality and agency” (Barnett 2010, 252).

Attention to emotion, affect, and performativity has opened another avenue through which geographers are theorizing ethics. For some, the embodiment of encounters with other people suggests an ethics that emerges from conviviality and solidarity, whereas for others such encounters must still provide the means for challenging structural inequities. Ethics of care also may draw on anarchist praxis. It is feminist geographies of care though that have been pivotal to this ethical project, beginning as Lawson writes, “from the centrality of care work and care relations to our lives and societies. Care ethics begins with a social ontology of connection: foregrounding social relationships of mutuality and trust (rather than dependence)” (2007, 3). While affect has been identified as an important element of social justice organizing, feminist scholars have warned about unjust circuits of power that may be reproduced through appeals to not only fear, but also outrage and empathy.

Questions of practice and relevance over time

Geography, like other disciplines, has long debated the relevance of its scholarship to explaining pressing social and environmental issues. Concerns of relevance in the discipline have revolved around its influence in political and scholarly debates, applicability in policy or practical application, and teaching. Questions of relevance are tied to a vibrant debate about the roles of scholars in social change, including as public intellectuals or scholar-activists. Some maintain a sharp distinction between the academy and social change, arguing that the best way for academics to engage in social change is through their scholarship and teaching. Others counter that academic efforts must be tightly tied and accountable to groups engaging in activism and political movement building. While these positions hold different understandings of the spaces of knowledge production, ultimately, these debates suggest that being a teacher and researcher entails active deliberation over ethics and ethical practice.

Practical examples of efforts to grapple with these issues are numerous. The Detroit Geographical Expedition and Institute was an experimental research and activist project co-founded in 1968 by geographer Bill Bunge and Gwendolyn Warren, an African American community
leader. It was intended to study and intervene in race and class injustice in urban space and continues to inform scholar activism and participatory research. Feminist, antiracist, and postcolonial movements and theory have developed transformative research methods and programs and have emphasized the values of self-reflexivity and obligations for ethical research and political practice. To name just one such method, participatory action research (PAR) has emerged out of efforts to shift power to (or build power among) marginalized groups, in part through creating more space for these groups to reshape research agendas and dominant representations as part of their mobilization for social change. Other efforts to foster just academic practice in the past two decades have included challenges to whiteness and heteronormativity in the discipline, organizing to prevent cuts to education funding and improve working and learning conditions, and campaigns to end the discipline’s active and complicit involvement in military activities. Most recently, mental health and the academy has entered onto the agenda of geographers.

Current emphases and future areas of research and practice

Conceptualizations of social justice have changed significantly from the focus on distribution in the early 1970s to include processes of group domination and multivalent strategies for social change, which both include and reject a role for the state. It is perhaps ironic that as conceptualizations of social justice have broadened, there has been a steady political effort to minimize the state’s role in classic (re)distributional concerns. The reconfiguration of the state role in social provisioning and regulation of the economy in turn have deepened material inequities at multiple geographic scales around the world. These reconfigurations, however, have been the grounds through which social justice continues to be reconceptualized and vibrantly lived.

Theorizing and transforming systemic relations of violence remains a pressing issue in geography, albeit addressed more among racialized geographers than the white majority. Harold Rose’s 1978 presidential address to the Association of American Geographers called on the discipline to pay closer attention to black interpersonal violence in US cities. He challenged (still frequent) explanations positing a black subculture of violence, and proposed instead that geographers investigate the interrelationships among growing economic despair, homicide, and stressful urban environments. Katherine McKittrick argues that ending racial violence will entail challenging modes of research and representation that “reproduce the axiomatic frame of survival, wherein the suffering body and the dying have always been the racial Other to the white Western-liberated human norm” (2011, 954). Responding to this challenge invites reflexivity about (who engages in certain spaces of) geographic knowledge production, and more so, imaginations for creating different ethical spaces of encounter.

The practical necessity of transforming systemic and interlocking relations of violence also employs the energies of geographers. The protest chant, “No justice, no peace,” which is commonly heard at US political demonstrations, is an example of practical social justice theorizing that deconstructs how dominant definitions of violence and state institutions of justice obscure the everyday workings of racial and class oppression. Challenging dominant epistemologies of violence and state security practices will continue to be part of efforts to create justice with peace. Wars, imperial occupations, and state-centric definitions and practices of security not only exert direct violence on people’s lives,
but also have enduring and wide-ranging effects, including on land use, political institutions, and trauma. Grassroots efforts to end violence and heal from interpersonal and intergenerational trauma are places where much is to be learned (and supported) about building a socially just world. Here, feminist and postcolonial attention to the symbolic violence of the gaze, appropriation of suffering, and the circulation of affect are deeply relevant. Moreover, feminist and queer interventions in social reproduction and care ethics will continue to generate possibilities for living otherwise.

Finally, global climate change, and its uneven ecological and social effects, represents a pressing issue that is fueling a movement for climate justice and is generating new policy, geopolitical, and theoretical terrains. The politics of disaster, emergency preparedness, and “resilience” are areas where environmental, social, and political-economic forces converge. Thus, bridging fields of knowledge will be imperative to developing just and ethical responses in the era of the Anthropocene. While global climate change is urgent, the danger of a politics of crisis is that it will reproduce existing hierarchies and forms of exclusion. This danger makes efforts to decolonize knowledge about environmental change and humanity all the more important.

Social movements

Byron Miller
University of Calgary, Canada

Social movements are typically a contentious form of social and political resistance based in collective action. Collective action necessarily requires that people work together in a cooperative fashion at the same time that they express opposition to other groups and forces. While considerable debate has centered on the question of whether “the political” is primarily antagonistic or associative, social movements are clearly both.

At the heart of traditional social movement theory is the free-rider question: why would rational, self-interested individuals participate in collective action when each individual’s impact on large-scale collective action is negligible and the benefits of collective action are public and free? Rational choice theory suggests that collective action cannot occur without “selective incentives,” that is, individual rewards for participation, yet clearly people come together to act collectively without such incentives. They do so because they form social bonds that cannot be reduced to individual self-interest. Accordingly, their motivations cannot be so reduced. Social bonds can take a variety of forms: shared social identity, affective bonds with others, attachments to place or region, or shared understandings and values. How social bonds come to be formed in the mobilization of social movements, as well as the strategies social movements employ in contention with other political actors, are fundamentally geographical questions.

Social bonds in place and region

The formation of social bonds of one sort or another is a prerequisite for all social movements. Social bonds are commonly, although not exclusively, formed through everyday lived experience in place-based social interaction. Pred (1981), drawing on the work of Hägerstrand, argues that social interaction and opportunities for bonding are shaped by daily time–space “paths and projects” that are usually structured by organizations and institutions. As people go about their daily time–space routines they participate in an internal–external dialectic in which experience and intention influence corporeal action and vice versa. Pred’s work points to the critical importance of place in the amassing of “mental (or internal) experiences that are fundamental to the shaping of … values, perceptions, attitudes, capabilities, preferences, and conscious or subconscious motivations and hence … goals and intentions (only some of which will be realized)” (Pred 1981, 242–243; italics in original). Such experiences, values, and understandings form the basis from which actors, including social movement actors, make choices.

Place, of course, cannot be reduced to the sum total of individual time–space paths. In Agnew’s (1987, 28) multidimensional definition, place consists of:

- locale, the settings in which social relations are constituted (these can be informal or institutional);
- location, the geographical area encompassing the settings for social interaction as defined by social and economic processes operating at a wider scale; and
- sense of place, the local “structure of feeling.” Or, by way of example, home, work, school, church and so
on form nodes around which human activities circulate and which in toto can create a sense of place, both geographically and socially. Place, therefore, refers to discrete if “elastic” areas in which settings for the constitution of social relations are located and with which people can identify. The “paths” and “projects” of everyday life, to use the language of … time geography, provide the practical “glue” for place in these three senses.

Place, in other words, must be understood as constructed by actors as they go about their diverse activities, and by diverse institutions, including the state. The “elasticity” of place is critical to its constitution. The social relations of place may be geographically extensive, even global. Such extensive relations mean that place is not necessarily inward-looking and exclusionary. On the contrary, as Massey has argued, place can be outward-looking and inclusionary – qualities that may be critical to the mobilization of geographically extensive social movements. At the same time, through recurring activity patterns and discourses, regional identities, conceived as bounded regions in our imaginations, are forged. These identities do not exist independently of the state and indeed may be reinforced and promoted by institutions of the state. Moreover, multiple and differently scaled regional identities commonly emerge, creating a rich palette of geographical identities and imaginations that social movements can draw from when trying to construct a sense of “we-ness” and solidarity necessary for mobilization.

Cities as a space of mobilization

While social movements can and do arise in any context where grievances combine with social interaction and collective consciousness, cities are especially powerful incubators of movement mobilization (Nicholls 2009; Miller and Nicholls 2013). The importance of cities to social movement mobilization has to do with much more than sheer population concentration. Cities are both territorial structures with characteristics specific to them that may give rise to place-specific grievances and relational places of interaction that facilitate not only the dynamic construction of identities and discourses, but also the sharing of information and resources.

In Castells’s (1983) classic analysis, “urban social movements” are seen to stem from three distinctly urban dynamics: (i) conflicts around the city as use-value rather than exchange value; (ii) conflicts around neighborhood identity, cultural autonomy, and communication; and (iii) conflicts around territorial (neighborhood) self-management. These conflicts are experienced at the urban or neighborhood scale and in large measure have their origins in place-specific structural and political arrangements. Such “collective consumption” movements are largely defensive, seeking to defend or reclaim urban “living space” from processes of commodification and state control. They represent reactive utopias that strive for place-based solutions to problems that are increasingly driven by global processes – what Castells terms the “global space of flows.” The geographical specificity of urban social movements raises critical questions of both the origins of the grievances they address, that is, do the problems urban movements address actually originate from processes operating at an urban scale and is urban-scale mobilization the most effective way to address their grievances? These questions lie at the core of Raymond Williams’s notion of “militant particularism” – later elaborated upon by David Harvey – which explores whether and how movements might shift from a focus on the deprivations and oppressions of everyday lived experience to a basis for, or articulation with, broader-scale systemic movements.
The tendency for most significant movements to emerge from urban contexts – which can range from large cities to more modest settlements – stems from the nature of social interaction in urban places. Cities are places where people concentrate in numbers sufficient to support the social institutions and practices necessary to produce the affective bonds, solidarity, and shared resources needed for social movement mobilization. Cities’ social diversity, moreover, provides a variety of norms, ideas, ways of life, and resources that, when mobilized, can foster diverse and creative strategies of resistance. The paths and projects that structure everyday social interaction, moreover, produce two critical types of social bonds or “ties”: strong ties of intense bonding and common identity, creating the sense of “we-ness” required for collective action; and weak ties of infrequent interaction and passing familiarity that nonetheless facilitate the sharing of information among different social groups (Granovetter 1983). Extensive weak-tie networks facilitate the sharing of information among groups and provide the basis for alliance-building – a necessity for most effective movements. Building broad-based and well-resourced movements inevitably requires the formation of alliances; opportunities to do so are, in the early stages of mobilization, most readily available in cities.

Geographies of systemic grievances

While many social movements appear to be specific to particular cities, regions, or countries, they often stem from broader systemic processes and state policies. As Peck has noted, cities are “where austerity bites,” but rarely does the imposition of austerity measures stem, in the first instance, from municipal policy agendas. Rather, uneven capitalist development creates uneven geographies of economic deprivation and wealth on urban, regional, and global scales, and state policies are applied to manage these circumstances. Since the 1970s, state policies have been increasingly neoliberal and emanate from scales “above” the cities and regions that suffer under them, including the global, for example, policies of the European Union (EU), International Monetary Fund (IMF), World Trade Organization (WTO), World Bank, and so on. Several of the most prominent movements of the early twenty-first century have opposed globalization and unfair trade, involving a variety of civil society and labor organizations from the Global South and North; austerity policies, as illustrated by Los Indignados/Podemos and Syriza; and inequality and increasing polarization associated with globalization and neoliberalism, most notably Occupy. The conditions that give rise to social movements are by no means limited to the economic realm, however. The Arab Spring focused on democracy and justice, although worsening economic circumstances and food shortages played a significant role in the movement. Immigrant rights and civil rights movements focus primarily on issues of recognition, albeit often with underlying economic objectives. The feminist movement focuses primarily on issues of recognition and voice; these of course have distributional implications as well. And environmental movements, such as the movement to halt climate change, are concerned with the integrity of nonhuman natural systems, often with an eye to the impacts degradation of these systems have on human wellbeing. In short, the systemic forces that give rise to the grievances that social movements express are diverse and complex, not only in the nature of the issues they address, but in their geographies. The geographies of systems, however, may be very different from the experiential geographies of those who suffer under these systems. In other
words, the lifeworld identities and values around which social movements mobilize have their own geographies which only partially overlap with the geographies of systems. Reconciling the two, that is, building movements that are sufficiently extensive to address systemic oppression and dysfunction, is “one of the most intransigent and paradoxical problems facing social movements” (Miller 2000, 67).

Framing and the geographies of mobilization

While economic systems, state systems, and ecosystems have material effects shaping the circumstances of everyday life in diverse lifeworlds, how those effects are conceived and experienced in everyday life cannot be “read off” their materiality. As Lefebvre has argued, and many others have subsequently elaborated, understanding the production of social space requires attention not only to its materiality but also to its representations and to lived, embodied experiences. Lefebvre’s trialectic of spatial practice (perceived space), representations of space (conceived space), and representational spaces (lived space) points to the importance not only of materiality but also of cultural and ideological frameworks and the lived, embodied experiences of material circumstances that are interpreted and understood through geographically specific lenses of culture and ideology. That material circumstances do not “speak for themselves” is illustrated through innumerable examples of hegemonic bargains that mute resistance, the discounting of future wellbeing in favor of a more comfortable and less contentious present, and ideologies of individualism and meritocracy that impede collective action. Cultural and ideological frameworks have their own geographies, varying by place and region. As Cresswell (1996, 8) explains, “space and place are used to structure a normative landscape – the way in which ideas about what is just, right, and appropriate are transmitted through space and place. Something may be appropriate here but not there.” These geographically variable normative landscapes have at least two consequences for social movement mobilization: (i) issue frames designed to effect mobilization in one place may be ineffective in others; (ii) strategies of protest and resistance that may be effective in one place may fail to be effective in others. Geographies of culture and ideology matter.

Given that places and regions “provide historically contingent but durable ‘schemes of perception’” (Cresswell 1996, 16), the development of place and region-specific “collective action frames” is a necessity for most social movements. Collective action frames are discourses that reference a variety of ideas, concepts, facts, norms, and ideologies around which collective action can be mobilized. They are critical to motivating individuals to act collectively, as well as to build broader alliances. Attention to place and region-specific normative landscapes and material circumstances are critical to the facilitation of collective action in those places and regions; in other places and regions where norms, ideologies, and material circumstances differ, substantially different collective action frames may be required. “Place-based collective action frames” (Martin 2003) perform three key functions: motivation, diagnosis, and prognosis. Motivational frames define the collectivity to be mobilized and values that spur it to action such as justice, rights, safety, equity, opportunity, and so on; diagnostic frames present analyses of the causes of the problems the collectivity faces; and prognostic frames lay out a course of action to be taken that may lead to a solution. Together, place-based collective action frames play a critical role in
defining grievances, moving individuals in particular places and regions to act collectively, and, in the best of circumstances, building alliances among groups that might not otherwise be allied. The creative process of collective action framing, moreover, is itself discursive and dynamic and not merely a response to a static cultural and ideological landscape. Norms, ideologies, and identities are not only drawn upon, but also shaped and defined in the process. In other words, processes of social movement mobilization are not merely reactive, but can also serve to produce new cultural and ideological landscapes.

The creation of effective place-based collective action frames, in the context of extensive strong-tie and weak-tie networks, is critical to social movement mobilization in “spaces of dependence.” Cox (1998, 2) defines spaces of dependence as the spaces of “those more or less localized social relations upon which we depend for the realization of essential interests and for which there are no substitutes elsewhere; they define place-specific conditions for our material wellbeing and our sense of significance. These spaces are inserted in broader sets of relationships of a more global character.” To secure the conditions of wellbeing in everyday life we must increasingly address the broader relationships of an ever more interconnected and global world, what Cox calls “spaces of engagement.”

Networked mobilization in a global world

The central dilemma of modern social movement mobilization is how to move from relationships built in place to engage relationships and power dynamics that may operate at much broader scales. The notion that the grievances that arise in localized realms may need to be addressed at broader scales is not new. More than a decade before Castells’s (1983) analysis of specifically urban social movements, Lefebvre (2003/1970) argued that the problems that confront urban residents can no longer be analyzed in terms of independent cities and urban agglomerations because urbanization processes had become global. Two years prior, when coining the term “the right to the city,” Lefebvre argued that the central problem facing society was the conflict between abstract space – based in the processes of commodification and bureaucratization – and social space – the space of use-values produced through the complex social interactions of everyday life. Noteworthy is the fact that Lefebvre did not conceptualize the problems of the city in discrete, bounded, territorial terms, but rather relationally, and in terms that suggest geographically extensive processes.

While Lefebvre’s relational understanding of social and political conflict presaged contemporary geographical approaches, the reconciliation of social movement mobilization with systemic processes remains problematic. While many movements strive to be global, they must be attuned to place-specific circumstances and identities. Analyses of social movements increasingly focus on networks as a means to understand how mobilization in diverse places might be joined up.

Network analysis has long played an important role in social movement research. Granovetter’s work during the 1980s on strong and weak ties represents one body of work among many examining the formation and significance of networks in localized contexts. What differs in the contemporary context is the role of information communication technologies, social media, and global travel, allowing networks to expand their reach dramatically, seemingly without geographical limits. The development of geographically extensive networks has facilitated dialogue and alliance-building on a global scale, allowing the
antiglobalization movement to challenge the forces of capitalist globalization wherever they operate (Routledge 2003; Featherstone 2008).

The building of extensive social movement networks is, however, fraught with tension. In an increasingly global world, identity construction has become increasingly complex. No longer are collective identities built primarily on the basis of frequent local interaction, although this remains one of several mechanisms of identity construction and social bonding, producing traditional constructions of tightly knit, place-based communities. In a world of global communication and global travel, cosmopolitan identities and bonds have become more common among global elite who live their lives in transnational circuits of interaction. While cosmopolitans’ experiences and perspectives may be grounded in diverse places around the globe, fostering tolerance and broad cultural competence, they may also be divorced from the places and experiences of the considerably less mobile and privileged. At the opposite end of the spectrum are individuals who have relatively little social interaction, producing very parochial and individualist identities. Significantly, virtually everyone in modern societies is now connected to electronic and print media, making discourses, cultural practices, and a variety of information from one’s own city, region, and country readily available. Access to, and production of, this information is often promoted by states, business interests, and cultural institutions, giving rise to place- and territorially based “imagined communities,” often without the production of the strong or even weak ties developed in traditional place-based communities. In the context of this increasingly complex landscape of social identities, contemporary movements attempt to mobilize and build alliances.

Contemporary social movements are increasingly focused on building networks (Routledge 2003; Featherstone 2008; Nicholls, Miller, and Beaumont 2013), recognizing the geographical diversity of material circumstances, interests, and identities that must be addressed in mobilization and alliance-building efforts. Central to contemporary mobilization efforts is recognition that networks are not free-floating spaces of open access, but are contextually embedded in places, regions, countries, institutions, and so on (Nicholls 2009; Nicholls, Miller, and Beaumont 2013). Networks are not only spaces of inclusion; they are also spaces of exclusion. They connect some, while leaving others disconnected. Indeed, the employment of spatial technologies of disconnection is common among states and other institutional actors that seek to undermine social movements (see Miller 2013).

Effective contemporary movements must not only actively strive to include diverse actors and groups that share the movement’s goals, movement activists must also recognize their own positionality and address power differentials within networks. Attempts to build broad inclusive movements are rarely simple or straightforward but are, rather, processes drawing on a multitude of actors, resources, and institutions. In the early stages, movements tend to grow through pre-existing relational ties as individuals, groups, and institutions reach out to potential allies. Such network-building efforts often involve “jumping” or “shifting” scales, as growing movements recognize the advantages of drawing from a broader resource base, assembling more voices, or working within state political opportunity structures that may be more favorable. Growing beyond networks of pre-existing relational ties is more difficult and typically involves the work of “brokers” or “imagineers” (Nicholls, Miller, and Beaumont 2013) who can help to build relationships among individuals, groups, and institutions that previously had no connection. While these new relationships may be extremely important, they may also be fragile.
and unstable because social integration and relationships of trust are weakly developed and the circumstances and positions from which the participants come may be extremely different. Under such conditions, encounter, discussion, and negotiation in “convergence spaces” become vitally important. According to Routledge (2003, 345; italics in original), convergence spaces: (i) “comprise diverse social movements that articulate collective visions, to generate sufficient common ground to generate a politics of solidarity, that is, multiscalar collective action”; (ii) “facilitate uneven processes of facilitation and interaction. The diverse groups and movements that converge in such spaces enact a practical politics consisting of at least five processes: communication, information sharing, solidarity, coordination and resource mobilization”; and (iii) “facilitate multiscalar political action by participant movements. Social movements engaged in grounded material struggles, and articulating place-specific concerns, also actively participate in forging a globalizing network of such struggles.” Convergence spaces can take a variety of forms: conferences, forums, joint campaigns, and ad hoc meetings. Critical is that they provide opportunities for discussion and the building of shared understandings, solidarity, and, in some cases, shared identity. Social movements, in other words, do not encounter the political landscape as fixed, but are themselves constitutive of it.

While convergence processes are an important component of geographically extensive movements that bring activists together from diverse places, regions, and circumstances, there is no guarantee they will actually converge on common objectives and strategies. Under such circumstances, multiscalar organizational structures and strategies are frequently employed, providing a common broad-scale framework and substantial autonomy and flexibility to pursue place, region, and country-specific strategies and campaigns. As Routledge, Cumbers, and Nativel argue (see Nicholls, Miller, and Beau-Dumont 2013), “multi-scalar networks of support and solidarity” recognize the diversity of place- and region-specific cultures, ideologies, and circumstances and facilitate broad coordination, providing an alternative to universalist strategies that may neglect geographical difference. Nonetheless, there is no guarantee that compatible strategies will be pursued across multiscalar networks. Indeed, many movements, such as the Right to the City movement, have been plagued by incompatible framings and objectives that have undermined a coherent understanding of the movement (Mayer 2009). Such problems are likely unavoidable, and a relatively small price to pay, for movements that seek to respect the social, cultural, and geographical diversity of the world in which we live.

Social reproduction

Cindi Katz
City University of New York, USA

Social reproduction encompasses the daily and long-term reproduction of the means of production, the labor power to make them work, and the social relations that hold them in place. Under capitalism, social reproduction entails the production and reproduction of the capitalist and laboring classes as such, the means and arenas of capital circulation, and the physical and discursive conditions to maintain the production and reproduction process over time and across space. It includes both the reproduction of capitalist social relations as a whole, along with the sphere of everyday life, which may appear outside of the relationship between waged labor and capital but is wholly entwined with it. In other words, social reproduction includes the production and reproduction of a differentiated labor force and the cultural forms and practices that at once maintain these differences and make them common sense. These distinctions may be constructed as sectoral or related to skill, education, and training, but they mobilize differences associated with gender, race, sexuality, and nation even as they produce them. The material social practices associated with social reproduction build upon, reproduce, and reshape inequalities that enable and enhance capital accumulation, racial capitalism, and patriarchy among other means of uneven development.

Social reproduction is at once the “fleshy, messy” stuff of everyday life and the structured practices that unfold in dialectical relation to production. These material social practices take place across geographic and temporal scales, encompassing daily and generational relations that are as much intimate as global in their effects and charge (Marston 2004). The form and content of social reproduction, as much as the means of its provision, are forged through struggle, making it a contradictory realm of both the continuation of capitalist social relations and the possibility of their transformation. Geographers have been attentive to geographical variations in what constitutes social reproduction (e.g., Cravey 2003; Laurie, Andolina, and Radcliffe 2004; Mullings 2009; Brickell and Yeoh 2014; Meehan and Strauss 2015; Kofman and Raghuram 2015), and marked the environment as part of the means of production, thereby recognizing environmental care and rehabilitation as part of social reproduction (Di Chiro 2008; Marks 2015).

Production and social reproduction are historically as well as geographically contingent. What is required of a labor force – and what is considered socially necessary labor – varies by time and place, as do the work and other resources required to reproduce the labor force (or an individual worker) on a daily, monthly, yearly, and generational basis. What may be required of a worker in New York City will differ from what is required for the daily reproduction of a worker in Guangzhou. Among other things, the cost of living will differ, the clothes one is expected to wear may be different, educational requirements will vary, and so on. What is considered necessary for the production of any given labor force is a social and political economic question, and changes with and alongside the shifting ground of capitalist social relations in any given time and place. This dialectical relationship between
reproduction and production is the outcome of both intra- and interclass struggle, and encompasses such things as education, health care, child care, and so-called benefits packages, or what is conceived of more broadly as the “social wage.” What constitutes the social wage is historically and geographically contingent, as is who is considered responsible for the provision of its components: the individual, the household, the state, capital, or the private institutions associated with “civil society.” Within these arenas the means of accomplishing social reproduction varies as well – in the household labor may be provided by family members or employees such as child minders, housekeepers, cooks, tutors, and the like, or through the purchase of such things as prepared meals, laundry services, child-care services, home health-care services, and so on. Individuals may do the work of self-care on their own or may avail themselves of therapists, sex workers, and personal groomers, among a growing array of services available for those who can afford it. The state may provide for social reproduction directly through public education, social housing, publicly funded health care, police and fire departments, highways, or public utilities. It may also provide for social reproduction through tax relief and policies geared to the provision of social welfare, child care, infrastructural development, and unemployment insurance. The mix of what is entailed in social reproduction and how it is accomplished and paid for by whom is a social, economic, and historical geographical question.

At another scale entirely, globalized capitalist production brings geographically disparate labor pools in more direct competition with each other, and can exert a homogenizing influence on the conditions of production and social reproduction. Through the expansion of capitalist social relations and the loosening of barriers to investment and trade, foundry workers in Ohio are put into competition with industrial laborers in Gujarat, where the costs of social reproduction – and thus wages – are lower. Likewise, when production shifts to places with fewer environmental regulations or their lax enforcement, the lower costs of maintaining and reproducing the conditions of production enhance capital accumulation. In these ways and others social reproduction is at the heart of capital accumulation, which is predicated on uneven geographical development and labor differentiation. The latter relies upon the reproduction of inequality through constructions of difference around race, gender, class, sexuality, and location. Thus, while the globalization of capitalist production can have a tendency to homogenize the conditions of production and social reproduction, the nature of uneven geographical development in combination with the rootedness of so much of what is entailed in social reproduction means that as production moves to areas of cheaper labor and lower environmental costs, the responsibility for and costs of social reproduction in the settings left behind or threatened with disinvestment are offloaded from capital to other sites such as the state, nongovernmental organizations, the household and family, and the individual. While this situation may leave those who are “stuck in place” having to cover more and more of the costs of their own social reproduction, it also suggests an arena ripe for organizing labor to ensure that any “homogenization” of the conditions and relations of social reproduction pushes the costs back to capital.

Social reproduction is a term often associated with Marxist political economy. Marx wrote about reproduction at the scale of the individual laborer and capitalist – what he called simple reproduction – in Capital, Volume 1, and of the reproduction of capitalist relations as a whole, which he referred to as expanded reproduction,
in *Capital*, Volume 2. Throughout his discussions of the contingent, historically grounded, and contested processes of reproduction, however, Marx’s focus was on capitalist production and on the waged labor–capital relationship. Unwaged reproductive labor, the domestic sphere, or what is now often referred to as caring work, do not figure significantly in Marx’s writings, to say nothing of social relations of difference apart from class or the other realms of social reproduction such as those associated with the production and exchange of knowledge and the sphere of everyday life. Marx associated these cultural forms and material social practices with the “superstructure,” which rested on and shaped the forces and relations of production or the “base,” and his interest was largely in the latter. Many Marxists continue to consider the realm of social reproduction as external to the creation and circulation of value, which theorists of social reproduction, many of whom are Marxist-feminists, see as limiting their analysis and praxis (Dalla Costa and James 1972; Federici 2004; Katz, Marston, and Mitchell 2015).

Henri Lefebvre is a notable exception to this tendency. While most geographers are familiar with his work on the production of space, Lefebvre focused three volumes on the “critique of everyday life.” Lefebvre understood the cultural forms and practices of everyday life in all of their mundane triviality and “colonization” by consumerism as “critical” material social practices wherein the possibility for rupture was immanent in the routine and quotidian. He framed everyday life as the site in which all activities were encompassed and encountered in all of their variation and contestation, creating a “common ground” of practice, social engagement, desire, and possibility. Likewise in geography, Allan Pred’s (1981) consideration of time geography as a way to examine the individual in relation to a social formation producing and reproducing one another as they are structuring and structured by time and space offered a specifically geographical understanding of social reproduction and the paths and projects of everyday life. Pred’s work deepened the analysis of everyday practice with attention to its necessary temporal and spatial constraints. In this effort, he was attentive to the intricate social realms – intimate and more global – of any “individual path” in articulation with a myriad of “institutional projects” so that the production and social reproduction of everyday life encompassed biography formation intertwined with the constitution of social institutions and their associated structural practices. Other Marxist theorists with an appreciation for everyday life and its critical possibilities include Pierre Bourdieu whose notion of the habitus is a way of understanding the durable socially structured systems that at once produce social life and are its outcome. Implicit but often difficult to imagine in the ongoing interrelated “structuring structures” of Bourdieu’s model is the possibility of social transformation – the incremental and more dramatic shifts that inhere in and produce everyday life and its myriad institutions and practices. Indeed, Bourdieu wrote incisively about how schools function to teach the skills and inculcate the discipline appropriate to participating in a capitalist workplace while at the same time naturalizing the sorting they perform in a classed and socially divided society. In a more lively and culturally rich vein, Paul Willis’s landmark book, *Learning to Labor* (1977), addressed how working class boys in Britain encounter the class-bound hierarchies and disciplinary practices of public education, and engage them in ways that at once express their interests, disdain, and desires and consign them to a future on the shop floor. Willis’s work, which is exemplary of the Birmingham cultural studies tradition, demonstrated brilliantly how social reproduction is an indeterminant process
of structurally constrained but active “choices” and “decisions” by social actors who resist the narratives of conventional schooling to make themselves otherwise. His work shows the concrete and intimate ways that people make themselves and their paths in and against the social formations in which they live, and how their everyday material social practices help to constitute those very social formations and the social relations associated with them.

By looking concretely at how social reproduction was accomplished historically through everyday practice in and against structuring structures across geographic scale, this work complemented and added immeasurably to Marxist understanding of social reproduction as at once the reproduction of the laborer and of the class relationship from the point of view of an individual worker or firm and the reproduction of capitalist relations as a whole, because it brought the cultural forms and practices through which social reproduction is accomplished – or not – to the fore. It remained to others, however, to look more closely at the labor involved in ensuring social reproduction – simple and expanded. The contributions of Marxist-feminists have been crucial in these realms. One of the most pivotal and inspiring texts was a 1972 manifesto by Mariarosa Dalla Costa and Selma James, which laid out in bold terms how the naturalized, unending, and unrecognized work of women in the home produced the commodity most central to capitalism – labor power. Withholding this labor, they argued, had the capacity to destroy capitalist (and patriarchal) relations of production and subvert conventional hegemonic social relations of production and reproduction (see Federici 1975).

Such analyses of the work of social reproduction as the gendered and largely unwaged work of reproducing the labor force expose the multiple layers of structured exploitation that women face in the heteronormative nuclear family. Working for a share of their husband’s wages – what economists describe as the “family wage” – women providing reproductive labor in the home are doubly alienated and doubly exploited. While many marriages and familial relationships are rooted in love and sustained by care and mutual aid, it remains that what is constructed – and may be experienced – as a consensual familial relationship is at the same time a structured set of relationships that extract value from the body of the housewife in the form of reproductive labor. While the fruits of her labor benefit and are enjoyed by her husband or partner and children, the value produced by domestic labor is tapped by capitalists in the course of the production process and contributes substantially to capital accumulation. Drawing an analogy to the terminology of racial capitalism, we might understand this relationship as gendered capitalism. Both forms of capitalism, which are everywhere entwined, enable and hide the deeper exploitation of women and people of color in distinct, overlapping, and intersecting ways.

Another revealing aspect of domestic labor has been that the increased participation of women in the wage labor force did not result in the transformation of their reproductive roles as many had imagined. Women working outside the home – which is by now commonplace and for many has always been the case – generally work a “double shift”; their labor outside the home (often in the caring professions) is preceded and followed by their reproductive labor – cooking, cleaning, shopping, laundering, child-rearing, and so on – at home. In each case, she produces value for the owners of the means of production directly in the workplace and indirectly in the home through producing and reproducing the labor power of herself, her husband or partner, and children.
Starting in the 1970s and picking up steam in the 1980s, feminist political economists and others provided rich analyses of these social relations of production and reproduction and the extraordinary, but commonly invisibilized, labor involved in producing the worker on a daily basis and over generations. Focusing on the domestic sphere, they documented the unwaged work of child care, food preparation, cleaning, laundering, scheduling, and other aspects of what is now referred to as “care work” and “affective labor,” and analyzed its contribution to the relations of production under capitalism and capital accumulation more generally. Looking at the articulation between capitalism and patriarchy, feminists examined how the naturalized labor of women over the life course produced labor power – a commodity sold to capitalists in the workplace – and thereby contributed to the extraction of surplus value by capitalists. For some theorists this situation spurred a movement to compensate domestic labor – the Wages for Housework movement, which was meant not as an end point in itself, but as a “political perspective” (Federici 1975). That is, the radical intent of the Wages for Housework movement was that it would force recognition of the role of women and domestic labor in producing uncompensated but necessary value for capital. Without ready workers able to sell their labor power to capitalists there could be no production and no extraction of surplus value from the worker. Cheapening and devaluing domestic labor enhance labor exploitation. The struggles associated with the Wages for Housework movement were seen as revolutionary in their capacity to undo the naturalized assumptions and practices of patriarchy, heteronormativity, and capitalism, along with the differentiated social positions and roles associated with them. Wages for Housework was, then, a call to women to organize with other women against the isolation and individuation of household labor, and thereby to “subvert the community,” and undermine capital accumulation.

Other feminist responses to the social reproduction work of women in the household and elsewhere had a less revolutionary imaginary perhaps, but include the enduring radical aspiration to socialize domestic labor through collective arrangements for its accomplishment, including for example shared kitchens, communal living arrangements, and collective child-care spaces. Still other approaches have advocated policies that recognize the economic contributions of caring work and provide public support for the value of that work, and the more liberal-minded reworking of gendered relations of production in the household in a more individualized manner. Some imagined that technological advances in the home would reduce women’s work, but while these technologies altered the nature of domestic work, most of them did little to reduce the time spent on it, and perhaps worse, served to elaborate on and extend its expectations (Strasser 1982).

Of course the domestic work of social reproduction is not just gendered, it is raced and classed, and often involves stretched geographies of care involving the labor of women from the Global South and poorer countries working in the homes of people in wealthier parts of the world. As Angela Davis (1981) and many others have noted, for many black women, housework and reproductive work in general, have long been performed outside of the home initially under conditions of slavery and then for depressed wages often under informal conditions, which do not provide benefits or security (Glenn 2012). Likewise, the intimate relations of social reproduction are often quite global. So-called nanny chains or the extended geographies of care work more generally involve women of color from poorer nations migrating to wealthier places to
SOCIAL REPRODUCTION

care for the children, homes, elderly, and health needs of people there. Among other things, and crucially, their migration is enabled by the labor of their extended families who take care of these needs – covering the work of social reproduction – in the migrants’ home environments, and by immigration policies that foster these sorts of exchanges to try and ensure that such migration remains temporary and that family members and communities in the sending countries receive remittances (Pratt 2012; Parreñas 2015). And yet the necessity of social reproduction and its accomplishment one way or another – by extended family in one place and hired labor in another – is at the heart of these policies and the demands that call them forth. These policies and practices rely on, as they maintain and reproduce, uneven development and the social relations of production and reproduction associated with racialized and gendered class difference. Whether temporary or permanent, labor migration represents a transfer of wealth between nations. Labor is after all a form of variable capital, and when it is produced, reproduced, and nurtured in migrants’ country of origin, it represents a transfer of capital between nations no less significant for being embodied than flows of financial capital or commodities produced cheaply.

While there are many critical insights in this work on the labor practices and exchanges of value in social reproduction, there are three themes in particular that have profound implications for the study of social reproduction as both central to capitalism and as the stuff of everyday life. The first theme is recognizing the home and family, along with other institutions such as schools and community groups, as sets of relationships structured to draw value out of unwaged work, to build consent around these structured relationships, and/or to contain and manage the contradictions of production and reproduction. Dalla Costa refers to these institutions and the sphere of social reproduction as the “community,” arguing that the community functions as a sort of “social factory,” producing value for capitalism while appearing to be outside of production. But along with this key role, the home and the sphere of social reproduction more generally are a key arena where the contradictions and crises of capitalism are managed. Analyses of social reproduction can reveal the unremarkable cultural forms and practices through which the social relations of capitalism and other structured relations of domination are managed, mediated, hidden, and reproduced, but also and importantly, can be recognized, remade, and resisted.

The second theme is the centrality of race, gender, age, and sexuality to capital accumulation. As suggested above, unwaged and other caring work, differentially exploited, globally sourced, and intimately deployed, is naturalized through institutions such as the family and the household, the nursery, and the school, and with them, the gendered, age-graded, and racialized divisions of labor that comprise and animate them. As long as these relations are naturalized their structural underpinnings and outcomes are obscured, as are their intricate and important connections to class exploitation and capital accumulation. As George Caffentzis (1999, 162) notes, “The problem with Marxist theory was that it could only explain the reproduction of the capitalist-waged-worker relation. But the revolutionary subjects of the ’60s were mostly unwaged.” Today these subjects would include the unemployed, the incarcerated, students, peasants in the Global South, those engaged in the informal economy, and housewives, among others. These populations have been recognized as a sort of safety valve for capital accumulation by comprising what Marx understood as a “labor reserve army,” but also through their profitable
and strategically stabilizing containment, management, disciplining, and distracting. Unwaged workers, then, are very much part of the labor force and are differentiated through the production and reproduction of race, gender, age, and sexuality. Critical attention to social reproduction can illuminate the ways these differences are produced, are structured in relation to class, and are sustaining to capitalism. Their recognition as such would highlight the potential for altering them along with the social relations that hold them in place in and through the material social practices of social reproduction.

Finally, the Marxist feminist position on value production through reproductive labor has important ramifications in terms of locating contradiction and possibility in capitalist crisis. “Once we see the community as a productive center and thus a center of subversion, the whole perspective for generalized struggle and revolutionary organization is re-opened” (Dalla Costa and James 1972, 13; emphasis in original). As suggested above, organized labor, the factory worker on strike, and waged workers more generally can no longer be constructed as the only revolutionary subjects – or even the most likely. While some Marxist theorists continue to question what constitutes social reproduction under capitalism, and whether or not certain types of nonwaged labor and extra-market relations produce value, it is clear that theorizing social reproduction beyond the reproduction of the waged labor–capital relation brings with it a new way of imagining – and organizing – the working class, and opens up new arenas for mobilizing resistance to various relations of domination and exploitation.

Across the board it is important to remember that social reproduction is always contested, and plays out according to concrete historical and geographical conditions that are shaped through struggle. Social reproduction is always already fraught with tension and possibility; its “fleshy, messy” practices are essential to the production of value through the wage labor–capital relation, but at the same time can be reservoirs of possibility and potential change as well as self-care and reconstitution, which themselves can be a form of resilience. Alongside and through these practices, however, capital is accumulated through the looting of value produced in this sphere of everyday life. This dialectical relationship adds to the potency of social reproduction, but also its perils.

This dialectical relationship undergirds and sustains the capitalist mode of production. By definition if social reproduction is in crisis so too is capitalism. Periodic crisis is in fact part of uneven development, and often resolved through the so-called spatial fix, although there are many other means of crisis resolution depending in part upon its nature, location, extent, and historical geography. Crises of accumulation occur, for instance, when excess capital pools and cannot be productively employed, or productive capacity is idled for lack of demand in existing markets or lack of a labor force adequate to the task. In other words, when there is too much time between the production of commodities, including labor power, and their sale, or if there is no way to expand markets geographically or to intensify production, then capital accumulation falters and may be in crisis. While such crises may be ameliorated through the material social forms and practices associated with social reproduction such as investments in education or infrastructure, they may provoke a crisis in social reproduction as well.

A crisis of social reproduction occurs when existing social, political economic, or environmental conditions and relations can no longer be reproduced, for example, if commodities once created cannot be brought to market, if the time between production and consumption is too long, if flows of capital cannot be invested in
productive activity, or the material forces and grounds of production are degraded. Likewise, a crisis of social reproduction occurs if the labor force cannot be reproduced in a given time and place or find means to labor productively in a given setting. Such crises may be resolved by labor migration, but can also lead to a large number of people looking for employment and finding none as has become common in many parts of the world. The burgeoning of such populations itself threatens the stability of capital accumulation. One way that surplus labor is “managed” is through containment strategies of various kinds – the coercive structures of state violence and incarceration are the most pernicious, but so too is the structural and systemic neglect of social welfare, health care, housing, and education which fail populations excessed by production and accumulation crises subjecting them to harm and early death. In another realm, the military and militias absorb many young people with few other options. The attenuation of higher education both in the ways it can draw young people with few employment options or because the credentials required for various positions have been expanded is another means of managing the contradictions of capitalist accumulation and the crises that accompany them.

These examples suggest some of the ways social reproduction encompasses the structured material and discursive practices and institutions that hold capitalist social relations together, and can manage their inherent contradictions through state policy and practice, the affective labor of the domestic sphere, and the social work associated with civil society. These institutions and practices are wide-ranging, and include those associated with education, the judiciary, the military, the “nonprofit industrial complex,” and cultural governance, among others. These contradictions, discontinuities, and possibilities for social transformation are inherent in capitalist production, but also in the reproduction of capitalist social relations. The centrality of reproduction to capitalism and what its work consists of, then, are critically important political questions, which are often sidestepped in conventional Marxist praxis and analysis, but which have played a growing role in more recent social movements such as “occupy,” various “mothers’” movements, and social activism around “commoning,” for example.

As is well known, capitalist production requires a class of people who own the means of production and a class of people who do not own the means of production, and are free to sell their labor power as a commodity to those who do. In Volume 1 of *Capital* Marx explains the violent historical practices of primitive accumulation, which alienated masses of people from the means of production, “freeing” them to sell their labor power to capitalists who were taking ownership of the means of production, and leaving them with little choice for economic survival but to do so. Primitive accumulation, as the name implies, was understood as “the original sin of capitalism,” outside of and prior to capitalist social reproduction and production, and the relationship between the violence and coercion of original accumulation to production remains a historical one. But there is a parallel here with the everyday work of social reproduction, and the coercion, violence, displacement, and dispossession associated with practices akin to primitive accumulation remain an integral part of capitalist relations in the present. The historical and ongoing role of primitive accumulation, or what David Harvey (2003) has dubbed “accumulation by dispossession,” relates directly to social reproduction in as much as primitive accumulation describes the process of looting the “outside” of capitalist social relations: nonmonetized or noncapitalist material practices – including the
“fleshy, messy stuff of daily life” and material social practices and relationships outside of the waged labor–capital relationship.

The confluence of primitive accumulation and social reproduction is a cornerstone in the scholarship of Silvia Federici (2004), who locates the historical primitive accumulation that preceded European capitalism in women’s bodies and material practices. In her book *Caliban and the Witch*, Federici argues that it was the subjugation of women and the forcible separation of “productive” and “reproductive” labor that allowed for the concentration of wealth necessary for the creation of capital. Tracing the development of capitalism through the history of reproductive labor, Federici argues that “primitive accumulation has been a universal process in every phase of capitalist development” (2004, 16). Jennifer Morgan’s (2004) historical study of reproductive labor under slavery similarly locates the site of primitive accumulation in women’s bodies. African slaves and their descendants, Morgan shows, performed both productive work and reproductive work by reproducing the labor force daily and generationally. Under slavery, women produced both the commodity and the labor force, which were one and the same. The wealth that was accumulated in slaveholding economies and then put into motion as industrial capital was extracted from black and brown women’s bodies. Social reproduction and reproductive labor, while commonly naturalized as outside of production and capitalist social relations, are central to the production of value both through the production process, which requires the reproduction of labor, and through accumulation through dispossession, which extracts value from noncapitalist spheres, from racialized and gendered bodies, from the material practices of reproduction, from the environment, and from the future in the form of credit.

Social reproduction is the material social practices through which people reproduce themselves on a daily and generational basis and through which the material bases and social relations of capital are maintained, invigorated, and renewed. These material practices are also spatial practices. Social reproduction encompasses the stuff of everyday life, is grounded in the production and consumption of use-values in the everyday environment, and is embodied. But beyond the realm of the everyday, social reproduction involves the reproduction of the conditions of production, which among other things includes the physical environment – the built forms and spaces of production and the environmental resources and physical conditions that enable ongoing production.

Social reproduction has political economic, cultural, and environmental aspects. As a set of structured material practices, it must be “held together” through consent and the production of commonsense understandings of its compass and the nature of its provision. But social reproduction also refers to the making and maintenance of the forces and material grounds of production. Much of the work of political ecologists essentially addresses social reproduction especially at its confluence with ongoing primitive accumulation in underdeveloped and postcolonial settings, although this work is rarely understood by these researchers or others as of a piece with social reproduction. But, much of the early work in political ecology was concerned with environmental destruction resulting from increasing pressures brought to bear on the social reproduction of peasant and rural social formations as they were incorporated, directly and/or indirectly, into a global capitalist system. A focus on social reproduction offers a theoretical and practical framework that brings together Marxist, feminist, and antiracist work
on the social relations of production with environmentalist work focused on the deterioration of environmental resources and landscapes of labor, and can enhance the political horizons of both concerns. Likewise, work focused on environmental justice is directly connected to social reproduction in its concerns with the uneven environmental conditions in which people carry out their everyday lives and children come of age. Political organizing around social reproduction and environmental justice has found common ground and made common cause in many places – rural and urban, Global North and South – around the stark and growing issues of the uneven distribution of waste and value at all scales. In these ways and others, social reproduction is a key concept of geography, and its analysis offers scholars and practitioners powerful means of understanding the everyday environment and the social relations that hold it in place and might change it.

Social resilience and environmental hazards

Hugh Deeming
Northumbria University, UK

The etymology of the word “resilience” has been traced from its use in ancient Greece, via the reign of the English king Henry VIII, to its modern multidisciplinary applications across the disciplines of materials science, systems theory (e.g., ecological and social-ecological), psychology, disaster risk reduction, and others (Alexander 2013). The consistent interpretation, which tracks through much of this usage, is the idea of “bouncing back,” that is, there has been a tendency for resilience to be associated with the concept of equilibrium, or rather the return to equilibrium after perturbation. This idea of resilience as an indicator of a type of system plasticity has been referred to as “engineering resilience.” In recent decades, however, other academic interpretations have diverged from the idea that resilience can be considered as a factor in the maintenance of some sort of quantifiable stasis and, rather, propose a more flexible situation where resilience allows a system to maintain not equilibrium, but functional persistence. From an ecological perspective, resilience is viewed as an attribute that allows systems to operate within any one of a number of alternative stability regimes, with each regime determined by prevailing conditions/stressors. For example, a lake can either function in a clear or turbid condition depending on environmental factors. In terms of understanding a social system’s ability to persist, use of the concept has included the focused investigation of three characteristics: coping (resistance), self-organization, and learning from experience (adaptation). It has been suggested that social resilience, understood through this lens, depends on complex interactions between ecological, social, economic, infrastructural, and institutional components, which if effective can allow the system to respond to predictable disturbances, as well as to unforeseen shocks.

Resilience has become a focus of attention as societies have come to realize the unpredictable complexity of nature and the operation of social and ecological systems within it. Rather than vulnerability, which has been associated with a pessimistic focus on a system’s potential for harm, resilience has emerged over recent years as a positive, forward-looking system attribute. As a result of the attention paid to it, the concept of social resilience has developed through both analytical approaches, which concentrate on measurement, and normative approaches that are more metaphorical than empirical. These focus on judgments and prescriptions over subjectively aspired-to system conditions, rather than the isolation and quantification of specific variables. This duality has led to significant criticism, wherein the term has been accused of becoming so malleable in its application as to leave it without a distinct meaning. However, further attempts at better definition have included its separation from the related concept of transformation, that is, this separation has reinforced the perspective that the principal attributes of a resilient social system are inherent in its capacity to maintain its function, rather than being a driver of transition or transformation to a fundamentally different regime. It is this
resilience for functional persistence that has been identified as a problem for resilience-based strategies. This is because there may be risk involved in maintaining regimes that have been socially inequitable from the outset, for example, states of poverty and autocratic government that have proved to be highly resistant to change. From this perspective, it could be argued that resilience can be viewed as a constraint, in that it limits a society’s adaptive potential to actions that maintain the status quo ante. From this perspective, resilience can be viewed in terms of its ability to disguise and perpetuate the negative aspects of path dependence. However, given the multiple usage of the concept, it is important to take this as an opportunity to review how some of the principal approaches to understanding social resilience, and particularly social resilience to environmental hazards, have developed over recent decades.

One of the earlier modern uses of the concept was in the field of psychology in the 1940s and 1950s, where researchers initially regarded resilience as a personality trait. However, further work on the role of external conditions in defining childhood resilience led to a hypothesis that resiliency was developed through social processes rather than being a predetermined characteristic, that is, personal resilience became a function of social interaction. This view was useful because it allowed individuals’ resilience to adversity to be scaled up to higher social levels. From this perspective, mental health research has highlighted the importance of access to social support, which reduces mental health problems following disaster.

Returning to the idea of system persistence, Wildavsky (1988) developed his theory of organizations by distinguishing between the concepts of resilience and anticipation. He argued that anticipation focuses on avoiding and mitigating known and specific hazards, whereas resilience is inherent in an organization’s “capacity to cope with unanticipated dangers after they have become manifest, learning to bounce back” (Wildavsky 1988, 77). This understanding is useful in that it supports the idea that general resilience is an important mediator of the impacts associated with surprise events. Viewed in these terms, it is perhaps a little disheartening to find that a particularly powerful determinant of an individual’s perception and self-efficacy in the face of hazards is their personal experience of those hazards. While such a finding supports approaches that propose learning as a principal determinant of resilience, it is also limiting in that, if known hazards are those that people engage with best, the challenge of encouraging engagement with the unanticipated is obvious. In terms of risk perception, this tendency is referred to as “preparing for the last disaster.” Much civil protection doctrine is constructed around what are effectively anticipation-only approaches, which could be said to de-emphasize the fact that surprise events may require innovative and flexible responses rather than the pre-scripted actions.

One of the most widely recognized approaches in the development of the resilience concept is that of social-ecological systems (SES). Holling (1973) was arguably the first to incorporate resilience into the discipline of ecological systems science in a way that challenged the notion of systems operating at or around equilibrium. He suggested that systems constantly operate in a transient state. He used the idea of the “adaptive cycle” (i.e., growth or exploitation; conservation; collapse or release; and reorganization) to describe the way ecosystems develop and persist over time (even though some constituents of that system may experience extinction, to the benefit of others). He illustrated how this model could be used to identify how ostensibly closed systems, such as lakes, could be seen to respond to external...
(principally anthropogenic) perturbations (e.g., eutrophication, overfishing), through regime persistence or, alternatively, through crossing thresholds into alternative stability regimes (e.g., from clear to turbid), while maintaining their primary function (i.e., of being a lake). He referred to these alternative stability regimes as “domains of attraction.” The term “social-ecological system” evolved from this approach, in order to further emphasize the role of humans in nature. Berkes and Folke (1998) stressed that the separation between social and ecological systems is effectively artificial and arbitrary and suggested that social and ecological dimensions be attributed equal weight in any analysis.

SES theory incorporates issues of scale through the concept of panarchy. Panarchy describes how system persistence is determined by the interrelationships between the slow adaptive cycling experienced at a system’s macrolevel and the more rapid cycling that occurs at the meso and micro (i.e., local) scales. As an example, panarchy can be imagined as the feedback processes that operate through the cascading social scales of county, town, neighborhood, and household.

The persistence or destruction of nonhuman systems will ultimately be determined by the environmental stressors to which it is exposed (whether natural or anthropogenic). However, the key determinant of human agency is intention. Through their intent, humans give effect to their capacities for learning and technological progress. Therefore, human social systems can be seen to have a greater capacity for adaptation (i.e., the collective capacity of the human actors in the system to manage their resilience, whether this is done effectively or not). Adaptability has, therefore, been proposed as a crucial social component in the regulation of SES. This is despite the fact that adaptive behavior and self-organization within the system may be intentional or unintentional in relation to its effect on the system or interrelated systems. Social actions should also be understood to have the potential to push the system closer to, or over, thresholds into different stability regimes or even toward collapse. Such a process, wherein resilience is reduced rather than increased by actions taken, is referred to as maladaptation. Maladaptive actions are, however, often difficult to differentiate from effective actions, because their results may still be viewed as successful by some observers.

Actions or circumstances that push a social system beyond the tenable boundaries of its normal functioning (i.e., beyond its domain of attraction) can take a system beyond resilience and into transformation, creating a fundamentally new system with radically different ecological, economic, or social (including political) characteristics. Pelling (2010) discusses transformation and suggests that it may be triggered by any economic, political, or environmental shock. In terms of social contracts, such events can precipitate perceptions of manifest failure in what are perceived by the public to be institutions of security against these shocks. For example, sea level rise has been associated with the dispersal, and effective destruction, of many small communities built on eroding coastlines, after decisions to cease erosion prevention work have been introduced top-down from higher political levels.

Incorporating these considerations and the principle that resilience involves an element of anticipation and planning for the future, the concept of social resilience has gained increasing recognition in the literature. Adger, for example, has defined social resilience as “the ability of groups or communities to cope with external stresses and disturbances as a result of social, political and environmental change” (2000, 347). However, this conceptualization of resilience as a social capacity for delivering system persistence has also crossed from the academic/empirical sphere into that of governance and practice. In
places it has morphed into the more normative concept of “community resilience.” While apparently compelling, the attraction of applying a social metric such as “community” to any understanding of system persistence is challenging, not least because of the lack of an adequate definition of “community” as any sort of uniformly coherent social unit. For example, the consideration of community in terms of exposure to environmental hazards could legitimately focus on the concept of place communities (e.g., populations resident in a seismic zone). However, in wider resilience terms, the risk-mitigation and recovery-enabling resources available to different individuals and groups within any place-based population would likely depend much more on their connection to other, less geographically dependent, forms of community, for example interest, identity, support, and circumstance. Furthermore, communities of practice – which can comprise practitioners as well as engaged publics, whose collective intent is to mitigate disaster impacts – are increasingly utilizing modern social media in order to connect and share experiences and to advocate for disaster risk reduction causes across the globe.

In terms of understanding organizations as formalized social structures, it has been suggested that anticipation strategies again provide the most popular focus for understanding their capacity to survive disruptions. However, such approaches are also acknowledged as offering the temptation for these organizations to develop resistance and efficiency strategies that could actually undermine rather than enhance their resilience to the unexpected. Weick and Sutcliffe (2007) propose that high-reliability organizations (HROs) (e.g., nuclear power plants) are less likely to degrade their resilience in this way because they operate on a set of key principles that enhance their ability to respond dynamically to known, as well as new and emerging, hazards. These are a preoccupation with failure; a reluctance to simplify; sensitivity to operations; a commitment to resilience; and deference to expertise (i.e., rather than rank).

Despite its association with anticipation, the capacity of a social system to resist hazard effects is a fundamental factor in increasing resilience through the reduction of harm, particularly from high-probability hazards. For example, the benefits of technologies such as flood barriers, or legislative measures such as seismic building codes, have in reality reduced the impacts of predictable hazards. However, resilience is also associated with an element of recovery from impact (i.e., the bouncing back). Therefore, a social system’s ability to substitute resource elements (e.g., information networks, human or electronic), to act with resourcefulness and to do so with rapidity, have also been identified as fundamental in defining that system’s resilience capacity. In an increasingly interconnected world, the fact that nobody can have complete knowledge about future hazard effects further highlights the importance of understanding resilience in terms of enhancing these attributes. Not least because of the increasing risk that hazard effects can become linked or compounded in unanticipated ways (e.g., the impact of the 2011 floods in Thailand on the global availability of computer hard disk drives), Furthermore, the attributes that ultimately enable effective response to surprise events to be achieved with dynamism and flexibility may not necessarily be those that are normally associated with civil protection. It has been proposed, for example, that social resilience be defined as “a process linking a set of adaptive capacities to a positive trajectory of functioning and adaptation after a disturbance” (Norris et al. 2008, 131). From this perspective, social resilience is no longer considered as something that can be achieved
simply by, for example, building flood barriers. Rather, it should be seen as something that encompasses a more complex approach that nurtures a social system’s ability to create and to maintain social wellbeing through the development of an ability to dynamically link its own capacities for economic development, social capital, information and communication, and community competence.

This idea of wellbeing as a desirable manifestation of effective adaptation to a new postdisturbance environment is useful, because it equates resilience with collective health and quality of life. If a population has sufficient dynamically linked capacities, then hazard perturbations do not have to turn into disasters. Such thinking emphasizes the importance of acknowledging the importance of any work undertaken to increase social equity and to reduce vulnerability, not just in relation to predictable hazards, but more generally in terms of mitigating the root causes, dynamic pressures, and dangerous conditions that create all forms of social vulnerability. This perspective resonates with some of the critiques of SES and organizational theory, in that it brings power relations to the fore. Understanding resilience as a social process that is manifested in sustainable collective wellbeing and an ability to rally resources to deal with “known” hazards as well as unanticipated shocks, reduces the temptation to externalize chronic social inequities from the equation (i.e., where vulnerabilities not directly related to predictable hazards are displaced as a draw on others’ budgets rather than on one’s own).

SES theory in particular has been criticized for downplaying the contested nature of social interactions (e.g., the resilience of whom and at whose expense greater resilience comes) and the “wicked” complexity of society–nature dependencies (e.g., the fact that it is often the most vulnerable populations who are forced to live in the most hazardous environments). This argument proposes that these inherent social complexities and inequalities reveal that, unlike nonhuman ecological systems, not all human social systems can self-organize and adapt in any sort of optimal way, that is, there are usually winners and losers.

This complexity and the degree of latency involved, which blurs the predictability of how any particular population will actually react to a hazard-related disturbance, means that quantifying social resilience remains problematic. However, the evolving understanding of the many factors involved has allowed first attempts to be made at developing baseline indicators by which to measure and monitor the disaster resilience of places (Cutter, Burton, and Emrich 2010).

When considering community resilience in the context of natural hazards, a traditional view would be to focus on the interface between the hazard/disaster and the narrowly constrained emergency response, preparedness, and mitigation activities that have become the remit of civil protection practitioners (i.e., the emergency services). However, the focus has evolved from the simple questioning of whether a society would be more resilient if a perfect warning system, flood control measure, or response capability could be designed. It has been proposed that social resilience encompasses much broader issues. The lenses through which resilience has been viewed have revealed that social systems require a much broader and more complex frame through which to understand their resilience and how it is generated, regenerated, maintained, degraded, or lost, than can be provided within even the quite advanced sociotechnical hazard and risk management systems. Even with the best will, social resilience is not something that can be created purely through altruistic intent or policy directive. Understanding social resilience to environmental hazards increasingly requires a
recognition of the exposed populations’ broad entitlements and access to a range of capital resources, as well as the capability for them to be deployed and used effectively in ways that allow those people to “cope with a hazardous event or trend or disturbance, responding or reorganizing in ways that maintain their essential function, identity, and structure, while also maintaining the capacity for adaptation, learning, and transformation” (Field et al. 2014, 5).

Institute of Development Studies, UK

Vulnerability and social vulnerability

The term “vulnerability” is widely used in general and in a range of academic disciplines including psychology, social work, ecology, gender studies, sociology, anthropology, and geography. It has many definitions but is often used in a lax and undefined way, especially by the public, media organizations (including non-governmental organizations), and governments. Like the term “sustainability,” it is in danger of being used uncritically and of losing its validity as a basis for rigorous analysis. This is especially the case when it is used to convey ideas of victimhood or incapacity without reference to any particular threat.

“Vulnerability” is a term that is used to guide significant amounts of spending in welfare and health (including psychiatry) and in relation to environmental hazards. Because it is employed across disciplines, its academic use needs to be rigorous to counter its potential to mislead when used by media and politicians, who may find it convenient to use the term imprecisely. The primary difference between rigorous and lax usage concerns causation and attribution, and the need to specify:

- what has caused a particular entity (person, household, etc.) to be liable to suffer harm;
- what the specific threat is that is defined in relation to this liability to suffer harm.

This is especially important in regard to environmental hazards, and the modified term that is widely used in that context, “social vulnerability.” It is the causation aspect that tempts politicians to refer to natural disasters, because this enables them to avoid acknowledging that there are social factors that cause vulnerability over which they have some control.

Table 1 provides some of the more widely used definitions of vulnerability in relation to natural hazards; they do not necessarily refer to social vulnerability, as this tends to be taken for granted when authors refer to people and human systems. A general definition of vulnerability is the potential of an entity to suffer harm, which involves the characteristics of someone or something that may lead them to suffer as a result of a particular event or process. This is common to all the definitions given in Table 1. In terms of causation, it is therefore necessary not only to understand why the event can have harmful effects (e.g., the potential harm that can come from floodwaters, storm impacts, earthquake shaking), but also what causes the conditions that lead to possible harm (social processes that generate vulnerability).

Social vulnerability is a modification of the concept that emphasizes two aspects:

1. the objects of interest or the entity that exhibits vulnerability are people and the social system; and
2. the causes of vulnerability are to be found in social systems (i.e., the economic, political, and cultural aspects of society).
SOCIAL VULNERABILITY AND ENVIRONMENTAL HAZARDS

</table>

Note: See also weADAPT 2011; Adger 2006.

It is thus distinct from vulnerability, where the focus is on physical structures: although these structures are part of the social system, it has a different entry point and different policy connotations. Social vulnerability is therefore definable as the likelihood that people and the way they live will be harmed by a natural hazard because of the influence of economic, political, and social factors. In this definition, vulnerability is relevant when a hazard occurs: one can be vulnerable only in relation to a particular type of risk. This precision avoids the lax usage that ascribes vulnerability to poverty or marginality. While many poor people may be vulnerable to a flood, they may not be badly affected by an earthquake (poor people’s houses may be too flimsy to cause death or injury if they collapse).

Vulnerability should therefore be defined in relation to a particular hazard. The potential for harm is different depending on the type of hazard, the sort of damage it can do, and the particular characteristic (of a person or entity) affected. Vulnerability is therefore “activated” only in the context of a particular hazard. The likelihood of harm is a consequence of already pre-existing conditions that are socially constructed. However, there is an alternative view that considers vulnerability to be a characteristic that is independent of any particular hazard. This approach may be useful in identifying large cohorts of people who share general characteristics that they are likely to be harmed by a broad range of hazards, although it runs the risk of becoming unspecific, for instance, when the term vulnerability is correlated with poverty.

The widespread correlation of poverty with vulnerability should not imply that there is a simple causal relationship. Poverty is often
invoked in relation to disasters as part of humanitarian arguments against inequality and injustice and how these can be linked (as causal factors) with disasters. But it can be misleading, as is the common assumption that most disaster victims are poor. This is largely a function of the high proportion of poor people in many less developed countries: when it strikes, a hazard is likely to find many poor people exposed to it. Another related statement is that poor countries are “more vulnerable” because they are the ones that experience most (or the worst) disasters. Poverty may generally be a good predictor of negative impacts of a hazard, but it is entirely possible for a disaster to affect predominantly middle-income and even rich people, depending on their actual characteristics of vulnerability. For example, there are cases where a high proportion of death and injury caused by earthquakes has been suffered by the middle class, as in Izmir (Turkey) in 1999. This is typically a result of the people living in badly (and corruptly) constructed buildings.

Environmental hazards

These are defined here as hazards caused by processes of the natural environment. Other problems are often described as environmental hazards, but these are generally derived from human sources such as pollution (of soil, air, or water) which then affect or become embedded in the natural environment. Because these are caused by human action (industry, agriculture, transportation, mining, nuclear and other energy sources) they are not included here. This discussion of social vulnerability is related in the strict sense to environmental hazards that arise from geotectonic and climatological processes. However, environmental damage (e.g., air pollution, including greenhouse gas emissions, deforestation, built environment, and urban heat island effects) can intensify some natural hazards. This is especially evident with global warming and the causal link with extreme climate events (IPCC 2012).

Social vulnerability as a reflection of socioeconomic differences

As with earthquakes, each type of hazard needs to be assessed according to how particular characteristics of people and human systems may or may not be affected by it. Vulnerability varies across different categories of people according to the way economic, political, and social factors affect them. Gender is one significant differentiating factor that leads to higher and lower levels of vulnerability. In many parts of the world gender relations may make women more vulnerable than men to specific hazards. For example, in Bangladesh, traditional gendered behavior means that women are reluctant to evacuate to safety when cyclone warnings are issued unless they have the permission of their husband or a male relative. For this and other reasons (e.g., being responsible for the care of children and elderly relatives, and cultural prohibitions on learning to swim), mortality among women is often much higher. Another aspect of gender relations may make men more vulnerable, as for example when gendered culture is expressed as “macho” behavior. In some countries some men appear to be willing to drive into floodwater, resulting in higher male mortality rates (admittedly with a much smaller sample size). There is also some evidence in developed countries that husbands may experience more significant mental disturbance after floods, because of their sense of failure to protect their family and home. So social vulnerability in relation to gender behavior can have what appear to be opposite
SOCIAL VULNERABILITY AND ENVIRONMENTAL HAZARDS

effects, depending on the hazard and the cultural context.

Others key drivers of social vulnerability include class, caste, ethnicity, age, and (dis)ability (Wisner et al. 2004). Each of these factors may predispose particular people to be more or less likely to be harmed in relation to a specified hazard. The key analytical value of social vulnerability is that it enables disasters that are triggered by environmental hazards to be understood in relation to people's different characteristics as determined by social factors and processes. A key factor is the economic context. A poor person may have a weak immune system because of inadequate nutrition (often as a result of poverty). In a hazard such as a flood, where diseases transmitted through fecal contamination of water may be a danger, this can be a characteristic that increases vulnerability. Having a low-income livelihood may mean that a household cannot afford to improve its house to withstand a hazard, or that they can only pay low or no rent, and so live in a dangerous location (perhaps a hillslope in a city). However, having higher income is no guarantee that people will spend what it takes to live more safely, even when they are well aware of the hazards they face.

Political factors affect vulnerability in two ways. First, the power relations of a society determine the allocation of assets and production resources (e.g., land tenure systems in many countries are highly unequal and may be class- or caste-based), the income distribution and allocation of services (health and education), and welfare (unemployment pay and pensions). This can clearly affect aspects of vulnerability that are related to poverty, gender, ethnicity (discrimination in allocation of assets, income, services, and welfare) and disability. Many studies of the impact of Hurricane Katrina in 2005 argue that these factors were very relevant in the disaster. Resource allocation is also a very significant component of vulnerability in many less developed countries. Second, the type of power system affects the level of resources available to, and the efforts made to prepare for (and to respond to), disasters. For example, a government that restricts or represses civil society is likely to have a reduced level of disaster preparedness because NGOs and other organizations cannot advocate for risk reduction and are restricted from organizing their own activities. This political connection with vulnerability has been identified, for example, in Myanmar (in relation to Cyclone Nargis in 2008), China (in regard to several disasters and disease outbreaks), North Korea (famine), and the United States (Hurricane Katrina). A related political factor involves the freedom of the media, and the extent to which it can act without censorship. This link was famously made by Drèze and Sen (1989) in relation to famine, in a comparison of India and China: in the former, a relatively free media can act as a watchdog for the formation of food crises, while in China hunger and other disasters are concealed and those who might reveal them suppressed.

As the popularity of the perception of disasters as being socially constructed has grown in recent decades, a number of critiques and embellishments of the vulnerability concept have emerged. In the 1980s the notion of vulnerability was challenged on the basis that it led to a perception of people (especially in developing countries) as victims (Anderson and Woodrow 1998/1987). This critique argues that it is essential to acknowledge (and support) people’s own capacity in dealing with hazards. However, there is potential for confusion here: capacity can logically be seen as the opposite end of a vulnerability spectrum. Therefore people may have capacities in certain areas of their ability to withstand hazards but not in others. This approach was accompanied by a widespread
introduction, mainly by nongovernmental organizations (NGOs) and the International Federation of Red Cross and Red Crescent Societies (IFRC), of participatory vulnerability and capacity assessments that are designed to involve people at grassroots in reducing their own vulnerability.

A linked critique argues that the vulnerability concept arose among Western academics and ascribes to people in developing countries a “colonized” characteristic in which the concept helps fulfill power relations (e.g., Bankoff 2003). In disaster situations in developing countries, people are defined as vulnerable in order to provide justification for Western agencies (e.g., international organizations, development banks, and NGOs) maintaining a power hierarchy that privileges the developed countries as benefactors. This critique argues that greater allowance must be made for the people affected by hazards to exercise their own capacities. It also acknowledges people’s own culture and priorities rather than those of the outsiders who claim to be helping. This is part of a wider critique of disaster risk reduction organizations for giving priority to their own goals (“intensive risks”) when many of the risks that people face in developing countries are related to everyday (“development”) problems (e.g., of health, education, nutrition, crime) – what have been called “extensive risks.” This also shows that analysis of social vulnerability has mainly emphasized economic and political factors and excluded culture and people’s own notions of risk (IFRC 2014). Moreover, it relates to the fact that many people voluntarily expose themselves to hazards (e.g., in floodplains, volcanic slopes, coasts, and fault zones), often using cultural justifications (such as explaining the causes of disasters in religious terms or responding to them in a fatalistic way).

Measuring vulnerability and using vulnerability analysis

Vulnerability analysis, which refers to social vulnerability in the context of natural hazards, describes a range of tools developed in the research and the practice of organizations that conduct disaster risk reduction (DRR) activities. It emerged in recent decades, and is used mainly by NGOs and international organizations to assess different levels of vulnerability and their causes. In most cases, vulnerability analysis involves efforts to disaggregate people into different levels of vulnerability and to assess their likely harm in relation to natural hazards. Generically these assessments have been termed “community vulnerability assessments” (CRA) when they are conducted at the local level and are aimed at supporting DRR at the local level (often termed “community-based disaster risk reduction,” or CBDRR). A CRA is typically based on participatory methods (such as participatory rapid/rural appraisal, or PRA), and is usually claimed to involve the “community” in designing and implementing DRR activities. Most large NGOs, the Red Cross/Red Crescent, and international organizations have their own (very similar) versions of CRA (see IFRC 2006 for an example). There are more recent initiatives (mainly by large NGOs and some international organizations) to use similar methods for assessing vulnerability to climate change in order to inform and carry out community-based adaptation (CBA).

These approaches and activities tend to be based on an idealized notion of community, which lacks analysis of the causal factors (especially systems of power) that are involved in generating vulnerability. In other words, they ascribe to a normally very heterogeneous set of people in a location a collective characteristic, such as “vulnerable community.” This is partly in
tacit recognition of the inherent difficulty of changing power relations when engaged in short-term DRR or CBA projects (which are normally of three to five years’ duration). CRA methodologies assess key areas of social vulnerability, including livelihoods and their asset base, income levels and other economic variables, environmental hazards, and institutional linkages within and beyond the “community.” There is a tendency to sidestep or play down issues such as unequal access to land and other resources, and low income from poor livelihoods. These are typical vulnerability factors that cannot easily be addressed because of power relations and the short-term involvement of the outside organization. Analysis of local vulnerability that is actually caused by power systems is often absent, including assessment of land tenure, elite capture, and problems of participatory methods. This is also partly a function of how DRR and CBA are implemented: programs, projects, and their budgets are spatially restricted and focus on localities at the expense of understanding networks of power and systems of economic and political determinants of vulnerability.

At the macro (national and international) scales, there are other, more quantitative, initiatives to assess vulnerability to natural hazards and/or climate change. These tend to make estimates or use secondary information to assess the numbers of people exposed to relevant hazards of a specified territory, the type and potential intensity of those hazards, the likely effects on different components of the physical structures of that territory (e.g., infrastructure, built environment, health and education facilities, economic assets), and the degree to which mitigation and preparedness measures are in place for the relevant hazards. A recent approach is the World Risk Index (UNU–EHS 2014); others have included a “hot spot” approach that identifies locations that are “vulnerable” to particular extreme events (e.g., World Bank 2005).

What is the opposite of social vulnerability?

If social vulnerability is reduced, what is there instead? Is it capacity, capability, or resilience? This issue forms the basis for a great deal of discussion. One of the first challenges to the use of the term “vulnerability” came from people and organizations that considered it conveyed the idea of victimhood and portrayed vulnerable people as having little capacity of their own. As a result of this critique, CRA and vulnerability analysis claimed to respect and measure capacities (sometimes capabilities) rather than vulnerability alone. While the concern over labeling is understandable, it produces confusion as to whether vulnerability and capacity are conceptually different, or whether they lie on a scalar continuum with vulnerability (likelihood of being harmed) at one end and capacity (less likelihood of being harmed) at the other. Where the two are regarded as distinct, it becomes conceptually difficult to determine the basis of the difference between them.

More recently, the issue has been further complicated by the rise of the use of the term “resilience,” and more specifically of “social resilience.” Like “vulnerability,” “resilience” has origins in a number of disciplines (especially psychology, engineering, and ecology) and a very large literature both about the conceptualization involved and its application in policy. It has become standard terminology for a number of important international organizations and some aid donors (notably the UK Department for International Development, or DFID). It is
SOCIAL VULNERABILITY AND ENVIRONMENTAL HAZARDS

also incorporated into much of the academic and policy discussion about climate change. Whether resilience constitutes the basis for a separate conceptual and analytic approach is a significant debate. The term is becoming widespread, despite concerns that it is often used to avoid the need to determine causation. There is a danger that using the term resilience suppresses the need to ask why people need resilience and what has prevented them from being resilient already. There is considerable discussion of this, especially in regard to the conceptual difficulties of playing down vulnerability in favor of resilience in the social ecological systems framework (Béné et al. 2012; Béné 2013; Cannon and Muller-Mahn 2010; Miller et al. 2010).

Conclusion

As with many concepts in the social sciences, social vulnerability is located within debates and competing notions of causation (of disasters) and the relative significance of different types of attribution, framings (of the way in which hazards, social factors, and processes and exposure to risks interact), analytical traditions (geography, ecology, sociology), and political bias (the validity of social construction). The current rise of resilience as a means of framing preparedness for both disaster and climate change is likely to continue, mainly because of its adoption by donors and governments, and its influence on sources of funding. The main problem of whatever conceptual framework is the degree to which it allows for analysis of causation: of the reasons why people are harmed by hazards and climate change. If resilience as an approach can protect that necessity, it may become valid and have the potential to integrate development (improvement of human wellbeing and reduced vulnerability to risks of all types), climate change adaptation, and disaster risk reduction (through preparedness and prevention). Until 2015 these three areas have been dealt with internationally by three entirely separate United Nations processes: the Millennium Development Goals (MDGs), the Kyoto Protocol (under the United Nations Framework Convention on Climate Change, or UNFCCC), and the Hyogo Framework for Action (HFA). In 2015 each of these was revised. HFA has been replaced by the Sendai Framework for Disaster Risk Reduction, following the Third UN World Conference on Disaster Risk Reduction at Sendai. The MDGs have been replaced by the Sustainable Development Goals, and the Twenty-first session of the Conference of the Parties of the UNFCCC led to a new climate change agreement at the Paris meeting in December. Although there are signs of greater integration across these areas, they are still regarded by many as weak and inadequate. For geography and its academic and research contribution, there is a danger that political and funding preferences of donors and governments will continue to channel efforts into a parallel set of separate activities, despite the significant existing research that argues for integration across the three areas. Whether this is done in relation to a concept of social vulnerability or of resilience matters less than ensuring that the analysis is integrated and that it insists on understanding the social causation of vulnerability.

Social-ecological transformation

Ulrich Brand

Social-ecological transformation is an umbrella term which describes political, socioeconomic, and cultural shifts resulting from attempts to address the socioecological crisis. Under this conceptual and epistemic heading, such terms as green, great or social-ecological transition, great or societal transformation, green economy, and sociotechnical transition have increasingly come into use. Their goal is to provide a comprehensive understanding of current global environmental change and to contribute to a social and political strategy for dealing with the crisis. Research programs for the social sciences have been oriented accordingly (Hackmann and St Clair 2012).

The concepts and related debates have gained specific importance, first, due to the increasing acknowledgment that existing sectoralized and top-down forms of global or regional environmental management have failed and, second, in view of the “multiple crises” of the financial system, the economy, nature, energy provision, and food. There is a strong consensus in the literature that profound societal changes will be required in order to get a grip on these multiple crises. In the context of this consensus, however, the socioecological crisis is approached from the positions of divergent normative interests and different theoretical perspectives, with the result that a variety of different and even contrasting analyses and proposals concerning the ways out of the crisis have emerged (Brand et al. 2013).

The following noncomprehensive overview first addresses important flagship reports issued mainly by political organizations and think tanks. These are seen as indicators of a shift of perception within state apparatuses on various spatial scales and as an attempt to shape the corridor of social-ecological transformation. Second, key aspects are presented of the academic debate which have to some extent influenced these political flagship reports, but have also raised more fundamental theoretical and political questions. In the outlook, conclusions are drawn regarding a critical perspective on social-ecological transformation.

Social-ecological transformation in flagship reports

1 The concept of a green economy, which puts forward the claim of being able to overcome the economic and ecological crisis, was promoted before and around the Rio + 20 Conference in June 2012. The United Nations Environment Programme (UNEP) started its Green Economy Initiative in 2008. In 2011, it issued a comprehensive report in which it identified a “widespread disillusionment with our prevailing economic paradigm, a sense of fatigue emanating from the many concurrent crises and market failures experienced during the very first decade of the new millennium, including especially the financial and economic crisis of 2008. But at the same time, we have
seen increasing evidence of a way forward, a new economic paradigm – one in which material wealth is not delivered perforce at the expense of growing environmental risks, ecological scarcities and social disparities” (UNEP 2011a, 1).

In line with the United Nations Development Programme (UNDP), the United Nations Department of Economic and Social Affairs (UN DESA) argues for a great green technological transformation, with a scaling up of clean technologies, waste reduction, and sustainable agriculture. In its report with the same title, it states that a green economy “embodies the promise of a new development paradigm, whose application has the potential to ensure the preservation of the Earth’s ecosystem along new economic growth pathways while contributing at the same time to poverty reduction” (UN DESA 2011, v).

The European Commission has developed a plan for sustainable growth: the promotion of a resource-light, ecological, and competitive economy. In a communication of September 2011, the commission stated the necessity to fundamentally transform the European economy within the time span of one generation. It saw reducing resource use and increasing resource efficiency as key mechanisms for coping with environmental problems and resource shortages and, at the same time, strengthening European competitiveness (European Commission 2011; for a similar approach see the green growth strategy of the OECD 2011).

An example for an initiative at the national level is a report by the German Federal Government’s Advisory Council on Global Change (WBGU) entitled “Social Contract for Sustainability.” Its plea for a great transformation (WBGU 2011) specifically refers to Karl Polanyi’s concept in which he explains the passage to industrial capitalism during the nineteenth century, in order to emphasize the magnitude of the socioecological challenge. One point of departure is the assumed global transformation of values toward a sensitization for ecological questions (WBGU 2011). In order to promote and strengthen this transformation, the report states that a new “global social contract” (WBGU 2011, 8, 276) is needed. Central to realizing the great transformation, along with the transformation of values, are “pioneers of change” (such as innovative individuals, NGOs, and companies in all sectors of society and the economy) and a “proactive state” (WBGU 2011, 203). The latter is to create an adequate framework for change agents and to promote required innovations.

The common denominator of these reports and strategy papers is that they consider economic growth desirable, necessary, and capable of reconciliation with the environment. They express, first, a belief, akin to that which prevailed at the beginning of the sustainable development discourse in the early 1990s, that comprehensive win–win situations can be created; and second, firm trust in the existing political and economic institutions and elites, which they see as both able and willing to guide this process.

The shortcomings to particularly focus on are: first, the concepts argue for strong regulatory frameworks and thus neglect the prevailing power relations. In the current crisis, regulatory frameworks tend to develop in an authoritarian direction in order to secure access to resources for particular countries or regions (Lander 2011). Moreover, the economy which is to be politically regulated is mainly understood as the formal capitalist market economy. Accordingly, gender perspectives and their focus on social
reproduction and reproductive work are largely absent in the debate about a green economy (Deutscher Frauenrat 2011).

Second, whereas a relative decoupling of economic growth from resource use and environmental impact can be observed in many advanced capitalist economies, it is far from clear how the necessary absolute reduction might be achieved within the paradigm of economic growth. Since 2008, strategies for coping with the multiple crises have not gone hand in hand with the reorientation of production and consumption patterns designed to promote sustainability. They thus face the danger that improvements in resource efficiency may be overcompensated by the quantity of resources consumed in a growing economy (UNEP 2011b).

Third, neoliberal open-market policies and fierce competition have led to deindustrialization in many countries of the Global South. What is reasonable from a neoclassical perspective is that production that takes place where it is economically most efficient has pushed many countries into the new/old strategy of resource extractivism (Lang and Mokrani 2013). In most countries in Latin America, even in Brazil and Mexico, this seems to be the only viable development strategy capable of alleviating poverty. And it is the flip side of the green economy, since the rare Earth metals needed for green high-tech products mostly come from the countries of the south.

Finally, in addition to the universalization of the Western model of production, globalization implies what can be called an “imperial mode of living” (Brand and Wissen 2013). The logic of globalized liberal markets is reflected in the everyday practices in which access to cheap and often unsustainably produced commodities and labor power are normalized. Currently, this logic is being universalized among the upper and middle classes of newly industrialized countries. The social relations underlying the imperial mode of living, and possible ways for overcoming them, have hardly been challenged at all during this crisis and have been insufficiently reflected in the reports cited above.

The academic debate about social-ecological transformation

Aside from the political-strategic debate, there is also an academic debate over social-ecological transformation. Most of the approaches here have a longer history. Nevertheless, like the political debate, the academic one has gained momentum in the context of the current multiple crises. The various contributions emphasize, first, that socioeconomic, political, and cultural changes have to go beyond incremental steps and toward particular policy fields, such as climate change or biodiversity policies. Second, transformation is understood as a manifold nonlinear process, since it deals with dynamic, multidimensional, and complex systems as well as potential tipping points. Third, it is acknowledged that technical innovation is necessary, but not sufficient, while social innovation is central to social-ecological transformation (Brand et al. 2013).

Within this framework, several approaches can be distinguished, as follows.

1 The concept of social metabolism/socioecological transition developed in the interdisciplinary context of the Vienna Institute of Social Ecology. It conceptualizes social-ecological transformation from the perspective of the use of energy and material. The history of humankind is understood as a succession of “sociometabolic regimes” that differ in their energy sources and in the “colonization” of nature. Hunters and gatherers, the first sociometabolic regime, relied on the solar energy stored in the plants and animals available on their territory, but did not
social-ecological transformation

systematically influence the reproduction of these resources. By contrast, agrarian societies, while still relying mainly on solar energy, started to systematically intervene in nature – to “colonize” it – in order to enhance its productivity.

Industrial societies, the thus far last stage of human development, invented increasingly sophisticated and, at the same time, destructive forms of the colonization of nature. Even more important, they replaced reproducing biomass as the main source of energy with fossil fuels, which now, given the prevailing patterns of production and consumption in the Global North and the fact that two thirds of the world’s population are currently in transition from the agrarian to the industrial regime, is imminently threatened with exhaustion. Given further that the remaining fossil resources cannot be burned without exacerbating global warming, the social metabolism of industrial society today faces a fundamental crisis (Haberl et al. 2011). The current pattern can thus be understood as a “structural exhaustion of opportunities” (Fischer-Kowalski 2011) of the existing sociometabolic regime. It has given rise to a social-ecological transformation which may either take on the form of a catastrophic break with industrial metabolism or, if the patterns of energy generation and consumption are radically changed, may result in a new, sustainable sociometabolic regime.

Whereas the concept of social metabolism is mainly concerned with the physical basis of the social-ecological transformation, transition research and management focus on societal and institutional aspects as well as on technological and social innovation. Furthermore, their temporal and thematic scope is significantly narrower than that of the social metabolism/socioecological transition approach. Starting from the analysis of concrete transition processes in such sectors as energy and agriculture, transition research has developed a “multilevel concept” of major societal shifts toward sustainability (Verbong and Geels 2010), according to which transitions often originate in societal “niches,” then spread to the level of “regimes” (institutional structures), and finally contribute to transforming “landscapes” (the overall social, political, economic, and cultural setting). Radical innovation is considered to take place primarily in niches, while at the mesolevel of regimes, changes occur more incrementally because of path dependencies and lock-in processes. The interplay of the three levels is key to sustainability transitions which are understood as “long-term, multidimensional, and fundamental transformation processes through which established sociotechnical systems shift to more sustainable modes of production and consumption” (Markard, Raven, and Truffer 2012, 956). Transitions can be the results of evolutions and/or of clear-cut goals.

Transition management aims to utilize the findings of transition research in order to inform and shape the governance of concrete reform processes (Kemp, Loorbach, and Rotmans 2007). Collaboration between actors and learning processes is fundamental. Governance can influence cultures and discourses, actors and structures, as well as innovations in order to accelerate and trigger transitions. However, command and control strategies are not possible owing to the complexity and uncertainty of transition processes. The transition management approach sees its role in the debate
on social-ecological transformation as providing methodologies which are of practical and policy relevance (Wesely et al. 2014).

Transition research and management has been criticized by proponents of approaches in the tradition of practice theories (see Røpke 2009 for an overview). According to these theories, there is a producer and manager bias in transition management. Consumers and complex configurations of everyday life are treated more or less as external to the system of innovation. However, according to Shove and Walker, they are a constitutive part of it. Neglecting them conceptually is like an “act of writing to an audience that might not be listening” (Shove and Walker 2008, 1012). The crucial concept for a better understanding of the causes of the socioecological crisis, and for discerning possible ways out of it, is that of social practice. It refers to shared behavioral routines constituted by sets of interconnected elements: the social and political institutions that facilitate them, the sociotechnical configurations, such as the physical infrastructures, that enable them, the available knowledge and prevailing symbolic orientations that, consciously or not, guide them, and the forms of power that are inscribed in all these elements (Spaargaren 2011).

Because of its habitualized character, an environmentally detrimental social practice, such as driving a car, is only to a very limited extent accessible to intentional steering and management or to consciousness-raising campaigns. This makes social-ecological transformation a far more complicated process than it is assumed to be in transition research and management. It is a process which cannot be influenced from any preferential entry point, but which has to address the various elements which constitute social practices (Shove and Walker 2010). Overcoming automobility, to take this example, would require an understanding of driving, not only as a form of movement with the intent of relatively rapidly overcoming a distance, but also as an issue which has to be addressed in terms of the prevailing and power-laden conceptions of progress, freedom, and masculinity and their institutional and infrastructural manifestations.

The central motives and arguments in the context of the degrowth debate maintain that the orientation toward economic growth as the crucial point of reference of economic policy and as an indicator of prosperity and quality of life no longer holds (Kallis 2011). The issue of the suitability, or lack thereof, of markets as a mechanism for dealing with ecological and social problems is another core point of commonality. Some authors argue for an internalization of ecological and social costs; others go further and add that more structural changes as well as a decolonization of economics and of our minds from the domination of economism, and a move toward a different collective imagery, are the preconditions for meaningful change. Degrowth is “a multifaceted political project that aspires to mobilize support for a change of direction, at the macro-level of economic and political institutions, and at the micro-level of personal values and aspirations. Income and material comfort is to be reduced for many along the way, but the goal is that this is not experienced as welfare loss” (Kallis 2011, 878). Normative principles, such as cooperation and social justice, are being reintroduced, while social movements are seen as the major subjects of change. Many contributions to the debate
do not focus so much on crises or secular trends of diminishing growth rates in highly industrialized countries. Rather, they propose a “voluntary, smooth and equitable transition to a regime of lower production and consumption” (Schneider, Kallis, and Martinez-Alier 2010, 511). Degrowth is thought of as a conscious societal process based on a change of values.

Contributions from a critical geography/political ecology perspective (Robbins 2004; Perreault, McCarthy, and Bridge 2015) differ from the approaches described above in focusing more explicitly on issues of power and domination. Where the social metabolism approach addresses mainly physical materiality, political ecology also takes into account the materiality of social structures. In political ecology, the terrains and processes of governance, which transition management tries to shape in order to facilitate sustainability transitions, are less understood as solutions than as part of the problem. Like practice theories, political ecology focuses on the reproduction of social relations, but also addresses the contradictions inherent in them and, unlike the degrowth debate, the political ecology perspective sees economic growth as a social relation intrinsically linked to societal domination that reproduces social structures.

From a political ecology perspective, nature is societally – that is, socioeconomically, culturally, and politically/institutionally – produced and appropriated. The focus is not on “the environment,” but rather on the social forms of the appropriation of nature: that is, the forms in which such basic social needs as food and housing, mobility, communications, and health and reproduction are satisfied. This is not to deny the material peculiarities of biophysical processes for they are, under certain circumstances, no longer reproducible, but they are shaped by society. And conversely, the materiality of nature shapes societal processes. Importantly, the production of scale is considered crucial in transforming the conditions of access to natural resources and reshaping societal nature relations.

Political ecology argues that the metabolism of human society with nature, which is essentially mediated by labor, assumes a particular form in capitalist society: the production of use values for the sake of exchange value and/or profit; a hierarchy between capital and wage labor as well as other forms of labor; and, moreover, the development of a modern state separated from the capitalist economy and the class relationships. The dynamics of the capitalist economy consists of the valorization of human labor power and of nature.

Therefore, a crucial assumption regarding social-ecological transformation is that in modern capitalist societies, change takes place continually. “The bourgeoisie cannot exist without constantly revolutionizing the instruments of production, and thereby the relations of production, and with them the whole relations of society. Conservation of the old modes of production in unaltered form, was, on the contrary, the first condition of existence for all earlier industrial classes. Constant revolutionizing of production, uninterrupted disturbance of all social conditions, everlasting uncertainty and agitation distinguish the bourgeois epoch from all earlier ones” (Marx and Engels 1998/1848, 243). The decisive question is what kind of logic of transformation is to predominate.

Outlook

For a theoretically adequate understanding of transformation, it is useful to link political ecology with critical political economy and social
theory, especially critical state and hegemony theory. In so doing it can be shown that capitalist societies, with their tendencies to destroy their own material foundations, can in certain ways develop stabilizing forms of the societal appropriation of nature. The societal regulation of interaction with nature is possible and does in fact occur; herein lies a central dynamic of politics (Görg 2011). The regulation of societal nature relations does not imply abolition of the largely destructive forms of appropriation of nature. However, the destruction of nature will not necessarily become an urgent problem for overall capitalist development, since dangerous negative impacts can be spatially externalized and temporarily postponed. This can be seen in climate change, many effects of which will occur in the future; those that are indeed manifested in the present usually occur in more vulnerable, peripheral places. Crises will particularly occur at the local and regional levels – or are already occurring there today. However, that fact does not necessarily call the fundamental structures and developmental dynamics of capitalism into question. With regard to a possible scarcity of resources, we can also see that in the interplay of fears of global scarcity and local valorization strategies, the regulation of societal nature relations today means new exploration for tar sands, fracking for natural gas in slate formations, energy crops which involve the control and utilization of land, or a partial switch to solar energy. Insights into the changing forms of capitalist regulation help to understand the direction of capitalist development, for example, toward a selective greening of capitalism.

The thus enhanced critical concept of transformation focuses on complex societal and social-ecological relations and, in particular, on their dominant development dynamics. Moreover, it focuses on structures and processes by means of which society organizes its material foundations, including its metabolism with nature – socioeconomically, politically, culturally, and subjectively.

Such an analysis would consider the structure and power of sustainability discourses (Brand 2010) and the tendencies toward the “neo-liberalization of nature” (Castree 2008), that is, the shifting politico-economic and sociocultural dynamics of the appropriation of elements of nature. And it would acknowledge the still powerful structures, interests, and instruments of financial market capitalism. It would ascertain that in spite of all tendencies pointing toward greater sustainability, the state and the international political institutional system have tended to reinforce the dominant conditions and developments. The term “imperial way of living” (Brand and Wissen 2013) identifies a determining factor why very little is happening politically, along with such other factors as power strategies, including repression of criticism and alternatives, and political co-optation.

Again, this has political-strategic implications. First, research into social-ecological transformation needs to consider and evaluate the various strategies and possibilities for dealing with the multiple crises, that is, business-as-usual or more authoritarian alternatives, an imperial deepening of global fragmentation, social-democratic steering at various spatial levels, or more radical-democratic alternatives.

Second, analyzing hegemony, capitalist regulation, and its social forms means considering how the corridor of both top-down and bottom-up alternatives tends to be systematically narrowed down to a form of capitalist ecological modernization. It remains to be seen whether projects like the greening of the economy or green capitalism will be potentially capable of ushering in a new accumulation dynamic by changing the energy and resource base.
The question of a democratic shaping of society and of societal nature relations would appear crucial. That implies the democratic control of resource use, but also of the manifold processes of production and consumption. This is an important research perspective to determine what the already existing democratic forms of resource control are, which struggles will be necessary in order to generalize them, and how they are to be stabilized institutionally. It must also be determined which demands can be made in a comprehensive sense for the democratic structuring of society’s interaction with nature and to what extent the concrete strategies for a green economy or a green new deal have a supportive effect or not. Taking the perspectives presented into account, it would be necessary to evaluate whether, and to what extent, a “passive revolution” in the form of an eco-capitalist modernization might take place in response to the multiple crises and how it could be addressed from an emancipatory perspective.

The concept of socio-nature is used to argue that “society” and “nature” should not be analyzed in abstraction from one another but, rather, that they are inseparable and always already coproductive. It has been promoted as offering a radically reimagined political ecology, rooted in historical materialism but engaging with the processes of production that lead to heterogeneous material and discursive human and nonhuman entanglements. An extension and critique of the Lefebvrian notion of the production of nature, it represents an attempt to create dialogue between Marxist approaches and poststructural approaches such as actor-network theory. Theorists arguing for the concept of socio-nature reject Marxist contentions that nature is the substratum to society, while also contending that nature is not merely a social construction. Instead, focusing on historically and geographically situated materiality helps researchers to see that socio-natural entities are never fixed but are always in a process of becoming. The concept has been applied to diverse contexts, such as local food systems, gardens, and the politics of water resource management, and has been most influential within political ecology.

Erik Swyngedouw developed the notion of socio-nature in the mid-1990s from his readings of, in particular, Karl Marx, Henri Lefebvre, David Harvey, Donna Haraway, and Bruno Latour. Arguing that “society and nature, representation and being” are inseparable from each other in the city (1996, 66), he was critical of much research on the political economy of cities for its tendency to sideline environmental issues. Concurrently, he contended that the existing theoretical vocabulary was insufficient to develop a critical and transformative reading of cities. Although Marx had argued that social development has natural foundations, and that social relations transform the natural environment, so-called natural processes were still being characterized as external to the social. It has been argued that this focus on social transformations of nature might imply that “nature” is “subsumed under social control” (Swyngedouw 1999, 446) and that the separation of social and natural relations hides the processes that produce hybrids. In contrast, Lefebvre’s notion of the production of nature embodies material, representational, and symbolic practices; while insisting on the materiality of socio-nature’s component elements, Lefebvre argues that their “content can be approached only through the excavation of the metabolism of their becomings” (Swyngedouw 1999, 447). As such, he emphasizes process and flux as opposed to ontological essentialism. Swyngedouw’s significant theoretical intervention was to draw this Marxist literature together with the poststructuralist writings of authors such as Latour and Haraway to analyze how cities are produced as “hybrids” or “cyborgs.” Latour (1993) had famously argued in We Have Never Been Modern that “nature” and “society” are merely labels – the outcomes of processes of “purification” associated with modernity, and that this could be studied empirically by tracing the networks (involving human and non-human actants) through which “quasi-objects” or “hybrids” had emerged. Authors who have
employed the concept of socio-nature, however, argue that it is not sufficient to merely follow actants as they come to be enrolled in networks, as this could hide the historical-geographical processes through which they were produced. While there is nothing intrinsically ahistorical about actor-network theory, it is often associated with ethnographic work that traces networks in-the-becoming rather than after the event. Instead, proponents of socio-nature argue that Latour’s approach of following actants could be combined fruitfully with Lefebvre’s focus on temporalities. In such ways, the concept has been most influential as a dual critique of research on political economy that views “nature” as a mere backdrop to “society,” and of broadly poststructural research that has emphasized processes of becoming in the present, rather than histories of the processes of production that underlie them.

Through its roots in Marxist theory, work on socio-nature builds on the two related notions of “processes of production” and “metabolism,” which are explored in turn here. The focus on processes of production puts labor at the heart of analyses of socio-nature. In one sense, this is very similar to Neil Smith’s work on the production of nature, wherein nature is materially transformed through capitalist relations rather than preceding them. Here, a socio-natural analysis highlights the social in what might appear ostensibly natural. Beyond this, though, analyses emphasize the entangled “networks of power” that enroll and reconstitute “parts of nature” (Swyngedouw 2007, 10). The question, in other words, is not simply about what labor was involved in producing particular socio-natures, but also over the emergence of sociopolitical struggles, the mobilization of elite groups and concurrent “discursive and material enrolements of nature” (Swyngedouw 2007, 10). For instance, adopting this approach in a study of the genetic modification of plants would lead to a focus not only on the appearance of new plant forms. Instead, such an analysis might examine the uneven relations in the plants’ production, for instance contrasting the wealth and power of large multinational companies that research, develop, and patent seeds with the relative lack of power of small-scale African farmers. Such research might also examine the discourses that surround and entwine these socio-natures, exploring their changing meanings, values, and uses. In this sense, a genetically modified plant is never just a plant but it is an embodiment of historical-geographical processes that are always in flux and transience.

Metabolism was at the heart of Marx’s (1970, 283) conceptualization of labor, which he viewed as “a process between man and nature, a process by which man, through his own actions, mediates, regulates, and controls the metabolism between himself and nature.” However, Swyngedouw (2006, 109) argues that much Marxist analysis during the twentieth century sidelined these society–nature connections, viewing labor as merely social and, through this, ignored material metabolic relationships and partially blinded social sciences to questions of political ecology. He therefore promoted a re-engagement with the metaphor of metabolism, viewing metabolic circulation as “the socially mediated process of environmental – including technological – transformation and trans-configuration, through which all manner of ‘agents’ are mobilized, attached, collectivized, and networked” (Swyngedouw 2006, 113). Processes of metabolic circulation lead to the production of heterogeneous assemblages. While some authors view these assemblages as in many ways similar to Latour’s “hybrids,” those arguing for socio-nature claim there are fundamental differences. First, they contend that “hybrid” is suggestive of a mere mixing of ontologically separate or pure things, whereas metabolic circulation stresses that the constitution of cities
is intrinsically heterogeneous. Second, they are critical of Latour for being dismissive of the question of power; in actor-network theory, “power” is held and negotiated through networks and might become apparent through the research process, while analyses of socio-nature might take uneven power relationships as their starting point. While heavily influenced by actor-network theory, therefore, socio-nature cannot be viewed as an easy reconciliation of historical materialism with poststructuralism, but rather as an ongoing critical dialogue.

While offering a lens through which to view society–nature relations in general, work on socio-nature has tended to focus on specific projects, issues, or places. Through this geographical specificity has emerged a concern about the relationship between socio-nature and scale. Following Neil Smith’s (1984) contention that the process of producing scale can involve producing nature, Swyngedouw (2007, 11) maintains that “scale is not ontologically given, but socio-environmentally mobilized through socio-spatial power struggles.” By conceptualizing scale as emerging through relational processes, rather than as pre-given, socio-nature is again influenced by poststructuralists such as Latour, who critiques polarized ontologies of local versus global. In Swyngedouw’s reading, the scalar constitution of sociospatial relations forms through the forging of relational networks, which exist in dialogue with produced territorial configurations. In other words, socio-nature is not only an attempt to move away from artificial social or natural abstraction, but to see metabolic circulation as intrinsically embedded in a scalar politics. He grounds these ideas in his examination of changes in the Spanish waterscape under the Fascist political regime of General Franco. Under Franco’s direction, over 600 dams were built in Spain, leading to a dramatic shift in the country’s hydrological landscape. In this research, Swyngedouw shows how the techno-natural arrangements of rivers and dams produced new socio-natures; indeed, he contends that it is not possible to understand any form of “social” change in Spain without concurrently understanding changes to the hydrological process. They are, in other words, indistinguishable from each other. Central to these socio-natural changes was a particular scalar politics – also intrinsically bound up in metabolic circulations. This research shows how Franco’s physical reorganization of the country’s hydrological networks went beyond the practical goals of developing a reliable water supply and producing hydro-electricity and rested on: (i) a desire to eradicate regionalism; and (ii) a need to expand its geopolitical outlook in order to attract support and financial aid from the United States for the construction of dams and watercourses. In relation to the former, the material connections between once separate river basins, and the interbasin transfer of water, were designed in part to both integrate national territory and produce a coherent national cultural identity. In relation to the latter, for the hydrological transformation to take place, it was not possible for Spain to maintain a resolutely nationalist outlook. In this example, it becomes apparent that the metabolic circulations that produce socio-natures concurrently disturb essentialized notions of scale.

Literature on socio-nature often refers to the closely related notion of techno-nature, with some authors using the terms interchangeably. There is, in other words, some conceptual fluidity around the term. In some cases, “techno-nature” stands as shorthand for antipurification – an acknowledgment that nature is increasingly transformed by the interference of technology. Others argue that the concept has scope beyond this, suggesting that it denotes not only a quasi-object but also an ideology. Research on socio-nature has tended to employ
SOCIO-NATURE

the notion of techno-nature more specifically to refer to the enrollment of technologies by elite groups for the mobilization of particular socio-natures. Here, technologies provide some of the tools through which socio-natures are transformed, while also embodying particular socio-natural relations.

Research associated with socio-nature has tended to focus on its conceptual development and its practical applications, rather than on methodological implications and innovation. As a result, studies have drawn heavily on methodological approaches that developed alongside some of socio-nature’s theoretical influences, such as actor-network theory. While much research adopts a broadly similar “follow the actor” approach to that suggested by Latour, and while authors such as Swyngedouw acknowledge the agency of nonhumans, the focus of socio-nature analyses is often more explicitly on human actors. However, the concurrent and continuing focus on historical materialism frequently leads to detailed historical empirical research, documenting decisions around particular schemes, and tracing the uneven power struggles that lead to particular developments being rejected or achieving success. Swyngedouw’s examination of the (re)production of the Spanish waterscape offers a particularly clear example of such a historical focus. At the center of his analysis of these socio-natures in Spain is a focus on power. First, he is interested in how elite groups came to be in a position that allows them to reconfigure techno-natural arrangements. Through this, he emphasizes that Spanish society has organized itself partly in response to its desire to control water. Second, Swyngedouw explores the ways in which the relations bound up in socio-natures shift when there are changes to discourses around water, uses of water, management structures around water, or the materiality of water itself. In producing this analysis, he produces a forensic reconstruction of the events surrounding the waterscape’s gradual reconfiguration, concurrently detailing the physical and political (in its broadest sense) changes.

Socio-nature research is not only based on archival work, however. First, it increasingly draws on interviews and ethnography. Alkon (2013), for example, has examined how advocates of organic agriculture acknowledged the food it generates as the product of labor, but are likely to celebrate the role of farmers while ignoring the role of other (often immigrant) farmworkers. Rather than attempting to reveal a political truth, Alkon instead emphasizes the emergence of situated socio-natures and examines the ways in which labor practices and the agency of socio-natural entities are selectively rendered visible or invisible. Such work steers future research on socio-nature to explore the processes through which purification occurs, especially through the hiding of the labor process in socio-natural entities, rather than attempting to (merely) reveal the hybrid entanglements of socio-natures. Second, recent work on socio-natures has more explicitly engaged with flows and movements (the materiality of metabolic circulations). Linton and Budds (2013), for instance, emphasize the agency of water and point toward a fuller recognition of the political as not only encompassing but also potentially being driven by the nonhuman. This research has stressed water’s “unruliness,” which can result both in efforts to regulate and order it, and in its active disruption of social power structures. These authors have developed the related notion of the hydrosocial cycle to further highlight the inseparability of water’s social and physical dimensions. While emphasizing the intrinsically political nature of water, the concept’s resemblance to the widely known hydrological cycle also emphasizes the physical power, flow, and changing materiality of water.
This emphasis on the agential role of water itself addresses criticisms of work on socio-nature as being ontologically imbalanced toward the “social.”

In spite of the conceptual advancements associated with “socio-nature,” various criticisms have been leveled at its application to empirical contexts. First, while the concept stresses the demolition of nature/society dichotomies, addressed through the study of “materially discursive practices” (Swyngedouw 1999, 447), some commentators have criticized a tendency to focus on how quasi-objects such as water embody human political tensions and human social inequalities. In contrast, it might be argued that socio-nature retains many of the central arguments of actor-network theory but develops these in a theoretically coherent manner that responds to wider criticisms claiming that actor-network theory produces analysis that is more descriptive than transformative. A second criticism leveled at socio-nature is that it “redraws the very binary it seeks to upturn, naturalizing either the natural or social, while treating the other as something to be demonstrated through research” (Alkon 2013, 667). In other words, much of the applied research associated with socio-nature begins either with something ostensibly natural (and demonstrates how it is also social) or with something ostensibly social (and demonstrates how it is also natural). So, while focusing conceptually on historically and geographically situated heterogeneous assemblages, the concept’s application has (ironically, given its criticism of Latour’s hybrids) been critiqued for a tendency to either reproduce binaries or place greater emphasis on one “side” than the other.

The solid phase of soils contains both organic and mineral matter. Except for the small percentage of world soils composed of organic materials, most soils are dominated by mineral matter. Soil minerals provide structural support and the initial intergrain porosity necessary for adequate permeability and water storage. Soil minerals also provide a major contribution to soil reaction and mineral nutrition to plants. They function geochemically to buffer drainage waters, absorb and exchange nutrients and pollutants, and even function biologically as a home to microscopic organisms. Soil minerals are useful pedologically because they greatly impact soil development pathways and processes. Thus, they can be used to provide evidence of past soil-forming processes or used to determine the provenance of regolith (soil parent materials). The significance of soil minerals to the character of soils is widely recognized by land managers, who may use colloquial terms for the soil minerals, and by pedologists, who recognize mineralogy at various levels in soil taxonomic systems. Both the USDA’s Soil Taxonomy (USDA 1999) and the FAO’s World Reference Base for Soil Resources (FAO 2015) use soil mineralogy at various levels, ranging from the highest to lowest levels of the systems.

Soil minerals can be either primary or secondary. Primary minerals are those that originate in a rock-forming environment and are often thermodynamically unstable in the soil system and, thus, eventually become altered by chemical weathering. Secondary minerals are those minerals that form in the soil environment and are, therefore, more thermodynamically stable in the environmental conditions found in soils. Nonetheless, it is important to note that changing environmental conditions through time may lead to unstable secondary soil minerals as well.

Mineral groups present in soils

Minerals are classified by their chemical composition and crystalline structure. Seven major groups of minerals are recognized in nature, all of which may occur in soils, but their prevalence in any soil geographic region is a function of factors such as the origin of the regolith the soils have formed in (parent material), climate control on mineral formation or degradation, and the age of the soil, which impacts how weathered the soil mineral suite will be. The mineral groups described here occur over large areas of the globe or are important to understanding soil formation and behavior.

Halides, sulfates, and other very soluble minerals are composed of elements ionically bonded as salts. Common soil minerals in this group are halite (NaCl) and gypsum (CaSO₄•2H₂O), which can occur in parent materials, but more typically form in the soil environment under dry climatic conditions. In soil classification, the importance of these minerals to formation and use of the soils is recognized by salic and gypsic diagnostic horizons in Soil Taxonomy, and by reference soil groups (RSGs) such as Gypsisols in the World Reference Base (WRB). Soil management issues arise when using these soils for irrigated agriculture, because these salts...
are often toxic to plant growth or can cause nutrient uptake imbalances. Drainage of salty irrigation waters may also cause ecosystem stress in receiving basins.

The most common sulfide mineral in soils is pyrite (FeS₂), which may occur in geological deposits, but also forms in wet coastal settings such as tidal flats. Oxidation of pyrite leads to the formation of sulfuric acid, which produces extremely acid conditions (pH < 4) in soils, severely limiting plant growth. Such soils are known as acid sulfate soils. Geographically, these soils occur in low-relief marine coastal regions and present challenges to agricultural and building development, largely because the sulfates become more pronounced after the soils are drained and aerated.

Carbonate minerals such as calcite (CaCO₃) and dolomite ((CaMg(CO₃)₂) are extremely widespread and important soil minerals, and are geographically diverse in their occurrence. Carbonate minerals occur as primary minerals in many Pleistocene-aged, glacial and eolian deposits of mid-latitudes. In humid climates, these minerals are leached from soils by acidic, percolating soil waters. The depth of dissolution and leaching of these minerals acts to delineate the boundary between genetic soil horizons and the (C horizon) parent material. Calcite also occurs as a secondary mineral in soils of semi-arid and arid regions, forming in situ or accumulating as wind blown dust and washed into the soil by rain. Forms of secondary calcite accumulation in soils have been studied quite extensively, enabling their use as calibrated and relative dating features in soils in the southwestern United States and elsewhere. Classic studies have recognized up to six stages of morphological expression of secondary carbonate, ranging from accumulation of minor masses and pendants to entire horizons completely engulfed and cemented to the point that additional deposits of secondary calcite accumulate in a laminar fashion on top of the cemented horizon (Gile, Peterson, and Grossman 1966; Machette 1985). These studies show that, for many soils, the accumulation of secondary calcite and carbonates is time-dependent and thus related to the age of the land surface. Evaporation of capillary water associated with shallow groundwater is another mechanism of calcite accumulation that has historically led to confusion in soil geomorphic interpretations. The occurrence of secondary calcite in various forms is important to land use and soil classification. Soil Taxonomy recognizes calcic and petrocalcic diagnostic horizons, which impact classification at several taxonomic levels, while WRB recognizes the RSG Calciols and the qualifiers calcic and calcareous.

With few exceptions, calcite is the dominant secondary carbonate mineral in soils, making secondary carbonates in soils a significant carbon sink in the terrestrial carbon cycle. Estimates are varied and dependent on calculation methods, but secondary carbonate minerals are believed to account for approximately 38% of total carbon stored in soils.

Oxide minerals are those with a metallic cation bonded with the oxide anion (O²⁻). Oxide minerals comprise a diverse group. They include residual primary and secondary minerals of low solubility, as well as secondary minerals that form and dissolve with changes in soil redox (oxidation–reduction) conditions. The most stable oxide minerals in soils are those formed with the cations titanium and zirconium, namely the minerals rutile and zircon. While only comprising a small fraction of most soils, their extreme low solubility implies that they can accumulate residually in soils that are experiencing chemical weathering. Therefore, they can be used as a stable index mineral to assess parent material uniformity, the degree of chemical weathering when compared to the parent regolith, and to
SOIL AND CLAY MINERALOGY

determine the volumetric changes (collapse or expansion) that soils have experienced during pedogenesis.

Iron oxides are probably the most important oxide minerals in soils. Iron oxide minerals refers to what is more correctly named iron oxyhydroxides and hydroxides, which denotes their structures as consisting of various crystalline and poorly crystalline forms that have hydroxide groups and water molecules as part of their atomic structure. Structural differences produce different physical and chemical properties of the iron oxides and are used as the basis for classifying and recognizing the various iron oxide mineral types. A thorough treatment of iron oxides is not possible here, but recognizing that most red, brown, and yellow colors in subsoils are a function of the type and crystallinity of iron oxides present is critical. They are a very important pigment, especially in subsoil horizons, enabling their occurrence and red-brown colors to be used in environmental assessments of wetland hydrology and for on-site waste disposal. A lack of strong subsoil pigmentation is typically attributed to the lack of appreciable quantities of iron oxides and is thus used to determine that soil redox chemistry has crossed a threshold and enabled the iron minerals to be chemically reduced. Because iron has such a strong affinity for oxidation, the reduction of iron connotes environmental conditions that are limiting the presence of oxygen, while also providing a source of electrons for reduction. Typical conditions for limiting oxygen, and thus creating anoxic conditions in soils, include soil saturation or compaction, while the source of electrons to cause reduction is from microbial respiration. Iron oxides are known to adsorb phosphorus, thus limiting ecosystem productivity and agricultural development; they can adsorb heavy metal pollutants as well.

Manganese is a related transition metal that behaves similarly to iron in redox reactions, but is not considered as important because it is less abundant and is less important as a pigment. Nevertheless, in certain soil systems manganese oxide minerals can be important in the formation of black and bluish pigments, and their presence as coatings in soils provides information about soil redox and/or pH conditions that allow mobilization and precipitation of manganese.

The aluminum hydroxide gibbsite, Al(OH)₃, is the most common secondary mineral that forms in soil environments. Gibbsite exhibits extreme low solubility and is most important in soils that have experienced severe, long-term weathering, such as some tropical soils. Gibbsite and other less-frequently occurring aluminum oxide minerals are not strong pigments and do not behave like iron and manganese, so have received less attention in the literature. Poorly crystalline and amorphous aluminum compounds are important in many soils, and are used in recognizing certain kinds of soil horizons, but are not considered further here.

Taxonomically, oxide minerals in soils are also very important. They are used to define mineralogy classes of soils at even the highest levels of classification, for example, the soil order Oxisols in Soil Taxonomy and the RSG Ferralsols. In addition, pigmentation produced by the presence/absence of oxide minerals is important in recognizing lower levels of taxonomy, such as aquic subgroups in many soil orders, along with the qualifiers in WRB.

Silicate minerals are the largest and likely the most important group of soil minerals. Silicate minerals have as their basic structural organization the silica tetrahedron, formed through the bonding of one silicon atom with four oxygen atoms. Silicate minerals are divided into groups based on how many oxygen atoms
SOIL AND CLAY MINERALOGY

Figure 1  Ball and stick representations of silicate mineral structures, arranged according to increasing sharing of O\(^{2-}\) at the corners of silica tetrahedra: (a) neosilicates, or isolated tetrahedra; (b) sorosilicates, which share one corner of each tetrahedron; (c) cyclosilicates, which share two corners of each tetrahedron; (d) single-chain inosilicates, which share two corners of each tetrahedron; (e) double-chain inosilicates, which share two or three corners of each tetrahedron; (f) phyllosilicates, or layer silicates, which share three corners of each tetrahedron, all in the same plane; (g) tectosilicates, such as quartz, which share all four corners of each tetrahedron in a 3-D network. Source: Adapted with permission from Schaetzl and Thompson (2015). Cambridge University Press, Cambridge.

are shared between tetrahedra, the geometrical arrangement of the linked tetrahedra, and the type and number of other cations bonded into the structure (Figure 1). In general, a greater degree of oxygen sharing leads to greater stability of the minerals and, thus, increased resistance to weathering. Quartz is the dominant silicate mineral in many soils of the world, reflecting its stability and resistance to weathering, which results from a dense network of shared silicon and oxygen bonds. Its resistance to weathering allows quartz to accumulate as a residual product in many highly weathered soils. Like some of the oxide minerals discussed previously, the stability of quartz allows it to be used as a stable index mineral, in comparison to other, more weatherable, silicate minerals.

Many silicates are primary minerals that originated in rock-forming environments, for example, quartz. However, there are some notable examples of secondary silicate minerals that have formed in soils proper. The latter minerals are important to interpreting pedogenic environments or paleoenvironments of
soil formation. The most important secondary silicates are phyllosilicate minerals and opal. Opal in soils is most commonly the result of biogenic formation of phytoliths in plant cells and is used as an indicator of the type of vegetation growing on the soils. Grasses and sedges tend to be the most prolific producers of biogenic opal and, in combination with the study of phytolith forms, can be used to interpret the occurrence of vegetation communities during soil formation.

Perhaps the most important group of silicate minerals in soils is the phyllosilicate minerals, which are also called layer- or sheet-silicate minerals. The terms layer or sheet silicates are commonly used because the structural units of the minerals run in long layers, or sheets, rather than more complicated 3-D crystalline networks typical of other silicate minerals such as quartz. To complicate matters, most phyllosilicates in soils occur in the clay-size fraction (e.g., <2 μm diameter), so the term “clay minerals” is applied to these minerals, even though many other mineral groups also occur in the clay fraction. The reason for the strong interest in these minerals is that they possess a negative electrical charge that has tremendous environmental importance, namely the ability to attract and retain cationic substances, referred to as the cation exchange capacity (CEC). The negative electrical charge is produced by the substitution of cations of lower charge into the structure (e.g., substituting Al\(^{3+}\) for Si\(^{4+}\) in the tetrahedron), resulting in a crystal structure with a negative charge imbalance. The CEC of a soil is of utmost importance to agricultural productivity through the retention of plant nutrients that behave as cations.

Phyllosilicates in soils may be primary or secondary, but it is the secondary mineral types, or clay minerals, that receive the most attention in soil science, because they form in the soil environment. Thus, they reflect a variety of soil-forming factors and environmental conditions, such as duration of weathering and soil solution chemistry as influenced by plant uptake, acid leaching, or drainage water concentration. The most common primary phyllosilicates are chlorite, muscovite, and biotite mica, which are common in igneous and metamorphic rocks, while muscovite mica is also a common constituent in sedimentary rocks. Serpentine is a primary phyllosilicate mineral in soils that originates from ultramafic volcanic rocks. While not widely distributed, where serpentine occurs the soils are often toxic to plants because of low concentrations of ecosystem-essential elements and high levels of toxic metals.

Phyllosilicates are classified on the basis of structural and compositional criteria. The first criterion is how the layers of cations are structurally coordinated with oxygen atoms. The cations are organized in sheets of linked tetrahedra or octahedra. In an octahedron, the cations are bonded with six oxygen atoms, which forms an eight-sided structure. Silicon is the main cation of tetrahedral layers and aluminum is the most common cation in octahedral layers, but these cations are readily substituted, which creates a negative layer charge and may define different mineral species. The broadest grouping of phyllosilicates is as 1:1 or 2:1 minerals (Figure 2). The 1:1 minerals have one layer of cations coordinated as tetrahedra and one layer as octahedra. Kaolinite is the most common 1:1 mineral. The 2:1 minerals have two layers of tetrahedra that are separated by an octahedrally coordinated layer of cations. Illite, vermiculite, and smectite group minerals are all common 2:1 minerals. Other criteria related to crystal structure composition or arrangement are also used by mineralogists to further define mineral species within these groups.

A critical feature used to define different minerals and their change through weathering is the nature of any material in the interlayers between the 1:1 or 2:1 sheets. For example, the interlayers
SOIL AND CLAY MINERALOGY

From left: 1:1 minerals kaolinite and serpentine; halloysite with interlayer water; 2:1 mica group with interlayer potassium residing in a cavity in the tetrahedral sheet that bonds the layers together; vermiculite with hydrated interlayer cations such as Mg\(^{2+}\); smectite group with expanded interlayers and hydrated cations; chlorite (2:1:1) with a continuous interlayer of octahedrally coordinated cations; hydroxy-interlayered vermiculite or smectite with clusters of octahedrally coordinated cations, commonly Al\(^{3+}\). Source: Adapted with permission from Schaetzl and Thompson (2015). Cambridge University Press, Cambridge.

of muscovite and illite have potassium (K\(^{+}\)) ions that act to bond the 2:1 layers together. Loss of interlayer potassium from these minerals results in greater charge imbalance and greater CEC of the resulting minerals, unless satisfied by another substance. The nature of the interlayer is very important to the identification and behavior of certain clay minerals. For example, smectite group minerals primarily have water in the interlayer position, and the drying and re-wetting of the interlayer causes large shrink–swell volumetric changes that affect land use.

Another example is the infilling of the interlayer by relatively insoluble aluminum hydroxide layers, producing minerals known as hydroxy-interlayered vermiculite (HIV) or smectite (HIS), which tend to reflect acidic, soil-forming environments of humid climates.

In the soil environment, secondary phyllosilicates form via the transformation of existing phyllosilicates, alteration of primary minerals (mostly silicate minerals), or by crystallization from soil solution components. Specific mechanisms of formation are not well understood because of the fine size of clay minerals, but recent innovations in high-resolution transmission electron microscopy have yielded new evidence. Some mechanisms of mineral formation include (i) the removal of cations from the crystal structure, as in illite losing interlayer potassium to become vermiculite; (ii) the hydrolysis of silicate minerals with synthesis of phyllosilicate minerals at the interface, as for instance smectite forming from basic primary minerals and, with more total hydrolysis removing even silica, kaolinite forming from feldspars or other 2:1 phyllosilicates; and (iii) the formation of hydroxy polymers that fill the interlayers of 2:1 clays, such as vermiculite.

Geographically, the occurrence of secondary clay minerals has been demonstrated to be related to climate and landscape stability (Folkoff and Meentemeyer 1987). In humid tropical and subtropical climates, low–activity clays such as kaolinite dominate soils, especially in older soils (Figure 3). Smectite or other 2:1 clays are common in tropical or subtropical soils that occur in
climates less conducive to leaching or that have soil-forming conditions that retain basic cations or supply inputs of fresh, base-cation-rich, parent materials, such as from volcanic ash. In high latitudes and the humid mid-latitudes that are dominated by Pleistocene glacial and periglacial deposits, the clay minerals are typically mixed, containing 1:1 and 2:1 minerals in variable concentrations that reflect inheritance from parent materials. Only the upper soil horizons show appreciable infilling with hydroxy interlayers to form HIV/HIS or degradation of illite to form vermiculite or smectite. In arid regions, where weathering is typically minimal due to the
dry conditions, secondary phyllosilicates largely reflect parent material inheritance. However, experimental and field evidence suggests potassium ions may refill the interlayer space of some high-charge clay minerals such as smectite, thus producing the widespread occurrence of illite in arid-region soils (mica in Figure 4) (Wilson 1999).

Soil Taxonomy and WRB both recognize the importance of clay minerals. For instance, the order Ultisols and the RSGs Lixisols, Acrisols, and Nitosols are groups with low-activity clays, namely kaolinite, with low amounts of charge. Low available charge tends to limit agricultural or ecosystem productivity and is typically interpreted to be the result of long-term weathering. A prevalence of smectite, with its shrink–swell potential, is the hallmark of the Vertisols in both taxonomic systems. The shrink–swell activity in Vertisols causes notable microlandforms, known as gilgai, and also presents hazards for building development. Other soil orders and RSGs are not determined by specific content or types of clay minerals present, but it is important to note that most intensive agricultural regions of the world have clay fractions dominated by mixtures of 2:1 minerals with high CEC.

Soil microbes and invertebrates and their roles in soil ecosystems

Soils contain living (biomass) and dead (necromass) organic matter, with varying amounts of gases and liquids, all within a structural matrix of mineral particles. The interactions between the various geological, hydrological, and atmospheric facets overlap with those of the biosphere, leading to the union of all, overlapping in the pedosphere. Soils, in addition to the three geometric dimensions, are also greatly influenced by time, the fourth dimension, over which the physicochemical and biological processes occur.

Plants and soil biota (microbes such as bacteria and archaea), and fungi and fauna (mostly invertebrates, including protozoa, nematodes, small arthropods, and worms) are of vital importance to soil formation and pedogenic processes. Plants introduce organic substrates into soils as products of growth, senescence, and death, while soil microbes and invertebrates utilize these organic substrates as an energy source and in the process contribute their own organic substrates through consumption, growth, and death. For microbes, the dominant constituents include microbial cell wall residues. For fungi, the main constituents are extracellular polysaccharides, carbohydrates, and amino sugars (glucosamine, galactosamine, and muramic acid). The diversity of archaea and bacteria is as yet little known, but with the use of new massive parallel sequencing devices, we are beginning to develop an appreciation of the very large biodiversity of these organisms as well.

Soil fauna may also be characterized by their presence/absence in the soil, or by their microhabitat utilization (Figure 1). Transient species, exemplified by the ladybird beetle, hibernate in the soil but otherwise live aboveground in the plant stratum. Gnats (Diptera) are temporary residents of the soil; the adult stages live aboveground. Their eggs are laid in the soil and their larvae feed on decomposing organic debris. In some soil situations, dipteran larvae are important scavengers. Cutworms are only temporary soil residents; their larva feed on seedlings by night. Some nematodes that parasitize insects and beetles spend all or part of their life cycle in soil. Periodic residents spend their life histories below ground, with adults, such as the velvet mites, emerging only to reproduce. The soil food webs are further linked to aboveground systems, making trophic analyses much more complicated than in either subsystem alone. Even permanent residents of the soil may be adapted to life at various depths within it, depending on their daily or annual life cycles.

Among the microarthropods, such as mites and collembola, the latter are examples of permanent soil residents. The morphology of collembolans reveals their adaptation for life in different soil strata. Species that dwell on the soil surface or in the litter layer may be large, pigmented, and equipped with long antennae and a well-developed jumping apparatus (furcula). Alternatively, collembolans living within mineral soil tend to be smaller, with unpigmented, elongated bodies, and they possess a much reduced furcula.
A generalized classification of soil biota by length illustrates a commonly used device for separating the soil fauna into size classes based on body length: microfauna, mesofauna, macrofauna, and megafauna (Figure 2). This classification encompasses the range from smallest to largest fauna, that is, from circa 1–2 μm for the microflagellates to >2 m for giant Australian earthworms. Body width of the fauna is related to their microhabitats. The different kinds of fauna tend to occupy different habitats. For example, the microfauna (protozoa, rotifers, tardigrades, nematodes) inhabit water films. The mesofauna, such as mites and collembolans, occupy existing air-filled pore spaces and are largely restricted to these kinds of existing spaces. The macrofauna, for example pocket gophers, have the ability to create their own spaces through their burrowing activities, and like the megafauna, can have large influences on gross soil structure.

Methods for studying these faunal groups are therefore mostly size-dependent. The macrofauna may be sampled as field collections, often by hand sorting, and populations of individuals are usually measured. There is considerable gradation in the classification based on body width. The smaller mesofauna overlap with the size range of the microfauna, and so forth.

The vast range of body sizes among the soil fauna emphasizes their effects on soil processes at a range of spatial scales. Three levels of participation may be suggested: (i) “Ecosystem engineers,” such as earthworms, termites, or ants, alter the physical structure of the soil itself, influencing rates of nutrient and energy flow, (ii) “Litter transformers,” the microarthropods, fragment decomposing litter and improve its availability to microbes, and (iii) “Micro-food webs,” which include the microbial groups and their direct microfaunal predators (nematodes and protozoans); these fauna are all key players in nitrogen and phosphorus remineralization, particularly in root rhizospheres and decomposing plant material. These three levels operate on different spatial and temporal scales.
Fauna affect soils both biochemically and biomechanically. Although most of the discussion below focuses on biochemical effects [(ii) and (iii)], it is important to note that mega- and macrofauna are key components of soil development from a biomechanical perspective (i). The larger fauna are particularly important as biomechanical instruments, moving soil particles around via a process called bioturbation (Johnson 1990; Johnson, Domier, and Johnson 2005). Bioturbation is an important slope process, assisting in the creep of materials downslope, and it is also a key component of the genesis of certain soil types. Recent data have shown that soils undergo very different genetic pathways and their morphology changes rapidly, when bioturbators such as earthworms are introduced.

**Interactions of soil organisms and organic matter; aggregate formation and breakdown**

Decomposing organic matter is the main source of food for the soil fauna; hence they are attracted to it. As organic matter decomposes, however, its fate and influence on soil biota are far from being linear or additive (see entry Soils and the carbon cycle). Some forms of organic matter contribute to the stabilization of other forms, and the collective contributions of biota to the process lead to counterintuitive results. Nowhere is this more evident than in the emerging understanding of the role of soil microbes and fauna in the formation and degradation of soil aggregates, the importance of consortia of microbes to the
decomposition of complex organic compounds, and the relationship between changes in the flow of nutrients through food webs and the rates of mineralization.

Soil aggregates are composed of sand, silt, and clay particles that are bound together by soil organic matter (SOM) and inorganic compounds. Aggregates are hierarchically classified into water-stable size classes based on their solubility. The smaller size classes include a silt and clay fraction (<53 μm) and microaggregates (53–250 μm). These smaller factions combine with coarse particulate organic matter (CPOM, >250 μm) to form small macroaggregates (250–2000 μm), which in turn all combine with organic matter in the form of free light fractions (particulate organic matter outside of aggregates (POMLF) and residues (intra-aggregate particulate organic matter, or iPOM, 250–2000 μm) to form large macroaggregates (>2000 μm). The organic components originate largely from plants in their original forms, surface litter, structural materials, and roots and root products (sloughed cells, exudates, and mucigels). These compounds are further degraded by microbes and invertebrates, resulting in the primary binding agents that are mostly microbial in origin (Six et al. 2004); it is these components that function best in the formation of aggregates.

**Faunal feeding effects; the phenomenon of “optimal grazing”**

Apart from the transformation and direct inputs of organic substrates, soil invertebrates indirectly affect the decomposition of organic substrates by enhancing the activities of soil microbes through grazing, comminution, and dissemination (Coleman, Crossley, and Hendrix 2004). Moderate levels of consumption of microbes by protozoa and invertebrates can stimulate further microbial growth through the principle of *optimal grazing*. Assuming that microbes exhibit logistic growth tied to available resources with a carrying capacity K, microbial growth rates are maximized (“optimal”) at population densities of K/2. Higher growth rates translate to increased utilization and transformation of organic substrates and increased production of microbial-derived organic substrates. Given that invertebrates consume more nitrogen than they require for growth (i.e., invertebrates are net mineralizers of nitrogen), enhanced microbial growth through grazing and subsequent excretion leads to increased nitrogen availability for plants. When this process plays itself out within the rooting zone of plants, a positive feedback can occur wherein plants and the soil food web feed off one another’s excess and waste. Under this scenario, plants exude excess photosynthate in the form of labile carbon substrates from their roots, which in turn are utilized by microbes and subsequently as food for microbivorous invertebrates, and these microbes then release nitrogenous waste that is utilized by plants.

Many invertebrates feed directly on plant materials and organic substrates. The fragmentation or comminution of these materials by soil fauna enhances their decomposition. For plant structural materials, comminution increases the surface areas of the materials and exposes cytoplasm, thereby enabling greater access by microbes. Decomposition is further accelerated as the feeding activity often results in the translocation of nitrogen from the soil to the substrate in the form of fecal material and through fungal hyphae. Grazing by invertebrates disseminates microbes from one organic source to another as many microbes adhere to invertebrate exoskeletons and cuticles and survive passage through their digestive tracts.
Towards an integrative framework for soil and soil organisms interactions

Soil fauna exist in food webs containing several trophic levels (Moore and de Ruiter 2012). Some are herbivores, since they feed directly on roots of living plants, but most are microbivores, subsisting upon dead plant matter or living microbes associated with it, or a combination of the two. Still others are carnivores, parasites, or top predators. Analyses of soil food webs have emphasized the numbers of the various organisms, as well as their traits, and trophic resources. The structure of these food webs is extremely complex, with many “missing (poorly described or unknown) links,” although tools such as stable isotopes are revealing C and N transfer through trophic and species levels within the soil food web (Crotty et al. 2012).

A framework that links soil microbes and invertebrates directly to pedogenic processes, as described above, is beginning to emerge. Soil food webs and the differences in microbial and invertebrate life forms within them offer a starting point to connecting the components of the detrital food web to soil pedogenesis and SOM dynamics (Coleman, Crossley, and Hendrix 2004). Coleman et al. earlier identified a bacterial-based fast cycle and fungal-based slow cycle within soils. Subsequent studies revealed that these fast cycles and slow cycles were borne from the trophic interactions of detritus to bacteria and their consumers, and from detritus to fungi and their consumers. These dominant trophic pathways, or “energy channels,” are ubiquitous across ecosystem types and grounded in the basic architecture of soil food webs and their structural stability. This complexity can be condensed into the dominant pathways beginning with pools of detritus or SOM that differ in quality. These pools would serve as the primary energy sources for a suite of bacteria and fungi, each of which is consumed by a host of microbial consumers and predators. Metabolic wastes and by-products that cycle back as energy sources and binding agents would be factored in, much as C and N are in the current generation of models. This approach preserves the basic premise of material transformations that occur in the soil carbon models and material transfers that occur in food web models in a way that provides a common currency.

In more arid regions, for example large areas of the Sahel, Australia, and the arid regions of North America, the keystone roles of termites in transporting and concentrating both organic and inorganic nutrients are of similar magnitude to that of earthworms in more mesic habitats (Whitford 2000), and should be borne in mind when considering faunal effects on SOM on a global scale.

Changes in land use and impacts on detrital food webs

The impacts of changes in land-use practices are of increasing interest to ecologists worldwide. With changes from agroecosystems to pasture lands and longer-term succession into forested ecosystems come significant changes in the detrital food web. Thus the more frequently disturbed tilled agricultural system tends to be more bacterial-dominated versus the fungal-dominated no-tillage or pasture land (Wardle et al. 2004). Land abandonment by humans is another form of land-use change. Soil communities respond more slowly to changes occurring with land abandonment than in the communities aboveground. Slow development of the belowground community may be an important factor controlling ecosystem services and the outputs (goods) provided by these restored ecosystems (Wardle et al. 2004).
Roles of soil fauna in ecosystems worldwide

Global experiments and syntheses have continued to address and quantify the role of soil fauna in ecosystem processes and, in particular, have led to increased evidence for their contribution to C cycling. Global multisite experiments have shown that soil fauna are key regulators of decomposition rates at a range of scales, even at biome and global ones. García-Palacios et al. (2013) conducted a meta-analysis on 440 litterbag case studies across 129 sites to assess how climate, litter quality, and soil invertebrates affect decomposition. This analysis showed fauna were responsible for approximately 27% average enhancement of litter decomposition across global and biome scales.

Information about the role of soil fauna in food webs and how it will respond to environmental change and influence aboveground processes has advanced considerably. Loss of species due to varying management practices, such as erosion, pollution, urbanization, and the resulting effects on ecosystem function and services, are becoming widely recognized. These resulting changes are related to larger issues of biodiversity loss, desertification, and elevated greenhouse gas concentrations, drawing international attention to the importance of soils, and in particular, to soil biodiversity. We are now able to answer basic questions about soil fauna, including such topics as: (i) What are the roles of cosmopolitan versus endemic fauna species? (ii) What is the local and global biogeographic distribution and range of faunal species? (iii) What are the factors influencing the distribution of key species? and (iv) How will the loss of species affect ecosystem functioning (Wall et al. 2012)? Food web ecology, with its emphasis on community assembly and disassembly, has the potential to answer these questions.

Conclusions

Studies of the distribution, abundance, and roles of soil fauna and their associated bacteria, archaea, and fungi are poised on the threshold of new discoveries. Some of this is the result of new techniques in genomics, aided by an increasing awareness of the importance of aboveground and belowground linkages in soil ecology. The combined influence of the importance of soil food webs and the need for a greater understanding of the as yet unknown extent of biodiversity of soil organisms worldwide makes the future decade or so bright with promise for the rising generation of researchers.

Soil development: numerical indices

Daniela Sauer
University of Göttingen, Germany

Background and definition of soil indices

Studies of soil development generally aim at improving the understanding of pedogenic processes – both their character and their rate, as well as their outcomes – over time. In many cases, it is useful to know not only which processes have taken place but also the degree to which these processes have proceeded over time, which may be assessed by various quantitative or semi-quantitative indices of soil development. Such information may then be used, for example, to (i) determine the chronological order of formation of soils on different land surfaces and, hence, estimate the ages of the respective land surfaces, (ii) compare pedogenesis in different climates, parent materials, or landscape positions, or (iii) compare paleosol development within a paleosol–sediment sequence.

Indices of soil development can be derived from field data, laboratory data, or both. Field data may be quantitative (such as horizon or profile thickness) or they may be recorded in classes (e.g., size of aggregates, abundance of coatings). Easily obtainable field data (e.g., soil color) may reflect important pedogenic processes (e.g., hematite formation or processes related to certain redox conditions) that are not always easily measured in the laboratory. Therefore, efforts at transforming ordinal field data into numerical values have been undertaken.

General assumptions of soil development indices include that (i) they should be based on data that reflect clearly defined and well-understood soil-forming processes, (ii) they should normally utilize data obtained from field observation, or from laboratory analyses that can be carried out in any ordinarily equipped soil laboratory, so as to ensure their potentially wide applicability and possible use in comparative studies, and (iii) they should work in all kinds of environmental conditions, the environmental boundary conditions of their applicability need to be defined, or they need to be adjustable to different environmental conditions. Most soil development indices have been derived to ascertain the intensity of weathering and pedogenic transformation of a soil parent material. Soil thickness may or may not be included in a soil development index.

Field data suitable for constructing soil development indices

Field data utilized in soil development indices generally should reflect soil-forming processes that proceed over time, leading to predictable and well-understood changes in soil morphology. The latter include soil texture (reflecting clay formation, clay illuviation, and perhaps eolian silt accumulation), clay films or
SOIL DEVELOPMENT: NUMERICAL INDICES

argillans (indicating clay illuviation), rubification or reddening (indicating the formation of iron oxides, especially hematite), melanization or darkening (indicating organic matter accumulation), soil (profile or horizon, eluvial or illuvial zone) thickness, dry/moist consistence (mainly reflecting clay formation and illuviation), soil structure, and abundance of pedogenic carbonates and other illuvial materials (gypsum, salts, etc.), as well as their location within the profile.

Importance of the timescale considered

Some soil properties exhibit their main changes during certain periods of soil development, rather than progressively throughout the period of soil formation. For example, soil structure formation and melanization are dominant processes in young soils, on timescales of decades to a few millennia. On the other hand, such young soils exhibit little rubification and rarely any clay films. These properties usually develop in older soils, depending on climate and parent material. Therefore, indices that combine various soil properties, each of which may have their main changes in different phases of soil development, are particularly useful for studying soil chronosequences that extend well back, into the Pleistocene. Soil chronosequences comprising only Pleistocene soils may be better examined using properties that exhibit appreciable changes within the longer time span covered by the chronosequence (e.g., carbonate accumulation, rubification), but which exclude properties such as soil structure and melanization that form quickly and then do not change appreciably over the longer timescale. The latter may be used for assessing Holocene soil development, for which, in turn, rubification, for example, cannot be used.

General numerical soil development indices based on field data

Redness rating (Torrent, Schwertmann, and Schulze 1980)

Redness rating (RR) has proved useful in numerous studies of Pleistocene soil chronosequences, especially in Mediterranean climates, where rubification is a major pedogenic process (Figure 1). It is calculated as: 

\[
(10 - H) \times C/V,
\]

where \( H \) is the numerical value preceding YR in the Munsell hue, and \( V \) and \( C \) represent value and chroma. RR is not useful for environments or time spans where the Munsell hue is 10YR, as in most older and well-developed soils, thus resulting in RR = 0. For example, most soils in cold or temperate climates have a Munsell hue of 10YR. Progressing rubification may also be masked by subsequent eolian or volcanic additions to soils.

Figure 1  Maximum redness rating (RR) in B horizons of three soil chronosequences in Mediterranean climates. Black quadrats = San Joaquin Valley, California (Harden 1982); white quadrats = Sacramento Valley, California (Busacca 1987); crosses = central western Spain (Dorronsoro and Alonso 1994).
Soil age (ka)

Field morphology rating scale (Bilzi and Ciolkosz 1977)

This rating scale has been developed for soils in humid-temperate climates. It can be used for (i) evaluating the degree of pedogenesis by comparing soil horizons to C horizons, and/or (ii) evaluating distinctness of horizons by comparing the properties of adjacent horizons. The comparisons are done by allocating one point per unit difference between the two horizons (e.g., for textural class, grade of structure, amount of clay films). The points are then summed over the profile.

Profile development index (Harden 1982)

The profile development index (PDI) has become the most widely used soil development index based on field data (Figure 2). It has been successfully applied to soils in a wide variety of environments, although most of this work has been done in Mediterranean and humid-temperate climates. The procedure is as follows.

1. The properties of each soil horizon and the parent material are described in the field.
2. Each considered property is evaluated by assigning 10 points per class crossing between the parent material and the soil horizon.
3. The values obtained in step 2 are normalized to a scale from 0 to 1. The normalized morphological property (NMP) values of all considered properties are summed up for each horizon.
4. The result of step 3 is divided by the number of included properties to calculate the morphological horizon index (MHI).
5. The MHI is multiplied by horizon thickness.
6. The results of step 5 for each horizon are summed up through the profile to calculate the PDI.

The number and kind of soil properties that are included in the index calculation can be adapted to the environmental conditions and processes that have taken place in the soils under investigation.

To include or not to include profile thickness?

Because of the way that step 6 is defined, the numbers obtained in the profile index will include the increase in profile thickness with progressive soil development in the index. This approach may or may not be applicable to all soils. That is, when choosing a method to calculate a profile index, one has to decide whether soil thickness should be included. An index that includes soil thickness may increase in a soil chronosequence even though the horizon property values remain constant. Therefore, if one wants to identify solely the intensity of pedogenesis, excluding profile thickness, one may compare, for example, the maximum

![Figure 2](image_url)
SOIL DEVELOPMENT: NUMERICAL INDICES

NMP or MHI occurring in each pedon of a chronosequence or, after step 6 of the PDI calculation, divide the index by profile thickness. Alternatively, to include soil thickness in the index, one may artificially adjust all profiles to the depth of the thickest soil, either by assigning an index of zero to each pedon for the part between its soil depth and the soil depth of the thickest soil, or by increasing the thickness of the lowermost exposed soil horizon of each pedon so that all pedons have the same thickness (Birkeland 1984).

Numerical soil development indices based on laboratory data

Indices related to the processes of clay formation and illuviation

Clay accumulation in B horizons is a common process in various kinds of soil environments, including particularly Mediterranean, humid-temperate, and savanna ecosystems. It can be assessed through the clay accumulation index (CAI) proposed by Levine and Ciolkosz (1983), which is calculated as: CAI = Σ [(Bc – Cc) * T], where Bc = clay content of B horizon (%), Cc = clay content of C horizon (%), and T = B horizon thickness (cm). Progressive clay translocation from E to Bt horizons is often calculated as the ratio of clay content in Bt horizon (%)/clay content in E horizon (%). This ratio is applicable only where the present E horizon is the source of additional clay in the Bt horizon. This may not be the case where, for example, the original eluvial horizon has been replaced by a younger deposit, or where the primary clay content of the parent materials of the E and Bt horizons differ.

Indices related to pedogenic iron oxides

Formation of, and pedogenic processes associated with, iron oxides (such as crystallization, remobilization, and translocation) occurs in almost all kinds of environments. Various Fe ratios are commonly used for assessing these processes. For example, the Fe_d/Fe_t ratio (Figure 3) reflects the proportion of total iron (Fe_t, obtained, for example, by x-ray fluorescence analysis or combustion with hydrofluoric acid) that has been transformed into iron in pedogenic iron compounds (Fe_d, obtained by sodium citrate-dithionite extraction), whereas the Fe_o/Fe_d ratio characterizes the proportion of iron in amorphous and poorly crystalline iron oxides and hydroxides (Fe_o = Fe extracted by acid ammonium oxalate), as compared to the total amount of iron in pedogenic iron compounds (Fe_d) (Torrent, Schwertmann, and Schulze 1980). Other commonly applied iron ratios include the (Fe_d–Fe_o)/Fe_t ratio, characterizing the proportion of iron in well-crystallized pedogenic iron oxides (Fe_d–Fe_o) as compared to total iron (Fe_t), and the ratio Fe_d in B horizon(s)/Fe_d in the C horizon.

Indices reflecting progressive silicate weathering and leaching of mobile elements

In many environments where there is an excess of precipitation over evapotranspiration, water percolates through the profile at times during the year, and leaching occurs. Leaching removes soluble substances from the soil system. As soils of this kind get increasingly weathered, ratios of insoluble to soluble substances increase, making such ratios valuable as indices of weathering, pedogenesis, and leaching, and, hence, soil age. Commonly applied indices of this group include the molar ratios of SiO_2/Al_2O_3 or (Fe_2O_3 + Al_2O_3)/SiO_2, reflecting the processes
of desilication (removal of Si) and formation of kaolinite, gibbsite, and iron oxides from the relatively enriched Al and Fe. Ratios of mobile elements released during silicate weathering (e.g., Na, K) to an immobile element (mostly Ti or Zr) are often used as well (in the form both of elements and of oxides). There is some discussion about whether Ti is completely immobile or whether it can be co-illuviated with clay. Also Al is not immobile in all soils; it is readily translocated during podzolization and clay illuviation. Chittleborough (1991) thus suggested a weathering ratio (WR) based on Zr as an immobile element: \[ \text{WR} = \frac{(\text{CaO} + \text{MgO} + \text{Na}_2\text{O})/\text{ZrO}_2}{\text{Al}} \].

Among a number of similar weathering indices developed by geochemists, the one that has been most widely adopted in pedology is the chemical index of alteration (CIA) (Nesbitt and Young 1982). It is calculated from the molar proportions of feldspar constituents as: \[ \text{CIA} = \frac{\text{Al}_2\text{O}_3/((\text{Al}_2\text{O}_3 + \text{CaO}^* + \text{Na}_2\text{O} + \text{K}_2\text{O}))}{100}, \] where \( \text{CaO}^* \) is Ca after subtraction of Ca in carbonates and apatite. Sauer et al. (2010) preferred a weathering index based on the molar element ratio \( (\text{WI}_{\text{MER}}) \) for use in pedology, calculated as: \( \text{WI}_{\text{MER}} = (\text{Ca}^* + \text{Mg} + \text{K} + \text{Na})/\text{Al} \), where \( \text{Ca}^* \) is Ca after subtraction of Ca in calcium carbonates, because this ratio reflects most directly the progressing release and leaching of bases from silicate weathering during pedogenesis. Both indices should be calculated without potassium \( (\text{CIA} - \text{K}, \text{WI}_{\text{MER}} - \text{K}) \) when applied to paleosols in which postburial alteration may include metasomatic additions of potassium. See Duzgoren-Aydin, Aydin, and Malpas (2002) or Schaetzl and Thompson (2015) for reviews of chemical weathering indices.

**Index of profile anisotropy (Walker and Green 1976) and modified index of profile anisotropy (Birkeland 1984)**

These two indices are based on the concept that anisotropy of soil properties increases with time, as occurs in most soils, except for soils characterized by strong pedoturbation (e.g., steppe soils or Gelisols). The index of profile anisotropy (IPA) is calculated as: \( \text{IPA} = D \times 100/M \), where \( M \) is the weighted mean value of a soil property in the profile and \( D \) is the mean deviation of the horizon data of that property from the weighted mean value. The modified index of profile anisotropy (mIPA) uses the parent material data \( (\text{PM}) \) instead of the weighted mean value \( M \): \( \text{mIPA} = D/PM \). It is determined as follows.

1. The deviation of each horizon from the parent material with regard to the respective property is calculated and multiplied by horizon thickness.
2. All profiles are artificially adjusted to the thickness of the thickest soil by increasing the thickness of the lowest horizon.
The sum of horizon deviation data is divided by this thickness.

**Soil-specific numerical soil development indices**

The indices introduced above may be applied to soils in a comparatively wide range of environments. In addition, another family of indices is designed to reflect specific soil-forming processes that take place in specific environments. For example, pedogenesis in many desert environments is commonly described in stages of secondary carbonate accumulation (Gile and Grossman 1979). A quantitative numerical index, based on the amounts of secondary carbonates in a profile (g cm\(^{-2}\)), was introduced by Machette (1985). Amounts of secondary carbonates (cs) in each horizon (g cm\(^{-2}\)) are calculated as 
\[
cs = ct - cp
\]
where \(ct\) is the horizon’s present total amount of carbonates (g cm\(^{-2}\)) and \(cp\) is its initial amount of carbonates (g cm\(^{-2}\)); \(ct\) is calculated from present carbonate contents (g CaCO\(_3\) per 100 g soil), bulk density (g cm\(^{-3}\)), and horizon thickness (cm), whereas \(cp\) is calculated from the calcium carbonate content in the parent material and reconstructed initial bulk density (g cm\(^{-3}\)) and horizon thickness (cm). The amounts of secondary carbonates of all horizons are then summed.

Muir and Logan (1982) introduced an eluviation/illuviation coefficient (EIC) that had originally been developed by Rode (1935) for describing the degree of podzolization. It is calculated as in equation 1, where \(S_{hi}\) and \(X_{hi}\) are the percentages of the soil constituent of interest \(S\) and an internal index element \(X\) in the illuvial soil horizon, and \(S_{oi}\) and \(X_{oi}\) are the original percentages of the same constituents, obtained from the parent material. The EIC is converted into a percentage (by multiplying by 100), a negative EIC indicating a percentage loss, a positive EIC indicating a percentage gain of the soil constituent \(S\) in the respective soil horizon, as compared to the parent material.

\[
\text{EIC} = \frac{S_{hi}/X_{hi}}{S_{oi}/X_{oi}} - 1
\]  

An index of podzolization based on soil color and horizonation was introduced by Schaetzl and Mokma (1988), calculated as: 
\[
\text{POD} = \Sigma (\Delta V \times 2^{\Delta H})
\]
where \(\Delta V\) is the difference in color value (moist) between the E horizon and B horizon (or subhorizon), and \(\Delta H\) is the number of Munsell hue pages by which the E and B horizons differ. Thus, \(\Delta V\) is multiplied by \(2^0 = 1\) if the horizons have same hue, by \(2^1 = 2\) if there is one page difference, by \(2^2 = 4\) if there are two pages difference, and so on. The resulting differences between the E horizon and each B subhorizon are summed. If several E subhorizons are present, the one with the highest Munsell value is used.

**Conclusions**

Numerical indices of soil development have been applied successfully in numerous studies to assess the degree of pedogenesis, for example, in soils of different ages or on different positions in the landscape. They have thus helped to improve the understanding of the influence of the various soil-forming factors on pedogenesis. Moreover, they have been used for establishing chronologies of land surfaces or cycles of alternating sedimentation and soil formation, thus contributing to the reconstruction of landscape evolution. Successful application of soil development indices requires some knowledge about various factors that may affect the indices in the soils under study. For example, the material exposed in the C horizon may not be the same parent material. 
that the soil horizons above have developed in. In fact, sedimentary discontinuities in soil profiles are not often addressed in the literature but are nevertheless rather common in nature (Schaetzl 1998). In addition, soils that have developed over long time spans have usually experienced major climatic changes (e.g., glacial/interglacial cycles) and geomorphological processes including erosion and redeposition (Sauer et al. 2010), and have possibly received additions of dust and/or volcanic ash. Such processes need to be taken into account when applying soil development indices to older soils.

Soil erosion and conservation

Tom Vanwalleghem
University of Cordoba, Spain

History, definitions, and importance of soil erosion

Soil erosion is the process by which soil particles are detached, transported, and deposited by water, wind, gravity, or biota. Soil erosion, as part of the geological cycle, is a natural process. However, anthropogenic disturbance of the landscape, mainly by replacing the natural vegetation cover with agricultural crops as well as by tilling and disturbing the soil, leads to an increase of erosion rates by a factor of 10–100 (Montgomery 2007). This type of accelerated erosion generates an imbalance with the rates by which soils are formed, generally resulting in a net loss of soil, resulting in decline of soil fertility and, potentially, the total loss of soil cover. Also, the increased sediment and nutrient load to downslope water courses generates problems such as deteriorating water quality and damage to infrastructure, for example, the infilling of reservoirs behind dams. The field of soil conservation encompasses the efforts of humans to correct this imbalance and, ideally, reduce soil erosion to long-term geological rates, or even to put practices in place that will encourage soil deepening and increased fertility. Soil conservation practices include changes in soil management and the implantation of engineering structures. Thus, their proper implementation requires an understanding of erosion processes (Morgan 2004).

The first evidence of human-induced soil erosion can be dated back as early as the Mesolithic Period, as hunter-gatherers cleared natural forest vegetation by fire (Dotterweich 2013). In general, important and widespread periods of erosion in history can be found with the arrival of the first farmers; this association holds throughout the world. In areas with a long land-use history such as the Mediterranean, clear signs indicating the advanced degradation status of the landscape, such as heavily truncated soils, are visible throughout the landscape. Although within a complex mix with many other factors, such as drought, socioeconomic change, or soil salinization due to irrigation, the decline of some ancient civilizations, such as the Maya or Easter Island’s, has been linked mainly to soil erosion.

Each of the driving forces for soil erosion – water, wind, gravity, and/or biota – varies greatly in space and time. Thus, the resulting detachment, transportation, and deposition of soils are therefore controlled by different variables at different places. Anthropogenic perturbation of the erosion cycle, usually called accelerated erosion, has been most pronounced on agricultural land and can lead to rapid land degradation. Some of the areas that are currently most affected include Africa south of the equator, Indo-China, Myanmar, Malaysia, Indonesia, South China, Northern Australia, the Pampas, and swaths of the high-latitude forest belt in North America (Bai et al. 2008). Areas with a long history of land degradation, such as the drylands around the Mediterranean, have largely been stripped of their soil cover and have now often become more stable landscapes. Typical
soils in such areas are shallow and with a high rock fragment cover.

Current global estimates indicate that among the different erosion processes, water and tillage erosion are the most important on agricultural land, resulting in a global flux of sediments of, respectively, 28 Pg year\(^{-1}\) and 5 Pg year\(^{-1}\). About 2 Pg year\(^{-1}\) of sediment is mobilized by wind erosion (Quinton et al. 2010). Tillage erosion refers to the direct translocation of soil by tillage operations, and is discussed in more detail below.

Although mass movements have been widely studied by geomorphologists and are important processes of local sediment generation in mountainous catchments, they have generally been considered negligible in the larger context of soil erosion. Sediment budgets from cosmogenic nuclides seem to suggest that their importance to the global sediment budget is limited (Willenbring, Codilean, and McElroy 2013). Currently, no global estimates exist for erosion by mass movements on agricultural lands. This discussion, therefore, mainly deals with water and tillage erosion, dominant on agricultural land, although wind erosion is also briefly discussed because of its local importance. For further details on the other erosion processes, the reader is referred to geomorphological literature, for example Anderson and Anderson (2010).

**Water erosion**

Water erosion processes are generally subdivided into splash, sheet or interrill, rill, and gully erosion. Splash erosion refers to the direct impact of raindrops on soils, which breaks up soil aggregates and transports the individual soil particles away from the impact zone. Sheet erosion then refers to the erosion by the runoff water that flows as a laminar or turbulent sheet downslope. The effects of sheet flow are complex and encompass both the transport of splashed soil particles, erosion by the sheet flow itself if the flow’s shear stresses exceed the soil’s resistance, and a partial protection of the underlying soil from raindrop impact. Rill and gully erosion occur further downslope, where sheet flow converges and, using the increased stream power, erodes a distinct and often deep channel or gully (Figure 1). Most prediction models use a critical drainage area \((A)\) and slope \((S)\) threshold relation of the form \(S = aA^b\), with site-specific parameters \(a\) and \(b\), to delimit the areas in the landscape where rills and gullies are expected to form. The subdivision between rills and gullies is generally based on size, using a critical cross section of 0.929 m\(^2\) (1 ft\(^2\)) to distinguish them (gullies are larger).

Water erosion is strongly scale-dependent because of the interactions between these different erosion processes, each active in a different area of the landscape, and sediment deposition, which also occurs at distinct locations in the landscape, such at the foot of hill slopes or in low relief valleys. These complexities make measurement of soil erosion, and especially the spatial extrapolation of results, a difficult task. Erosion can be measured directly by determining the elevation changes at the soil surface with techniques ranging from reference markers, such as erosion pins, to repeated terrestrial LiDAR measurements. Various types of tracers have also been used to track soil redistribution on the landscape over a range of timescales. Fallout radionuclides, such as \(^{137}\)Cs, \(^{210}\)Pb, or \(^{7}\)Be, which fall out of the atmosphere at known rates and accumulate in soils, especially near the surface, allow for the averaging soil erosion and deposition rates over timescales ranging from days to 100 years (Guzmán et al. 2013). In addition to these nuclides, other tracers, such as rare Earth or magnetic iron oxides, have been artificially incorporated to the soil – a type of erosion...
experiment. After a rainfall event or after several years, the determination of the concentration of such tracers allows the experimenter to calculate erosion extent and intensity. The most widely used method of determining the extent of soil erosion, however, is the direct measurement of sediment production in catchments or plots of a known size. This method is also known as universal soil loss equation (USLE). It also provides for direct comparisons of soil erosion under different management systems or conservation practices.

Sparked by the 1930s dust bowl, the United States Soil Conservation Service (currently the Natural Resources Conservation Service) initiated the most significant soil erosion field plot measurement program to date. Currently, plot measurements have been collected worldwide as a result of individual research efforts. Available data now comprise >10,000 plot years. Montgomery (2007) reviewed these soil erosion field plot data under conventional agriculture and reported median and mean soil erosion rates of 18.4 and 48.6 ton ha$^{-1}$ year$^{-1}$, respectively, far exceeding rates of soil formation. Soil conservation programs generally consider soil losses between 5 and 12 ton ha$^{-1}$ year$^{-1}$ to
SOIL EROSION AND CONSERVATION

be tolerable, because they can be matched by natural pedogenic processes. Ongoing research on the spatial and temporal variability of soil formation rates will allow setting more precise and site-specific tolerable thresholds.

The various soil erosion prediction models that currently exist can broadly be categorized as empirical or physically based. The choice of model depends mainly on the objective: the first group is geared towards prediction (forecasting) while the latter type of model is used best for explaining (back-casting). The most widely used model is the universal soil loss equation (USLE) and its subsequent modifications (Renard et al. 1991). Based on a statistical fit of the available plot data described above, the USLE model is considered an empirical model. It predicts the average annual soil loss \( A \), ton ha\(^{-1}\) year\(^{-1}\), as a function of five factors: rainfall erosivity \( R \), soil erodibility \( K \), slope length and gradient \( LS \), soil cover \( C \), and management \( P \):

\[
A = R \times K \times LS \times C \times P
\]

For example, to calculate erosion in an olive orchard in Cordoba, Southern Spain, the \( R \) factor calculated from local climate records is 850 MJ mm ha\(^{-1}\) h\(^{-1}\). The soils are Vertisols with a \( K \)-factor equal to 0.047 \( \text{t ha}^{-1} \text{MJ}^{-1} \text{mm}^{-1} \). On a typical field of 180 m long with an 8% slope, the \( LS \) factor is 2.47 and typical \( C \)-values for this crop are around 0.34. Without additional conservation practices such as terraces, the \( P \) factor is equal to one. The mean annual soil loss can then be calculated for this case as 850 \( \times \) 0.047 \( \times \) 2.47 \( \times \) 0.34 \( \times \) 1 = 33.6 ton ha\(^{-1}\) year\(^{-1}\).

The various physically-based soil erosion models are largely based on the concept of sediment transport capacity. Most draw heavily from generalized sediment transport equations originally developed for fluvial conditions, such as ANSWERS, CREAMS, GUEST, LISEM, PESERA, or WEPP (Merritt, Letcher, and Jake-man 2003). Finally, models such as WaTEM/SEDEM apply a hybrid approach, combining USLE-based sediment production with posterior sediment routing, using the sediment transport capacity concept.

Most of these models do not include gully erosion. In spite of some valuable efforts, such as the (revised) ephemeral gully erosion model, at present no widely validated model exists for predicting gully erosion rates.

**Tillage erosion**

Tillage erosion or translocation is the loss and accumulation of soil by tillage operations such as plowing or cultivation (Van Oost et al. 2006). Soil moved during a downslope tillage operation is not fully compensated by the corresponding upslope tillage operation so that, overall, tillage results in net downslope soil transport. A general equation describing the tillage erosion or deposition rate \( E \) is:

\[
E = k_{til} \frac{\partial^2 h}{\partial x^2}
\]

Tillage translocation rates are thus controlled by slope curvature in the direction of tillage (with \( h \) = elevation) and a tillage transport coefficient, \( k_{til} \), that incorporates the various effects related to the characteristics of the tillage operation itself (number of passes per year, direction, speed and depth of tillage, and the tillage implement used). Finally, soil bulk density effects are included in \( k_{til} \).

Field measurements have shown that tillage transport coefficients are an order of magnitude larger for mechanized moldboard plowing, as compared to noninversion animal-powered tillage, which is still common in some developing countries. These data explain why, historically,
water erosion rates have been much higher than tillage erosion rates. Presently, though, water and tillage erosion processes are often equally important, as intensive mechanization is now widespread. However, because the travel distance of soil particles due to tillage erosion is limited to the field scales, tillage erosion commonly results in the formation of benches or hedges at downslope field borders. Although it can exert an important control on the spatial variability of soil properties, tillage erosion does not contribute directly to sediment export from a catchment because the almost all of the eroded soil stays within the field. Some research has pointed to positive feedback effects between water and tillage erosion in areas, where gullies are regularly filled in by tillage and easily form again each year (Gordon et al. 2008).

Wind erosion

Wind erosion, the initiation, transport, and deposition of soil by wind, is an important process in certain areas – known as hotspots. These areas include sandy, peaty, and loess soil types in large fields without barriers, and arid areas that support little vegetation cover (Nordstrom and Hotta 2004). These hotspots are mostly in the Northern countries of Europe, the Great Plains of the United States, the Sahel of West Africa, large parts of Australia, northern Kazakhstan, and Inner Mongolia in Asia. The erosion risk in these places depends on factors such as vegetation cover, soil roughness, and moisture, all of which vary temporally.

Wind erosion occurs when the wind velocities exceed the threshold friction velocity to move soil particles. It often is focused during distinct periods of the year, usually when critical values are lower due to dry conditions and low soil aggregation. Apart from soil surface conditions, the amount of total erosion will also depend on wind energy and duration. The best prevention is offered by windbreaks and measures that increase surface cover or create aggregates that resist entrainment. Most of these measures are similar to conservation measures geared toward water erosion.

From the previous sections, it is clear that both water and tillage erosion processes have shaped our agricultural landscapes and soils significantly. The interaction between soil formation and soil erosion along a slope is part of the catena concept. For this reason, truncated soils are widespread on hillslopes in many agricultural fields (Figure 2). As soils are the main terrestrial stock of carbon and nutrients, soil erosion has also led to important lateral fluxes of associated soil components, such as carbon, nitrogen, and phosphorus. Current estimates calculate the agricultural erosion flux of carbon to be 0.5 Pg C year\(^{-1}\) and estimates of the fluxes of nitrogen and phosphorus are estimated to be 23–42 Tg year\(^{-1}\) and 2.1–3.9 Tg year\(^{-1}\), respectively. For comparison, the amounts of nitrogen and phosphorus added through chemical fertilizer are 112 and 18 Tg year\(^{-1}\). This implies that soil conservation, or its absence, especially in developing countries where fertilizers are not readily accessible to farmers, can have an important impact on the nutrient budget. Soil erosion processes also play a crucial role in the global carbon flux in other ways; the burial of eroded soil and the dynamic replacement of carbon on eroded sites leads to long-term carbon storage in actively eroding agricultural landscapes (Quinton et al. 2010).

Soil conservation: definition and principles

Soil conservation is aimed at obtaining a maximum level of production from a given area of
Figure 2  Soil erosion is evident on this hillslope in France. The whiter areas on the shoulder slope are eroded, allowing the bedrock to show through. Photo by R. Schaetzl.

land, mainly by maintaining soil losses below a threshold level (Morgan 2004). Soil and water conservation usually go hand in hand, as promoting infiltration and reducing on-site runoff is paramount to reducing soil loss. More recently, soil biodiversity and other ecosystem functions have also received attention within the framework of soil conservation (Palm et al. 2014).

There are two main approaches to soil conservation: (i) agricultural measures and soil management, aimed at reducing on-site runoff and sediment generation, and (ii) mechanical measures, aimed mainly at reducing off-site effects. When designing soil conservation programs preference should always be given to agronomic treatments, although mechanical measures can be locally indispensable, for example in gully restoration or for farming in steep terrain with terraces.

Soil conservation has a long history, possibly beginning with agricultural terracing at around 6000 BCE in the Middle East. From here, the practice spread globally. In fact, ancient management systems have been used at many locations around the globe, as templates for developing new conservation strategies, for example,
Soil erosion and conservation research emerged in the late eighteenth century (Dotterweich 2013) and currently most countries have active research and extension programs.

With respect to soil conservation, agronomic practices and soil management strategies are based on (i) enhancing infiltration rates to reduce overland flow, and (ii) covering the soil to protect it from raindrop impact. Because plant roots contribute to soil cohesion and reduce sediment production by overland flow, maintaining a cover crop on the soil is often an important part of soil conservation management practices. The simplest way of assuring this is to grow crops continuously, year-round. Growing cover crops in between the main crop cycle(s) assures adequate soil protection during times when the soil would otherwise be bare and prone to erosion. In addition, these crops improve soil structure and fertility when incorporated into the soil. Crop rotation is another way of lowering long-term soil erosion losses, by growing soil-protecting crops of legumes or grasses after row crops such as wheat or maize, which allow more soil erosion because of the bare, interrow areas. Intercropping or multiple cropping, for example maize–legume, is another attractive option to increase canopy coverage and reduce soil erosion. Strip cropping – alternate strips of protection-effective crops with row crops – can be used on areas of moderate slope (Figure 3). High-density planting is a way of achieving a more complete soil cover in a monoculture system, and has been shown to be effective to control gully and rill initiation, even if limited to the concentrated flow zones. A more dense plant cover can also be simulated by mulching, which is the covering of soil with plant residue such as straw, maize stalks, or chipped pruned branches (Figure 4). Mulching is particularly useful in arid

Figure 3 Strip cropping used to break up long sloping fields, in combination with a detention pond for control of storm runoff and sediment (left corner). Photo by R. Schaetzl.
areas where rainfall does not permit growing crops year-round. In cold climates it is also used, but mainly to protect plants from low temperatures. Finally, severely degraded areas such as gullies or mine spills should be revegetated artificially in order to obtain a protective plant cover quickly.

Soil management is aimed at improving soil structure and fertility. This outcome can be achieved by improving the soil’s organic matter content or by applying soil conditioners, such as gypsum in sodic soils or lime in acidic soils. Conventional tillage is still the most common soil management practice globally, as tillage is an essential agronomic management technique that increases surface roughness, albeit temporarily, prepares seed beds, controls weeds, and enhances infiltration. However, the benefits of tillage can easily be offset by compaction under intense traffic or during wet conditions. In contrast, conservation tillage aims at maximizing soil cover by leaving surface plant residue and minimizing soil disturbance (Figure 4). It includes practices such as no-till, minimum tillage, ridge tillage, and direct drilling.

Mechanical soil conservation requires engineering techniques or structures, and often includes surface contouring, terraces, check dams, grassed waterways, grass buffer strips, and the use of various kinds of geotextiles. Its main
objectives are to modify the soil slope, to provide a controlled way of conveying runoff water from slopes to waterways, or to detain sediments before they enter the river courses.

Because of the high costs of soil conservation to farmers, for example, for terrace building or switching to new machinery adapted for direct drilling, a change to more sustainable agricultural practices is often supported by policymakers. Growing public concern about agricultural sustainability and off-site effects of soil erosion has resulted in a set of policy measures that, in many countries, have already contributed to lower erosion rates. In Europe, policies are a mixture of mandatory measures, for example, under the Common Agriculture Policy farmers have to comply with certain standard management requirements in order to receive direct government payments, and incentive-based measures, in which farmers that comply with so-called agro-environmental climate measures receive additional subsidies. The United States has similar conservation programs under the Conservation Reserve Program aimed at applying conservation measures on highly erodible land in exchange for financial and other benefits.

Soil fertility and management

Cynthia A. Grant
Agriculture and Agri-Food, Canada

Soil fertility is the quality of a soil that allows it to provide an adequate amount and balance of nutrients to support healthy plant growth, while maintaining overall soil quality and environmental sustainability. It is a function of the amount and form of nutrients present, their movement to plant roots, and their availability for uptake and utilization by plants. A fertile soil contains adequate soil organic matter, lies within a pH range that supports growth, and has a vibrant community of micro-organisms that participate in nutrient cycling. It lacks constraints that limit the ability of the plant to accumulate nutrients, such as compaction, poor aeration, toxic materials, and excess salts. In managed agriculture or forest ecosystems, soil fertility is often defined in terms of economic productivity, while in natural ecosystems it is related to the capacity of a soil to support a healthy natural plant community.

Historical development of soil fertility

The importance of soil fertility was recognized by early civilizations in Asia, Europe, India, and the Americas that developed agricultural practices at locations where the soil was initially fertile. Soil fertility, however, must be maintained and/or improved for sustainable crop production and the decline of many cultures was linked to soil degradation. In contrast, in Egypt, soil fertility was replenished each year by sediments deposited by flooding of the Nile River, allowing the development of its advanced civilization. In Asia, animal and human manures were used as nutrient sources and soil conditioners thousands of years BCE. In the Americas, active soil fertility management may also have been in place several thousand years BCE, as indicated by the development of the Terra Preta soils that were formed by large additions of charcoal, human excrement, and food waste; these substances greatly improved the fertility of the normally infertile Amazon soils. During Greek and Roman times, many of our current soil fertility management practices had already been adopted, including crop rotation and use of fallow, as well as the addition of soil amendments such as animal manures, green manures, compost, and liming materials. More detailed understanding of plant nutrition came in 1840 when Justus von Liebig published his book Organic Chemistry in Its Application to Agriculture and Physiology, in which he outlined the concept that plants derive carbon, oxygen, and hydrogen from the air and water, but access most of the other nutrients they require from the soil. He developed the “Law of the Minimum” proposing that plant growth will be constrained if one of the essential nutrients is deficient, even if all the other nutrients are present in adequate amounts (Figure 1). Since that time, essential nutrients for plant growth have been identified and factors contributing to soil fertility characterized. In 1913, Victor E. Shelford expanded the concept of limiting factors by proposing the “Law of Tolerance” suggesting that the growth of an organism will be limited if environmental factors, including nutrients, are outside of the
SOIL FERTILITY AND MANAGEMENT

Maximum plant growth is determined by the most limiting factor

Figure 1 Liebig’s “Law of the Minimum” for crop growth can be illustrated by a barrel. In this case, sulfur (S) is the most limiting nutrient. Figure adapted from Saskatchewan Ministry of Agriculture.

minimum or maximum tolerance range for that organism.

Nutrients required for plant growth

Plants require at least 16 essential elements for growth. As von Liebig determined, carbon (C), hydrogen (H), and oxygen (O) are provided from the air and water, while the other 13 are normally taken up from the soil. The three primary macronutrients, nitrogen (N), phosphorus (P), and potassium (K), are required in the largest amounts, while sulfur (S), calcium (Ca), and magnesium (Mg) are considered secondary macronutrients. Although the secondary nutrients are required in relatively large amounts, they are less commonly limiting than the primary nutrients and so are less frequently applied onto agricultural land. The remaining nutrients, the micronutrients iron (Fe), manganese (Mn), zinc (Zn), copper (Cu), boron (B), chlorine (Cl), and molybdenum (Mo), are needed in only very small amounts by plants. In addition, nickel (Ni) has been shown to be necessary for legumes and cereal crops, and is considered by many sources to be a seventeenth essential element. Cobalt (Co) is also needed for some crops, including legumes that require it for nitrogen fixation. Silicon (Si) can be beneficial for certain crops such as rice and sugarcane, but is not essential for growth. Plants may differ in the specific amount of each nutrient required, and each plant has an optimum nutrient range to support growth and a minimum requirement below which growth and/or reproduction is restricted. As Shelford observed, excess amounts of nutrients may also pose a problem, because of direct toxicity or through interference with the uptake and/or use of other essential nutrients.

Factors affecting soil fertility

Soil fertility depends on complex and often little-understood interactions among the chemical, biological, and physical properties of the soil. Soil is formed very slowly by physical and chemical processes, modulated by living organisms, acting on geological parent material, and is affected by climate and topography. Most of the soil’s initial mineral nutrient supply was provided by the decomposition or “weathering” of minerals in the parent material. Plant-available nitrogen is added to the soil when lightning converts atmospheric dinitrogen (N₂) gas into reactive forms, which then enters the soil by direct deposition or in precipitation. Plant-available nitrogen is also added to soils by biological fixation carried out by symbiotic or free-living, nitrogen-fixing bacteria. Atmospheric deposition also adds small amounts of sulfur and chlorine to soils. The size and nature of the mineral particles produced in the soil-forming process affect both the release and the retention
SOIL FERTILITY AND MANAGEMENT

of nutrients. For example, fine-textured materials such as clays can better release and retain nutrients than can coarser materials such as sand. The physical and chemical characteristics of the initial parent material will have a major influence on soil fertility, but as soils develop over time both natural and anthropogenic processes modify the initial fertility.

**Physical** aspects affecting soil fertility include texture, structure, and water-holding capacity. Soil texture is the proportion of sand, silt, and clay in the soil, while soil structure refers to the aggregation of the particles, affecting the soil porosity. Structure and texture interact to affect the ratio of water- to air-filled pores within the soil (plant roots respire and require oxygen), water movement in the soil, plant root growth, and the soil’s capacity to retain and release water and nutrients. Soil structure becomes more important as the yield potential of agricultural crops increases because many crops, especially spring-sown crops, have to produce a root system quickly to obtain the nutrients they require for optimum growth.

**Chemical** characteristics affecting soil fertility include pH, reduction–oxidation potential, cation exchange capacity (CEC), base saturation, carbonate content, salinity, and content of nutrients and potentially toxic compounds. Availability of both nutrients and toxic compounds are affected by soil pH and reduction–oxidation potential, as well as their reactions with soil organic matter, soil mineral particles, and one another.

**Biological** factors affecting soil fertility include the actions of many types of micro-organisms, micro-, meso-, and macrofauna, as well as plant root activity. The living soil microbial community plays a critical role in the development of soil from the original parent material and in the fertility of the soil after it has formed. Some organisms form symbiotic relations with plants; for example, *Rhizobium* bacteria form nodules on the roots of leguminous plants where they fix atmospheric nitrogen into forms that are transferred to and used by the plant. Similarly, mycorrhizal fungi have hyphae that enter the root of a host plant and also extend into the soil around the root. The hyphal system accesses a larger volume of soil than the roots alone, thus increasing the uptake of nutrients such as phosphorus and some micronutrients, a portion of which is released into the root cells for the plant to use. Such symbiotic associations, however, are not a “free service” to the host plant because the bacterium or fungus has to be supplied with energy in the form of carbon compounds by the host.

The types and abundance of organisms within soil are very dynamic. Populations can respond rapidly to changes in moisture, temperature, and available food sources. For example, microbial activity increases when a readily available food source is added, such as when crop residues are incorporated into the soil. Very importantly, the microbial breakdown (mineralization) of added organic material releases nutrients in plant-available forms, leading to the recycling of nitrate, phosphate, and other important plant nutrients. However, subsequent microbial activity may also form nitrate (nitrification) and convert the nitrate into gaseous nitrogen forms (denitrification) such as dinitrogen (N₂), nitrous oxide (N₂O, a greenhouse gas), and nitrogen oxide (NO₂) that are released to the atmosphere.

One of the end products of the microbial decomposition of raw organic matter is soil organic matter (or humus), which is the highly stable organic matter fraction remaining after most of the residue has decomposed (Soil Science Society of America 2014). The many beneficial properties of organic matter contribute to the fertility of the soil. Micro-organisms utilize organic matter as an energy source and can break down added crop residues, animal wastes,
biomass, and composts. The rate of breakdown often depends on the proportion of the different compounds in the organic material as carbohydrates are decomposed readily by bacteria, while lignin is broken down by basidiomycete fungi. The carbon to nitrogen ratio (C:N ratio) of the added material is also important, with decomposition proceeding more rapidly when the C:N ratio of the residue is narrow. In addition, the decomposition of residues with a narrow C:N ratio, such as alfalfa, releases plant-available nitrogen whereas decomposition of residues with a wide C:N ratio, such as cereal straw, removes plant-available nitrogen from the soil, at least during the initial stages of decomposition. Soil organic matter also plays a number of critically important roles in soil quality. Not only does it contain nutrients, but it can also adsorb nutrients and absorb large amounts of water. Thus, it helps soil to retain a reservoir of both nutrients and moisture for plant growth. Very importantly, soil organic matter and organic compounds produced during decomposition of added organic matter assist in the formation and stabilization of aggregates. The production of stable aggregates improves soil structure and tilth, which aids root growth, aeration, water infiltration and drainage, and resistance to compaction and erosion. Good soil structure provides an environment conducive for root growth and microbial activity.

Fertility depends on the available rather than the total nutrient content of the soil. Plant-available nutrients are the nutrient forms that the plant can absorb and utilize. Only a small fraction of the total nutrient content of a soil is immediately available for uptake by roots from the soil solution, the water surrounding the roots and soil particles. The concentration of soluble nutrients that are available for crop uptake in the soil solution is usually too small to meet the total requirement of a harvested crop. Consequently, the concentration of most nutrients in the soil solution must be replenished many times throughout the growing season from the large reserves of plant-available nutrients that are (i) adsorbed to the soil surfaces; (ii) in soil minerals or organic matter; or (iii) in soluble forms that can move rapidly into the soil solution.

The surfaces of soil organic matter and clay-sized mineral particles have both negative and positive charges enabling them to retain positively and negatively charged ions, respectively, through adsorption (the retention of atoms, molecules, or ions on the surface of solids by chemical or physical bonding) so as to maintain electrical neutrality. Plant nutrients are generally present in the soil as ions, either positively charged cations such as Ca$^{2+}$, K$^+$, NH$_4^+$, or negatively charged anions such as H$_2$PO$_4^-$, or SO$_4^{2-}$, and are retained in soil by being held on the adsorption sites. The CEC is the total amount of exchangeable cations that a soil can adsorb, or hold, on the negative exchange sites. Adsorbed cations can be readily exchanged with cations present in the soil solution. Cations that are not held on the exchange sites can move in soil water below the rooting zone of plants, so a high CEC can protect cations from leaching loss, but can also limit their mobility. Soils with a high CEC can hold more cations, which can replace those in the soil solution when they become depleted by root uptake. Therefore, soils with a higher CEC generally have more inherent fertility and greater productivity than do low CEC soils. Most of the soil’s CEC is permanent, while some is pH-dependent. A pH-dependent charge develops because, as soil pH increases, the concentration of H$^+$ ions in the soil solution decreases and that of OH$^-$ in the soil solution increases. In response, the H$^+$ ions from the hydroxyl and water groups at the edges of the clay colloids or the surfaces of oxides or soil organic matter can move into the soil solution or be neutralized by the OH$^-$ ions, increasing the
negative charge on the particle edge or surface. Conversely, in very acid soils (pH less than \( \approx 5.5 \)), kaolinite (a type of clay mineral) and iron and aluminum oxides in soil may develop positively charged sites that can hold anions, helping in the retention of phosphates and sulfates.

Nutrients in the soil solution are in equilibrium with the nutrients adsorbed on cation and anion exchange sites and those present in easily dissolved solid forms. This equilibrium is shifted when plants absorb nutrients from the soil solution, causing nutrients to be released into the soil solution (Figure 2). The ability of the soil to replenish the nutrients in the soil solution from the nutrients in the adsorbed or solid phase in the soil is the soil’s nutrient buffering capacity. Fertile soils have a high buffering capacity and are not depleted of nutrients as rapidly as less fertile soils.

Nutrients taken up by roots must be present in the soil solution or held on sites adjacent to the root. Nutrients can reach the sites on roots where absorption takes place through interception, mass flow, and diffusion. Interception occurs when the root grows and comes into direct contact with the nutrient, but roots normally contact less than 1% of the soil surfaces in the rooting zone. Therefore, only a small proportion of the nutrients present in the soil can be accessed by interception. Mass flow is another mechanism by which plant roots access soil nutrients. Mass flow is the movement of dissolved nutrients in the soil water, through the plant uptake of water from the soil pores. This convective flow of water to the root is driven by water uptake by the plant and its movement up through the plant in the transpiration stream. Mass flow is important for highly soluble nutrients, because the concentration of soluble nutrients in the soil solution, and hence the amount of nutrient moving to the plant root, will be relatively high. However, for sparingly soluble nutrients, such as phosphorus or potassium, movement to the root via mass flow will be small. Mass flow can also lead to leaching of nutrients below the plant rooting zone. Diffusion is the third mechanism of nutrient movement to plant roots. Diffusion is the movement of an ion through a water film from an area of high concentration to an area of low concentration. This form of movement is much slower than mass flow. Diffusion is important for moving low-concentration nutrients to the root surface; however, because of the slow rate of diffusion, the limited movement of nutrients by this pathway poses a substantial challenge for the plant. Therefore, a high density of roots is important to ensure that nutrients such as potassium and phosphorus that have low concentrations in the soil solution can be accessed.

Soil fertility will therefore be affected not only by the amount of nutrient present in the soil but also by factors affecting the ability of the plant to access the nutrient. Important contributors to plant nutrient uptake include factors affecting
root growth and function (e.g., compaction and temperature), factors affecting the supply and form of nutrient (e.g., pH and aeration), and factors affecting the mobility of nutrients (e.g., soil moisture and temperature).

Soil degradation

Soil degradation refers to the deterioration of soil properties and functions that lead to a decrease in soil quality, making it less suitable for purposes such as crop production. Soil degradation often leads to reductions in soil fertility. It has many causes, including nutrient depletion, soil erosion, compaction, salinization, acidification, and loss of organic matter.

Nutrient depletion from soils can occur when the nutrients removed in the harvested crop are not replaced. The risk may be minor with micronutrients if the soil reserve is very large and the amount removed by the crop is very small. However, with macronutrients such as nitrogen and phosphorus, nutrient removal is much greater, so there is greater risk of soil depletion. Nutrient depletion is a major concern in tropical soils, where the nutrient content of the soil is often inherently low and increasing population pressure has led to intensification of production, high rates of nutrient removal, and limited return of nutrients. Conversely, in developed regions, particularly in regions with intensive livestock production, excess accumulation of nutrients can occur if nutrient input is greater than removal. Buildup of nutrients in the soil can increase the risk of off-site movement and contamination of air and water.

Another major cause of soil degradation is erosion, where topsoil is removed by the action of wind or water, removing with it valuable nutrients and organic matter. Topsoil loss reduces soil fertility, impairs tilth, and can lead to environmental problems when nutrients are deposited into water bodies. Soil formation is a very slow process and topsoil loss from erosion cannot be easily corrected.

Degradation due to soil compaction can reduce soil fertility by limiting plant rooting, aeration, and water movement into and within the soil. Compaction can occur naturally, or through pressure caused by machine traffic.

Salinization is the accumulation of salts, generally occurring when saline water evaporates from the soil surface, leaving behind soluble salts. Salinity can develop from the use of poorly managed or low-quality irrigation water, where salts added in the water are retained in the rooting zone and not leached from the profile. It can also occur if drainage patterns are disrupted, allowing an elevated water table to bring salts to the surface. Similarly, under dryland conditions saline groundwater from a shallow water table can rise to the surface by capillary action. Dryland salinity is accentuated when water use by plants does not utilize the incoming precipitation, such as when deep-rooted trees are cleared and replaced by annual crops or when summerfallow is included in the rotation. The unused precipitation increases recharge to the groundwater, causing water tables to rise, leading to more evaporation and accumulation of salts in the rooting zone. High concentrations of salts in the soil reduce a plant’s ability to absorb water and nutrients and may cause direct toxicity.

Acidification is the reduction in soil pH. It is a natural part of the soil formation (pedogenesis), occurring when basic cations are removed from the soil by leaching. Acidification also results from nitrogen reactions in the soil, whether from applications of fertilizers or growth of legume crops. Over time, acidification can interfere with crop growth and nutrient availability.
Soil fertility management

The basic principle of soil fertility management is to adopt practices to allow economically optimum crop yields with minimum adverse environmental impacts. Long-term sustainability requires that nutrient losses and exports from the systems are balanced with nutrient input and recycling, and that the physical, chemical, and biological properties of the soil are not compromised over time (Figure 3).

Nutrient availability is maintained by applications of organic or inorganic fertilizers and, if the soil is acidic, by liming. An international program called the 4R Nutrient Stewardship (International Plant Nutrition Institute 2012) has been developed by the fertilizer industry to promote sustainable nutrient management. This involves providing the right source of nutrients to the crop at the right rate and the right time using the right method of application so that as many of the added nutrients as possible are utilized by the crop. Defining the “right” approach to each of these management factors involves the economic, social, and environmental dimensions of stakeholder goals. In 4R Nutrient Stewardship, managers consider these goals while selecting best management practices. Best management practices must be developed in relation to site-specific factors such as soil and climatic conditions, crop type, economic factors, and the agronomic practices of the producer.

Plant nutrients can be added as both organic manures and synthetic fertilizers. Synthetic fertilizers tend to contain a limited number of nutrients at a higher and strictly regulated concentration, as compared to organic manures. Most synthetic fertilizers provide nutrients in a soluble form that is quickly available for crop uptake. Organic manures, such as barn or farmyard manure, biosolids, crop residues, fishmeal, and other by-products, are normally lower in nutrient content than synthetic fertilizers, so a larger volume of material must be applied to meet crop nutrient demands, increasing transportation costs. The nutrient composition and availability of any type of organic manure will tend to vary from batch to batch, making it difficult to calculate the amount to apply to achieve a given rate of nutrient addition. Also, the balance of nutrients in organic fertilizers rarely matches crop requirements, leading to either over- or under-fertilizing with some nutrients. Plants absorb nutrients primarily in the inorganic form, so organic manures must decompose, usually by microbial activity, to release these inorganic ions before roots can take up the nutrients. As a result, the rate of nutrient release from organic manures is generally slower and less predictable than that from synthetic fertilizers. However, organic manures often contain a range of nutrients and are an excellent source of organic matter that can contribute both to the nutrient supply and to the physical and biological properties of the soil.

Application of adequate amounts of nutrients is essential to replace nutrients removed in the harvested crop, so as to maintain crop yields and to avoid nutrient depletion and soil degradation. However, environmental problems can also occur with excessive or poorly managed fertilizer inputs, whether from organic or synthetic sources. Emissions of reactive nitrogen to the atmosphere can harm the ecosystem and human health, by contributing to acidification, greenhouse gas production, eutrophication, formation of ground-level ozone and particulate matter in the atmosphere, and loss of biodiversity. Phosphorus movement to fresh surface water is a major cause of eutrophication. Trace elements such as cadmium that are naturally
Figure 3  Overview of nutrient behavior. Dashed lines represent nutrient gains or losses in the soil system; solid lines represent internal transformations within the soil system. Sustainable crop production requires that nutrient losses and exports in crop products are balanced by nutrient imports and recycling. Diagram courtesy of Dr Don Flaten, University of Manitoba.

Present in phosphate rock and phosphorus fertilizers can accumulate in the soil, leading to long-term soil degradation and human health concerns. Carbon dioxide emissions from the large amounts of fossil fuel used in fertilizer production and transport can also contribute to climate change. Therefore, proper soil fertility management is important not only to ensure sustainable food production over time, but also to prevent negative direct and indirect environmental effects. Nutrient management practices that match supply to the crop demand
closely, in terms of both rate and timing of the applications, can improve nutrient use by crops and reduce potential negative environmental impacts.

The importance of soil fertility management in ensuring economic crop production and avoiding negative environmental impact has helped to encourage the development of improved fertilizer products and practices. Enhanced-efficiency fertilizers utilize either physical coatings or chemical additives to slow their release into the soil solution or delay their chemical transformation in order to reduce losses and improve efficiency of crop use. Site-specific management techniques can be used to vary fertilizer application rates within the field, so that rates are matched more closely to crop requirements. Better methods of soil testing and in-field plant nutrient determination can more accurately determine whether nutrient applications are required. New genetic techniques are also being adopted to develop crops that are more efficient at accessing and using nutrients.

Soil fertility management is not just a matter of applying the correct amount of nutrients in either synthetic or organic form. An integrated soil fertility management strategy combines techniques to maximize nutrient use efficiency with practices to improve water use as well as overall agricultural productivity and sustainability. Local sources of crop residues, animal manures, biosolids, and municipal wastewater nutrients should be returned to the soil to help close the nutrient cycle by returning nutrients removed from the soil back to the soil–plant system. Yield constraints should be minimized by control of weeds, pests, and diseases. Use of crop cultivars with a high yield potential, a diversified rotation, and optimum seeding and tillage practices should be used to optimize crop yields and take the greatest advantage of nutrient and water resources.

Conservation agriculture practices, such as reduced tillage, should also be adopted to reduce the risk of soil degradation and to maintain long-term soil fertility. Such practices retain crop residues on the soil surface to protect it from erosion and to allow more water to infiltrate, rather than run off or evaporate. Conservation agriculture also aims to increase soil organic matter content by retaining more organic matter in the system. Other important soil fertility management practices include diversified crop rotations, production of legume crops, maintenance of soil cover with cover crops and mulches, retention of crop residues, use of available organic manures, including composts and green manures, and efficient use of inorganic fertilizers.

Conclusions

Soil fertility provides the base for a healthy and vibrant plant community. Improved understanding of the complex interactions between the physical, chemical, and biological factors that influence nutrient dynamics is critical to the development of effective nutrient management strategies for economically optimum production in managed ecosystems, while also minimizing negative environmental effects. As the world’s population grows, soil fertility management will play an increasingly important role in ensuring food security and the long-term sustainability of our natural and agricultural ecosystems.

Leibniz Center for Agricultural Landscape Research (ZALF), Germany

A soil map portrays information on the locations and properties of soils. There are two main components to a soil map: spatial and tabular. The spatial component is the map itself, consisting of polygons (or raster cells) that delineate soil types as map units. Map units are cartographic entities that help simplify the map by grouping similar delineations of soils. Each map unit is symbolized to correspond to a legend. The tabular component of a soil map is a summary of the range of physical and chemical properties for each soil type along with interpretive information based on those properties, for example, capabilities or limitations for crops, construction, and sanitary facilities. Today, the tabular data are typically stored in a soils information system. For example, in the United States this system is called NASIS or the National Soils Information System.

The process of soil mapping includes gathering information about the soil landscape and communicating that information in a format suitable for the end user. Part of that process involves synthesizing the available and known information and condensing it to meet the requirements of the map. Classification is a means for simplifying the complex soil landscape into easily communicated concepts and units. Even though the soil landscape is complex, practical limitations almost always restrict direct observations to a small fraction of the landscape. Because of this limitation in sampling, the soil mapper must have a systematic means for extending observations taken at a single point to a greater area. This is the essence of many forms of mapping.

The characteristics of a soil at a single location, that is, a pedon, can be described using a set of established taxonomic definitions for relating what is observed (e.g., World Reference Base or the US Soil Taxonomy). A set of pedons can be grouped together by similar characteristics and described by defined taxonomic units called soil series, taxadjuncts, or phases. However, as more pedons are grouped together, the heterogeneity of the spatial unit is likely to increase. Synthesizing this information is the challenge of the soil mapper. To successfully manage this challenge, the soil mapper must have a deep understanding of natural processes on the landscape and the ability to organize the information in a useful manner.

History and purpose of soil maps

Beginning at least by the fourth century, soil maps have been linked to the valuation of land, which during early times was mostly dependent upon soil productivity. By the late nineteenth century, more emphasis was placed on the soil maps as a source of information for determining crop suitability and best management practices (Krupenikov 1993). In the early twentieth century, interest in soil maps grew beyond the agricultural sector. Soil maps were able to...
SOIL MAPPING AND MAPS

provide valuable information for residential and commercial development, locating sources of aggregate, sand, clay, and other building materials, and helped guide land conservation efforts. Interpretative (derivative) maps created from soil maps can spatially represent a variety of properties such as erodibility and corrosivity, and suitability for land uses such as for building construction, septic tank drain fields, wildlife habitat, and road construction. Today, as environmental issues rise in importance and as recognition of soil’s role in ecosystem services increases (e.g., water quality, carbon sequestration), new demands are being made from soil maps.

Although regions of the world were described by the characteristics of their soil by the ancients, the earliest known linking of soil attributes to a map was for cadastral purposes. These maps were focused on local areas, and map units were based on property boundaries rather than the actual distributions of the soil properties. Soil maps that would be widely published required accurate base maps onto which the thematic information could be drawn. The base maps were needed to provide location references for transferring observations to the map. The increased availability of accurate topographic maps at the turn of the nineteenth century coincided with the dawn of soil mapping as we know it today (Miller and Schaetzl 2014). As an example, when the US Soil Survey began in 1899, a lack of available topographic maps meant that soil mappers had to rely upon plat maps for spatial reference, or had to create their own base maps with a plane table and alidade (Lapham 1949). These early surveys were performed by crews camping and traveling on horse, sampling the soil at regular spatial intervals. Soil maps produced by this method had a cartographic scale of 1:63,360 and generally had less than 10 map units. As better base maps became available, soil maps became more accurate and detailed. Efficiency also increased, because more preliminary work could be done to guide field sampling. The advent of aerial photography for map making greatly enhanced soil mapping efforts by providing a better spatial reference, thereby improving mapping consistency (Bushnell 1929). The availability of aerial photographs as base maps also improved efficiency, because they included useful parameters for predicting soil properties (e.g., vegetation, topography). Today, the soils in almost all of the United States (more than 8 million km² of soil maps) have been mapped at least once, mostly at a map scale between 1:24,000 and 1:12,000. A majority of these maps were done on a county or multicounty basis and were drawn on aerial imagery base maps.

The progress of soil mapping in other parts of the world has varied, largely dependent upon government investment and landscape accessibility. Nonetheless, work has already been done to merge the various soil mapping efforts from around the world. Today, work is being done to leverage new technologies to produce an improved digital soil map of the world (Sanchez et al. 2009). A global map that is more accurate and contains more soil information is beneficial for addressing issues such as global climate change and global food supplies. At the same time, there has been a resurgence in interest for soil mapping at national levels as well, but with a greater emphasis on using remote sensing and geostatistical techniques to reduce the amount of field work required to create the map.

Fundamental concepts in soil mapping

Soil mappers rely on a certain degree of spatial autocorrelation in order to group areas on the map as homogenous delineations. It is also helpful to recognize that each delineation is not completely unique. In areas where the
original parent material is similar and has been subsequently modified by similar environmental conditions, soils in them are expected to have developed similar soil properties. This concept is expressed as the state factors of soil formation, which soil mappers use to predict the distribution of soil properties and to group similar soils. These state factors are identified as climate, organisms, relief, parent material, and time (Dokuchaev 1967/1883). Observing soil properties at every location on the landscape is a practical impossibility, for example, a mapper would need to make approximately 10,000 observations with a standard bucket auger in order to sample even 1% of the soil in a half hectare of land. Therefore, when all five state factors are relatively uniform, the soil mapper can make assumptions about the similarity of the surrounding soils to the soil directly observed. Similarly, by spatial association, the soil mapper can make a similar assumption about other parts of the landscape that also have the same state factors. This relationship between soils with similar state factors allows for multiple delineations to be described together as a single map unit. Thus a soil map with hundreds of delineations can use a fairly simple legend. Map units are also linked to tables or databases that provide information about each map unit. These tables add many dimensions to the soil map as the information about soil properties, and derived interpretations, have infinite possibilities.

To make determinations about the uniformity of the state factors across the landscape, soil mappers rely on a combination of field observations and a variety of base maps. One of the most valuable base maps currently used in soil mapping is the aerial photograph. These base maps not only provide spatial reference but also provide information about vegetation and topography – two of the most important state factors at the local level. Further, topography often provides indications of parent material, and parent material is generally related to time. Also, vegetation communities often develop in response to the climate, topography, and parent material. Therefore, aerial photographs provide soil mappers with a wealth of information for identifying areas expected to have similar soils.

The soil mapper draws map units that are as homogenous as possible, under the constraints of map scale, available information, and time. In practice, it is difficult to delineate perfectly homogenous map units, and thus, certain compromises must be made in the translation of the real world’s complexity to the map representation. In actuality, the spatial variability of the soil landscape makes it impossible to draw a completely accurate soil map. It is the goal of the soil mapper to produce the most accurate map possible for the intended purpose, within the constraints of the resources available.

Although soil mappers strive to gather as much information as possible for the mapping area, limitations in base map resolution, accessibility, and time are a constant reality. Map scale, which determines the minimum size delineation of the map, strongly influences soil mappers’ decisions for dividing an area into multiple delineations, or grouping similar soils into delineations. Because there is sometimes the need to group soils with known differences, there are different types of map units, with differing degrees of cartographic purity. When delineations can be made, such that the majority of the area meets the definition of the map unit (i.e., soil series), the map unit is considered to be a consociation. In cases where there is more variation in soil types than can be delineated separately, but there is a predictable pattern of the component soils, then the map unit is considered either a complex or an association. The term complex is used for map scales larger than 1:24,000, and the term association is used for smaller map scales. All of these map
units are named by their constituent soils. When the variations in soil types do not have a spatial pattern, but the soils can be grouped because their differentiation is not important for the purpose of the map due to some overriding property such as flooding, then the map units are referred to as undifferentiated groups. In all of these cases, any dissimilar inclusions in the map units are noted, along with their respective composition percentages. These minor components may be important in differentiating between two map units which have the same major component, but which occur on two different landforms. For example, the hypothetical Alpha series may be mapped as a coarse-loamy deposit on both till plains and outwash plains, but the map units on the two different landforms may have very different minor components.

Soil maps can differ in intensity, as determined by the intended uses of the finished product. Lower intensity mapping, such as may be used in forests, requires fewer observations per land area and results in a less detailed map. This lower level of detail is reflected in the scale of the map, the number of soil map units delineated, and the sizes of the delineations. Higher intensity mapping is typically performed in areas where more specific soil information is needed, as in agricultural landscapes. The US Soil Survey recognizes five orders of soil mapping intensity (Table 1).

Producing the soil map

Soil mapping starts in the office. Before heading to the field to start digging, reference materials including aerial photographs, digital elevation models and maps of bedrock geology, landforms, vegetation, and topography are assembled and studied. Before digital elevation models became common, stereoscopes and stereo-pairs of aerial photographs were used to evaluate slope steepness and shape. Using these data, soil patterns begin to emerge before a single hole has been dug. Depending on the area being surveyed, different attributes of the various base layers become important in attempting to predict soil patterns. In this way, the soil mapper develops a preliminary mental model for how soils are distributed in the area. This model may or may not eventually be recorded in the form of a block diagram or other graphical representation (Figure 1). The soil mapper then applies this initial model to delineate potential differences across the soil landscape, either by manually drawing them on aerial photographs or by sketching them digitally using a geographic information system (GIS). Thus, preliminary work done in the office greatly increases the efficacy of fieldwork. However, subsequent field investigations remain critical for validating, or recalibrating when needed, the mental model developed by the soil mapper (Figure 2).

After the preliminary linework has been drawn, the soil mapper begins to test and apply their mental model in the field. To do this, they plan traverses to verify expected soil patterns and to explore areas where more information is needed. The term traverse is used to refer to this stage of the mapping process when preliminary models are being tested. Most traverses are designed to cross the landscape in a way that allows the soil scientist to see an entire toposequence of soils – soils on the uplands to the lowlands – and those in between. Sometimes, just getting to the survey area is a challenge, requiring kilometers of hiking or boating, using trucks, all-terrain vehicles, and other modes of transportation. In more remote areas, overnight camping is necessary. As they walk across the land, soil mappers dig or auger holes where changes in soil characteristics are likely. These changes could be variations in vegetation, landscape position,

*This is about the smallest delineation allowable for readable soil maps produced in a paper format. In practice, the minimum size delineations are generally larger than the minimum size shown.*
Figure 1  Example of a block diagram, which communicates the soil mapper’s broad-scale conceptualization of the soil landscape (Minger 1991). Although such diagrams communicate much information about the soil landscape, they do not fully capture all the parameters that a soil mapper integrates to produce the final soil map.

slope, or other observable differences that may or may not have been evident from the base maps examined in the office. It is important that these field observations are tied to specific locations. Today, soil mappers track their location using global positioning system (GPS) units.

Field observations are typically made using hand tools such as spades, bucket augers, and probes (Figure 2b). When practical, motorized tools such as truck-mounted probes and backhoes can also be used. Terrain, accessibility, and soil types will determine which tools are best suited for the job. As the soil mapper excavates the soil profile, they record changes such as color, texture, density, rock fragment content, as well as concentrations of salts and other minerals. They also look for a direct observation of the water table and/or redoximorphic features that may indicate a seasonally high water table. Altogether, this information will help the soil mapper to classify the different soil types as defined by soil series. A soil series is the finest level of classification and akin to classifying a plant or animal to the species level. Soil series are represented by a range of soil properties linked to soils that share the same parent material and state factors. Although concepts of soil series are defined by the state factors, classification of a soil into a series is done by specified ranges of soil properties to avoid issues with interpretation.
Soil mapping is a process that includes diligent work both in the office and in the field. The process (a) begins with research and careful examination of available base maps, which (b) guides investigations in the field, and (c) is completed in the office using GIS software.

Once the mapper finishes with fieldwork, they return to the office to summarize their findings and adjust their preliminary maps. As observations are accumulated, the soil mapper’s mental model is calibrated, strengthened, and refined. Eventually, emerging patterns form the basis for a working legend, or list of soil series found in the survey area. A key can then be developed to help the mapper more quickly identify the appropriate soil series at future field sites, based on site conditions and important soil characteristics. Once the commonly occurring soil series have been identified, representative sites are chosen and a representative soil is described in more detail. At this point, samples can be taken for laboratory analysis of soil chemical and physical properties that are not observable in the field. After all the map units have been delineated and soil types have been defined, transects (making soil observations at regular intervals) may again be performed to quantify map unit composition.

In the past, soil maps were commonly hand-drawn on aerial imagery, compiled to orthophotography, and then digitized. Modern soil mapping methods encourage linework to be recorded in a digital format from the very beginning, eliminating several steps that can potentially introduce error into the final product. The modern digitizing process usually involves “heads-up” editing, which uses a combination of GIS reference layers and field observations. Digital map finishing, including the addition of other data layers such as roads, streams, and political boundaries, is usually performed by cartographers before final publication of the map, in order to give the map reader a way to relate the soil boundaries to key geographic landmarks (USDA-NRCS 2014a). In the past, soil maps were published as hardcopy books. More recently, those maps have been digitized and published on CDs/DVDs or made available on the Internet as either a downloadable product or interactive maps (Figure 3). The benefit of online soil maps is that information for large areas across political boundaries can be organized in one location and made accessible to a general audience. The technology of online GIS is
Figure 3  Screenshot from the US Web Soil Survey (USDA-NRCS 2014b). This soil map is in an online GIS that allows users to select an area of interest, access map unit information stored in the database, and download the data in a variety of formats.
developing rapidly and will continue to change how we interact with soil maps in the future.

Future of soil maps

Soil maps will continue to be updated and improved, especially as to the level of map detail and accuracy, with some expansion into previously unmapped areas. Future soil mapping will continue to deal with the constraints of time and money that can be spent on a single project. However, soils will be more accurately described as more time is spent assessing soil properties with field and laboratory testing. Many current soil maps can be improved with further observations and GIS modeling techniques, using remote sensing and digital elevation models.

A major change for soil maps in the future will be the shift from polygon to raster data models in a digital environment. The raster data model is gaining in popularity because of its efficiency at storing large amounts of information. Data storage efficiency is important for covering larger areas with more detailed information. Because of this, raster data models are better suited for applications such as precision agriculture and environmental modeling. There is a push in the United States to create raster versions of the current vector-based soil maps as a first step in making digital soil maps available. In other parts of the world, where soil mapping in the field has not been as intensive, new digital techniques are being emphasized to develop soil maps that more fully utilize the resolution capabilities of the raster data model.

In addition to the changes in the production process and formatting, the purposes of soil maps continue to evolve and expand. Highly urbanized areas were often initially dismissed when soil surveys of the more rural surrounding areas were taking place because of their lack of agricultural potential. In recent years, the demand for soils information in these areas has increased; major cities like Berlin, London, New York, and Detroit have been surveyed or such surveys are in progress. Urban soil maps are being used for a variety of city planning purposes. Due to the unique nature of urban environments, soil classification systems have recently been amended to accommodate urban soils.

Conclusions

Despite the fact that we live in a rapidly evolving world of technology, knowledge of the very ground beneath our feet will remain an important part of human life. Soil maps communicate knowledge about soil resources, which is essential for sustainable management and conservation of soil along with the other natural resources that interact with it. Although the monumental efforts of mainly the past 100 years have produced an excellent repository of soil maps, especially in the United States, these maps need to be regularly updated to incorporate current understanding of soil science, utilize modern technologies, and reflect changes that have occurred in the landscape.

Soil mass balance

Kyungsoo Yoo
University of Minnesota, USA

Soils form at the intersection of the lithosphere, biosphere, atmosphere, and hydrosphere. They are comprised of a solid phase, consisting of minerals and organic matter, a liquid phase consisting of water and dissolved constituents, and a gaseous phase. Quantitatively assessing the fluxes (i.e., moving masses) of materials within and across the boundaries of a soil body, and the coupled changes in the total inventory and distribution of soil constituents, defines the soil mass balance approach (Figure 1). This is a key endeavor in understanding soil genesis and the relationship of soils to terrestrial ecosystems. Defining a soil system is synonymous with delineating its boundary, a task that is limited only by the researcher’s ideas and goals. The system may be a volume of soil material, various depth intervals, a horizon or a set of horizons, or the entire soil profile. As much as a mass balance can be constructed for soil systems of varying spatial scales like these, it can also be constructed across different time scales. For example, a flux that is crucial in describing soil mass balance in days to months may be less significant when addressing soil genesis over time periods of thousands to millions of years, but may be key to effective soil managements. Therefore, choosing the most appropriate fluxes for the soil constituent of interest depends upon the temporal and spatial scales of the research question.

Simonson (1959) described a soil’s material composition as a result of four main suites of pedogenic processes: additions, losses, translocations, and transformations. This view has functioned as a fundamental precept for the soil mass balance approach in understanding soil genesis and biogeochemistry for decades. For instance, research on the coupled processes of eluviation and illuviation has sought to close the mass balance of iron and clay by describing vertical translocations and transformations, and their association with organic and mineral materials. Similarly, hydrochemists measure cations in soil water exiting the soil profile and use the data to infer biogeochemical changes in soils by utilizing mass balance concepts. Similar approaches can be done on watershed scales. Additionally, concerns about soil erosion as a threat to soil sustainability begin from the consideration of soil mass balance.

Widely used soil mass balance approaches

Moving beyond concepts and theory to define explicitly quantitative treatments of soil mass balance is an integral part of current research on soil genesis and biogeochemistry. For the soil constituents modeled by mass balances, analytical instruments must first be used to determine their concentrations in units of mass per mass or mass per volume. This approach provides a dilemma when the research question focuses on the abundance of a constituent, for example clay or iron. Because concentration is a relative measure, a soil constituent’s concentration may increase despite some of the constituent being lost from the soil, due to greater losses of other soil constituents. For example, the concentration of iron may be greater in a soil than in its parent...
SOIL MASS BALANCE

Input flux of $j$

$I_j$

Output flux of $j$

$O_j$

Figure 1 A soil system exchanging its constituent, $j$, with its surrounding environment. The mass change (i.e., $\Delta M_j$) in the soil system, if its transformations to other constituents do not occur, is equivalent to the mass difference between the input and output fluxes (i.e., $I_j - O_j$).

By calculating mass fluxes, the extent of cumulative losses or additions of various soil constituents during soil formation can be determined. When the calculations are made for individual horizons within a soil profile, the vertical distributions of the fluxes inform us of the long-term translocations of soil constituents within the profile. These horizon-based fluxes may then be integrated for an entire soil profile to characterize soil genesis in terms of the evolution of soils from parent materials with associated mass fluxes. By applying this approach to soils with well-constrained soil-forming factors and of known age, researchers can develop a highly quantitative understanding of the environmental controls on soil-forming processes, and on rates and pathways of pedogenesis. The geochemical mass balance approach therefore offers a powerful means to quantify the processes depicted in Simonson’s (1959) conceptual view of soil formation.

Wide application of the geochemical mass balance to characterizing elemental behaviors in soil formation is partly facilitated by the routine procedure of obtaining oxide concentrations in

where $h_p$ is the thickness of parent material that has been converted to a soil horizon with the thickness of $h_w$, $m_{j,\text{flux}}$ is the mass loss (negative) or gain (positive) of constituent, $j$, during the formation of the soil horizon [kg m$^{-2}$], $C_{j,w}$ is the mass fraction of the constituent, $j$, in the soil horizon [kg kg$^{-1}$], $C_{i,p}$ is the mass fraction of $i$ in the parent material [kg kg$^{-1}$]; $\rho_p$ is the bulk density of parent material [kg m$^{-3}$]; $\rho_w$ is the bulk density of the soil horizon [kg m$^{-3}$]. From the equations 1 and 2, the following equation 3 is derived for calculating $m_{j,\text{flux}}$ in the soil horizon:

$$m_{j,\text{flux}} = h_w \rho_w \left( C_{j,w} - \frac{C_{i,w}}{C_{i,p}} C_{i,p} \right)$$ (3)
soil and geological materials. The mass balance approach has been also modified for situations where aeolian inputs are significant, or for soils that are continuously rejuvenated by erosion. Although the application of the quantitative mass balance has been largely for elements with pedologic or ecological significance, such as silicon, iron, aluminum, calcium, phosphorous, and potassium, the method has the potential to be applied to quantifying the long-term inputs of elements acquired from contaminants, or from agricultural fertilizer or other kinds of soil amendments.

In contrast to the geochemical mass balance model that has been largely used for soils on geomorphically stable landscapes, a physical mass balance model has been developed for actively eroding landscapes. In eroding landscapes, soils function as a critical component of landscape evolution because they are the location where physical and chemical weathering are most active. A *geomorphic soil mass balance* relates a soil to a topographic location on a hillslope, and the soil's mass is constrained by (i) colluvial inputs (from upslope) and outputs (to lower hillslope areas) as well as (ii) soil production from the underlying geological materials (Figure 2).

\[
\frac{\partial h}{\partial t} = -\nabla \cdot Q - \rho_r \frac{\partial e}{\partial t}
\]  

(4)

where \( h \) is soil thickness (m), \( Q \) is the volume of colluvial flux crossing a unit contour line (m³ m⁻¹ yr⁻¹), \( e \) is the elevation of soil to bedrock boundary (m), \( \rho \) is bulk density (kg m⁻³), and the subscripts \( s \) and \( r \) represent soil and bedrock, respectively. The elevation change at the soil-bedrock boundary (i.e., \( -\frac{\partial e}{\partial t} \) in equation 4) is frequently referred to as *soil production*, as it is equivalent to the material flux from the bedrock to the overlying regolith and soil. The soil erosion rate is calculated as the difference between colluvial outputs and inputs, and soil losses via erosion are compensated by soil production in a steady-state system. When landscape morphology is a primary concern, this volumetric representation of colluvial flux and soil production provides a strong theoretical foundation for geomorphological research.

This simple mass balance approach has been central not only to numerically modeling landscape evolution but also in motivating researchers to seek key feedbacks in geomorphic systems. This approach has a long conceptual history in geomorphology, dating back to G.K. Gilbert (1909). A soil geographer, Donald Johnson (Johnson, Domier, and Johnson 2005), independently proposed the surprisingly similar concept of dynamic denudation, where physical interactions between soil organisms and properties of soils and geological materials, via bioturbation, were emphasized as responsible for producing, mixing, and eroding soils and thus forming soil and landscape morphology. It is, however, the recent widespread application of radioisotope dating tools that has assisted the expansion of the application of the model. Among these dating tools, the most widely used include cosmogenic radionuclides such as \(^{10}\)Be.
SOIL MASS BALANCE

\( t_{1/2} = 1.3 \text{ million years} \) that accumulates as atmospheric fallout in soils. With isotopic dating tools such as this, researchers have begun to constrain the turnover time of the soils on eroding landscapes. The outcomes, when combined with this mass balance, facilitate the quantification of functional relationships between soil production rates and soil thickness (i.e., the soil production function) or the relationship between colluvial flux and topographic attributes such as slope gradient and curvature.

The previous two mass balance approaches have focused primarily on geologically inherited materials in soils. Soil carbon mass balances have developed largely independently, but their importance has grown sharply because of the significance of soils in the global carbon cycle. Soil organic carbon storage has been modeled as the balance between plant carbon inputs and losses via the microbial decomposition of organic matter. One well-accepted view is that decomposition of organic matter follows first order kinetics, such that decomposition loss rates increase in direct proportion to the amount of organic matter present in soils. This concept is expressed in this mass balance:

\[
\frac{dC}{dt} = I - kC \tag{5}
\]

where \( C \) is the soil organic carbon storage \([\text{kg m}^{-2}]\), \( t \) is time \([\text{yr}]\), \( I \) is the plant carbon input rate \([\text{kg m}^{-2} \text{ yr}^{-1}]\), and \( k \) is the decomposition rate \([\text{yr}^{-1}]\). One of the direct implications of this model is that the greatest accumulation rates of carbon are observed in young soils over the course of soil formation, a point that has been confirmed in field observations using a soil chronosequence (Schlesinger 1990). Despite the simplicity, this model offers an explanation of the global pattern of soil carbon storage as a balance of net primary productivity and decomposition (Amundson 2001).

Over the past decades, primarily driven by the societal needs to better constrain the soil carbon pool, the soil carbon mass balance has become increasingly sophisticated, while its basic conceptual structure as written in equation 5 has been maintained. New developments include but are not limited to: (i) diversifying pathways of carbon fluxes, (ii) the division of the soil carbon pool into subpools with differing susceptibilities to decomposition, and (iii) the incorporation of a rapidly evolving mechanistic understanding of environmental controls on decomposition rates.

Criticisms and future of soil mass balance approaches

The above mass balance models, despite sharing soil systems as a common object, have been advanced by different scientific communities, each with unique research interests and agendas. One direct consequence of this is the differing – often described as conflicting – views of the boundaries of soil systems. For example, soil scientists, who are familiar with pedogenic processes operating within a three-dimensional continuum from soil to parent material on stable landforms, may find difficulty in adopting the term “soil production,” which geomorphologists use to refer to mass fluxes across the boundaries between bedrock and physically perturbed colluvial soil on actively eroding landforms. Likewise, researchers studying soil carbon have largely focused on balancing carbon in the topmost layers of soil profiles that are accessible and thus easy to replicate, while more recent data demonstrate the globally significant presence of subsoil and deep subsurface carbon. One might criticize these discrepancies as limitations of the mass balance approach. However, the ability to identify these poorly quantified zones of soil and critical zone research has been made possible due to existing mass balances. Soil mass balance
SOIL MASS BALANCE

has been therefore, in hindsight, an essential tool to advance our understanding of soil genesis and biogeochemistry.

New, important findings in soil genesis are being made increasingly at the interfaces of two or three mutually excluding mass balances, or by merging them. The unification of geochemical and geomorphic soil mass balances will allow for the expansion of quantitative assessments of soil biogeochemistry to rugged or marginal landscapes that are under increasing pressure for urban and agricultural uses, especially in developing countries. The same integration may also benefit geomorphologists in better understanding the biogeochemical impacts of landscape evolution, such as the long-postulated hypothesis that orogenic activities have contributed to global cooling events in the geologic past. Lastly, on the issue of the global carbon cycle, emerging interests in the nonbiological fluxes of carbon transported via colluvial and alluvial sediments, and via inland waters, call for the integration of all three solid phases (geochemical, geomorphic, and biological) in a soil mass balance. Therefore, the development and application of increasingly complex soil mass balance models is an integral part of ongoing research which should produce novel insights into issues related to soil sustainability, landscape evolution, the global carbon cycle, and human health.

Soil taxonomy and soil classification

Craig A. Ditzler
Jon Hempel
USDA NRCS National Soil Survey Center, USA

Overview of the system

Soil taxonomy replaced the classification system of the United States that was published in 1938 (Baldwin, Kellogg, and Thorpe 1938). There were several reasons for the change. Classes in the 1938 system focused on their central concept, but the limits of the classes were not well defined, making it difficult to classify soils that had properties intermediate between two classes. Class definitions were based on the prevailing notions of soil genesis at the time, but where genesis was unknown or in dispute, soils could not be classified consistently. Classes were defined on native conditions, meaning that some cultivated soils could not be easily classified. Due to these and other problems, it was determined that an entirely new system was needed.

In response, soil taxonomy was developed by the United States Department of Agriculture (USDA) in the 1970s, and has been updated several times. The effort was initially led by Dr Guy D. Smith from the 1950s to the early 1970s. Successive drafts of the system were developed and field tested within the United States and other countries. It had several specific objectives (Smith 1963). It needed to organize the several tens of thousands of kinds of soils known to exist around the world into useful classes whose members share key properties considered important for understanding the soil’s response to use and management. Also, the classes were designed to reflect, but not be directly defined by, soil genetic processes because processes cannot be observed directly. Very importantly, the classification system was designed to fulfill the practical goal of supporting soil-mapping projects of the National Cooperative Soil Survey (NCSS) in the United States and similar efforts in other countries.

In achieving these goals, soil taxonomy has organized our knowledge about soils and improved our ability to communicate about them. It has helped us to understand relationships between different kinds of soils. It has enhanced our ability to obtain information through experimentation and observation on a few selected soils and to extend and apply that knowledge to other soils in the same or similar classes.

The system was first published in 1975 as Soil Taxonomy: A Basic System of Soil Classification for Making and Interpreting Soil Surveys (Soil Survey Staff 1975). A second edition was published 24 years latter (Soil Survey Staff 1999). Since then, several revised versions of the taxonomic keys have been published and are available online (Soil Survey Staff 2015a). Each successive version reflects the expanding knowledge of soils around the world.

Grouping soils into classes, by its very nature, reflects the intended purpose and goals of whoever may be designing the classes. For example, an ecologist might group soils by their natural ecological types – tropical rainforest soils, prairie soils, hardwood forest soils, desert soils, and so on. A surficial geologist might group soils based on their parent material – glacial till soils, lacustrine sediment soils, weathered granitic rock
SOIL TAXONOMY AND SOIL CLASSIFICATION

soils, eolian sand soils, and so on. An engineer might group soils according to their particle-size distribution – sandy soils, gravelly soils, clayey soils, and so on. There are as many ways to classify soils as there are purposes for doing so, and thus many soil classifications systems exist around the world.

Soil taxonomy is a morphogenetic system; it is based on the morphology and inferred genetic history of the soil. Soil scientists studying the origin and characteristics of soils (pedologists) consider soil as a three-dimensional natural body. Soils form a continuum extending both laterally across the landscape, and to some depth (ranging from less than one to several meters). Successive layers or soil horizons are formed in the soil due to natural soil-forming processes, acting over time, on an initial parent material.

How soils form and why we can map them

The morphogenetic view of soil was first proposed by the Russian scientist V.V. Dokuchaev in the late nineteenth century. It was expanded upon in the United States by scientists such as Coffey, Marbut, and Whitney in the early twentieth century. As knowledge of soil genesis grew, earlier concepts of soil as simply the weathering product of geologic materials were expanded to recognize that soil is the result of the interaction of five fundamental factors of soil formation: parent material, climate, organisms, relief, and time. Parent material is present at the starting point of the soil formation process. Examples include alluvium, wind-blown sands, glacial deposits, weathered bedrock of various types, colluvium, thick deposits of organic matter (as in bogs), and many others. Parent material provides the initial physical and chemical properties to the soil. Climate, especially precipitation and temperature, is an active soil-forming factor that regulates the intensity of parent material weathering and translocation of materials within soils. Freeze/thaw cycles promote the physical breakdown of mineral particles. Temperature regulates many biological and chemical weathering and transformation processes. Precipitation supplies water to dissolve and translocate mineral and organic constituents from the surface to deeper soil layers, and affects the kind and amount of vegetation that can be supported. Organisms, which include microbes, earthworms, insects, burrowing animals, plants, and humans, also affect soil development. They contribute to soil mixing, cycling of nutrients, and add organic material to the soil. Relief (landscape position) further influences the rate and intensity of soil formation locally. Low-lying, concave positions receive runoff water and sediment from higher positions, thus increasing the water available to move into and through the soil. Higher, convex positions tend to shed water and sediment, thus lessening the amount of water entering and passing through the soil. Topographic aspect (the compass direction that a slope faces) is an important component of the relief factor. In the Northern Hemisphere, south- and west-facing slopes receive the most direct solar radiation and tend to be warmer and dryer than north- and east-facing slopes.

The longer these soil-forming factors act upon the soil, the more the original parent material is changed. Gradually, the soil comes to reflect the state factors that interacted to form it, until in some soils a state of equilibrium with its environment is achieved. Some soils have been forming for relatively short time periods, such as those developed in recent eolian or alluvial deposits. Others are thousands of years old, such as those formed in materials deposited by the last continental glaciers. Soils on very stable landform surfaces that have remained relatively unchanged
for long periods of geologic history are extremely old and weathered.

The five factors of soil formation interact to control the processes responsible for soil formation. These processes include physical and chemical weathering, biological activity, chemical reactions, additions of new material, translocation of constituents within the soil, and leaching of material out of the soil. The effect of these ongoing processes is expressed by the development of distinct layers (soil horizons) that can be observed in many soil profiles (Figure 1). These horizons differ from one another in any number of properties such as thickness, color, texture, structure, salinity, pH, fertility, mineralogy, consistency, organic matter content, and so on. Soil horizons are the morphological expression of the interaction of the factors of soil formation at that location, and form the basis for soil classification.

A fundamental tenet of soil science states that where the factors of soil formation are the same (or similar), the soil horizons of that soil body will be the same (or similar). As a consequence, soil bodies tend to occur in repeating patterns in the landscape, because the state factors occur in predictable, repeating patterns. If one understands the local factors of soil formation, the kind of soils in the area can be understood, predicted, and mapped (Figure 2). The fact that soils form predictable natural bodies makes mapping their spatial distribution and geographic location possible, and at a variety of scales (Hudson 1992). In the United States, the NCSS has been conducting soil mapping for over 100 years, and maps are available for most of the United States (http://websoilsurvey.nrcs.usda.gov/). Soil surveys have also been conducted in many other countries. As more and more soils were identified, the need for a classification system to organize this knowledge was recognized.

### Diagnostic horizons in soil taxonomy

A key feature of soil taxonomy is the use of diagnostic horizons and features to define taxonomic classes. They are defined based on a combination of morphological characteristics that can be observed in the field, as well as other properties that must be measured in a laboratory. Soil taxonomy includes definitions for 66 different kinds of diagnostic horizons and features. Diagnostic horizons at the soil surface are called epipedons (Gr. epi, over, and pedon, soil). Other diagnostic
horizons are simply called subsurface horizons. Two examples (one epipedon and one subsurface horizon) are provided here to illustrate this concept. Many of the world’s grasslands have a thick, dark surface horizon rich in organic matter and high in native fertility. It is formed as a consequence of abundant inputs of organic matter to the soil by deep-rooted grasses with high belowground biomass, coupled with the mixing activity of fauna. This diagnostic surface horizon is a mollic epipedon (L. mollis, soft) (Figure 3). Some arid and semiarid soils have a subsoil horizon rich in calcium carbonate. Typically this horizon forms as a result of water dissolving calcium carbonate in the surface horizon and carrying it downward as it percolates into the soil. The water only moves a relatively short distance into the subsoil before being taken up by plant roots, or moving back up, toward the surface, due to evaporative demand. Left behind in the subsurface are any dissolved minerals that the water contained, such as calcium carbonate, and these accumulate over time. This diagnostic subsoil horizon is a calcic horizon (L. calais, lime) (Figure 4).
The thick, dark surface horizon of this soil from Wisconsin is a diagnostic horizon known as a mollic epipedon. Photo by Dr Randy Schaetzl, USDA Natural Resources Conservation Service.

The use of diagnostic horizons and features that are defined by measurable and observable soil properties and that infer pedogenesis is an effective strategy, first used by soil taxonomy, to integrate pedogenic theory into soil classification. An important advantage is that it does not require prior knowledge of the genetic history of the soil. Rather, one needs only to identify the kinds of diagnostic horizons and features that are present based on the properties of the soil.

Structure of the system

Soil taxonomy is a hierarchical system with six categories, or levels: order, suborder, great group, subgroup, family, and series. The highest category – the order – has 12 entries. All of the soils known in the world belong to one of these 12 soil orders. As one moves progressively lower in the system, from order to series, the number of classes within each category becomes more numerous and more narrowly defined. Also,
because members of each class share all of the properties required for the class above it, the number of characteristics used to differentiate the classes within each category increases in the lower classes.

To classify a soil, one starts at the beginning of the key, with soil orders, and works through the keys progressively. As soon as the listed criteria are met at a particular level, the soil is placed in that class and then the criteria for the next level are considered. To illustrate the hierarchical nature of the system, consider the Spodosol order. As currently documented in the United States it consists of 5 suborders, 22 great groups, 121 subgroups, 425 families, and 747 soil series.

The characteristics of the classes within each category are defined so as to reflect the major soil-forming processes, or at least those that have exerted significant control on the formation and development of the soil. Soil orders are separated based on the presence of properties resulting from major soil-forming processes, often operating over large geographic areas. Suborders are defined based on the presence of properties that exert major control over currently active soil-forming processes. These commonly consist of dynamic climatic controls such as the soil moisture or temperature regime. Great groups are defined based on the presence of properties that exert additional controls over the development of the soil in its current environment. These are often static properties such as the presence of a specific diagnostic horizon or feature. Subgroups are defined by the presence of properties that either reflect a relationship to similar soils in other categories, or are unique properties not recognized in any other class. Soil families consist of properties that are particularly important to the use and management of the soil. These include capacity factors such as soil texture or depth, as well as intensity factors such as soil temperature or inherent ability to hold and exchange nutrient cations. Finally, soil series are separated by narrowing the range of important properties so as to reflect important use and management considerations and to facilitate identification in the field while making soil maps.

Naming conventions

Soil taxonomy uses a unique mnemonic system of nomenclature for naming the classes (Heller 1963). The class names therefore are very effective at communicating the overall soil characteristics to those trained in its use. At each level (above the soil family) short formative elements, derived mostly from Greek or Latin roots, are combined in specific ways to form the names of each class.

Soil order names all begin with a syllable from the root word used to represent the order, and end with the syllable sol (L. solum, soil). The beginning and ending syllables are connected with the vowel i (Table 1). For example, the order name Aridisol is based on the Latin word aridus (dry). This soil order contains many of the world’s dryland soils. The name Histosol is based on the Greek word histos (tissue) and consists of soils formed in thick deposits of decaying organic material. The other orders are named in a similar fashion. For the names of the soil classes below the order level, the names end with a short formative element syllable derived from the Latin, Greek, or other word used for the order (e.g., id for Aridisols, ist for Histosols, etc.) as shown in the second column of Table 1.

Suborder names consist of two syllables, for example Aquolls or Fibrists. The first syllable is connotative of either a major soil property or the moisture or temperature regime of the soil. The second syllable is the soil order’s formative element. For example a soil belonging to the Calcids suborder is an Aridisol (denoted by the

second syllable id) that has a calcic diagnostic horizon in the subsoil (denoted by the first syllable calc). Table 2 lists some of the formative elements used in suborder names. Currently soil taxonomy recognizes 68 suborders.

Great group names are constructed by adding one (or sometimes two) formative elements to the beginning of the name of the suborder, for example Haplorthods or Endoaquolls. They consist of three or four syllables. The formative elements describe the presence of (or sometimes lack of) additional important soil properties that exert further control on the soil-forming process. For example, a soil in the Petrocalcids great group belongs to the Aridisols order, and Calcids suborder. Importantly, though, it has a petrocalcic horizon (cemented calcic), so it is placed in the Petrocalcids great group. Table 3 lists some of the formative elements used in

Great group names. Currently soil taxonomy recognizes 337 great groups.

Subgroup names consist of the great group name, proceeded by an adjective term (ending with *ic*) describing some important soil feature that is either shared by another class (these subgroups are intergrades), or that is unique to the subgroup (these subgroups are extragrades). The adjective descriptor is a separate word, not joined to the great group name, for example *Lithic Dys-trudepts* or *Aeric Haplaquods*. In addition, one subgroup within each great group is named with the adjective “Typic,” for the central concept of that group, which may, or may not, be the most extensive. For example, a soil belonging to the *Aquic Petrocalcids* subgroup is a member of the *Petrocalcids* great group and has a water table within 100 cm. Table 4 lists some of the formative elements used in subgroup names. Currently soil taxonomy recognizes 2264 subgroups.

Soil family names consist of the subgroup preceded by multiple terms indicating properties that are important to the use and management of the soils. Family names usually include three to five terms, all used to describe conditions such as particle-size characteristics, mineralogy, soil temperature, cation exchange activity, calcareous and reaction classes, rooting depth, rupture resistance, or classes of coatings and cracks. The rules for assigning these terms are described in soil taxonomy. Currently in the United States, 10,895 taxonomic families have
been recognized. Many additional soil families have been recognized in other countries as well.

Soil series make up the lowest categorical level of soil taxonomy. Their definitions include characteristics such as kind and arrangement of soil horizons, physical properties such as color, texture, and consistence, and chemical properties such as pH, salinity, and so on. Many soil series were recognized prior to the development of soil taxonomy, and they were used to help define the classes when soil taxonomy was developed. Series names do not include the mnemonic terms described above. Rather they are assigned short names derived mostly from local places or physiographic features near where the soil occurs, for example Miami, Clinton, or Kalkaska. In this way, soil series names are easy to pronounce and remember locally. They do not, however, contain the information supplied within the terms used in the higher categories, and are therefore only effective for communicating with people who are familiar with the specific soil series. Currently in the United States, 22,253 soil series have been recognized, and several new ones are defined each year, as new information surfaces during mapping operations. Many additional soil series have been defined in other countries. Descriptions of all current US soil series can be accessed online (Soil Survey Staff 2015b).

Two examples of soil names at the various class levels are shown in Table 5. The Tonuco soil series is found in the deserts of southern New Mexico. It is a member of the Aridsoil order. The presence of a calcic horizon places it in the Calcixerdermic suborder. Cementation of the subsoil places

It is in the Petrocalcid great group. It is a member of the Typic Petrocalcids subgroup because it has no features found in any other subgroups of Petrocalcids. The family terms indicate the soil has sandy textures, mixed lithologies, warm soil temperatures, and a shallow rooting depth. The Rappahannock series is a soil formed in moderately thick organic deposits within tidal marshes of coastal Virginia. The thick organic soil materials place it in the Histosol order, and the high degree of decomposition of these materials places it in the Saprist suborder. Its high content of oxidizable sulfur compounds places it in the Sulphisaprist great group. The presence of mineral materials below the organic material makes it a Terric Sulphisaprist. The family terms indicate...
that the underlying mineral material is loamy and has mixed lithologies. The soil also has relatively high pH (euic) and warm soil temperature.

**General descriptions of the soil orders**

The hierarchical nature of soil taxonomy lends itself well to the production of maps at various scales. Soil orders, as the highest and most generalized level, are effectively shown on small-scale maps, such as those at global or continental scales (Figure 5). Progressively lower categories (suborders, great groups, etc.) can be depicted on progressively larger-scale maps, such as those of nations, regions, watersheds, and eventually farms, fields, and research plots. A brief description of the geographic distribution and environmental setting of each of the 12 soil orders follows, in alphabetical order.

**Alfisols** are naturally fertile soils with high base-cation saturation levels and a clay-enriched subsoil horizon. They form in a wide range of parent materials and occur under broad environmental conditions ranging from tropical to boreal, although most form on parent materials rich in calcium-bearing minerals. Alfisols develop primarily (though not exclusively) under forest vegetation. Translocation of clay and other weathering products from the upper horizons, and their subsequent accumulation in the subsoil, are important processes in Alfisols. Soil-forming processes are in relative balance so that base-cations such as calcium, magnesium, and potassium are supplied to the soil through weathering; the processes of leaching are not sufficiently intense to remove them from the soil before plants can utilize and recycle them. Thus, the soils remain fertile. Alfisols are extensive worldwide, occurring on every continent except Antarctica. Globally, they occupy about 10% of the ice-free land area.

**Andisols** are relatively young soils that are mostly of volcanic origin. A few Andisols have formed in nonvolcanic parent materials, particularly in cool, moist environments with relatively high levels of soil organic matter. The dominant pedogenic processes in Andisols are weathering and mineral transformation (with little or no translocation) of the volcanic alumino-silicate minerals (often glassy) to form short-range-order (poorly crystalline) minerals, such as allophane, imogolite, and ferrihydrite. Most Andisols are highly productive soils, in part because their unique mineral constituents provide for high water-holding capacities. Periodic volcanic eruptions provide fresh tephra that resupplies nutrients and maintains a favorable fertility status. One negative aspect of their unique mineral makeup is a propensity to adsorb phosphorus strongly, making it unavailable to plants. Andisols occur in a wide range of environments but occupy only about 1% of the ice-free land area globally, mostly concentrated along the Pacific Ring of Fire, an area of frequent volcanic activity.

**Aridisols** occur throughout the world in dry and desert environments. Intense or prolonged climatic dryness is their dominant feature. Evaporation exceeds precipitation in these environments, thus limiting the amount of moisture available to support plants. Because little or no water moves completely through the soil profile, salts such as calcium carbonate, sodium, gypsum, or sodium chloride often accumulate in some part of the soil profile. Globally, Aridisols occupy about 12% of the ice-free land area, in both hot and cold deserts.

**Entisols** have little or no soil profile development, and are often found on geologically young landscapes. They occur in a wide range of environments in settings such as steep, actively eroding slopes, floodplains that receive frequent deposits of alluvium, and shifting sand dunes. Consequently, there has been little opportunity

SOIL TAXONOMY AND SOIL CLASSIFICATION

for soil-forming processes to develop many soil horizons. Many Entisols are quite productive agriculturally, in part because they are minimally weathered and thus retain large amounts of primary minerals. Globally, Entisols occupy about 16% of the ice-free land area.

_Gelisols_ are soils of cold landscapes, with permafrost in the subsoil. Extreme cold is their dominant feature, with cryoturbation an important physical process in many of these soils. Unique “patterned ground” land surface features are characteristic of some areas. These include sorted and unsorted rock circles and stripes, large polygonal surface patterns, ice wedges, frost boils, pingos, and more. Gelisols occur in both the northern and southern circumpolar high latitude regions and are found in tundra, taiga, and boreal forest environments. They are important globally because they store large amounts of carbon as peat, often cryoturbated deep into the subsoil. Globally, Gelisols occupy about 9% of the ice-free land area.

_Histosols_ form in thick masses of decaying organic material, and usually on very wet sites. Their organic layers vary in color, botanical origin, amount of mineral soil material mixed in, degree of decomposition, pH, and other properties. Histosols are found in the tropics, temperate areas, and boreal forests. They form in environments where rates of inputs of organic matter exceed losses due to decomposition. Generally these are cool, wet environments where precipitation exceeds evaporation, or areas with persistently high water tables. Therefore, Histosols are common in low-lying areas with waterlogged, anaerobic conditions. Globally, Histosols occupy about 1% of the ice-free land area.

_Inceptisols_ are youthful soils with a limited, but noticeable, degree of profile development. As a group, they have profiles exhibiting more development than the Entisols, but are less developed than any of the other orders. Inceptisols tend to be found on relatively young geomorphic surfaces that are sufficiently stable (and old) to have resulted in weak but noticeable profile development. Common settings include upland slopes, stream terraces, and recently glaciated landscapes. Inceptisols are found in wide-ranging environments from the tropics to the tundra and from semiarid to humid climates. Globally, Inceptisols occupy about 17% of the ice-free land area.

_Mollisols_ are dark-colored, naturally very fertile soils, which are found primarily in grasslands and savannas. The thick, dark surface horizon is rich in organic matter, which accumulates as the result of inputs from decaying roots, especially short, mid, and tall grasses common to prairie and steppe areas. There is a high belowground biomass production and tight biocycling of nutrients. Their naturally high native fertility is due to nutrients distributed throughout their profile, and to their high organic matter contents and excellent soil structure. Globally, Mollisols are predominantly in temperate grasslands at mid-latitudes. They occupy about 7% of the ice-free land area.

_Oxisols_ are highly weathered tropical soils with low natural fertility. Most Oxisols are on old landscapes that have undergone multiple cycles of weathering, erosion, redeposition, and renewed weathering, leaving only highly resistant minerals that retain very little native fertility. The few reserves of soil nutrients are concentrated mostly in the living and dead plant tissues at the site and these are quickly lost upon clearing and cultivation. Most Oxisols are naturally forested, but many are now being cleared for agriculture, which is possible with consistent inputs of chemical fertilizers. Globally, Oxisols occupy about 8% of the ice-free land area, mostly at latitudes between the Tropics of Cancer and Capricorn.

_Spodosols_ are coarse-textured, acidic soils with low fertility and accumulations of soluble organic
SOIL TAXONOMY AND SOIL CLASSIFICATION

matter and iron/aluminum oxides in the subsoil horizon. They are found mostly in forested areas with cool, moist climates in the humid boreal zones, but also occur on wet sites in tropical or subtropical areas. The genesis of these soils is driven by the production of organic acids from decaying leaf litter, which form organometallic complexes with iron and aluminum compounds released by weathering. These complexes are translocated downward in the profile and accumulate in the subsoil. Most Spodosols are minimally productive as agricultural soils, but many sustain thriving forests. Globally, Spodosols occupy about 3% of the ice-free land area.

_Ultisols_ are acidic soils with low base-cation saturation values and a clay-enriched subsoil horizon. As such, they have only low to moderate native fertility. They are found mostly in warm humid climates under forest vegetation where long-term leaching of nutrients from the profile has exceeded the rate of nutrient release from mineral weathering. Plant nutrients are typically concentrated in the upper part of the profile (due to biocycling) and decrease with depth. With adequate fertilization, Ultisols can be made to be quite productive. Globally, Ultisols occupy about 8% of the ice-free land area.

_Vertisols_ are dark-to-black, very clayey soils that develop deep cracks in a dry season. They are dominated by clay minerals (smectites) that swell when moistened and dramatically shrink when dry, forming the deep cracks. They are very sticky and plastic when wet and very firm and hard when dry. Most Vertisols are in grasslands or savannas, but a few are in forest, or even desert shrub. Commonly, Vertisols form from parent materials that have neutral pH or are calcareous, such as sandstone, shale, chalk, or limestone. Some Vertisols have developed a unique pattern of microrelief known as gilgai – an intricate pattern of micro-highs and lows repeating over scales of around 3–10 m. Gilgai forms because of the mixing that occurs in these soils as they swell when wet. Many Vertisols sustain highly productive agricultural systems. Globally, Vertisols occupy about 2% of the ice-free land area.

Soil water

Tim Beach
Jonathan M. Flood
University of Texas at Austin, USA

This entry reviews the types and roles of soil water, its movement, its environmental contexts, and what is known about its trends and geography.

Soil water in the hydrologic cycle

More water exists in soils than in rivers, the atmosphere, life forms, and swamps and marshes put together. If we include permafrost, then soil water is the third-largest reservoir of the Earth’s fresh water after glaciers and lakes. The quantity of soil water, like all types of water, varies tremendously around the planet due to all the factors of the hydrologic cycle. Much of this soil water is the main source of water for ecosystems above and below ground and for crops and pasture lands (Shiklomanov 1993).

Soil water exists at the nexus of the critical zone within the hydrosphere, atmosphere, biosphere, and lithosphere, and is at the leading edge of the major hydrologic processes of precipitation, infiltration, storage, evaporation, and transpiration. Its presence or absence influences planetary albedo, humidity, and temperature, which in turn impact global energy and water circulation.

Soil water types

We usually define soil water by the force that holds it to the surface. Soil water has four general types: structural water, gravitational water, capillary water, and hygroscopic water. Structural water exists within the bonds of minerals such as gypsum (CaSO₄·2H₂O) with its two water molecules, as opposed to its waterless cousin, anhydrite (CaSO₄). Soil water potential, or soil moisture tension, is the force, measured in bars, that holds water to a surface (Figure 1).

In nonstructural soil water, water sticks to surfaces by adhesion and cohesion. Adhesion is the strong electrical attraction of water molecules to a surface, such as a straw or clays or humus in a soil pore, in this case a micropore, <50 nm. This hygroscopic water, the thin layer of water molecules, is held too tightly to a surface (at ca. −15 to −31 bars or atmospheres) for plants to use, but labs routinely remove it by heating. Cohesion refers to the water molecules attached to other water molecules by positive charges of hydrogen atoms attracted to the negative charges of oxygen atoms. Gravitational water is not held with enough force (−1/3 bar) to overcome gravity and thus flows out of a soil after a few days. This water exists in so-called macropores and, if it does not drain, may cause plants to wilt by blocking oxygen flow.

Capillary is plant-available water held from −15 to −1/3 bars by cohesion that resists the pull of gravity but not the pull from plant roots (Figure 1). It is thus the source for...
SOIL WATER

Figure 1 Soil water types.

most ecosystems and crops, and many aspects of environments govern how much capillary water is available for plants: rainfall and evapotranspiration, water table depth, soil textures, and the network of mycorrhizae and root systems. Soils tend to be moist where precipitation exceeds evapotranspiration, but this varies by soil texture and water table depth and height of the capillary fringe above the water table.

Four states of water in soils are also referred to by scientists: saturation, field capacity, wilting point, and hygroscopic (discussed above) (Figure 1). Saturation refers to the point when water fills soil macropores and moves out by gravity unless held in place by a high water table, for example in wetlands. Field capacity refers to the maximum plant extractable soil water held by cohesion. Wilting point occurs when soil water is held by adhesion as hygroscopic water and plant roots cannot overcome the tension with which water molecules attach to each other. Thus, as with too much water, too little water causes plants to wilt.

Soil texture is an important determinant of water holding capacity: clay holds more water than sands and silts, but more of this water is too tightly held by adhesion to the clay surface. Likewise, sand texture holds soil water too loosely and much of this water is in macropores where water drains by gravity. Loam soils, especially silt loams, have the highest level of plant available water, one of the reasons loamy textured soils are more productive. For example, the water holding capacity of sand is about $0.075 \text{ cm cm}^{-1}$, clay is about $0.12 \text{ cm cm}^{-1}$, and silt loam is about $0.2 \text{ cm cm}^{-1}$. Water holding
capacity increases for each texture with more organic matter. For example, silt loams increase to 0.24 cm cm$^{-1}$ with more than 3% organic matter, and Histosol soils (dominated by organic matter) may have a water holding capacity of up to 0.65 cm cm$^{-1}$ (USDA 2016a).

Soil structure also affects soil water flow, and soil horizons with granular structure (the most macropores) allow the fastest flow. The rate of flow generally decreases from granular to blocky, to columnar, to massive structures. This means in many soils that gravity water in the soil will flow through granular or blocky layer but perch above massive and clay layers such as Bt horizons. Thus rainfall may saturate the soil pores and flow may occur as throughflow in soil pores under gravity and as Dunne flow or Hortonian flow on the soil surface.

Soil moisture regimes

The United States Department of Agriculture (USDA) has classified the world into soil moisture regimes – a useful shorthand for understanding average soil water conditions. These include aquic, udic, ustic, xeric, and aridic divisions from wettest to driest, which along with soil temperature regimes provide a general framework and a base for understanding global-scale environmental change problems. For example, regions with ustic and aridic regimes have ephemeral water and high evapotranspiration rates, which allow us to map and upscale problems such as water stress and salinization (USDA 2016b).

Movement

Soil water can move in any direction depending on gravity, capillarity, roots, porosity, permeability, texture, and structure. The main pathways into soils are infiltration through raindrops, fog drip, upward flow from capillary fringe or rising groundwater tables, and runoff. Stems of plants are important to infiltration in stem flow or directing water to roots, and thus soil water may have a patchy distribution around rhizospheres. Percolation is the downward transit of water in soils, and a key parameter of soil usage for engineering land uses. A common classification of soils is the soil permeability class, ranging from very rapid to very slow and from more than 25 cm hr$^{-1}$ to less than 0.13 cm hr$^{-1}$. Scientists estimate water movement through soil with some derivation of the Richards’ equation (Pachepsky, Timlin, and Rawls 2003), a modified version of Darcy’s law (groundwater). The key variables in this equation are pressure head (water engineering) and the unsaturated hydraulic conductivity.

Hydraulic conductivity measures the ability of soil or other geologic mediums to transmit water along a hydraulic gradient. Conductivity is primarily governed by the intrinsic permeability of a material – symbolized as $K$ in equations – and to a lesser extent by the density, viscosity, and distribution of the passing fluid. The USDA and other state and federal agencies document and make available hydraulic conductivity classes for soils and geologic strata. These run from highly conductive coarse sands to nearly impermeable fine clays and fragipans. Conductivity classifications help determine best land-use and irrigation strategies (USGS 2016c).

Another salient soil water classification is the natural drainage class, or simply drainage class. Drainage class refers to the moisture condition of the soil in its natural state over the course of a year. The classification scheme categorizes the degree, frequency, and duration of soil wetness over time. Seven classes exist, determined by soil color, water table characteristics, soil texture and morphology, and the soil’s position in the landscape. The seven classes are: excessively
drained, somewhat excessively drained, well drained, moderately well drained, somewhat poorly drained, poorly drained, and very poorly drained (USGS 2016c).

Environmental contexts

Geography

There are many dimensions to the global distribution of soil water; one useful dimension is the distribution of plant available soil water per year. The factors of plant available soil water are inputs, outputs, and storage (Dunne and Wilmott 1996). Despite multiple variables, the main variable that stands out on a global map is precipitation minus evapotranspiration. The highest soil moisture occurs in the tropical rainforest zones due to high input and output, the lowest occurs in subtropical deserts due to low input and high output, and the second-highest occurs in mid-latitude forests and taiga due to low input and very low output as well as storage in Histosol soils (Figure 2).

In 2014, The Jet Propulsion Laboratory (JPL) deployed a new satellite, called SMAP (Soil Moisture Active Passive), with soil moisture sensors for the top 5 cm of soil (http://smap.jpl.nasa.gov). This system will improve our knowledge of the planet’s upper soil moisture at a finer resolution and provide critical information concerning the scale and intensity of emerging flood or drought events.
**Soil color**

Soil moisture leaves visible clues in terms of either dark colors associated with high soil organic matter and thus arrested decomposition from water saturation and redoximorphic features, or mottles or color variations in soil associated with wetness. Iron oxides in well-drained soils make them yellow or reddish. Wet soils have reduced colors (gray, blue, green) of whole horizons or mottling with distinct or prominent contrasts in reduced and oxidized colors. The in situ reduced color soils will begin to oxidize with exposure and water removal in half an hour or less. Soils that go through wetting and drying cycles will have redox concentrations and depletions, meaning areas redder with \( \text{Fe}^{3+} \) and grayer with \( \text{Fe}^{2+} \). The reduced zones may develop iron masses, concentrations, or iron and manganese nodules, depending on time and specific environments.

**Soil catena**

Soil water is one of the key characteristics that vary along soil catenas. Soil water characteristics on catenas depend on texture, structure, infiltration, local water tables, and the steepness of the catena. Generally, however, well-drained soils occur on the steep shoulder and backslopes followed by crests, and less well-drained soils occur in depressions and foot and toe slopes associated with water flow convergence or high water tables.

**Soil water and society**

Soil water is a critical element in agricultural productivity at every scale. The riverine cradles of civilization along the banks of the Tigris, Euphrates, and Nile had annual pulses of nutrients and restorative soil water for the vast rainless stretches of the fertile river valleys. This may have also led to the demise of Mesopotamia because salinization accompanied irrigation there. Agriculture still uses 70% of global freshwater consumption, mainly to increase soil water through irrigation, and this comes at the cost of salinization in dry regions (UNESCO 2012).

Altering soil water content by way of irrigation has been important to agriculture for millennia but tended to rely on the redirection of stream energy or animal power to distribute water into soils. In the past half-century, fossil fuel-powered pumps have been used to remove groundwater from tube wells and have brought prosperity to marginal agricultural regions. Groundwater pumping tends to positively impact societies in the short term, but negative impacts on regional hydrology often create serious water shortage or water quality problems over the long term (Konikow and Kendy 2005). Over-pumping to increase soil water for higher agricultural yields depletes aquifers and often impacts regional hydrology that supports soil moisture away from the places where water is applied. More efficient irrigation applicators such as drip tube systems, traditional agricultural technologies such as braided terracing, and regionally appropriate cropping and landscaping decisions may reduce some deleterious effects of human–soil water interactions (Postel et al. 2001).

**Soil water trends**

Lastly, soil degradation in all of its forms affects soil water. This is true in terms of soil pollution affecting water quality directly from contaminants attached to eroded soil particles, or indirectly from salt water intrusion or inundation in low spots from irrigation runoff. The most obvious impact on soil water is the steady loss of soil through erosion of A horizons, which often have better soil moisture holding capacity, and exposure of B horizons, which often have lower
SOIL WATER

water holding capacity and infiltration. Soil erosion continues to be high around the world (Montgomery 2007), and will likely increase with climate change (Nearing, Pruski, and O'neal 2004). The combination of continued high accelerated soil erosion and global warming makes severe decreases in soil moisture more probable in many places (IPCC 2016, 184–185). Indeed, the whole range of global warming scenarios produces decreased soil water, because of evaporation in winter and spring from both increased temperatures and reduced snow cover (IPCC 2016, 166; UNDESA 214).

Soils represent the largest terrestrial stock of carbon in the global carbon cycle, with more than 2300 Pg (Petagrams or $10^{15}$ g = billion metric tons) of carbon stored in soil organic matter (SOM) and 950 Pg held as carbonates in the upper 3 m. This entry focuses only on SOM because it is the biologically active fraction of soil carbon that exchanges with the atmosphere through natural and anthropogenic processes. The amount of SOC found in soils globally is considerably larger than the carbon stored in the living biomass or atmosphere (Table 1). Globally, inputs of carbon (C) to soils are roughly balanced by losses via decomposition, but because the atmospheric C exchange with soil is so large ($\approx 60$ Pg year$^{-1}$) the potential for changes in SOC and its influence on atmospheric carbon dioxide ($CO_2$) are large.

Historically, soils have contributed to planetary cooling by sequestering atmospheric C into SOM. Warming of the atmosphere in recent decades, however, may reverse this trend and contribute to further atmospheric warming: as soils warm, decomposition of SOM is enhanced if moisture does not become limiting, releasing more CO$_2$ to the atmosphere (IPCC 2013). Moreover, changes in land use have led to large releases of CO$_2$ from soils. Although plant growth and C uptake can also occur in response to warming, even small perturbations to the soil can have major ramifications for atmospheric CO$_2$ levels.

Why carbon cycling in soils is studied

Soils represent the largest terrestrial stock of carbon in the global carbon cycle, with more than 2300 Pg (Petagrams or $10^{15}$ g = billion metric tons) of carbon stored in soil organic matter (SOM) and 950 Pg held as carbonates in the upper 3 m. This entry focuses only on SOM because it is the biologically active fraction of soil carbon that exchanges with the atmosphere through natural and anthropogenic processes. The amount of SOC found in soils globally is considerably larger than the carbon stored in the living biomass or atmosphere (Table 1). Globally, inputs of carbon (C) to soils are roughly balanced by losses via decomposition, but because the atmospheric C exchange with soil is so large ($\approx 60$ Pg year$^{-1}$) the potential for changes in SOC and its influence on atmospheric carbon dioxide ($CO_2$) are large.

Historically, soils have contributed to planetary cooling by sequestering atmospheric C into SOM. Warming of the atmosphere in recent decades, however, may reverse this trend and contribute to further atmospheric warming: as soils warm, decomposition of SOM is enhanced if moisture does not become limiting, releasing more CO$_2$ to the atmosphere (IPCC 2013). Moreover, changes in land use have led to large releases of CO$_2$ from soils. Although plant growth and C uptake can also occur in response to warming, even small perturbations to the soil can have major ramifications for atmospheric CO$_2$ levels.

Recently, much attention has been paid to improved land-use and land management strategies that may promote C sequestration and offset an estimated 5–15% of annual anthropogenic C emissions. Improving SOC levels in soils has been suggested to be a win–win policy, because in addition to the likely climate mitigation benefits of carbon sequestration, SOC enhances soil fertility, helps reduce soil erosion by improving structure and enhancing porosity, and promotes diverse soil food webs that through decomposition and retention facilitate better nutrient cycling and plant productivity.

SOM also plays a major role in the formation of stable aggregates that improve soil structure and enhance water-holding capacity, gas exchange, and root growth. Through its reactive chemical structure, SOM also acts as a major buffer for toxins and heavy metals.

Assessments and accounting of SOC

A full accounting of SOC embodies interactions with climatic and anthropogenic changes on immediate timescales, but these interactions are
tempered by longer-term factors involving ecosystems and landscape properties such as topography and geology. An assessment of SOC stocks (amounts) and fluxes (in both gaseous and dissolved phases) can be gained from at least three main types of scientific approaches: (i) field and lab-based studies of variations in SOC over gradients in time, topography, mineralogy, vegetation, and climate—such gradients allow mathematical equations to be derived from SOC-landscape associations; (ii) inventory-based studies such as soil taxonomic mapping or soil-vegetation mapping—these maps allow spatial distributions of SOC to be linked to assessments of stocks and fluxes; and (iii) model-based assessments that are constructed from fundamental principles of land–atmosphere C exchange processes and are grounded in lab and field data. All three approaches are key to the accurate assessment of C fates under climate and anthropogenic change.

How carbon cycles through soils

SOC pools exist in a dynamic balance between inputs of C from vegetation and losses that are dominated by decomposition. Plants fix CO₂ through photosynthesis, and the majority of C inputs to the soil occur when fresh plant components senesce or die and this C is transferred to soil through litterfall and roots. Some C-rich photosynthate is immediately transferred to the soil via root exudates and mycorrhizal associations. Soil fauna and micro-organisms then begin to process and decompose the fresh organic material, thus C contained in these plant materials will either be incorporated into microbial biomass or be respired as CO₂ (or as methane (CH₄), depending on the reduction/oxidation status of the soil). Newly formed microbial biomass in turn represents a fresh pool of material for further decomposition as the microbial population turns over. The rate at which SOM decomposition proceeds will be strongly dependent upon the climatic and physiochemical conditions of the soil. Most photosynthate-C exchanges rapidly with the atmosphere upon decomposition, resulting in large fluxes of CO₂ relative to the small amounts transferred to more stable SOC pools. Although decomposition is the primary way that SOC is lost from soils, other processes such as combustion during fire, erosion, and deep leaching can represent quantitatively important fluxes of C. Research seeks to define the nature of these stable pools and the numerous processes that stabilize C by retarding the rate of decomposition (Figure 1) relative to the rate of input of new C.

Inputs of C to soil—plant productivity sets an absolute upper limit to potential C inputs to the soil system. For this reason, in many areas, SOC stocks are correlated with primary productivity, although only part of the total carbon that gets captured by plants becomes biomass; on average, about half of all assimilated carbon is respired back to the atmosphere as CO₂. In soils, the proportion of net primary productivity (NPP) allocated to belowground (roots) versus aboveground plant biomass varies widely, from <1 up to >80% across global biomes. Belowground, the depth distribution of roots declines precipitously in all biomes, with the uppermost 20 cm of soils receiving about 60–80% of all root inputs of C. Belowground, C can enter the soil directly through roots, as they die and decompose, through their exudates, or indirectly through C flow to mycorrhizal fungi and the subsequent turnover of the fungal hyphae. The tight coupling between root distribution and SOC distribution with depth in many soils is often cited as evidence for the importance of root inputs in maintaining SOC stocks of mineral soils.
SOILS AND THE CARBON CYCLE

Figure 1  The regulation of C cycling pathways through soils. Inputs that occur via annual net primary production (≈40–70 Pg C year\(^{-1}\) globally) can be lost before entering the soil. After C enters the soil via leaf and root litter contributions, it can be lost to heterotrophic respiration (Rh) (≈40–70 Pg C year\(^{-1}\)) or can be stabilized by energetic, physical, or chemical processes (≈2–10 Pg C year\(^{-1}\)) through the regulation of decomposition.

Aboveground plant material takes a more indirect route in its transfer to SOC. Before senescence or litterfall, biomass (and its C) can be lost to photooxidation, in situ herbivory, combustion, or crop removal, depending on environmental conditions such as shading, allelopathy, moisture, or harvest patterns, respectively (Figure 1). In agricultural systems, for example, harvest can remove significant portions of aboveground material, leaving roots as the main source of SOC. At the other extreme, in cold, excessively wet climates where decomposition processes are retarded, aboveground litterfall will often accumulate on the soil surface as organic (O) horizons, with accumulation rates fast enough to be measurable over annual to decadal timescales. Conversely, vertical mixing by biological or physical processes can bring SOC to the surface, or these processes can physically transfer new SOC into deeper soil horizons, as
exemplified by freeze–thaw processes in Gelisols, and by the action of earthworms or other soil fauna. Leaching and downward transport of dissolved organic matter and subsequent sorption onto mineral surfaces is also a major mechanism of vertical transport of SOC in soils.

*Decomposition of C in soil* is the main pathway for C loss from soils. And yet it is also one of the critical ecological processes for maintaining life on this planet. In natural terrestrial ecosystems, nutrient recycling via decomposition of SOM accounts for the vast majority of plant-available macro- and micronutrients in the soil. Decomposition is the net result of three concurrent processes: comminution or fragmentation of larger plant detritus by soil fauna, leaching of soluble compounds, and microbial catabolism. Annually, most newly fixed plant substrate returns to the atmosphere via respiration and microbial metabolism, especially in mature ecosystems, where the SOC fluxes and stores may be in a steady state.

*Stabilization* of SOC can be thought of as any process that acts to slow the decomposition process (Figure 1). Conversely, destabilization processes act to enhance decomposition. SOC stabilization can undergo several phases of progression and regression. Therefore the long-term fate of SOC is reflected in the SOC stocks, but over shorter timescales net fluxes between the soil and atmosphere can be either positive or negative.

In some soils, particularly in peats and permafrost soils, biological energetics play a key role in decomposition. Here, certain plant-derived substrates such as lignin and some paraffinic macromolecules selectively accumulate during the initial phases of decomposition until more labile substrates are exhausted. Thus, litter can take months to decades to fully decay. Water saturation, anoxia, and cold temperatures contribute to the buildup of highly decomposed humic and dissolved counterparts, with other soil properties (e.g., porosity) and environments (e.g., depth) influencing decomposition as well (Marschner et al. 2008).

Many soil processes regulate decomposition of SOM, and the ultimate fate of C represents the net effect of these regulation processes over time and the conditions under which the soil formed. Regulation processes that govern SOC decomposition and stabilization may operate on somewhat different timescales, simultaneously in different parts of the soil, or interactively over the course of soil formation. They can be broadly grouped into three categories: (i) biological energetics, (ii) physical accessibility of substrate to microbes and their enzymes, and (iii) mineral interactions of SOC. Enhanced regulation promotes C storage in soils, while limited regulation promotes decomposition and C loss (Figure 1). Persistence or accumulation of SOC is evidence for strongly regulated systems, but, given enough time in the absence of exogenic processes such as erosion, most (e.g., >99%) natural and xenobiotic compounds will be fully mineralized to CO₂ or other inorganic forms. As a result, on the timescale of millennia, only a fraction of a percent of carbon captured by NPP becomes stabilized as SOC (Figure 1).

### Stocks and pools of SOC

SOC stock refers to the weight of C within a given volume for a given soil depth (e.g., kg C m⁻² stored in the upper 1 m of soil). Dynamics of SOC, which are important for understanding land–atmosphere exchange, include assessments of C flux between land and atmosphere. These fluxes, naturally, affect C stocks. Turnover refers to the rate at which C cycles or is replaced by new C in the soil. Mean residence time is the average time that a C molecule might reside in the soil and is in most cases equal to the
SOILS AND THE CARBON CYCLE

turnover time. For example, a turnover time or mean residence time of 10 years suggests that most of the carbon in that soil is replaced over a decade. In reality, SOC is composed of a diverse range of compounds that vary in their inherent degradability and susceptibility to stabilization by physiochemical processes. As such, most major SOC models use a number of conceptual pools of C that have characteristic turnover times. In mathematical models, each pool has a separate fractional coefficient and a $C_{stock}$ that when multiplied represent the C flux from that pool. The sum of each product for each pool equals the decomposition flux from the soil.

The simplest conceptual framework for SOC utilizes the steady-state geochemical model in which inputs and outputs are assumed to be equal, and a mass balance is achieved. The steady-state model is justified by observations that rates of C inputs and outputs to and from soils, as measured by flux rates, are much larger than rates at which C is stabilized by soil. This assumption is typical of mature soils and ecosystems. In very young systems, however, rates of input typically exceed rates of output, thus C is sequestered. In cases of disturbance (discussed below), outputs can exceed inputs where C is lost from the system and over time can re-accumulate SOC or adjust to a new state.

Decomposition rates can be assessed for soil profiles, soil samples, soil horizons, or specific depth increments. Estimates of sizes and decomposition rates for pools can be based on fractionations using chemical extractions (McKeague, Brydon, and Miles 1970) or physical means (Christensen 1992). Carbon isotope ($^{13}C$ and $^{14}C$) measurements on soils and soil fractions are particularly helpful method, used to constrain sizes and rates of C pools (Balesdent, Wagner, and Mariotti 1988) even where measurements provide only partial information on pool sizes and turnover.

Spatial distributions of SOC stocks are important because they reflect important variations in plant productivity, nutrient status, and elemental concentrations. SOC stocks reflect the influence of pedogenesis on C dynamics over long time periods that include past changes in climate, vegetation, erosion, and so on. One way to assess SOC dynamics of such soils but at larger spatial scales would be to use spatial information of the five soil-forming factors (climate, organisms, relief, parent material, and time) as well as human impacts (Amundson and Jenny 1991). Changes in SOC contents along such gradients in temperature, slope, biome type, or elevation, which represents gradients of several environmental factors, have improved our understanding of controls over SOC. Nonetheless, few studies have provided multifaceted predictive equations for SOC and soil factors, probably because of the complexity of factors that control SOC. Stocks of SOC can be highly variable even over small distances if the environmental factors which influence C inputs, decomposition, and stabilization also vary at the same distances/gradations. In addition to inputs, decomposition and stabilization, lateral losses (such as to cropping, wildfire, or erosion) or gains (such as downslope sedimentation) can be as important to C stocks assessments as spatial variations in plant production and decomposition. Because of these circumstances, varying methods for assessing stocks have been applied across different spatial scales.

Maps of SOC stocks have been constructed from maps of soils and from biome or ecosystem association maps. Geospatial analysis of soil profile data has also been used in which multivariate data are used to represent spatial variations in SOC typically at regional scales. Classification or taxonomy-based SOC stock assessments relate key soil-forming processes to SOC stabilization (Batjes 1996). And yet, key uncertainties exist for a full accounting of the SOC budget at any
Spatial scale. First, SOC stocks develop over long, often millennial, timescales, whereas SOC fluxes are dominated by more recent and shallower processes. Second, soil maps often delineate complexes of several different soil types within a discrete mapping unit (polygon). Such complexes can reflect significant variations in properties, but the exact spatial location of any given soil within the map unit remains unknown. SOC maps or assessments have also been constructed for various biomes or ecosystems (Figure 2). Uncertainties in this approach arise from mismatches between current and past vegetation communities over the timescale of soil development. Last, data-intensive geospatial techniques have been applied to investigate and model SOC variations at local to regional scales (Viscarra Rossel et al. 2014). In instances where such approaches to mapping SOC have been compared, interesting differences emerge. Because of recent advances in global-scale geospatial mapping of key environmental variables, digital soil mapping applications are also feasible at global scales (Sanchez et al. 2009). Importantly, spatial variation of SOC stocks caused by human land use and management are often underestimated, as there is a mismatch in spatial scales between land management practices and the scales at which SOC stocks are normally mapped.

Figure 2  Mean SOC storage in soils, by depth (kg C m$^{-2}$) and according to biome. Based on data from Jobbágy and Jackson (2000), Table 3, and on data for permafrost regions from Hugelius et al. (2013) (n for tundra permafrost = 200; n for boreal forest permafrost = 324). Standard deviations about the mean were similar to the reported mean values for each depth increment, which reflect the heterogeneous nature of soils and SOC within the biomes.

** Examples: fertilization, drainage, liming.
†† Direct burial of wood products or conversion to biochar (Lenton 2010).
**SOILS AND THE CARBON CYCLE**

*Depth variations in SOC stocks* are particularly important because surface zones are where most disturbances occur. In most soils, C storage is highest in the upper profile, owing to proximity of plant detritus, and generally declines with depth. However, the high bulk densities and relatively slow turnover of deep soil C account for large masses of deep soil C. The decline in SOC concentration with depth is most pronounced in well-drained soils because decomposition is normally high throughout the profile while C inputs decline exponentially with depth. In poorly drained soils, the high soil water content has a strong influence on the depth profile of SOC because of moisture controls over gas diffusion, root production, and decomposition. In the deeper profile of all soils, C stabilization is influenced by soil mineralogy, aggregation processes, and factors that influence soil morphology. Over centennial to millennial timescales, processes such as cryoturbation (soil movements from frost heave that bury SOC), repeated sedimentation to the soil surface, or peat accrual can lead to the accumulation of very large SOC stocks. For example, in the circumpolar permafrost region, peatland SOC storage in Histosols (peats) and Histels (permafrost peats) often exceeds 100 kg C m$^{-2}$ (see Figure 2). Although the majority of the world’s peatlands are situated in the cold climates of the Northern Hemisphere (Gorham 1991), there are also substantial stocks of SOC in tropical peatlands, especially in Southeast Asia (Page, Rieley, and Banks 2011).

**Decomposition and turnover of SOC**

Variations in SOC turnover are as important as variations in SOC stocks because turnover is a gauge for biogeochemical reactivity and the potential for land–atmosphere C exchange. Fast turnover reflects a rapid cycling through the plant–soil–atmosphere cycle; slow turnover reflects the regulation of decomposition by soil processes and therefore a sequestration of C relative to fast cycling (Figure 1). Turnover of SOC typically declines or slows with depth in a manner similar to the depth distribution of SOC stocks (Masiello *et al.* 2004). The decline in turnover rates with depth can be linked to three mechanisms of C stabilization. When viewed as regulators of decomposition, these mechanisms can promote or diminish C storage and may dominate stabilization in different parts of the soil or over different timescales (Figure 1). In shallow soils, where C stocks and turnover are driven by water and nutrient cycling, plant and microbe-based energetics tend to regulate decomposition. Organic horizons at the surface typically reflect the chemistries of plant substrates and the decomposition pathways dictated by redox reactions, combustion history, and nutrient stoichiometries that regulate plant–soil interactions. In thicker organic soils, redox and moisture status persist as controls over decomposition (Maltby and Immirzi 1993); thus peatlands act as “hotspots” for C stabilization in any biome or ecosystem. In the upper profile of many mineral soils, such as in A horizons and transitional B horizons, SOC stabilization is typically dominated by aggregation (Six *et al.* 2002). Deeper in the profile, the accumulation of mineral weathering products creates conditions favorable for the stabilization of SOC (Torn *et al.* 1997) via mineral sorption and precipitation reactions.

Despite the large stocks and advanced ages of SOC in many deep soils (Masiello *et al.* 2004), deep SOC also can be reactive and dynamic, especially under conditions that disrupt the mechanisms of stabilization. Fast-cycling C, which has important implications for C cycling under climatic and anthropogenic disturbances, has been detected at depth by several investigators (e.g., see citations in Trumbore 2009).
The role of disturbance

Initially, many types of disturbance result in a net C release from ecosystems and soils, typically because oxidative decomposition or combustion can act on newly exposed organic matter and because disturbances temporarily cut off plant inputs to the soil. Left to recover, SOC stocks can re-accumulate according to the balance of plant inputs and decomposers if there is no additional factor retarding decomposition such as poor drainage (Figure 3).

*Generalized models of disturbance* could greatly help to improve assessments of SOC. Wildfire, cropping, insect outbreaks, earthworm invasions, exposure or burial by urbanization, sedimentation, erosion, thermo-erosion, and ground subsidence are all examples of disturbance events that change SOC stocks and flux, and which may be large or pervasive enough to significantly impact the land–atmosphere C exchange. Some processes, such as deep burns or permafrost degradation, can destabilize SOC stored at depth. Because deep C typically had been immobilized for centuries or millennia, its destabilization and release reflect significant perturbations to the steady-state models so often used in SOC assessments.

Several attributes of disturbance are important to the dynamics and fate of SOC. The depth of disturbance into the soil is important because of the depth dependency of inputs, stocks, and turnover times. In general, disturbance to vegetation and shallow soils are likely to have immediate impacts on the net SOC storage (emissions versus sequestration) but the impacts are usually short-lived (Richter et al. 1999) because of the rapid C cycling that occurs near the soil surface. In contrast, disturbances that impact deeper SOC stocks will have longer-lasting effects. The duration of the disturbance event also matters, as does the severity of the event relative to SOC or the soil properties that stabilize/destabilize SOC. The return interval of the disturbance event relative to input and turnover will dictate the C storage at intermediate to longer timescales. Last, the area impacted by the event is multiplied by the change in storage. Thus, it is paramount to assessing the impact of disturbance on atmospheric C budgets. Accounting for such
attributes of disturbance provides a framework for understanding impacts on SOC fate.

This link between SOC turnover rate and “recovery” period of the stock relates to the concept of steady state and to depth profiles of declining inputs and turnover times. In many assessments, disturbance causes sudden C loss, while recovery occurs over longer time periods (Sanderman and Baldock 2010). Deep disturbances and prolonged or pervasive disturbances that impact soils at depth are receiving more attention because the net impacts to SOC and land–atmosphere exchange are likely longer lasting owing to smaller inputs and slower turnover times in deep soils.

**Anthropogenic disturbances and management of SOC**

Today, 38% of the Earth’s land area is under agricultural production. Such widespread land-use changes have had a dramatic effect on the quantity and quality (C pools and nutrient provision) of SOC. Most soils under native vegetation have SOC levels that have evolved into a quasi-steady state. However, when land is cleared for agriculture, SOC levels normally drop by 30–50% from preclearance levels. Globally, it has been estimated that agriculture has resulted in the loss of 78 Pg C or about 19% of the anthropogenic C emission since 1850, with most this loss being attributed to the change in land use resulting in accelerated decomposition of SOC. The decomposition process results in a net release of CO₂, further accelerating potential global warming.

The reasons for this near universal decline in SOC following land clearing are twofold. First, natural C inputs to the soil decline. In a production system, a large fraction of aboveground plant material is removed in harvest or ingested by grazers. Most crops have also been bred to maximize C allocation to harvestable plant parts. Second, losses of SOC to decomposition and erosion typically increase owing to stimulation of microbial activity by fertilizer addition, irrigation, or tillage; relative to native plants, the labile nature of crop residues makes them more readily decomposable. The only exceptions to the near universal decline in SOC are in regions where there are severe constraints to plant growth and the implementation of agriculture brings management to alleviate these constraints. Examples include irrigation in water-limited regions and phosphorous fertilizer applications in ancient, highly weathered soils. In such circumstances, primary productivity is increased under agricultural management, overcoming the reduced C return and accelerated loss mechanisms listed above.

Agroforestry represents another major anthropogenic perturbation to the terrestrial C cycle. In general, soil C stocks in plantation forests are under influences similar to those in other agricultural practices. Soil C sequestration in agroforests is often delayed, however, due to the longer timescale of forest growth relative to crops. The initial SOC losses due to site preparation are compensated for after a couple of decades of growth and increasing C inputs to the soil.

There has recently been considerable interest in halting and even reversing the decline in SOC in order to improve soil health, while also sequestering more CO₂ from the atmosphere. In general, any of several crop management practices can result in increased inputs and/or reduced losses of SOC (Table 1; see also Lenton 2010). In pasture systems, improved grazing management and optimized nutrient management have been shown to increase SOC retention. Meta-analyses of field trial data indicate that local climate and soil properties will be important determinants of whether or not any
given management practice will improve SOC stocks. Importantly, these sequestration rates will diminish within a few decades as SOC contents achieve a new equilibrium. Given the recent estimates of SOC sequestration (Lenton 2010) and the benefits of SOC sequestration for soil health, increased research, efficacy, and verification are likely to occur.

SOILS AND THE CARBON CYCLE

Weathering is the physical, chemical, and/or biochemical breakdown of rocks and minerals at the interface between the lithosphere and the atmosphere (Bridge and Demicco 2008). It is the starting point of pedogenesis because it produces regolith, which is defined as loose, unconsolidated deposits at the Earth’s surface (Alexander 2013). Regolith originates from hard bedrock via weathering and biological processes. Regolith can have one of two origins: residual regolith (or residuum) which is formed in situ as bedrock weathers, or transported regolith which is transported to a site by wind, water, gravity, and so on (Schaetzl and Thompson 2014). The part of the regolith in which a soil develops is called its parent material. Rocks are weathered along fluid and gaseous pathways such as fractures, joints, faults, and so on. Weathered rocks are not necessarily covered by soil. Weathering is driven by the energy of the sun and involves exchanges between lithosphere, hydrosphere, atmosphere, and biosphere at low temperatures and under mainly subaerial conditions.

Weathering has traditionally been divided into physical (or mechanical) weathering and chemical weathering, but it is becoming increasingly apparent that biochemical weathering is also important (Velde and Meunier 2008). In reality, physical, chemical, and biochemical weathering processes work together. Alteration of the chemical or mineral composition of Earth materials does not occur during physical weathering, only a physical breakage of rocks into smaller pieces. Breakup of rocks and minerals create more surface area for chemical weathering, which operates mainly on the available surface area of minerals. Chemical and biochemical weathering both alter the chemical and mineralogical composition of rocks and regolith, producing new solid materials (e.g., clay minerals) and dissolved substances such as ions. Many of the dissolved solutes exit the soil system in groundwater or are biocycled by vegetation (Bridge and Demicco 2008).

During weathering, the fabric of the parent rock changes progressively from unaltered through to the most weathered zones (Figure 1). Weathered rock that retains much of its geologic fabric is called saprolite. Taylor and Eggleton (2001, 157–159) considered that regolith is composed of saprock and saprolite, where saprock is the altered coherent rock and saprolite is the altered soft rock. Together, saprock and saprolite form residual regolith, or residuum (Taylor and Eggleton 2001, 1–3), and above the saprolite, the altered soft rock is referred to as the pedolith (Figure 1).

Velde and Meunier (2008) proposed new definitions for altered rock facies based on physical properties that are easily observable in the field, that is, conservation or destruction of the primary rock structure and physical resistance (coherent, friable, soft, clay-enriched). Weathering profiles developed under temperate climate exhibit two altered rock types: coherent rock which may be sampled as self-sustained pieces that preserve the original rock texture and friable rock, which when sampled becomes gravel. According to these observations, one can distinguish three facies:
Physical weathering

Bedrock on the surface may weather, or disintegrate, physically from the stresses of heating and cooling, wetting and drying, and/or freezing and thawing. Physical weathering (PW) is the term used to describe the disintegration of rocks and minerals into smaller pieces. The main physical and mechanical processes of weathering are the *abrasion* and *comminution* of rocks and minerals as a result of erosive, expansive, and compressive forces and hydration along grain boundaries (Retallack 2001). Abrasion is the rubbing of rocks against each other, whereas comminution refers to the physical breakup of rock by faulting as a result of tectonic movement. Abrasion and comminution can occur simultaneously. They involve rocks rubbing against one another, chipping and breaking off small pieces.

Rocks deep below the Earth’s surface support the weight of the overlying column of rock. Lithostatic pressures can cause rocks to expand in the direction of least compressive stress, producing joints parallel to the principal stress direction (Bridge and Demicco 2008). As a result, all rocks contain fractures. This release of lithostatic pressure – often termed *unloading* – is most often due to the removal of overlying material by erosion.

Physical weathering acts on these joints to pry rocks apart and to break them into smaller pieces. Rocks can be physically weathered by *wedging* – prying them apart at cracks. The wedges can be formed by either ice or salt crystals. One of the main drivers of PW at the Earth’s surface is the *freeze–thaw* cycle of water and the associated growth of ice crystals. Wedging occurs as the result of the expansion of water as it is converted to ice. Cracks filled with water are forced further apart when the temperature drops below freezing. The splitting process in freeze–thaw produces fresh, angular fragments of rock (see Figure 2). The growth of salt minerals

**Figure 1** Classification of a typical weathering profile. Adapted from Migoń 2010. Reproduced by permission of The Geological Society.
in fractures and pores exerts increased pressure, analogous to ice. Additionally, the hydration of anhydrous salts (such as anhydrite to gypsum) within rocks (Bridge and Demicco 2008) can cause wedging and break off angular slabs or blocks of rock. These mechanisms are commonly cited as the main PW processes in arid regions, where extremes of temperature and moisture occur, and where many soils contain salts.

Other mechanisms of PW include the breakdown of rocks due to differential thermal expansion, and the contraction of individual rock-forming minerals during diurnal temperature changes. Plants and animals also have physical effects during weathering. A large number of animals make tunnels through hard rock and under the ground. Surface rocks also get crushed when animals tread on them or dig into them. Even earthworms make tunnels in the ground which leads to the breakdown of stones and rocks over a period of time. Plant roots at times grow deep into the cracks present in rock. As the plant roots grow thicker and deeper, rocks may begin to break. Both pressure release and wedging break up rocks and minerals, creating more surface area for chemical weathering (see Figure 2).

### Chemical weathering

Chemical weathering (CW) is the decomposition of rock materials by a series of chemical reactions. In most instances, the term biogeochemical weathering is more appropriate, as biota often interact chemically with the geological material to weather the minerals (Singer and Munns 2002). Chemical weathering generally occurs whenever water comes into contact with primary minerals (McBride 1994). The main processes of CW are solution, hydration, hydrolysis, oxidation, reduction, carbonation, and other reactions associated with inorganic and organic acids (Osman 2013). All forms of chemical weathering tend to promote the decomposition of minerals in rocks to a less resistant and more stable form, commonly a clay mineral (see Figure 2).

All minerals have two formation categories: primary and secondary. Primary minerals are formed at high temperatures and pressures through geologic processes. Usually, they form as molten materials (lava, magma) cool and harden. Consequently, they are unstable under atmospheric conditions. The stability of primary minerals (resistance against weathering) generally follows the Bowen reaction series, as those formed under high pressure and temperature tend to be less stable under atmospheric conditions. Secondary minerals form under atmospheric conditions (such as those found in soils) but may be unstable if conditions change from those of their formation. Primary minerals tend to release their ionic constituents as they weather; this can lead to the “new” formation (i.e., precipitation or neoformation) of secondary minerals. Secondary minerals can also be formed from the solid-state transition of a primary mineral, for example, mica→vermiculite. Many forms of CW also release cations, anions, and salts to the soil or regolith system; these may later recombine to form other secondary minerals.

The alteration processes that comprise CW occur between water (and its constituent dissolved substances, particularly acids) and minerals, operating at the mineral surface. Physical weathering, therefore, sets the stage for CW by increasing the surface area of minerals. Minerals are not ordinarily soluble in water, but in soils and regolith, acids, bases, and dissolved organic substances enhance their solubility. Most minerals in igneous and metamorphic rocks formed at around 1000°C and at many thousands of kilopascal pressure, under chemically reducing conditions. However, where they are exposed at the Earth’s surface at approximately 15–25°C, at
SOILS AND WEATHERING

*Ionic potential is defined as charge/ionic radius.

100 kPa pressure, and with abundant free oxygen dissolved in meteoric surface waters, primary minerals readily break down chemically (Bridge and Demicco 2008).

Dissolution occurs when rocks and/or minerals are dissolved by water. Dissolution of the most common ions of the Earth’s crust is largely determined by the pH of the soil solution (Figure 3). The dissolved material, typically as ions, is transported away in water or biocycled, leaving a void in the rock. Commonly, this kind of loss is what makes saprolite weaker than its parent rock, but because some minerals remain unweathered, the saprolite retains the structure of the parent rock. The readiness of a given ion for dissolution primarily depends on the ratio of its charge and radius (ionic potential, Table 1).
Hydration refers to the association of water molecules with minerals (Buol et al. 2011). During the hydration process, water molecules form a hydration shell around the ions of dissociated salts. Hydration primarily affects the mineral surfaces and (broken) edges of minerals, but in some cases it may dissolve the entire mineral (congruent dissolution).

Carbonation is a very active and common CW process, involving carbonic acid, and affecting mainly carbonate types of rocks (e.g., limestone, dolostone). Carbonic acid is naturally produced by dissolution of CO₂ in water. Carbon dioxide is available from the atmosphere and exists at high levels in regolith, because it is added as a product of microbial and root respiration. Thus, most carbonation processes are biochemical in nature. Carbonic acid is capable of dissolving many different types of minerals, bringing them into solution. The reaction for the dissolution of CaCO₃ is:

$$\text{CaCO}_3 + 2\text{H}_2\text{CO}_3 = 2\text{HCO}_3^- + \text{Ca}^{2+}$$

Carbonation can have an etching effect upon some rocks, especially limestone. The removal of cement that holds sand particles together leads to this disintegration.

Hydrolysis (splitting of the water molecules) is probably the most effective chemical weathering process. Hydrolysis occurs when primary minerals react with water, in the form of H⁺ and \(\text{OH}^-\) ions, to form other products. Hydrolysis is the reaction of acid (H⁺) with a cation-rich mineral grain to produce a clay mineral and various kinds of free cations. As a result, clay minerals accumulate in the soil and the cations are released, to later be leached or taken up by plants in solution (Retallack 2001). In hydrolysis, hydrogen ions (H⁺) in the water molecules replace other ions in the minerals. Due to this replacement, the mineral becomes susceptible to decomposition by further hydrolysis or other chemical reactions. Feldspars, the most common minerals in most rocks, are particularly prone to hydrolysis, reacting with water and free hydrogen ions to form secondary minerals. Hydrolysis is more rapid in silicate minerals characterized by well-developed cleavage (e.g., feldspars, pyroxenes) and is less effective in quartz. An example for hydrolysis (under acidic conditions) is shown by the following equation that describes the weathering of albite:

$$\text{NaAlSi}_3\text{O}_8 + 4\text{H}_2\text{O} + 4\text{H}^+ = 3\text{Si(OH)}_4 + \text{Na}^+ + \text{Al}^{3+}$$

Under less acidic conditions (pH 7) and long weathering, kaolinite may be formed, most typically in Ultisols:
When weathering further proceeds and Si(OH)$_4$ is progressively removed from the upper soil horizons, kaolinite disintegrates and loses silica (desilication), forming gibbsite (Figure 4). In this manner, reddish Oxisols with high gibbsite content develop. Al$^{3+}$ may also directly react with water, forming gibbsite. This process would be typical for soils of udic and perudic soil moisture regimes under tropical climates.

\[
\begin{align*}
\text{Al}^{3+} + \text{Si(OH)}_4 + \frac{1}{2} \text{H}_2\text{O} &= 3\text{H}^+ + \frac{1}{2} \text{Al}_2\text{Si}_2\text{O}_5(\text{OH})_4 \\
\text{Al}_2\text{Si}_2\text{O}_5(\text{OH})_4 + 5\text{H}_2\text{O} &= \text{Al(OH)}_3 + 2\text{Si(OH)}_4 \\
\text{Al}^{3+} + 3\text{H}_2\text{O} &= 3\text{H}^+ + \text{Al(OH)}_3
\end{align*}
\]

Commonly, the silicic acid that is released by hydrolysis precipitates to form amorphous clay minerals like allophane and imogolite, and other, more structured secondary phyllosilicates (e.g., smectites; Figure 4). Short-range order amorphous silicates are often the first weathering

**Figure 4** Weathering pathways for the common rock-forming minerals of the Earth’s crust. Adapted from Mason 1966.
product on volcanic parent materials, and are primarily found in Andisols. Halloysite (Al$_2$Si$_2$O$_5$(OH)$_4$·2H$_2$O) may also appear as a weathering product of volcanic ash (as the end product of the allophane-imogolite-halloysite sequence; Figure 4).

At higher pH and Mg concentrations, montmorillonite may be formed by the resilication of kaolinite (Jenny 1980) due to the process called neoformation, which involves the dissolution of kaolinite and its subsequent reprecipitation in the form of montmorillonite (Figure 4).

Oxidation reactions are those in which an element suffers electron loss when forming a compound (Retallack 2001). Oxidation is the process of addition of oxygen to minerals. The absorption is usually from O$_2$ dissolved in groundwater and that present in atmosphere. Oxidation is more active in the presence of moisture, resulting in hydrated oxides (e.g., minerals containing Fe and Mg). Oxidation in minerals occurs when oxygen reacts with iron-bearing minerals to form iron oxide minerals (iron rusting), for example, goethite.

$$\text{FeOOH} + e^- + 3\text{H}^+ = \text{Fe}^{2+} + 2\text{H}_2\text{O}$$

The latter minerals give rocks red or orange colorations, indicative of oxidation and aerated conditions.

The environment in which soils form may also be reducing, usually when waterlogged conditions exist. Reduction is important to weathering in such soils, because many cations are more soluble when reduced than when oxidized (Singer and Munns 2002). A common process in soils is the vertical fluctuation of the groundwater table which changes the location of the boundary between the phreatic (saturated) and vadose (aerated) zones. The location of the groundwater table and the level of water saturation control the pH and Eh (redox potential) conditions of the subsoil and determine the oxidation forms of several ions, including iron, manganese, and arsenic. The changes between reducing and oxidizing conditions will result in the electron transfer reactions between ions like Fe$^{2+}$ and Fe$^{3+}$, Mn$^{2+}$ and Mn$^{4+}$, and As$^{3+}$ and As$^{5+}$.

Ion exchange refers to two different processes in the crystal lattice of clay minerals. The first process is called the isomorphic substitution and results in the appearance of permanent charges in the clay minerals due to the replacement of Si$^{4+}$ by Al$^{3+}$ or Al$^{3+}$ by Fe$^{2+}$. The second type of ion exchange occurs in the interlayer of the 2:1 clay minerals, primarily in micas. This type of chemical weathering process is typical under acidic conditions where a large concentration of H$^+$ is available for ion exchange. With the removal of more than 50% of the interlayer K$^+$ (and replaced by H$^+$), the sheet alignment in micas is lost and distortion of the lattice may happen; the mineral eventually collapses and weathers. With the complete removal of the interlayer K$^+$, vermiculite and smectite-type layered silicates are formed.

Organic acids also play important roles in weathering. These acids can either be released directly from the organism or be derived as byproducts of organic decomposition. Chelation is a process in which metal ions are usually bonded to an organic compound (ligand). These organic complexes usually have aromatic (ring-like) structures which incorporate the metal ion. Once formed, this structure is stable and may persist in the soil (Buol et al. 2011). Because of chelation, otherwise insoluble metal ions become soluble and may subsequently be removed from the soil. This process is typical in Spodosols, where metal oxides (sesquioxides, such as Al$_2$O$_3$ and Fe$_2$O$_3$) are removed from the A-horizon in percolating water, forming A$_2$ or E-horizons (Schaeztl and Thompson 2014). These substances then accumulate in the deeper Bs or Bsh horizons. In other cases, however,
organic ligands are stabilized by the metal ion, resulting in the relative accumulation of the organic-metal complexes in the upper soil horizons. An example of the ring-like structure of a chelate would be a complex between an oxalate anion and a metal ion:

\[
\text{M(H}_2\text{O)}_6^{n+} + \text{OOC}^- \text{COO}^- = ((\text{H}_2\text{O})_4\text{M} - (\text{OOC})_2)^{(n-2)+} + 2\text{H}_2\text{O}
\]

Any one rock or mineral, however, weathers at different rates in different climatic conditions. Chemical weathering is slow in cold and dry areas. In the humid tropics, not only is the rate of weathering rapid (especially chemical weathering), but also the weathering products are lost quickly. In nature, physical and chemical weathering operate individually, or concurrently. In most cases, one accelerates the other.

Soils as relative-age dating tools

H.W. Markewich  
Milan J. Pavich  
US Geological Survey, USA  
Douglas A. Wysocki  
National Soil Survey Center, USA

Many geomorphic investigations rely on obtaining or inferring the relative ages of soils across a landscape, or among several landscapes. Relative ages (e.g., A < B < C, etc.) provide information about landscape age and stability, and allow for better understanding of pedogenic and other surficial processes since the initiation of soil formation, often called time zero. Combined with geomorphic process information (e.g., erosion rates) or numerical dating of parent materials for specific pedons, relative-age information provides information critical to decipher landscape evolution and environmental change. Understanding processes and mechanisms involved in soil development within a specific landscape enables the reconstruction of its pedogenic history, including pedogenic development rates. A quantitative pedogenic history in turn provides for objective prediction of future soil landscape changes. As both anthropogenic land alterations and global climate impacts occur, pedogenic predictive models become increasingly important for long-range land use planning, especially for agricultural sustainability and water availability.

Soil development and the state of the soil

Soil formation, or pedogenesis, is the transformation of raw parent material into a soil body. Jenny (1941) stated that, “Soils are those portions of the solid crust of the Earth the properties of which vary with soil-forming factors …” The state of a soil is quantifiable by five soil formation factors, which Jenny listed as climate (cl), organisms (o), topography (r), parent material (p), and time (t). The factors are quasi-independent variables that describe the state of the soil system. Jenny expressed soils as a function of these factors in a fundamental equation: 

\[ S = f(cl, o, r, p, t, \ldots) \]

where S denotes a soil or a soil property, the factors (in parentheses) are a sequence of variables or state factors, and the dots (\ldots) represent unstated, minor factors, for example, human influence or dust additions. If all state factors are known, or at least held constant, the equation can be rewritten as 

\[ S = f(t, k, \ldots) \]

where k is the total influence of factors other than t, and k is held constant. To estimate soil formation rates and soil or geomorphic surface age, we can compare soil and weathering profile properties as functions of time, or as proxies, and compare soils or landforms of different age. In such a comparison, as the equation shows, we select for soil age (time) but endeavor to hold other soil forming factors (k) constant.

Time, like the other state factors, is an independent variable. Conceptually, it is useful to define a starting point in time, so we define here time zero as the point in time that soil-forming processes begin to act upon unaltered parent material. The goal of most age studies – in soils
SOILS AS RELATIVE-AGE DATING TOOLS

(or in geomorphology) – is to estimate time zero of soil (or landform) formation.

In his fundamental state factor equation, Jenny demonstrated that soil properties change mathematically as a function of time, but also that properties co-vary as a function of the other factors. Fortunately, we can minimize or hold constant factors other than time in such comparisons, thereby clarifying the relationships between soil properties and the soil-forming duration (time).

Traditionally, and for relative-age dating purposes, we consider soil development as progressive and unidirectional, with profile thickness and horizonation (vertical anisotropy) developing steadily and increasing with time. We recognize that soils may regress or develop episodically (e.g., due to climate variations, erosion, or mixing processes), but for general soil–time comparisons, these aspects of pedogenesis must, necessarily, be regarded as secondary. The proven concept of directional pathways in soil development enables soil-to-soil comparisons via examination of how their morphologies and properties change as a function of age. Water availability and flow direction exert strong influences on soil morphology. We, therefore, constrain such comparisons to soils of equivalent drainage and landscape position. Moderately well and well drained soils generally exhibit the best progressive development and yield the most useful comparisons for dating purposes.

The soil/landform complex

Within a selected landscape, distinctive soils with shared characteristics are associated with (form on) equally distinctive landforms or morphologic units. Soils and landforms that display consistent geomorphic association conjoin space and time and represent a soil/landform complex. Such a complex has formed within a constrained time. Soil/landform complex examples include fluvial terraces and glacial moraines, as well as alluvial fans, pediments, sand dunes, emergent marine barriers, and landslide deposits. Because soil/landform complexes can have internal morphology differences, equitable comparisons as a function of time require that soil/landform complexes represent similar morphologic components within a landscape. For example, we cannot equitably compare footslope soils to those on summits.

An archetypal soil/landform complex would be an array of soils developed in alluvium on stream terraces that occur at differing elevations in a valley (Figure 1). Each terrace and its associated soils represent a soil/landform complex.

When comparing soils among two or more soil/landform complexes within the valley, it is important that the parent material be compositionally similar and that the soils have developed in similar topographic positions, and have undergone minimum erosion and (or) surface accretion. That is, we endeavor to hold the state factors other than time constant. When comparing very young soils, it is also advantageous to select soils that have developed under similar vegetation. For this river valley example, each soil/landform complex started developing at a different time (each soil has a different time zero), but all the soils have remained subaerially exposed and continued to develop under the same climate. By controlling or minimizing differences among the other four soil forming factors, we can prudently assume that the terrace soils differ primarily due to age (time since initiation of soil formation). This approach allows the researcher to evaluate the influence of time, or age, on soil development.

Geomorphic principles (cross-cutting relationships and ascendancy) provide an independent means to define relative terrace ages. Terrace

SOILS AS RELATIVE-AGE DATING TOOLS

Age increases with elevation. We know which terraces are older and which are younger, and this knowledge allows us to evaluate soil development on older versus younger terraces. We can apply this soil information to other landforms and evaluate their age using data from their soils as well.

The soil chronosequence

A sequence of soils developed on similar but different aged landforms in a given terrain defines a soil chronosequence. Simply stated, a soil chronosequence (Figure 1) is an array of soils in a specified geographic area, developed in similar parent materials, on similar landforms, and in similar topographic positions; these soils differ in their degree of profile development due predominantly to differences in age, or time since initiation of soil formation. As noted by Stevens and Walker (1970), the study of soil chronosequences is essentially examining time as a soil forming factor. Soil chronosequences can occur in all terrains. The fundamental unifying condition is that landforms or geomorphic surfaces of different age have formed in a region with uniform climate and parent materials. Typical examples are adjacent glacial moraines, or a sequence of fluvial terraces. Fluvial terrace chronosequences occur across various geologic terrains and climatic regimes, making them the most commonly studied chronosequence type. Soil chronosequences, however, also occur in other landscape systems, such as those produced by volcanic activity (adjacent basalt flows), eolian processes (stable and reactivated sand dunes), and crustal deformation (uplift) and (or) eustatic sea level changes (stepped marine terraces and shorelines).

Vreeken (1975) designated several chronosequences types, with post-incisive and pre-incisive chronosequences being the two most common. A post-incisive chronosequence consists of soils that began forming at different times on deposits of different age, and which have all remained exposed at the surface (Figure 1). They include soils developed on progressively younger surfaces, are the least ambiguous to interpret, and, hence, the most commonly investigated. A pre-incisive chronosequence includes soils that developed during the same time in one deposit, some of which subsequently undergo burial, but at different times. This chronosequence type may also include a soil that remains at the ground surface. An example of this chronosequence would be a soil array developed on a land surface that through time is partially buried by intermittent eolian activity. When the burying sediment is thicker than some critical level, soil formation ceases in the buried soil. The buried soils retain their original time zero, but development time ends at burial. The oldest soil in this pre-incisive chronosequence remains unburied. The unburied soil has the same time zero as the nearby buried soils but development continues to the present. The post-incisive chronosequence that includes soils developed on progressively younger surfaces, is the least ambiguous to interpret, and is routinely the most investigated.

Vreeken (1975) describes two additional chronosequences: (i) time-transgressive without historical overlap and (ii) time-transgressive with historical overlap. A time-transgressive without historical overlap chronosequence is a vertical soil sequence formed in, and separated by, parent materials. Soil development ceased upon subsequent burial(s). An example is a thick loess sequence with inclusive paleosols (Figure 2). Individual loess units and their associated paleosols represent climate cycles (e.g., dry vs wet climate). Such a chronosequence involves a succession of soil-forming environments; it does
not represent an age developmental sequence. To evaluate soil development rates through time in this chronosequence type requires other age controls. A time-transgressive with historical overlap chronosequence is a vertical or lateral soil sequence that developed on surfaces of differing age, which undergo burial at different times. Although a common chronosequence type, the pedogenic complexity and episodic history of pre-incisive sequences complicates chronosequence studies.

Soil age, soil development, and weathering

Soil chronosequences can occur on surfaces that have wide age ranges. Soils in most glaciated regions are late Pleistocene or younger in age. Unglaciated regions, however, can have soils and surfaces that span the entire Quaternary Epoch, and possibly the late Neogene. Many studies that use soils for determining relative age are in landscapes that are 100 000–1 000 000 years in age (middle-to-early Pleistocene) (Figure 1). In geologically recent terrains, for example, areas of late Quaternary and Holocene volcanism, and in anthropogenic terrains such as spoil piles in old mining areas and razed-building sites in urban landscapes, soil age commonly ranges from a several thousand years to as little as a few decades. Regardless of setting, soil formation depends upon land surface stability (no erosion or subsequent deposition). In other words, soil formation cannot begin until the geomorphic surface upon which the soils form is stable, that is, no longer eroding or accumulating new sediment.

It is important to distinguish among three interrelated terms – soil age, soil development, and weathering status. We define soil age as the amount of time that has passed since the soil began to form (time zero). Explicitly, it is
the time elapsed since the land surface became stable – when deposition of the parent material ceased – and processes related to weathering and soil formation began. Soil age generally is expressed in years before present. Soil development is measured or evaluated by the number, type, and thickness of genetic soil horizons. It encompasses any of a number of soil characteristics observable at the time of study. In general, the greater the number of horizons, the thicker the horizons, and the greater the differences between horizons, the more developed, and hence the older, the soil is assumed to be. Soil formation rates vary as a function of the kinds and intensities of pedogenic processes that are operative, and these are, in turn, a function of the climatic setting, parent material composition, and biotic and topographic influences. Consequently, soils with equal development are not necessarily equal in age or vice versa, that is, they may simply have been subject to different rates of soil formation, due to their environmental setting. Weathering status reflects the mineral composition of a soil. Chemical weathering sequentially removes and/or concentrates minerals in soils, depending on their weathering resistance. In general, when iron and aluminum oxides and kaolinite dominate as weathering products in soils, they indicate a more advanced weathering state. Soils dominated by smectites, mica, and feldspars, which are less stable in well-drained, slightly acidic surface environments, represent a less weathered state. Because parent material composition determines the initial weathering state for a soil, mineral composition alone is not a consistent age indicator. That is, some young soils may have inherited minerals in their parent material that generally occur in older, highly weathered soils. The soil here is young (recent time zero) but its weathering status is similar to that of older soils. Thus, one often compares soil–weathering status in the profile to that of the parent material to avoid this complication.

In chronosequence studies, a single numeric age can serve as an anchor that guides further relative age assessment based on soil development. Numeric soil age refers to the absolute age of a soil or a geomorphic surface. We often express numeric age as in years ago or years before present. We can obtain a maximum soil and associated landform age by determining the age of the parent material in which the soil has formed. The numeric age of the soil parent material can be determined, or sometimes bracketed, by using any of several techniques. The most common are radiometric techniques, such as radiocarbon analysis, and luminescence techniques, such as optically stimulated luminescence. An alternative approach for soils formed in pre-Pleistocene parent materials is to identify age distinctive fossils, thus providing a maximum biostratigraphic age for the parent material. We can use radiocarbon analyses of the stable soil organic-matter fraction to date soils younger than about 40 kyr. In arid and semi-arid environments, we can employ the radiometric techniques of radiocarbon and isotopic uranium and thorium disequilibrium analyses to date pedogenic calcium carbonate; this method is particularly useful for soils >40 kyr.

In most environments, determining the soil’s numeric age is more difficult than determining the parent material age. Meteoric $^{10}$Be soil residence time analyses, however, provide a promising solution to this dilemma. Such analyses give an estimate of the minimum time required for a soil to form (Pavich et al. 1986) and are particularly useful in humid environments, where little organic matter or carbonate accumulates in the soil or parent material. In these environments, $^{10}$Be soil residence time analyses is one of the few methods available for determining numeric soil age, especially for soils >40 kyr.
In summary, there exist a number of numeric dating methods to obtain absolute soil or sediment ages; this list continues to grow. In many soil studies, however, dateable material is lacking, the techniques are costly, and many rely on strict and often unobtainable assumptions, which is why we turn to relative-age dating techniques.

**Relative ages based on soil chronofunctions**

Relative-age dating establishes the chronological sequence of events, that is, which soil formed first, second, and so on, or which soil is younger or older. Relative-age dating does not provide the exact soil or parent material age, for example, how long ago in years a soil or geomorphic surface formed. Relative-age dating linked with chronofunction formation rates can estimate the magnitude of the age differences between two or more soils. By geomorphic principles (ascendancy), it can be established that geomorphic surface A is older than surface B. We can use quantified soil development differences to additionally show that surface A is slightly older than surface B, or is three times older, or ten times older. This added degree of relative-age distinction allows for more detailed age discrimination. For example, in three adjacent moraines it can be determined whether they resulted from three distinct advances (OIS 2, 4, and 6) or from a single major advance with three short pulses/surges (all OIS 2).

Relative-age dating relies on observable relationships and properties that yield a general chronological rank. Moreover, relative-age dating creates a chronologic framework that gives greater relevance to measured numeric ages, when they are available. We can assign relative ages to soils and (or) soil/landform complexes based on (i) geomorphic and stratigraphic principles (i.e., stepped river terraces and floodplains or nested glacial moraines), (ii) degree of morphologic soil development (horizon thickness, number, and distinctness), and/or (iii) differences in physical and chemical soil properties and weathering, as compared to the parent material. Soil morphology and development, as quantified by numeric age or constrained by relative geomorphic age, permit judicious estimates of the soil formation time, which is also known as the soil-forming interval. A key example is the accumulation of pedogenic carbonate (Bk, Bkk, and Bkkm horizons) in arid regions. Detailed field soil observations (Gile, Peterson, and Grossman 1966), coupled with age and geomorphic surface studies (Gile and Grossman 1979, and other investigations), defined a six-stage morphogenetic sequence that conceptualizes this process. This sequence is widely used to infer relative soil and landform age in arid settings where age measurements and geomorphic constraints are lacking or unknown.

Many soil properties (e.g., chemical depletion and clay content) commonly exhibit uni-directional change over time. Because of this, we can use the progressive soil development encompassed in a soil chronosequence to mathematically express soil formation as a function of time, that is, a soil chronofunction. Establishing a chronofunction requires a chronosequence with bracketed ages (geomorphic principles) or known ages (numeric techniques). When we plot soil data as a time function, it often is expressed as best-fit regression model (Figures 3 and 4). The function type (linear, logarithmic, exponential, etc.) varies, depending on the soil property measured and its pattern of change through time (Figure 4). In a chronofunction, soil properties represent dependent variables; time is the independent variable. The chronofunction is a mathematical relationship that quantifies the change in the observed soil or soil properties...
through time. Its slope defines the rate of change for that soil or soil property. Consequently, we can use chronofunctions to calculate development rates for measured soil properties. Figure 3 shows B horizon clay formation rates for glacial tills in different climate settings. It is assumed that soil properties change in a systematic way (linearly, logarithmically, etc.) with time (as shown by Figures 4 and 5) and that they can be measured in all of the soils for which comparisons are being made. In general, many soil properties change logarithmically through time, such as horizon and solum (A and B horizon) thickness, clay mass, bulk density, rubification (reddening), and weathering depth.

After chronofunctions are established and their soil–age relationships verified, we can then use them to estimate soil and landform ages for surfaces and places where such ages are otherwise unknown. We accomplish this by reversing the function to predict formation time or age from the given soil properties. Of equal import, a
SOILS AS RELATIVE-AGE DATING TOOLS

Figure 4  (a) Linear chronofunction developed using chemical indices ($\text{Fe}_2\text{O}_3 + \text{Al}_2\text{O}_3/\text{SiO}_2$) from soil B horizons with the maximum clay content. The soils developed on river terraces. (b) Logarithmic chronofunction for $\text{Fe}_2\text{O}_3 + \text{Al}_2\text{O}_3/\text{SiO}_2$ plotted against ages of soils developed in Atlantic Coastal Plain and outer Piedmont sedimentary deposits of the eastern United States. (Modified from Markewich and Pavich 1991, Figure 5b.)

chronofunction can also be used to determine how long it would take to develop selected types of profile, horizon, or property characteristics. Multiple measured ages, compiled for several soil/landform complexes, can theoretically facilitate the most rigorous and reliable calculations of soil and (or) landform development.

Soil properties that have the best potential for chronofunction formulation and, hence, relative-age assessment, are those that display change with depth through time. Examples include field-measured attributes for various horizons (e.g., thickness, color, texture, clay films, structure, consistence, pH, thickness and characteristics of organic and inorganic carbon accumulation, salt accumulation, etc.) and, where appropriate, properties of the weathering profile (weathering/oxidation depth, mineral abundances, and color) relative to the parent material. Laboratory-measured soil properties that change with depth also work well in this type of application. Examples include content of clay, carbon (inorganic and organic), specific major and minor elements (i.e., Al, Ca, Fe, Na, P, Rb, Si, Ti, Zr), and ratios thereof. These properties (field or laboratory), individually or in combination, are used for intersoil comparisons and serve as dependent variables in chronofunction formulations. When compared to the same properties in the unaltered parent
material, they allow for the comparison of one soil/landform complex to another within the same terrain.

Soil development indices

Because direct comparison of multiple and complex field and laboratory data across soils in a chronosequence can be complex, confusing and/or difficult, researchers often use the data to derive more integrative measures, known as soil development indices. Indices allow for simpler, yet quantitative, comparisons of soils of different ages. Importantly, soil development indices capture the complexity of soil development in a single number. This simplifies comparisons within or across chronosequences, when such indices are plotted against time to develop a chronofunction. A soil development index consists of a comparison of selected properties, usually by horizon, to that in the parent material or other selected control. This index may be expressed as a number or as a ratio.

Numerous soil morphological and chemical indices exist to characterize weathering and soil profiles. The focus here is on indices most applicable for soils developed in similar parent materials. Soil indices can be formulated for a single soil property or for a combination of soil properties, for one horizon or a combination of horizons, or for the entire soil profile (a soil development index). Commonly used soil profile indices include several based on soil morphology: (i) the index of Bilzi and Ciolkosz (1977), a rating scale that uses soil...
properties to assess genetic horizon development strength relative to the C-horizon; (ii) the soil development index (Harden, 1982), which relates up to eight field soil properties (clay films, texture plus wet consistence, rubification (hue and chroma), structure, dry consistence, moist consistence, color value, and pH) to parent material properties; and (iii) the POD index of Schaetzl and Mokma (1988) for spodic (podzol) soils, which relates soil development to the number and colors of soil subhorizons. Other indices relate laboratory-measured soil properties (particle size, elemental chemistry, etc.) for either the entire soil profile and (or) parent material. One example is the podzolization index of Duchaufour and Souchier (1978), which is a measure of the degree of chemical differentiation within a podzol profile. Indices developed for the whole soil include the index of profile anisotropy (IPA) (Walker and Green 1976), which relates soil-property variation of one horizon to the weighted mean of that property in the soil profile, and the modified IPA (Birkland 1984), which is similar to the IPA but takes into account horizon variations with respect to the parent material. We use horizon-to-horizon and horizon-to-whole-soil comparisons to develop a soil morphology index that relates field properties of the solum to those of the C horizon. Other properties helpful for estimating relative soil age include solum (A and B horizon) and argillic horizon thickness, and elemental ratios such as SiO₂/TiO₂ and Zr/Rb, which indicate the degree of soil weathering. Other elemental ratios employed for relative soil age estimation, particularly in warm–humid to tropical environments, include the ratio of K₂O + MgO/TiO₂ and the ratio of Fe₂O₃ + Al₂O₃/SiO₂ to clay mass and to time (Markewich and Pavich 1991) (Figure 4b).

Some indices are simple to calculate. A good example is the Duchaufour and Souchier (1978) podzolization index. Aluminum contents in the A, B, and C horizons are plotted and the values for the A and C horizons are connected on a graph, using a straight line from the maximum aluminum content in the B horizon to the y-axis. The amount of aluminum represented by the intersection of the two lines is divided into the maximum aluminum content to give the podzolization index, Kₐ. Figure 6 is modified from the author's 1978 publication and graphically represents the technique.

Some indices, such as the Harden index of soil development and the Bilzi–Ciolkosz index require a large suite of soil property data and are more complicated to calculate. The advantage is that more data goes into the final index values and, hence, the indices may be more robust. Figure 7 outlines the steps for determining the soil development index for a soil profile. We often determine which soil property or combination of soil properties is the best for a particular soil by measuring and comparing as many of the pedogenically significant soil properties as is practical. We then compare the calculated index values to age ranges, if known, either for the parent material, or for the soils.

By synthesizing results of a large number of chronosequences in a number of environments, we can compare soil forming rates across climates and parent materials. Bockheim (1980) developed chronofunctions for 32 chronosequences from seven climatic regions using linear and nonlinear models. Graphical comparisons of the chronofunctions illustrate how soil properties develop at dramatically different rates, depending mainly upon climatic regime (Figure 3) or parent material.

As chronosequence studies have progressed, research goals have expanded to include complex and interrelated challenges, such as (i) understanding how and why soil development rates change through time, (ii) whether rate
changes are due to the soil or a soil property attaining a steady-state, (iii) whether thresholds in soil development that mark significant decreases or increases in the rate of development exist, and (iv) the reasons or drivers for this type of threshold, such as the formation of impermeable horizons, climatic changes, such as increase in temperature or precipitation, or anthropogenic effects, such as deforestation.

Regardless of the specific goals, the soil chronosequence studies offer promise for greatly advancing our knowledge of the pathways and rates of soil and soil property transformations through time. The importance of this knowledge cannot be overstated. Soils are the underpinning of all terrestrial ecosystems. They function as biodiversity refuges, filters for natural and recycled waters, sinks for nutrients, carbon, and other greenhouse gases, and form the basis for our agroeconomy. Understanding the length of time necessary for soils to develop, and their relative ages, in different environmental settings is essential for model development in a world of increasing climate change with increasing acreages of human-modified soils and parent materials.

SOILS AS RELATIVE-AGE DATING TOOLS

Describe the soil profile

Assess the parent material

Quantify each field property

Normalize each quantified property

Comparison of soil properties

Calculation of the soil development index

Sum the normalized properties for each horizon

Divide each normalized property value by the total number of quantified properties. This gives the “horizon index”

Multiply the value determined in step (4) or (6) by the thickness of the horizon

Sum the horizon products determined in step (7) through the soil profile. This gives the “profile development index.”

Example for calculations in step (3)
Assign 10 points for each shift from parent material toward the finer, the more plastic, and the more sticky soil texture classes. Such as, if a horizon is one class finer in texture than the parent material than texture is assigned 10 points. If the horizon stickiness is two classes greater than the parent material, stickiness is assigned 20 points. Similarly, If horizon plasticity is one class more than the parent material, plasticity is assigned 10 points. This gives an overall texture value of 40 points.

Methods for normalizing (step 4) soil property values calculated in step (3) differs by property or combination of properties, but in general the process for step (4) is to divide by the maximum possible value of the point scale for that property. This produces a scale ranging from 0 to 1.

Figure 7 Outline of the steps required to determine the Harden soil development index. (Modified from Harden 1982, Figure 2.)

Soils in archaeological research

Vance T. Holliday
University of Arizona, USA

Soils are a potential source of much information in archaeological studies at all scales, from specific archaeological sites (or even parts of sites) to broad regions. Soils are literally a part of the physical stage upon which humans evolved. Soils are not only integral components of most natural landscapes, they are also significant components of cultural landscapes. Beyond physically supporting humans and their endeavors, however, soils are also indicators of the nature and history of the physical and human landscape. They record the impact of human activity, they are a source of food and fuel, and they reflect the environment and record the passage of time. Soils also affect the nature of the cultural record left to archaeologists because they may encase archaeological materials and archaeological sites. They are a “reservoir” for artifacts and other traces of human activity.

Soil forming processes also are an important component of site formation processes. Pedogenesis influences which artifacts, features, and environmental indicators (floral, faunal, and geological) are destroyed, which are preserved, and their degree of preservation. Two realms of soil science are most directly applied in archaeology. Pedology deals with soils as three-dimensional bodies, and thus is intimately related to the landscape and other aspects of the environment. Soil chemistry is concerned with the chemical properties of soils and thus provides a means of detecting past human impacts on soils.

Pedology in archaeology

Several components of pedology and the allied subdiscipline of soil geomorphology are widely used in archaeology, in particular in the subdiscipline of geoarchaeology. These components can be grouped into soil surveys, soil stratigraphy, soil geomorphology, and site formation processes.

Soil surveys in archaeology

With proper interpretation, a considerable amount of information can be gleaned from soil surveys for use in archaeological and soil-geomorphic investigations (Scudder, Foss, and Collins 1996; Holliday 2004). Surveys can provide a good base map and useful aerial photographs. They can also provide valuable information about surficial geology (Figure 1). Perhaps most significantly, soil surveys have the potential to aid in understanding landscape evolution and estimating the ages of various parts of the landscape (Figure 1). This is useful in predicting presence of archaeological sites and their age.

Most archaeologists are aware of soil maps as a useful resource, but their usefulness may be overestimated or misunderstood. For example, the purpose and preparation of soil surveys impose limits on their utility in archaeology. They are not designed for use as guides to local geology or geomorphology or for reconstructing prehistoric vegetation patterns. Instead surveys reflect mainly the local bedrock, sediments, and...
landforms. The degree to which the surveys accurately depict soil-geomorphic relations (see below) will vary tremendously from survey to survey, depending on the size of the features of interest, the area, and the training and experience of the mappers. During the course of the survey there will generally be little emphasis on or data gathering concerning the origin or historical development of the soils. Further, the interpretation of soils at a specific site can be problematic because soil surveys represent generalizations. Nonetheless, careful reading of descriptions and map legends for soils depicted on maps can provide general indications of geoarchaeologically important characteristics such as depth to bedrock, site wetness, landform type, and degree of soil development (see below).

Soils as stratigraphic markers

The unique physical and chemical properties that distinguish soils from sediments make soils quite useful for stratigraphic subdivision and correlation. Soils have thus been commonly used as stratigraphic markers in archaeological research (Mandel and Bettis 2001; Holliday 2004) (Table 1). However, the nature of soils also necessitates the exercise of a certain amount of caution in their use in stratigraphy.

The presence of a soil in a stratigraphic sequence marks the passage of some amount of time with no or very little erosion or sedimentation. However, the parent material for that soil, which is as old as or older than the soil, may have been deposited virtually instantaneously. If the soil in such a sequence is buried, the contact

**Figure 1** Soil map of the Harappa area, Pakistan (based on Amundson and Pendall 1991; Belcher and Belcher 2000). A soil survey around this famous Bronze Age site aided in reconstructing the evolution of the Holocene landscape and in understanding the relationship of the site to the Ravi River. The site was constructed on the oldest alluvial terrace (unit 20) but also adjacent to a channel (Rc) active during occupation. The pattern of stream meanders is clearly apparent around the site (soil units Rc, Sc, 16, 17, 18, 19).
Table 1  Stratigraphy of the “Loessic Paleolithic” in southern Tajikistan (modified from Holliday 2004, Table 6.4). Buried soils were key stratigraphic markers throughout the region, used to correlate multiple Paleolithic occupations.

of the top of the soil with the sediments that bury it marks the gap in time. This means that cultural material found at the top (in or near the soil) and bottom (deep below the soil) of even a thick deposit may be nearly contemporaneous. In addition, the artifacts near the top of the unit may be considerably older than an artifact immediately above, on the paleo-surface. Moreover, artifacts found on the paleo-surface may well represent a mixture of cultural material left on the surface during the entire period of soil formation. The artifacts and occupations are also subject to mixing by biological and geological activities, as well as stratigraphic compression. Bioturbation, in particular, is well known as an agent by which artifacts on the surface can quickly become buried (Johnson 1990; Van Nest 2002) (see below). The surface of a buried soil (or “paleosol”) may be a zone likely to contain archaeological material because it represents a stable landscape that persisted for some amount of time. The contact between the buried soil and the overlying sediment, however, may be time-transgressive because burial of the surface may take place at different times in different places or continuously over a long period of time.

Soils can be useful in identifying various sedimentary strata, but they should never be considered strata themselves or referred to as “strata” or “layers,” or otherwise treated like geological deposits (Holliday 2004). A soil profile is imprinted over and into geologic deposits through time, generally from the surface of the parent material downward, and, therefore, the boundaries between soil horizons often have no relationship to geological layering. Depending on the slope of the surface associated with the soil and variations in the permeability of the parent material, soil horizons can crosscut depositional layering.

For many of the same reasons, pedogenesis also can obscure sedimentary features and contacts. One of the criteria often used to differentiate between a B horizon and a C horizon is whether bedding in the parent material has been destroyed, but evidence of bedding can persist in a B horizon if the original beds included lenses of gravel. Otherwise, to document the sedimentology of parent material obscured by pedogenesis will require laboratory analyses. However, the original particle-size distribution of the parent material can also be modified by pedogenesis. Significant amounts of illuvial (postdepositional) clay can accumulate in soils, which can affect sedimentological interpretations.

Soil geomorphology

The “state factor” approach to soil genesis is the theoretical framework for much of pedology and is widely applied in soil geomorphology (Jenny 1941; Birkeland 1999; Holliday 2004; Schaetzl and Anderson 2005). Jenny (1941) defined the factors of soil formation (the external factors that drive soil forming processes) as climate, organisms (flora and fauna), relief (or landscape setting), parent material, and time, often written as the equation

\[ S = f(d, o, r, p, t \ldots) \]

where the upper case \( S \) is the whole soil. This equation defines the state of the soil as a function of the five factors (the “state factors”) and other, unspecified factors of local or minor importance (\( \ldots \)) (e.g., dust fall, groundwater fluctuations). The equation can be solved by studying the variation in a soil as a function of one factor, keeping the others constant or accounted for. For example, variation in soils due to differences in climate could be studied by keeping all factors except climate constant. Birkeland (1999) applied this approach to studying the evolution of soils. This approach also has applications in archaeology. The factors of soil formation that
are generally of most concern in archaeology are time and climate. Specifically, this includes using soils as indicators of age, past environments (climate and vegetation), and environmental change.

The concept that some time must elapse before a soil can form is probably one of the most significant soil-related aspects of archaeology. The presence of a soil in an archaeological site, or in any stratigraphic sequence, as noted above, indicates that there has been a significant period of landscape stability, during which there has been relatively little or no erosion or deposition. In many situations, such as alluvial or eolian depositional environments, deposition can occur in as little as a matter of days, years, or decades. Soils almost invariably take longer to form, usually at least 100 or several hundred years, commonly thousands of years.

The degree of development of a soil or specific pedologic features in a soil can be used as a relative indicator of the amount of time elapsed since deposition of parent material and the beginning of soil formation. In some situations, such data can also provide a rough indication of a soil’s numerical age. In a situation where there are a number of soils, either buried in a stratigraphic sequence or exposed at the surface in an array of surfaces and where the influence of the other factors can be considered negligible, held constant, or otherwise accounted for, a chronosequence can be defined. A chronosequence is where the soils with stronger profile development can be considered older than those that are less developed (Figure 2). Pedologic features that are time-dependent include overall profile morphology as determined by soil indices, horizon and profile thicknesses, contents of illuvial clay, calcium carbonate (CaCO₃), and humus, reddening of the B horizon, alteration or formation of certain clay minerals, and alteration or translocation of certain forms of iron, aluminum, and phosphorous (Birkeland 1999) (Figure 2). In an archaeological site with a chronosequence and also producing time-diagnostic artifacts, radiocarbon ages, or some other form of numerical age control, rates of soil formation can be determined. Such data can
SOILS IN ARCHAEOLOGICAL RESEARCH

then be applied in other sites in similar situations to provide an age estimate for natural or cultural deposits.

The goal of some archaeological research is the reconstruction of the climate during the time that a site or region was occupied, or the detection of climate change over a long period of occupation or relative to abandonment. Soils probably have limited applications for reconstructing climates in archaeological investigations, however (Birkeland 1999; Holliday 2004). In general, soils are not sensitive to discrete or even subtle climate changes which may be culturally significant. Such changes can be more easily detected from plant or animal remains than from soils. Furthermore, climate changes in the Holocene, the time period that most American archaeologists deal with, were often of insufficient magnitude to be detectable in the pedologic record. Furthermore, soil properties related to the time factor are often difficult to separate from those related to climate. Some pedologic properties, such as reddening of the B horizon, can be time- or climate-dependent. Following a climate change, some time is also required for the soil properties to reflect the new climate and, in any event, properties related to the previous climate may persist.

In some situations, however, soils have proven useful in providing general paleoclimatic and paleoenvironmental data. The properties of soils that seem to best reflect those climatic parameters include overall profile morphology, organic matter content, and depth of leaching. The last attribute is a function not only of the amount of CaCO₃ and more soluble salts in the soil but also of soil age and climate (Birkeland 1999; Holliday 2004; Schaetzl and Anderson 2005).

Environmental changes both directly and indirectly linked to climate have produced striking changes in the morphology of some Holocene soils in valleys of the Great Plains, including archaeological contexts. High water tables in the final millennia of the Pleistocene into the early Holocene produced a variety of buried soils. These soils have dark colors, suggestive of high organic matter contents (Figure 3). Gleying immediately below the surface horizons indicate a high water table at some times of the year (Reider 1990; Holliday 2004; Haynes 2008). Soils that overlie them, which probably date to the middle and late Holocene, formed in sandy parent materials with eolian and/or alluvial origins. The latter soils are well drained, with combinations of Bw, Bt, and Bk morphologies depending on their age, all indicative of well-drained conditions likely due to lower water tables, plus filling of the valleys with clastic sediments (Figure 3).

Information about archaeological environments gained from study of factors of organisms, relief, and parent material has only limited application (Birkeland 1999; Holliday 2004). Plant and animal distribution is so closely linked to climate that sorting out the effects of each is often difficult. The best results achieved along these lines have been vegetation reconstructions in restricted areas where the regional climate can be assumed to have been constant over time. Most of this work has focused on studies of the ecotone between forested and unforested (including both prairie and tundra) regions. Alfisols and Spodosols with E horizons will typically form under forested conditions, whereas Mollisols, Alfisols without E horizons, and Inceptisols are common in the nonforested areas. Because the forest boundary fluctuated through time as climate changed, the forest soils left their imprint in the subsequent nonforested soils. Mapping and dating of buried and altered forest and tundra soils also allowed for a reconstruction of shifts in the forest-tundra boundary throughout the Holocene in Canada, and similar investigations have been carried out.
SOILS IN ARCHAEOLOGICAL RESEARCH

along the ecotone of the forests of the Midwestern United States and the prairies of the Great Plains, and in archaeological contexts along the flanks of the Rocky Mountains (Holliday 2004).

Soils also can vary as the parent material or relief changes. These variations can influence soil profile morphology, making the tracing of a particular soil or using a soil as a stratigraphic marker difficult. This problem could be especially significant when working on a large archaeological site or over a larger area such as a drainage basin and where only limited natural or artificial exposures are available. On the timescale of the Holocene, probably one of the most significant influences that parent material can have on a soil is in water movement. Coarser-textured soils allow much faster percolation than do fine-grained soils. Water movement over and through soils is strongly influenced by slope position, that is, along a catena (Figure 3). Soils near the summits of slopes are better drained, but receive less effective moisture (due to runoff) than soils at the foot of slopes. Soils in upslope positions will also tend to have material constantly removed from their surfaces by erosion, whereas the soils at the foot of the slope will tend to accumulate materials eroded from upslope. The morphology of a soil can therefore vary markedly along a slope. This is an important consideration when using soils to date landscapes or when identifying or tracing buried soils. The concept of variation in soil morphology as a function of landscape setting can be quite useful in the reconstruction of landscapes and local environments, however. This principle is particularly applicable to buried soils, which represent buried landscapes (Figure 3).

Site formation process

The physical, biological, and chemical processes associated with pedogenesis can move, alter, and/or destroy archaeological materials and features (Johnson and Watson-Stegner 1990; Thorson 1990; Holliday 2004). For example, the shrinking and swelling that typifies Vertisols

Figure 3 Generalized catenary relationships of soil-stratigraphic units at the Lubbock Lake site, Texas. Source: Reproduced from Holliday 2004. © Oxford University Press: New York.
SOILS IN ARCHAEOLOGICAL RESEARCH

Figure 4  A sketch of a soil profile from Nabke, Guatemala, illustrating a buried A horizon disrupted and distorted by shrink-swell processes in a Vertisol. Based on Jacob 1995.

can result in movement of artifacts (up or down, or both) within the profile, which can disrupt the stratigraphic and cultural contexts of a site (Figure 4). Similarly, freeze-thaw and related processes of solifluction can move artifacts laterally or vertically and in some cases overturn a site. These processes can have subtle but significant impacts. Rooting, tree uprooting, and burrowing by biota can dramatically move artifacts and disrupt stratigraphy. Chemical transformations such as humification, podzolization, oxidation-reduction, and calcification all alter the chemical state of the soil and as a result can destroy anthropogenic plant and animal remains and metals.

Agriculture and Anthrosols

The development of agriculture has had pervasive physical and chemical effects on soils. Certainly no other preindustrial human activity has touched so much of the Earth’s surface as has agriculture. At its most basic level, farming is the replacement of some natural vegetation community with some sort of artificial vegetation, that is, an agroecosystem. This relatively simple and straightforward activity has a host of far-reaching effects on the landscape and on soils. The original plant cover can be partially or completely removed, leaving the ground bare for at least some part of the year and subject to erosion by water or wind. Cultivation loosens the soil, and the hooves of domesticated animals loosen or compact it. Devegetation alters soil water relationships, and can even affect groundwater. Plowing, excavation of irrigation ditches, and construction of terraced fields all physically disturb soils as well. Devegetation, additions of various kinds of plant residues (from burning and cropping), and fertilizers can all alter soil chemistry and nutrient balance. Changes in groundwater conditions can drastically affect the soil-forming environment. An elevated water table as well as irrigation also induces salinization if salts are present. Often, long-term irrigation leads to elevated water table levels. If this water contains measurable amounts of salts (as most irrigation waters do), salinization of surface soils can result.

The unique morphological (macro- and micro-) and chemical characteristics of soils provide an excellent backdrop against which past agricultural activities may be identified and measured (Courty, Goldberg, and Macphail 1989; Holliday 2004). The physical signatures of agriculture in soils are related to the disruption of the lateral continuity of, and vertical gradations between, soil horizons. These disruptions result
largely from plowing and construction of ditches and furrows. Probably the most obvious initial effect of farming is mixing of the upper solum by plowing. This process is widely recognized today in the identification of an “Ap” (plow-zone) horizon. Many taxonomic systems also recognize other soil horizons associated with long-term agriculture, such as the pluggage horizon (long-term manuring), the agric horizon (illuvial materials that have accumulated below a plowed zone), the anthropic horizon (see below) (Soil Survey Staff 1999), and Anthrosols (see below) (IUSS 2006).

At microscopic and molecular scales, effects on soils due to human activity are generally much more subtle than are physical impacts. The former usually require laboratory analyses for identification. Microscopically, the effects of agriculture include evidence for rapid infiltration of coarse-grained illuvial coatings in soils, caused by deforestation, and poorly sorted mineral coatings and infillings of charcoal and soil organic matter (SOM), due to farming. Among agricultural and pre-agricultural groups, anthropogenic chemical additions to the soil came primarily from human refuse and waste, burials, and the products of animal husbandry in barns, pens, and on livestock paths, in addition to more traditional soil fertilizers (Eidt 1984). Metallurgy and later industrialization introduced a much broader spectrum of chemicals and compounds to soils, such as heavy metals and hydrocarbons. The most common elements added to soils by human activity are carbon, nitrogen, phosphorus, and calcium, with lesser amounts of potassium, magnesium, sulfur, copper, and zinc. The most common chemical compound added to soils by humans in agricultural and pre-agricultural societies, and one that is also easily recognizable in the field, is SOM. Discard of organic waste (either in middens or as fertilizer) can add significant amounts of organic matter to the soil surface. Further, additional SOM can be produced and added to the soil by stimulation of soil biota and above-ground biomass subsequent to human activity due to more favorable nutrient conditions often associated with anthropogenic changes. These are notable characteristics of the Anthrosols described below.

Anthropogenic chemicals and chemical compounds can, in theory, be used as indicators of past human activity (Eidt 1984; Holliday 2004). Interpretations must be carefully made, however, because most can be removed from soil more or less readily by leaching, oxidation, reduction, or plant uptake. The proportional relationships of certain ions in soils has also been investigated archaeologically. Soil pH, for example, has some sensitivity to anthropogenic inputs. The concentration of cations in the soil strongly influences pH. Prolonged or more intense occupations tend to release more cations to the soil; therefore, pH tends to be higher under longer or more dense or more intensely occupied sites.

Phosphorus (P), in its common form as phosphate, is the only compound that is stable and generally immobile in soils (Eidt 1984; Holliday and Gartner 2007). Phosphorus added to the soil as organic products or inorganic compounds quickly bonds with iron, aluminum, or calcium ions to form relatively stable chemical compounds of inorganic phosphate minerals. In most soils, removal of these compounds cannot be stimulated by normal oxidation, reduction, or leaching processes, as is true of other elements. Anthropogenic P therefore accumulates at the site of deposition and is thus a sensitive and persistent indicator of human activity (Eidt 1984; Holliday and Gartner 2007). High levels of soil P content is the basis for the “anthropic” horizon (Soil Survey Staff 1999) and part of the defining characteristics of Anthrosols, which are those soils heavily modified by human activity (IUSS 2006).
Sources of anthropogenic phosphorus include human and animal waste, refuse (derived from bone, meat, fish, and plants), burials, and manure. With prolonged occupation, the accumulation of anthropogenic P in soils can become quite large (by orders of magnitude), in comparison to the contents of natural P in soils. Another factor which makes P suitable for geoarchaeological study is that anthropogenic P can persist in the pH range of most soils. Under acidic condition, P combines with iron and aluminum, whereas under basic conditions, P combines with calcium. Consequently, soil P analysis can and is being used successfully in a wide variety of archaeological contexts to indicate human input such as fertilization of fields, and in the study of household activity such as cooking (Eidt 1984; Holliday and Gartner 2007).

Anthrosols vary widely in their physical and chemical characteristics. The most obvious characteristic of Anthrosols is the presence of archaeological debris such as bone and charcoal, that is, Anthrosols tend to be associated with middens. Other physical features of Anthrosols include abrupt, smooth boundaries between horizons or layers, abrupt, laterally discontinuous layers, and dark matrix colors (low value and chroma) extending to depths greater than in natural soils in the area (Figure 5). These greater depths are usually due to artificial upbuilding of the soil surface by processes such as additions of significant amounts of manure in Plaggen soils (see below). Chemical signatures of Anthrosols include higher-than-expected values of organic matter relative to natural soils and, in particular, phosphate (see above). Anthrosols may exhibit some form of pedogenic alteration, although such alteration is relatively minor in many instances due to minimal anthropogenic additions.

The general group of soils identified as Anthrosols can include a wide array of soils, but three types have been described and discussed at some length: Plaggen, Dark Earths, and Terra Preta. Various other kinds of middens may also qualify as Anthrosols. Plaggen soils are most common on the sandy landscapes of The Netherlands, Germany, and Belgium, but similar soils are reported from other parts of northern Europe and Great Britain, Crete, Peru, and New Zealand. In Europe they developed in the Middle Ages as manure, forest litter, heather, and grass sod was removed from stables and strewn on fields. This mixture increased water-holding capacity and also deepened the plowzone, thus minimizing crop failure.

Dark Earths are common in cities throughout much of Europe. They are called Urbic Anthrosols by the IUSS (2006). Dark Earth is a term applied to dark-colored, seemingly homogeneous urban deposits with relatively high organic carbon content, elevated levels of phosphate, and abundant midden debris. In many ways they can be considered anthropogenic sediments rather than soil, but they have undergone
surface weathering and are typically considered a soil. In Britain these soils are linked to late-or post-Roman, Saxon, Viking, Medieval, and perhaps post-Medieval occupation.

The *terra preta do Índio* (“black earth of the Indian”) or simply *Terra Preta* soil of the Amazon Basin and neighboring regions are well-drained soils characterized by the presence of a thick black, or dark grey, topsoil which contains artifacts (Sombroek et al. 2002; Woods et al. 2009) (Figure 5). They are found adjacent to waterways on older terraces and interior uplands. In all settings the dark Terra Preta horizon contrasts strongly with underlying subsoils which are red to yellow Ultisols, Oxisols, Spodosols, and eutrophic Oxisols. The classic black Terra Preta and associated midden debris represent household or near-household trash dumps, but the more ubiquitous dark brown variety (sometimes called *Terra Mulata*), largely devoid of artifacts or other obvious human debris, may represent agricultural soils modified by repeated mulching and burning as means of increasing the soil nutrient status.

SOILS IN ARCHAEOLOGICAL RESEARCH

Soils in geomorphic research

Douglas A. Wysocki
Philip J. Schoeneberger
National Soil Survey Center, USA

Soils: the integrator of space, time, and process

Geomorphic research requires the integration of space (land features) and process (physical, chemical, biological) through time. Given that the Earth’s land surface has evolved over decadal to millennial timescales, the question arises as to how one successfully integrates space and time. One approach is to evaluate natural entities that encompass space and time during their genesis, and which show progressive development that varies predictably as a function of time. Soils are one such entity. Soil forms a continuum across the land surface at the interface of atmospheric, biological, and geological systems. Soil horizons and morphological characteristics result from, and are uniquely dependent upon, the processes that operate at this interface. Soils, landforms, and surficial sediments (or rocks), therefore, together comprise three-dimensional (3-D) systems that coevolve through the balance and interaction of physical and chemical weathering versus erosion and deposition processes. It is important to note that the chemical and kinetic energy that drives landscape evolution and soil formation derives from water that infiltrates into or flows over soils or surficial sediments.

Knowledge of soils thus also yields information about physical processes, near-surface hydrology, and age (time) in a given landscape.

Two key geomorphic applications stem from the soil space–time linkage: (i) soil landscape models based on geomorphic concepts that permit meaningful segregation of the soil continuum into natural soil units at various scales (e.g., hillslope, regional, and continental), and (ii) fundamental geomorphic principles (e.g., the geomorphic surface) combined with soil patterns, that allow the interpretation of geomorphic evolution or history for a soil, a landform, or a land area.

Soils: definition, development, and geomorphic function

Before addressing the key geomorphic applications in detail, two terms, “landscape” and “soil,” will be defined. In this entry, landscape is referred to as a group or assemblage of spatially related landforms observable from a given vantage point. Soil is a complex entity that has multiple definitions. For this discussion, soil is herein defined as a natural, 3-D body with definable boundaries that occurs on the land surface and is composed of solids (mineral and organic), liquids (water), and gases. It is characterized by horizons that are distinguishable from the initial material from which it formed, and that have formed from physical, biological, and chemical processes in the surface environment (Soil Survey Staff 2014). Most soils support or have the capacity to support higher plants.
Simonson (1959) explained soil formation through four interacting suites of processes: additions, removals, translocations, and transformations. Note that the four process suites are applicable to the formation of soil horizons, such as the dispersion and downward transfer of clay from an A or E horizon to form a clay-rich Bt (argillic) horizon, and to a soil body as a whole. The same suite of processes driven largely by geomorphic forces applies on landscape scales as well. On a holistic basis, additions, removals, translocations, and transformations create and modify landforms, sediments, and soils from microscopic to landscape scales. Consider, for example, material eroded from the flank of a hillslope. It is transferred and added at the base of a slope as colluvium or alluvium. This sediment either thickens existing soils or becomes parent material for another cycle of soil formation. Upslope, where this removal has occurred, the soil is thinned, and thus fresh parent material below is brought into the soil profile and begins to weather. This example shows how the soils on the two landscape positions are linked.

Another eloquent means to explain soil patterns is the factor (or factorial) approach, which was initially developed by Russian soil scientists in the 1800s, and later espoused by Hans Jenny (1941), a soil scientist at the University of California, Berkeley. This model describes soil as a function of five interacting state factors: climate, biological influences (organisms), topography or relief, parent material, and time. It is often stated as $S = f(Cl, o, t, p, t)$. This model has been widely applied to explain soil formation and distribution in a qualitative or semi quantitative manner. The model can be solved quantitatively, but this requires precise input values for the five factors. Further, the five factors are interdependent and change through time. Stated in another way, the model purports that a soil or its distribution can be explained after all its factors are adequately known. The difficulty lies in deciphering how the factors have interacted through time, that is, landscape processes modify topography and parent material as soils form, and climate and vegetation change through time. Soil development itself, which proceeds with time, can affect the factors; for example, subsurface pans (duripan, fragipan) impact water-flow, and have greater erosion resistance than adjacent horizons. These characteristics in turn can be a controlling influence on local relief or topography. Soil development in this case alters topography, and vice versa.

The important attributes in this entry’s soil definition are their spatial (3-D) form, the presence of horizons, and the differentiation of soil from its initial (or underlying) material. Consider the soil profile in Figure 1; the two-dimensional (2-D) exposure reveals several readily observable soil horizons and sediment relationships. Plants
grow in this soil. The upper boundary between soil and atmosphere is readily apparent. The lower boundary is recognizable, although it may require scientific judgment to make a precise distinction between the solum (genetically formed soil horizons that include all the A and B horizons) and the parent material or substrate. Less altered sediment is visible at depth. The boundary between the solum and the substrate in Figure 1 is gradual. The profile has a distinct A, Bw, Bk, 2BC, 2C horizon sequence. The upper horizons formed in loess, whereas the lower ones are in alluvium, which explains why gravel is present in the 2BC and 2C horizons, but is absent in the upper horizons.

A soil profile/pedon is an observational unit. Pedons and profiles have sufficient size to display the complete horizon sequence, often down to and including the parent material. Soil profiles or pedons are defined as being of a convenient size to describe, sample, and classify the soil. Soil horizons visible in a 2-D profile obviously also extend in three dimensions. The pedon is the 3-D conceptual equivalent of a soil profile. Nonetheless, both the profile and the pedon lack one crucial attribute. They lack naturally defined lateral boundaries, which are important aspects of our soil definition. No evident lateral boundaries occur in the profile presented in Figure 1. Lateral boundaries are not readily definable at this observational scale.

Geomorphic processes operate on a spatial scale larger than a pedon or profile. A profile or pedon does not have naturally defined lateral boundaries. A geomorphic entity should have a common set of properties that occupies a naturally defined land area. We must consider an entity larger than a profile to observe lateral soil change or boundaries. To that end, Figure 2 displays a broader landscape view of the soil in Figure 1. The right foreground shows the A, Bw, Bk, 2BC, and 2C horizons of the soil profile shown in Figure 1. These horizons, particularly the Bk, are readily traceable across the exposure. Note that the Bk thins and thickens in a repeating pattern. Field observation shows that the Bk horizon is thin under topographic highs, but it is also thin under topographic lows. The Bk horizon, as well as other horizons, changes thickness predictably at prescribed landscape locations. It is important to note that the changes in soil horizon thicknesses are not random. When soil properties correlate to landscape position, the delineation of soil areas (bodies) that possess relatively more uniform characteristics than the soil continuum at large is possible. This is the essence of soil mapping and soil survey. Soil surveys are maps that depict such soil delineations, and these are the most useful soil individuals for geomorphic research and studies. Soil surveyors delimit boundaries between soils by mapping out the observable and predictable differences in soil morphology including horizon type and thickness, soil color, texture, and structure across a landscape. In an ideal world, these soil boundaries correspond to measurable and observable properties of the surface landscape. For example, field observation confirms that the soil pattern in Figure 2 has formed due to the influence of repeating, shallow, closed depressions on the land surface. The depressions are scoured into Miocene-age alluvium of the Ash Hollow formation of the Ogallala group below. The depressions likely formed initially as deflation basins (caused by wind erosion). Pleistocene (Peoria) and Holocene (Bignell) loess and slopewash subsequently filled the depressions. The Bk horizons are thickest at the depression margins because evaporative discharge from the surface draws carbonate-rich groundwater up from below and concentrates CaCO₃ in the soil at these locations.

As can be seen, the soils on this landscape record a part of their geomorphic history. This
example illustrates the fact that to decipher the geomorphic history of a soil landscape requires systematic field observation and the application of some fundamental concepts of geomorphology and soil science.

The soil landscape

The state factor approach of Jenny (1941) and the process-systems approach of Simonson (1959) are important conceptual models for understanding soil formation and distribution. Neither approach, however, defines functional entities in the soil–landscape continuum. Therefore, to do that, this entry now turns to the catena concept.

First proposed by Milne (1935), the catena is a fundamental geomorphic concept that explains soil differences at the hillslope scale. A catena is a repeating sequence of soils that occurs from the top of the hillslope to the adjacent valley bottom. The catena concept includes both surficial stratigraphy and internal hillslope structure or lithology. Two main types of catenas exist (Figure 3). The first (Figure 3a) involves soils underlain by a single parent material or by similar bedrock. Despite this initially uniform parent material, the hillslope soils commonly display sequential and predictable change along the slope, usually resulting in spatially distinct soil types. Red-brown soils occur on the hilltop, where conditions are highly oxidizing.
Figure 3  Soil landscape relationships, illustrative of the catena concept.

Downslope, the soils become wetter and progressively more reduced, thereby displaying increasing amounts of patchy iron depletions and segregations. The soils also display textural variation across the hillslope. On the hilltop, soils (in this example) have formed directly in weathered granite residuum. Soils below the hilltop have formed in transported sediment that becomes finer textured downslope. Milne (1935) attributed the type of repeating soil sequence that embodies catenas to systematic patterns of (i) internal water-flow, (ii) chemical and physical weathering of bedrock, (iii) lateral sediment transport, and (iv) translocation of materials.
across and beneath the soil surface. In sum, the hillslope and soil sequence have evolved coevally through interrelated processes. Note that both the hillslope and the catena are geomorphic entities. The pattern of soils observable across the hillslope, therefore, is both a soil development sequence and a geomorphic record of landscape evolution.

In the second type of catena (Figure 3b), the hillslope contains several different kinds of bedrock, or parent material, rather than having been formed all in one uniform type of sediment. Nonetheless, the hillslope also displays a similar sequence of distinct soils. The soils display similar red-to-gray color sequencing downslope, and show downslope sediment sorting. Variations in bedrock downslope, however, lead to increased soil complexity, as the soil textural variation results from both lateral transport and changes in bedrock lithology. (Lateral sediment transport occurs in this catena, as in all catenas.) Because of lateral sediment transport down the slope, the surficial sediments form a drape on the landscape that is not exactly coincident with the underlying rock strata.

As can be seen from these two examples, the catena concept includes both surficial stratigraphy and internal hillslope structure or lithology. The catena is both a soil landscape and a geomorphic model or system that links slope position and parent material to soils. Lateral transfer and sorting contribute to the sequential soil variation across the hillslope. Erosion and sedimentation processes, driven by relief and water movement, redistribute sediment across the hillslope, creating subtle lateral differences in soils and soil parent materials. Recall that both parent material and topography are factors in Jenny’s (1941) model of soil formation. These examples of the sequential changes in soil morphology across a landscape show how soils and landscape evolution on hillslopes function across both time and space.

### Hillslope positions

Using the catena concept, correlations between soil characteristics and slope position can be used to link soils to specific landscape positions. This association involves a conceptual model that explains and communicates soil distribution and variation across space. To operationalize such a model, however, we must first define the various slope positions from slope geometry, independent of soil observation. Slope positions are distinguishable by shape, particularly in profile view and hillslope location, and both affect water-flow (surface and subsurface), erosion, and sediment transport and deposition.

Five slope elements are commonly defined (Ruhe 1975). From the top of the slope to the bottom, they are summit, shoulder, backslope, footslope, and toeslope (Figure 4). Summits are the nearly level, uppermost slope position. Summit soils generally exhibit the greatest degree of soil development in a given landscape, unless the summit is narrow and convex, in which case erosion may dominate over soil formation. Shoulders have a convex shape and occur just downslope from the summit. The shoulder slope is subject to greater erosion than the summit. Soils here tend to be similar to summit soils, but have much thinner profiles, especially if a caprock exists. Below the shoulder is the steepest, and generally linear, slope position, the backslope. Surface runoff, erosion, and sediment transport commonly reach peak values at this position. As a result, backslope soils display less development (thinner or absent horizons) and are generally, but not always, shallower to bedrock or parent material than are summit or shoulder soils. The slope position below the backslope, the footslope, has a concave slope curvature and a much lower slope gradient. Concordant with decreased slope gradient is a decrease in sediment transport capacity and thus surface
runoff. Thus, sediment is usually deposited here, either as colluvium or as slopewash. Note that this position delimits the transition from erosion to deposition on the hillslope. Footslope soils tend to be wetter and display lesser development, mainly because they accrete upward over time due to additions of sediment to their surfaces. This stands in contrast to higher slope positions, where erosion dominates over depositional processes. The footslope merges downslope with the toeslope, which has a slightly concave or even linear slope curvature. Low-energy alluvial processes such as slopewash or overbank deposition from adjacent channels dominate on toeslopes. Toeslope soils therefore accrete upward, are wetter, display limited horizonation, and are often younger than are soils on summit and shoulder positions. Buried soils are common on footslopes and toeslopes. These five terms are a simple, eloquent set of terms to communicate slope position and soil occurrence.

The overall slope curvature from summit to toeslope provides important visual clues about the internal structure of a hillslope. Hillslopes that are strongly convex from the summit through backslope profile occur in selected geomorphic settings, for example, where erosion-resistant bedrock underlies the hillslopes. Soils on these slopes tend to be shallow and usually display limited horizon development. Similar convex slopes, however, commonly occur in erodible material that can maintain a steep angle of repose. Slopes developed on thick loess are prime examples. Hillslopes with slightly concave backslopes and footslopes generally occur where the underlying material is relatively erodible, such as weakly resistant bedrock or unconsolidated sediments. Soils on these slopes, in contrast to bedrock-controlled slopes, are thicker and display greater horizon development. The concave portion of a slope, that is, footslopes and toeslopes, display a decreasing slope gradient. Both potential energy and overland flow velocity decrease at the slope inflection from a linear to a concave slope, leading to accumulations of colluvium or sediment derived from slopewash. Soils on these slopes often form by cumulic processes and usually have thick, poorly developed

Figure 4  Soil landscape relationships according to hillslope position. Modified from Ruhe (1975).
horizons, when compared to soils on higher hillslope positions.

Another soil-forming factor that changes across a hillslope is time, or soil age. Figure 5 shows hillslope modification by backwearing through four stages. At stage 1, the summit is stable and older than the narrow shoulder and backslope, while the footslope and toeslope receive sediment eroded mainly from the backslope and therefore are equivalent in age. In stage 2, the hillslope has retreated, but the summit remains stable and the shoulder is broader. At stage 3, the encroaching slopes have narrowed the divide and the hilltop is formed by coalesced shoulders. Erosion has consumed the summit. The hilltop is no longer a geomorphically stable position. The age of the hilltop slope now equates to that of the other slope positions and to the time (period) of backwearing. Stage 4 shows the narrow remnant of the original hillslope. These hillslope age relationships are important concepts that will be discussed in more detail below.

**Geomorphic components**

Erosion that drives mass transfer across slopes results primarily from hydraulic (e.g., raindrop impact, dispersion) and fluvial (i.e., detachment and sediment transport by running water) processes. Thus, water movement over the soil surface and the way a hillslope sheds or concentrates water as surface flow are significant geomorphic concerns. Recognizing this, Ruhe and Walker (1968) developed their concept of a 3-D hillslope. Put another way, they took the catena concept into the third dimension by describing and examining slopes in plan view, as well as along the profile (the 2-D catena approach). The components of their 3-D hillslope model are the head slope, side slope, and nose slope (Figure 6). Recent work by Schoeneberger and Wysocki (2012) added two additional components: the interfluve and the base slope (Figure 6).

The interfluve, a 3-D equivalent to a summit, is the uppermost landscape area; it is a stable component of the hillslope system, being less subject to erosion than many lower components. Wide interfluves are summits and contain the most well-developed soils. Below the interfluve, a hillslope undergoes both backwearing and headward stream incision, commonly focused along overland flow pathways. Head slopes have convergent flow paths (when considered in a downslope direction), side slopes have parallel flow paths, and nose slopes have divergent flow paths. Flow direction, therefore, concentrates water in the head slope, especially its lower part, which in turn is more likely to initiate rill and channel formation. Soils here are commonly the wettest of any slope position. Below the nose slope, side slope, and head slope is the base slope (Figure 6), where sediment deposition dominates over erosion and sediment transport. Base slopes are roughly equivalent to foot- and toeslopes. A colluvial apron or wedge of sediment commonly forms on the base slope. This transported material can range from coarse debris to finer sediments.
sorted by slopewash (nonchannel, overland flow) processes. On long, high-relief hillslopes or mountain slopes, soils on side slopes and base slopes often form in colluvial sediments that are in slow, gravity-driven transport down the slope. Slopewash occurs here, but is not the dominant process. The base slope does not typically include stratified alluvium associated with channel deposition. Distal base slope sediments, however, may grade into or interfinger with alluvial deposits.

Unless masked by changes in parent material, some degree of lateral sorting downslope is present on most slopes, even long, mountainous ones. Soil profiles on side slopes thus vary greatly in thickness, depending on the rate of erosion (high or low, respectively), the magnitude of the slope gradient, and the extent to which the bedrock is resistant to weathering and erosion. In many landscapes, the traditional assumption of prevalence of shallow soils over hard rock on hillsides and mountainsides is overly simplistic.

**Hydrology, hillslopes, and soils**

The catena concept encompasses both lateral transport of water and sediment, and soil water/wetness conditions along a slope. These are all contributing processes to soil formation, hence, landscape, and slope evolution. Overland or surface flow is the main driver of lateral sediment transport along slopes. Soil water results from infiltration at the soil surface. Soil formation depends upon such infiltration and percolation processes, as soil water is the matrix for chemical and geochemical transformations. Moreover, water-flow within and through soils transports soluble and colloidal constituents, leading to the development of soil horizons. Water-flow on level terrain primarily has a vertical, downward path into and through soil horizons. On hillslopes, even those with low slope gradient, however, lateral soil water-flow, also called throughflow, can occur. Throughflow is dominantly downslope, flowing beneath and roughly parallel to the surface. Figure 7 depicts three such
flow types and directions that occur on a head slope. Water as surface runoff (Hortonian overland flow) converges toward the thalweg (lowest portion of the slope, along the length of a valley).

Water that infiltrates has an initially vertical flow path. Vertical hydraulic conductivity through a soil generally decreases with depth, however, because of increasing bulk density, changes in size and kind of soil structure, and increasing clay content. Because of such changes with depth, soil horizons become preferential conduits for lateral flow (throughflow) at depth, along slopes. In a head slope, subsurface flow converges toward the thalweg, although its flow rate is much slower than overland flow, and water can take days to weeks to reach an equivalent point. This differential results in an accumulation of subsurface water in the lower parts of the head slope, temporarily forming a saturated zone there (Figure 7). The boundary of this saturated zone migrates slowly upslope during wet periods. It is important to note that throughflow may occur under both saturated and unsaturated conditions. Saturated flow occurs under positive pore pressure. Unsaturated flow is a function of matric potential.

Figure 7 Surface and subsurface soil hydrology in a head slope. The A, B, and C horizons of the soil are shown.
Historically, research on soil erosion has de-emphasized the contribution of such internal water-flow to soil formation and landscape evolution. Soil hydrology studies in recent years (e.g., Arndt and Richardson 1989 is this recent) have reintroduced and reinforced the importance of throughflow and have emphasized the need for a 3-D approach that accounts for lateral, divergent, and convergent throughflow pathways.

Soil landscape hydrology

As should be obvious by now, in the soil landscape, a number of key soil and geomorphic attributes control or greatly influence water-flow. Some have been mentioned already, such as parent material, slope and stratigraphic relationships (Figure 3), and soil horizonation and land surface shape (Figure 7). Water-flow can be predominantly downward, lateral, or even upward (toward the surface), depending upon the landscape and how it affects flow dynamics. The influence of the land surface on water-flow, and thus soil occurrence, also depends on climate, specifically precipitation quantity and intensity.

Consider three soil landscapes (Figure 8), all underlain by medium-to fine-grained glacial deposits and all containing closed depressions. These landscapes occur across a humid to dry subhumid climatic gradient (400–875 ml mean annual precipitation). In humid central Iowa (Figure 8a), water recharge from precipitation occurs at topographic highs and flows downward and laterally toward topographic lows, discharging at depression edges and concentrating CaCO₃ there due to evaporation from the soil surface. Water-flow at the basin center is downward, toward the water table. Due to the water-flow system, soil B horizons differ markedly along the slope. At the topographic highs, soils have a Bw horizon, at the depression edge a Bkg forms, and in depression centers soils have Bg horizons. This soil landscape relationship exists at most medium to large depressions, regardless of elevation and location within the landscape.

In eastern North Dakota (Figure 8b), under a moist subhumid climate, recharge occurs under
SOILS IN GEOMORPHIC RESEARCH

depressions that are situated in high landscape positions. Within depressions in intermediate positions, water-flow is dominantly lateral, resulting in the formation of a flow through wetland. Depressions that are at a low relative position are groundwater discharge sites. This flow pattern results in distinctly different soils at the various depressions. In the upland depressions, soils have a Btg (clay increase and gleying) horizon, due to their long-standing wet conditions but downward-flowing water (and clay). The intermediate depressional soils have Bg horizons (gleying). Soils in the low-lying depressions have Bkgz (carbonate, gleying, salts) horizons because precipitation and percolation are insufficient to remove soluble salts from the soil; therefore, both carbonates and salts accumulate at the discharge sites.

Under the dry, subhumid climate of southern Saskatchewan (Figure 8c), the landscape exhibits a still different macroscale flow pattern. The flow path under depressions is more localized because the regional water table is at greater depths. Regardless of landscape position, all depressions are recharge sites where percolating water flows mainly downward. Evaporative discharge dominates on adjacent topographic highs because of the limited percolation depth. Thus, soils in the depressions have Btg or Bwg horizons, whereas soils on the topographic highs have Bkz horizons.

Soil: a geomorphic entity

The catena concept establishes the link between space and time. Soils, parent materials, and surface age change along a catena (hillslope) due to sediment transport, erosion, and internal water-flow. The kinetic energy that drives landscape (geomorphic) evolution is expended in sediment transport and hillslope backwearing via slopewash and fluvial erosion. Water that enters the soil surface, in contrast, drives physical and chemical soil development across the slope. In low-relief landscapes, erosional modification is minimal and internal water-flow is the dominant driver of soil formation and variation. Landscapes such as lake plains and dissected coastal plains are examples. Erosion and slope development are limited in these landscapes but soils change in a predictable manner. The input energy is expended mainly as chemical and geochemical weathering, rather than as kinetic transport. Soluble and colloidal transfers occur within the landscape during soil formation, that is, in pedogenesis. The soil change across the landscapes represents geomorphic evolution. The geomorphic history of the landscape is recorded in the soils, rather than as erosional modifications.

An example of such a landscape is the Coastal Plain of North Carolina. Figure 9 displays a stratigraphic and soil cross-section of this region. Major streams are confined to inset valleys, and the adjacent upland is a broad, undissected divide. The general stratigraphic relationship is that coarser-grained, permeable deposits overlie finer-grained, less permeable materials. Stream downcutting and headward incision occurs only along slopes directly adjacent to the main valleys.

Despite the low relief, soils display distinct differences based upon distance from the low relief, divide centers. The major soils at the divide margin are within the Orangeburg and Norfolk series, which have yellowish-red to yellowish Bt horizons, respectively. The seasonal high water table is deep. Toward the divide center, however, the seasonal water table comes increasingly closer to the surface. The pedological result is a sequence of soils – Goldsboro, Lynchburg, Rains, and Pantego – that become progressively more poorly drained and have grayer Bt horizons as the divide center is approached. As can be seen here, landscape hydrology is the dominant
soil-forming influence. Water table depths are a function of both stratigraphy (strata that differ in hydraulic conductivity) and the limited local relief (long flow paths and low hydraulic gradient).

The soil sequence shown in Figure 9 extends from the divide center to a stream valley. The divide is stable; little or no erosion has modified the divide. Surface age is the same across the divide. The soils across the divide, given the material age, have resulted from hundreds of thousands to perhaps a million years of landscape evolution. The soils themselves are geomorphic products that occupy predictable locations. Following parent material emplacement, slope processes have had minimal effect on landscape evolution. In these respects, the soil sequence does not fully meet the classic catena definition.

The earlier discussion illustrates that hillslope profile terms provide key descriptive terms for defining soil position. The question arises as to what hillslope terms apply to the distinct soils in

**Figure 9.** Soil landscape and hydrology relationships in the low-relief, middle coastal plain North Carolina, USA. Modified from Daniels and Gamble (1967).

**Figure 9.** The divide is a hillslope summit. Additional soil landscape terms are needed to describe the divide positions on such landscapes.

### Soil landscape age assessment

Soil-forming processes occur at different rates and intensities through time. As a result, soils that have similar amounts of horizon development may not necessarily be the same age, and vice versa. To unravel the time–space association inherent in soil landscapes requires a conceptual means to assess time or soil age, independent of soil development. The hillslope stability and age relationships alluded to (above) underscore a set of fundamental geomorphic concepts or principles that allow for the relative age assessment of soils and surfaces across the landscape.

The first such concept this entry will discuss is the principle of superposition (Daniels, Gamble, and Cady 1971), which specifies the deposition sequence of sedimentary rocks, unconsolidated
SOILS IN GEOMORPHIC RESEARCH

sedimentary deposits, and extrusive igneous rocks. Sediment can only be deposited atop pre-existing materials. Therefore, younger sediments invariably overlie older deposits. Observe the strata depicted in Figure 10a. By the principle of superposition, Beds 1 through 4 represent a time sequence: Bed 2 is younger than Bed 1, Bed 3 is younger than Bed 2, and so on. Even if the absolute age differences of the beds are unknown, their relative ages are inferable by using this principle. The principle of superposition is not complex, but field application requires observations at key locations and consistent identification of units, and often is operationalized using data taken from drill cores.

Bed 4 in Figure 10a demonstrates another important detail. Note that it is topographically lower than most of Bed 3. Bed 4, however, stratigraphically overlies Bed 3 at the footslope. This stratigraphic context determines their relative age relationship. As illustrated here, there is often a limited area within which one can make field observations for age determinations in this manner. In Figure 10b, Bed 5 overlies both Bed 1 and Bed 2 and thus must be younger than either bed. Bed 5 does not stratigraphically overlie Bed 4 at any location. This raises the question as to whether it is younger or older than Bed 4. Further observation indicates that Bed 5 is inset below Bed 4. Therefore, Bed 4 confined the depositional processes responsible for Bed 5’s emplacement. An erosion event or cycle must have cut into Bed 4 before Bed 5 was deposited. This cross-cutting relationship, in and of itself, establishes that Bed 4 is older than Bed 5, and represents another important geomorphic concept – the principle of cross-cutting relationships. An event or feature that cuts into a deposit must be younger than that deposit.

An erosional (downcutting) event appears to have produced a hillslope that descends to

Bed 5. This raises the question as to the age of the hillslope. Slope processes would shed sediment onto the top of Bed 5, as would alluvial deposition from up valley. The top of Bed 5 and the hillslope are equivalent in age and both are younger than Bed 4. The hillslope and top of Bed 5 together represent a definable land surface area formed during a given time period, primarily by erosional and depositional processes (e.g., stream incision, hillslope retreat, pedimentation). This land area constitutes a geomorphic surface, which is a mappable land

Figure 10 Geomorphic surfaces in a soil landscape, illustrating various principles of geomorphology. See text for details.
SOILS IN GEOMORPHIC RESEARCH

area of uniform age. Note that the geomorphic surface includes two components – one erosional the other depositional. Nevertheless, these two components are time equivalent. An erosion cycle or event cross-cuts the pre-existing soils, slopes, and substrates. The erosion event and the geomorphic surface produced are younger than any entity (soil, surface, or depositional unit) that is cross-cut. In Figure 10a, soil 1 on Geomorphic Surface A is older than soil 2 or 3, which are equivalent in age and occur on the erosional and depositional components of Surface B, respectively. Despite being the same age, soil 2 and soil 3 differ because the substrates and components are contrasting.

Figure 10b depicts a second downcutting cycle and subsequent deposition of younger sediment below Surface B. A new geomorphic surface (C) forms; it has both an erosional and a depositional component. The landscape now has three geomorphic surfaces, each of which is underlain by different materials and each of which contains distinct soils.

The landscape depicted in Figure 10 corresponds to a set of adjacent stream terraces. As illustrated here, landscape evolution commonly proceeds episodically through time, which creates a series of stepped or faceted geomorphic surfaces along interfluves. As you ascend this landscape, the geomorphic surfaces increase in age. This case illustrates the principle of ascendancy and descendancy, which states that an erosion surface is younger than the youngest deposit or surface that it cuts across or truncates. By this principle, Surface C is the youngest, Surface B is intermediate in age, and Surface A is the oldest. From this example, one can also infer that an erosional surface is the same age as the alluvium to which it descends. This example illustrates the principle of descendancy. Based upon these principles, several time relationships of erosion surfaces can be summarized. Any erosion surface (i) is younger than the youngest material, landform, or soil it bevels, (ii) is younger than any erosion surface or erosional remnants that stand above it, (iii) is the same age as the alluvium to which it descends, (iv) is the same age or older than any deposits that lie on it, (v) is older than deposits in valleys below it, and (vi) is older than any erosion surface that occurs below it. We can infer the relative age of a hillslope (erosional surface) in the field by determining the alluvial level that it grades downward to in a smooth, concave profile.

The temporal and spatial relationships portrayed in Figure 10 apply to landscape evolution by fluvial erosion in general. Now consider the development of an arid, tectonic basin, as exists in the Basin and Range of the western United States (Figure 11). Crustal extension and faulting that began in the early Miocene drives long-term basin evolution. The geomorphic/stratigraphic/soil record is a result of successive fluvial downcutting cycles. In the initial downcutting, the oldest alluvial fans form along the valley flank. During a period of stability, erosion continues to modify the fan surfaces. As shown in Figure 11, the oldest geomorphic surface (Surface 1) eventually comes to consist of rounded erosional (fan) remnants termed “ballenas,” which are underlain by alluvial fan sediments. Surface 2, below the ballenas, consists of a fan piedmont with rounded finger ridges along the distal front. This surface is more complete than Surface 1, but is nonetheless dissected to some degree. Surface 3, which is cut into Surface 2, consists of several laterally adjacent landforms. Inset fans occur in the upper valley margin. The inset fans grade to a coalesced set of fan skirts that merge down valley with an alluvial flat. Each of these landforms results from lateral sorting and alluvial deposition through a specific time. Despite the lateral changes in sediment, distinctly different landforms, and suites of soils

15
that occur across Surface 3, it is age equivalent throughout its extent.

The question arises as to where on this landscape the “oldest” soil is found, in terms of relative age. The answer is Surface 3. Because hillslope processes have rounded the ballena summits (Figure 11a), the best-preserved and oldest soils will occur along the central ballena ridge, on summit positions. Surface 2 is less modified by secondary erosion than Surface 3; soils on Surface 2 are younger, but may be better preserved because of less secondary surface modification. Soils on Surface 3 are the youngest in this landscape. On this surface, soil characteristics are a function of sediment sorting. Soil patterns here have resulted from the integration of sediments, landforms, age, and, even in this environment, hydrology, as poorly drained soils may occur in the alluvial flat due to runon and throughflow. Note that the age sequence of geomorphic surfaces follows the principle of ascendency, that is, the geomorphic surfaces shown are a sequence of inset depositional surfaces of decreasing age.

Figure 11b depicts an erosional cycle caused by axial stream downcutting that has resulted in an incised floodplain with tributary valleys graded to it. This cycle yields geomorphic Surface 4, a depositional surface that again has distinct landforms, sediments, and soils. Its erosional component, which is not shown, is the adjacent mountain front. No scale is shown in Figure 11; the basin size can range from hundreds to thousands of square kilometers. The geomorphic concepts and the application of them remain the same regardless of basin size (Gile and Grossman 1979).

From the above discussion, it is emphasized that geomorphic surfaces are a spatial and chronological framework that applies to landscape evolution and soil distribution, and at a number of scales. A given surface may have multiple soils, but they will have a common duration of soil development. Soils will also display increasing (or at least, predictable) development from the youngest to the oldest surface in a landscape. Field identification of geomorphic surfaces is based on stratigraphic and geomorphic principles. Recurring soil patterns linked to a geomorphic surface may be used to delineate that surface in a similar landscape.

**Soil: a geomorphic record**

As stated at the outset, soils integrate across space and time. Figure 12 displays a dual parent material soil that contains a petrocalcic horizon. Field examination and description provide the following horizon sequence: A, Bk, 2Btk, 2Bkm. This soil’s horizon sequence, including the two substrates, forms a record of the site’s geomorphic history. From the horizon sequence, one can infer that a soil with a petrocalcic horizon formed in older alluvium. The presence of the petrocalcic horizon is noteworthy, as it requires a significant period to form (Gile, Peterson, and Grossman 1966). Younger alluvium later buried the soil. New soil horizons then formed in the fresh alluvium. The result is a composite or “two-storied” soil with a lithologic discontinuity separating the two parent materials. Soil formation is time transgressive and the soil in Figure 12, therefore, has a rich geomorphic history that can be inferred from the horizon sequence and stratigraphic units present.

Let us examine more closely the geomorphic history of the pedon in Figure 12. This pedon is on an upper fan piedmont similar to that shown in Figure 11. Detailed field study (Gile and Grossman 1979) has formally recognized and named the geomorphic surface on which the petrocalcic horizon exits as Jornada 1, with an approximate age of 500,000 years. The younger
deposit is a Holocene (≈7 ka) aged deposit, the Organ alluvium. The soil and geomorphic record here includes two deposition cycles, 500,000 years of landscape evolution, at least two periods of soil formation (likely more), and the associated climatic shifts that occurred during that time interval. One can derive much from the soil profile alone, but placing the profile into its proper stratigraphic, geomorphic, and hydrologic context gives a more complete perspective of its geomorphic history. In turn, subsequent soil observations based on the geomorphic and time context inherent in this profile have greater merit because the degree of soil formation is linked to the substrates, ages, and geomorphic position.

Summary

Soils serve as the matrix for biological and geochemical processes at or near the Earth’s surface. The cycling of key elements, as well as important trace metals, occurs within them. Further, soils form an absorbent but porous and permeable layer that mediates water infiltration and flow within and across landscapes. Soils provide a short-term water reservoir that sustains plant and animal life in terrestrial ecosystems for days to weeks. They are the medium we depend upon for much of the world’s food and fiber, and for filtering our waste products.

The quantification of soil formation through time and the associated links to geomorphic processes outlined above permit both a spatial and a temporal understanding of soils on landscapes. This entry has articulated several important principles in its discussion, which include the catena, hillslope and geomorphic components, soil landscape hydrology, and geomorphic surfaces.

By use of a soil geomorphic approach, an understanding is gained of how landscapes evolve through time. Where and why specific soils...
occur within a landscape can also be determined. This knowledge has some important applications. First, soils defined and recognized as geomorphic entities are a functional unit that has a common process, physical properties, and ecosystem function. To manage the soil landscape for long-term sustainability, functional entities at geomorphic and other scales must be identified and understood. Geomorphic entities define landscape scale units. Second, a geomorphic approach provides the chronological framework to understand soil and landscape change through time. This knowledge allows for the reasonable prediction of future soil conditions that will occur due to climate change and/or human influence. The scientific and societal value of such knowledge is important because our sustained existence depends on our soils.

Soils of cold and permafrost-affected landscapes

Charles Tarnocai
Agriculture and Agri-Food Canada

James G. Bockheim
University of Wisconsin–Madison, USA

Cold soils occupy approximately one-third of the world’s landmass. Because most of this area is dominated by permafrost, the genesis of these soils is also strongly affected by cryogenic processes. As a result, these soils contain large amounts of ice and they sequester and store large amounts of frozen organic materials, rendering them a huge storehouse of carbon in particular. Because of these unique properties, these soils could release this stored carbon if the climate were to warm, further enhancing atmospheric warming. Therefore, these soils do and will play an increasingly important role in both the global carbon cycle and global climate change.

In addition, they support both the vast arctic tundra and the northern circumpolar boreal forest, which are still in their natural states.

“Cold soils” is a loosely defined term. Some authors define cold soils as those soils having mean soil temperatures lower than 8°C at 50 cm depth (Rieger 1983). Others consider cold soils to be all soils in the permafrost region. These would then include soils in the southern part of this region, in which seasonal frost extends below the topsoil and stays frozen for several months during the winter. These soils are not frozen during the rest of the year. Regardless of which definitions are used, three major groups of soils occur in the Cold Soil Zone. The first group are the permafrost-affected soils. These soils are dominated by cryogenic processes and have permafrost in their control section (0–2 m). The second group of soils are those having deep permafrost. They are also affected by cryogenic processes. Although they have no permafrost within their control section, permafrost does occur at depth and may have existed closer to the surface during colder periods in the past. These soils are extremely dynamic and can change into permafrost-affected soils, depending on the shift in their thermal regime, often because of environmental or climate changes. The third group of soils are the seasonally frozen soils. These soils contain no permafrost, even below the control section. These soils are seasonally frozen below the topsoil during the winter, and they thaw during the following spring. Regardless, they are also affected by seasonal cryogenic processes (e.g., frost heave and ice lensing). Many of these soils contained permafrost immediately following recession of continental ice sheets.

Most of the cold soils occurring in the arctic, subarctic, and boreal soil climate regions are characterized by low temperatures and moderate amounts of precipitation. The arctic soil climate region has a mean annual soil temperature (MAST) of ≤−7°C. Mean daily temperatures above 0°C occur only during the short summers. The precipitation totals are generally low and precipitation occurs mostly in the form of snow. All of the arctic soil climate region is underlain by continuous permafrost. The subarctic soil climate region has a MAST between −7°C and...
<2°C. This area receives a moderate amount of precipitation, but most of it is in the form of snow. Permafrost is widespread in this region. Although the boreal soil climate region has somewhat warmer summer temperatures, the winters are still long and cold. The MAST for this region is between 2°C and 8°C. Although the southern portion of the boreal soil climate region is free of permafrost, the northern part contains discontinuous or sporadic permafrost (Figure 1). The Antarctic soil climate region has a MAST of <−10°C, and the mean annual precipitation is less than 50 mm per year (water equivalent).

Soil parent material in these regions is highly variable and is one of the main contributors to the wide variety of soils. Frost-shattered rocks and stony glacial deposits dominate large parts of these regions. However, fine textured sediments occur in lacustrine basins and along the seashores. Organic (peat) deposits are common, especially in the southern Arctic and the subarctic and boreal regions. The vegetation in the Arctic is partially vegetated tundra in the north and continuously vegetated tundra in the south. Open coniferous forests dominate the subarctic. The arctic tree line forms a natural boundary between the Arctic and subarctic regions. Lastly, a closed canopy conifer forest to aspen parkland and grasslands are associated with the boreal region. In Antarctica, vegetation is either absent or limited to isolated patches of moss, lichens, and algae. Higher plants (grasses) exist along the western Antarctic Peninsula.

Soil development and properties

A variety of soil-forming processes have influenced the soils in these areas. The development of seasonally frozen soils is dominated by soil-forming processes such as podzolization, brunification, luvification, and gleysation. Podzolized soils are usually sandy and have a B horizon that is enriched in Fe, Al, and organic carbon compounds. Many of these soils are classified as Spodosols. Brunification results in soils with red and red-brown B horizons, due to in situ weathering, and minimal translocation of soluble materials into these horizons. These are weakly developed soils that are commonly classified as Inceptisols. Luvification is the translocation of clay from the upper, lighter colored, horizon into the B horizon (argillic horizon). These soils classify as Alfisols, or if weakly developed, Inceptisols. Wetness causes gleysic processes and reduced conditions in many lowland soils. These soils, in most cases, are poorly drained with a high water table and so are classified within aquic suborders, or in Canada, as Gleysols.

Permafrost-affected soils and, to some degree, the soils with deep permafrost, are dominated by cryogenic processes. The mechanisms driving these cryogenic processes are the increase in volume when water freezes, turning it into ice, and the migration of water from warm to cold regions in the soil, feeding and growing the ice bodies. These processes increase the ice volume in the soil, resulting in differential frost heave, a form of mixing called cryoturbation. This process is eventually responsible for formation of patterned ground and cryogenic microstructures, sorting of coarse fragments, and burial of organic matter.

The most common soil features resulting from cryoturbation are irregular or broken soil horizons, organic matter incorporated into lower soil horizons, oriented stones, and cryogenic structures in forms such as platy, blocky, granular, amorphous, or massive soil structure. Massive structures develop as a result of cryostatic pressure caused by desiccation during freeze-back. At this time, two freezing fronts, one from the surface and the other from the permafrost table, compress the soil material, resulting in desiccation,

Compaction, and movement of materials within the soils. Cryodesiccation is the predominant process in hyperarid soils of Antarctica.

Another important characteristic of permafrost-affected soils is that most of the soil water occurs in the form of ice lenses, ice crystals, ice wedges,
SOILS OF COLD AND PERMAFROST-AFFECTED LANDSCAPES

and massive ground ice. Soil texture is one of the factors controlling ice build-up. Because they hold more water in general, fine-textured soils generally contain a higher content of ice in the form of ice crystals, ice lenses, and thick ground ice. This high ice content is due to the fine (clayey) soil materials that provide an avenue for the translocation of water from warm to cold. On the other hand, regardless of the texture or type of materials, ice wedges can occur in both frozen mineral and organic soils.

These processes and the resulting pedogenic features are very common in permafrost-affected soils of the northern circumpolar region, but they are less common in soils of Antarctica. Due to the dry, cold climate, soils in the Antarctic region are commonly associated with dry permafrost. In most cases, these soils lack ice-cemented permafrost because of the very low moisture contents, and few cryogenic features are found in them. For example, in the Transantarctic Mountain areas the soil moisture content is only <1–5% during the short summer. In the Antarctic Peninsula, however, the soils are slightly moister and may have some organic matter accumulations on the surface.

Unique thermal characteristics separate permafrost-affected soils from all other soils. In summer, the upper boundary of the permafrost is usually present 30–60 cm below the surface. Due to this perennially frozen layer, these soils have a steep vertical temperature gradient in summer. The temperature gradient can also be large if these soils are associated with patterned ground. For example, in permafrost-affected soils associated with earth hummocks in the Mackenzie River Valley, the soil temperature at the apex of the hummock can decrease from 14°C at the surface to 0°C at 60 cm depth (permafrost table) during the summer months. Horizontally, soil temperatures at the same depth under the interhummock depression, about 1 m away from the center, can be 4°C cooler.

Permafrost-affected soils underlain by a permafrost layer have an active layer that thaws during the summer and freezes in winter. As mentioned above, the active layer is generally between 30 and 60 cm thick, depending on the thickness of the surface organic layer, the soil texture, and the vegetation cover. The permafrost underlying the active layer is also very dynamic, especially in permafrost-affected mineral soils. Changes in vegetation cover because of forest and tundra fires, disturbance of the soil surface, and climate warming, can all lead to increases in the depth of thaw. As a result, the permafrost table (top of the permafrost) moves to greater depths. For example, after forest fires, the active layer depth could increase threefold in thickness, in part because the darker soil surface absorbs more solar energy. During this period, cryoturbated soil features and other cryogenic features can develop in this thicker active layer. Re-establishment of vegetation and the surface organic layer, which usually takes a century or more, results in a gradual re-establishment of the permafrost table to its original, shallower depth. Therefore, the cryogenic properties developed in the former, deeper active layer are preserved and are now frozen in the near-surface permafrost.

Peatlands associated with Histels (permanently frozen organic soils) and Histosols (unfrozen organic soils), which are common soils in the northern circumpolar regions (arctic, subarctic, and boreal), cover large areas in both Canada and Russia. These peatlands develop in wet areas as raw biomass (leaves, stems, mosses, and other plant materials) that is deposited on the surface. These organic materials are then restricted by decomposition due to low temperatures, saturated conditions, and low pH. This gradual build-up process produces 2–2.5 m-thick peat
deposits that developed during the past several thousand years.

Peatlands in the southern boreal region are composed of various types of fens, bogs, and swamps. These peatlands are not affected by permafrost. Further north, the occurrence of permafrost-affected peatlands has gradually increased. Most of the peatlands in the northern boreal and subarctic regions are perennially frozen peat plateaus, polygonal peat plateaus, and palsa. In the arctic region, all of the peatlands are composed of perennially frozen lowland polygons.

**Soil classification**

Until the 1970s, permafrost-affected soils in the various soil classifications were handled as northern extensions of the southern soils. Soil scientists from the United States and Russia divided these soils on the basis of soil-forming processes such as gleyzation, podsolization, brunification, salinization, and peat accumulation. Cryogenic processes and features were not considered to be part of the genesis of these soils. Canadian soil scientists were the first to recognize cryogenic processes as the dominant soil-forming process in permafrost-affected soils and, based on this concept, the Cryosol soil order was developed and incorporated into the 1978 edition of the Canadian System of Soil Classification. This new Canadian concept relating to permafrost-affected soils slowly gained acceptance and, by the early 1990s, the Gelisol order was developed and incorporated into the US System of Soil Taxonomy. Shortly after the development of the Gelisol order, a similar development took place when the Cryosol soil reference group was established to classify permafrost-affected soils in the World Reference Base for Soil Resources (WRB).

In the Canadian system, the Cryosol soil order includes both mineral and organic soils that have permafrost within 1–2 m depth (Soil Classification Working Group 1998). This soil order was further subdivided into great groups of Turbic (cryoturbated soils), Static (non-cryoturbated soils), and Organic (soils developed on >40 cm of peat) Cryosols. These great groups were further subdivided based on the soil development (chemistry of the B horizon, gleying, surface organic layers, and lack of soil development). The Organic Cryosol great group is subdivided on the basis of the thickness and rate of decomposition of the organic horizons.

The Gelisol order in the Soil Taxonomy also contains mineral and organic permafrost-affected soils, all with permafrost occurring within 1–2 m depth. Gelisols are subdivided into three suborders: Turbels (cryoturbated mineral soils), Orthels (non-cryoturbated mineral soils), and Histels (organic soils). Further subdivisions of these suborders are based on the presence of morphologies that may indicate processes such as gleying, podzolization, and salinization, and on the presence of ground ice. The Histel suborder is subdivided into great groups, based on the degree of decomposition of the organic materials. Glacic and Ruptic-Histic subgroups are associated with Gelisols containing massive ground ice (Glacic), while Ruptic-Histic subgroups are associated with variable thicknesses of organic matter in the subsoil. Anhydrous (meaning extremely dry) great groups were added to accommodate hyperarid Antarctic soils.

The Cryosol soil reference group in the WRB system includes only the mineral permafrost-affected soils that have permafrost within 0–1 m depth (IUSS Working Group WRB 2015). Permafrost-affected organic soils are not included in the WRB Cryosol group of
soils. They are included in the lower level of cryic units, in the Histosol soil reference group. Soils with permafrost within 1–2 m depth are included as lower case Gelic units in most of the soil reference groups.

The Russian soil classification system follows the genetic approach. This classification recognizes one, relatively small, group of Cryozems in the high-level group of soils associated with cryogenic soil features, but permafrost, as a thermal condition, does not play any role in the Russian soil classification system.

The classification of seasonally frozen soils was developed during the mid-twentieth century and the last version was published in Soil Taxonomy (Soil Survey Staff 1999). Most of the seasonally frozen soils in the cold soils region are one of the following.

- Inceptisols: These soils have a weakly developed subsoil and a light-colored surface soil horizon.
- Spodosols: These are mineral soils that are dominated by podzolization processes. They are commonly associated with an upper eluvial (leached) E horizon and lower illuvial B horizon.
- Histosols: These soils developed on organic materials (peat) are derived mainly from plants and contain 17% or more organic carbon.
- Entisols: These are mineral soils that have minimal pedogenic alterations, implying that their chemical and physical properties are similar to the associated parent materials.
- Mollisols: These are mineral soils with thick, dark surface horizons resulting from the incorporation of organic carbon into the mineral soil, mainly by roots. These soils are moderately rich in basic cations and clay.

Distribution of cold and permafrost-affected soils

In the early and mid-twentieth century, national soil maps were prepared in order to determine the distribution of these soils. These early soil maps used local classification systems and various mapping approaches. In Canada, permafrost-affected soils were mapped as cryic versions of nonpermafrost soils. Most of them were mapped as Cryic Regosols. Similarly, on the Food and Agriculture Organisation (FAO) Global Soil Map, permafrost-affected soils were mapped as gelic versions of the major soil groups – for example, Gelic Histosols, Gelic Gleysols, Gelic Cambisols – but most of the permafrost-affected soils were mapped as Gelic Regosols (IUSS Working Group WRB 2015). The soil map for the entire area of the former USSR was prepared by Fridland (2015), Naumov (1993), and Uspanov (1976). Following the Russian concept, only the soils strongly affected by cryogenic processes were mapped as permafrost-affected soils. On the Russian soil maps, however, these soils contained only a very small portion of the soils affected by permafrost.

The concept of Cryosols was developed in Canada during the 1970s and the Gelisol Order was established later in the United States. During the 1980s, national soil maps were prepared using the new concept in order to recognize the cryogenic properties in permafrost-affected soils, which distinguish these soils from those found in nonpermafrost regions. The availability of more robust geographic information system (GIS) mapping capabilities during the late 1990s led to the development of soil databases that covered the entire northern circumpolar soil region (NCSR). In order to develop these large, unified databases for the entire NCSR, all of the various national classifications needed to be integrated so that the soil maps could be
converted to the US System of Soil Taxonomy. Using these new, unified soil databases, soil maps (Figure 2) and other derivative maps were prepared for the entire NCSR. Based on these soil databases, Turbels were shown to be the dominant soils in the circumpolar permafrost region, covering approximately $6454 \times 10^3$ km$^2$.

The second most common soils were Histels, which cover approximately $2714 \times 10^3$ km$^2$, followed by Orthels, which cover approximately $1051 \times 10^3$ km$^2$.

Seasonally frozen soils are patchy in the discontinuous permafrost region but they cover the entire soil area below the southern boundary of the permafrost region. The most common soils in the nonpermafrost area are Inceptisols, Spodosols, Histosols, Entisols, and Mollisols.

**Global significance**

The global importance of soils in the polar regions was only recently recognized, when the role they play in global climate change was discovered. It is now widely accepted that climate warming has been, and will continue to be, much greater in both the northern and the southern circumpolar regions than in other parts of the globe. This warming is already in effect (Turner, Overland, and Walsh 2007; Barrie and Kochtubajda 2008), although the magnitude is variable from region to region.

Perennially frozen soils in the northern circumpolar region contain the single largest component of the terrestrial carbon pool. Tarnocai et al. (2009) estimated that the permafrost-affected soils in the northern circumpolar region contain approximately $1672 \text{ Gt}$ of organic carbon with approximately 88% occurring in permafrost-affected soils and deposits. This $1672 \text{ Gt}$ of organic carbon accounts for approximately 50% of the total below-ground global organic soil carbon. This total is greater than the amount of carbon stored in the atmosphere or the biosphere. Only the oceans store a greater amount of carbon than do these soils, and the oceanic carbon is much more difficult to release to the atmosphere.

Very little information is available for fluxes in both unfrozen and perennially frozen cold soils. Unfrozen cold mineral soils in the boreal forest of North America sequester about 60–100 g C per m$^2$ per year. The slow rate of decomposition in these soils results in relatively rapid organic matter accumulation. This organic matter, however, is affected by wildfires that can completely remove it. The only deep carbon that survives is that which is derived mainly from roots. Therefore, the carbon pools in these unfrozen mineral soils are low, and the turnover time for this carbon is only 100–1600 years.

Carbon dynamics in cryoturbated mineral soils (Turbels) are very different. Cryoturbation translocates the organic matter deposited on the soil surface into deeper soil horizons. This cryoturbated organic matter is then unaffected by wildfires and, due to the cold soil temperatures, can be stored for thousands of years. It has been estimated that, in Canada, about 9 million tons of organic carbon are added annually to these types of cryoturbated mineral soils.

Vegetation on Histels and Histosols annually deposits raw organic material (litter) on the soil surface. About 25% of this deposited material will decompose during the following years, but the rest will be incorporated into the organic soils as peat. Researchers working in the Mackenzie River Valley of Canada found that, in the sporadic permafrost zone, the mean carbon
Figure 2  This map shows the distribution of permafrost-affected soils (Turbels, Orthels, and Histels), deep permafrost soils, and seasonally frozen soils in the northern circumpolar area (Tarnocai et al. 2009). Reproduced by permission of John Wiley & Sons, Ltd.
accumulation rates for unfrozen bogs (Histosols) over the past 100 years were 88.6 ± 4.4 g C per m² per year. In the discontinuous permafrost zone, they found that the mean carbon accumulation rate during the past 120 years was 13.31 ± 2.20 g C per m² per year. It was also estimated that organic soils in the boreal region accumulate approximately 9.8 Mt of organic carbon annually. Based on these estimates, the Turbels, Histels, and Histosols together in Canada accumulate (sequester) approximately >18.8 Mt of organic carbon annually. Thus, these soils play a very important role not only for storing large amounts of carbon, but also for removing large amounts of carbon annually from the atmosphere and for safely storing it for thousands of years.

Effects of climate change

Temperature and ice content are probably the most important parameters for determining the vulnerability of permafrost-affected soils to climate change. The temperatures of the permafrost layers have increased in most permafrost regions during the past several decades. This increase has been most noticeable at the southern limit of the discontinuous permafrost zone, where the temperature of the permafrost is just slightly below 0°C (warm permafrost). The increase in ground temperatures here has resulted in permafrost degradation in the form of thermokarst development, deeper active layers, and surface subsidence. The surface subsidence is especially critical because this indicates that there is thawing of the ice-rich, near-surface permafrost. Thawing of the ice-rich permafrost not only affects the surrounding environment, but has already been influencing the stability of the human-constructed infrastructures, as well as the livelihood of the people living in the north.

The thawing of ground ice due to climate warming results in severe landscape changes. These changes come in the form of detachment slides, thermokarsting, retrogressive flow slides, and hydrological changes. In addition, the perennally frozen soils contain a huge amount of water in the form of ice. When this ice melts, the release of this additional water will affect the hydrology from local to global scales.

The thawing of frozen soils results in landscape changes that are generally of local affect. Because these soils contain huge amounts of organic carbon, the release of this carbon could affect, and probably will affect, global climate. It has been estimated that the amount of carbon released from the thawing of perennially frozen mineral and organic soils by 2100 will be between 50 Pg C and 250 Pg C. Estimates vary as to how much of this carbon will be released in the form of CO₂ and CH₄ and how much these greenhouse gases will increase future warming. It is clear, however, that removal of large amounts of soil carbon from permafrost-affected soils may also reduce or stop carbon sequestration in these soils. So, the impact of climate change has a double effect on these soils not only by releasing the stored carbon, but also by stopping the sequestering of carbon from the atmosphere.

Soils of desert landscapes

Leslie D. McFadden

University of New Mexico, USA

The world’s warm arid and semiarid regions occupy at least 40% of the Earth’s land surface. Soils here strongly reflect the limited precipitation and the generally sparse vegetation found. Soil scientists characterize such areas as having aridic or torric soil moisture regimes with soil water deficits several months long (Soil Survey Staff 1999). Well-developed soils that form in this moisture regime are most commonly classified as Aridisols. However, Entisols (weakly developed soils) dominate many desert landscapes, and Inceptisols, Mollisols, Alfisols, and Vertisols may also occur in marginal areas (e.g., cooler “high deserts” or slightly moister areas).

Globally, desert areas are increasing, due in part to anthropogenic activities that produce “desertification.” These trends are accentuated by global warming.

Water availability is the most critical, ecologically significant factor in desert biomes. The types and spatial distribution of soils strongly influence vegetation in desert landscapes, mainly through their influence on rates and magnitude of infiltration, water percolation depths, soil water storage, and evaporation. Understanding how future climate changes will affect the Earth’s deserts requires an appreciation of the nature of desert soils.

Classification and morphological characteristics of desert soils

Desert soils are characterized by a vertical sequence of horizons that typically exhibit master A, B, and C horizons (Figure 1) (Birke-land 1999; Schaetzl and Anderson 2015). Many properties of A and B soil horizons of desert soils resemble those of soils of more humid regions. A fundamental requirement in the classification of all Aridisols, however, is that they must presently experience an aridic soil moisture regime. Also, unlike soils of the Entisol order that lack subsurface “diagnostic horizons,” soils in the Aridisol order must have certain diagnostic B horizons which display specific properties that serve as the basis for soil classification. For example, the presence of translocated, or “illuvial,” clay is signified in descriptions of soils by adding the lower case “t” after B (i.e., Bt). To qualify as an argillic horizon, however, certain values (e.g., clay content, presence of translocated clay, horizon thickness) must be met. Argillic horizons are common to soils of both arid and humid regions. It is the key horizon to the Aridisol suborder Argids (Figure 1); the “Arg” prefix is derived from “argillic,” and the “id” suffix is derived from “aridic.” This same scheme is generally used to derive other soil order and suborder names.

The calcic horizon, which is key to the Aridisol suborder Calcids (Figure 1), is defined mainly on the basis of accumulations of calcite (CaCO₃) (hereafter referred to as soil carbonate). The
SOILS OF DESERT LANDSCAPES

Figure 1 A desert soil formed in mid-Holocene-aged alluvial deposits in the Chihuahuan Desert, southern New Mexico (Gile, Hawley, and Grossman 1981). The presence of an argillic (Bt) horizon in this soil, as well as the aridic moisture regime of this area, classifies it as an “Argid.” Note the white coatings of soil carbonate on gravel clasts in the Bk (calcic) horizon, which exhibits Stage II morphology.

lower case “q” (e.g., Bq). The cambic horizon, which is key to the Aridisol suborder Cambids, is a subsurface horizon that shows some, usually weak, evidence of obliteration of parent material structure or other inherited features, color change, and/or loss of parent material calcite. B horizons qualify as Cambic if they have experienced some measurable amount of soil development but fail to qualify as another type of diagnostic B horizon. Development of these morphological features is indicated by “w” (e.g., Bw). Other diagnostic soil horizons in Aridisols include gypsic and salic horizons, which are dominated by, respectively, sulfate and chloride salts. Soils with these horizons are most typically found in the most arid and warmest deserts, including “hyperarid” regions where very little or no rain falls.

Low contents of organic matter (e.g., humus) and pale colors are typical of most desert soils, with the exception of commonly thin biological surface crusts that form in some desert settings. These characteristics reflect the commonly sparse vegetation mantle in deserts and low production of organic matter by biota. Sustained high soil temperatures cause rapid oxidation and loss of much of the organic matter that ends up in the soil. Many thin, pale A horizons of desert qualify as Ochric horizons. In some semiarid grasslands, however, where organic matter production is higher, soils have A horizons that qualify as mollic epipedons.

In drier and “stony” desert regions, many A horizons contain little organic matter, but also typically have abundant vesicular pores throughout (Figure 2). Other typical attributes of such horizons include blocky and/or prismatic structure, subordinate platy structure, fine, often silty textures, and accumulations of calcium carbonate and clay, often present as oriented laminae. Commonly referred to as a “vesicular A (Av)
horizon,” this horizon is recognized only informally. Av horizons are usually found immediately below desert pavements, which are typically a one-pebble and/or cobble thick surface layer of generally closely packed, subangular to sub-rounded gravels (McFadden 2013). The surfaces of desert pavement gravels are commonly thinly coated (tens to a hundred microns) with a dark layer referred to as rock varnish. The varnish is composed mainly of iron and manganese oxides, clay minerals, and silica that accumulate, and hence thicken and darken, with time.

Some desert soils contain indurated subsurface diagnostic horizons such as duripans or petrocalcic horizons (Figure 3). Some of the latter exhibit zones of laminated, nearly pure calcite. In some cases, these subsurface horizons are more than a meter thick. One of the best examples is the impressively thick petrocalcic horizon associated with an ancient soil on the Mormon Mesa, in southern Nevada (Figure 3). This soil represents several overlapping, buried petrocalcic horizons that have been “welded” together during the past 5 Ma (Brock and Buck 2009). Other indurated horizons include those composed of cemented gypsum (petrogypsic horizon) or soluble salts (petrosalic horizon).

**Formation of desert soils**

The accumulation of soil carbonate, gypsum, or more soluble salts in desert soils mainly reflects the relatively shallow depth of leaching associated with limited precipitation. Periodically high soil temperatures also promote relatively high evapotranspiration values and losses of soil water. Consequently, a substantial amount of dissolved anions in soil water, such as carbonate and sulfate, are not flushed completely from the soil, forcing them to precipitate as minerals such as calcite and gypsum in the B horizon (Figure 1). Also, the limited supply of soil water and low concentration of organic matter in the
SOILS OF DESERT LANDSCAPES

A horizon diminish the overall magnitude of chemical weathering in desert soils.

CO₂ in the soil atmosphere strongly influences carbonate solubility and, therefore, affects the depth at which it accumulates. Equation (1) shows the factors in the desert soil environment that drive the solubility and precipitation of calcite where $K_{\text{calc}}$ is the calcite solubility product, $K_1$, $K_{\text{calc}}$, and $K_{\text{CO}_2}$ are dissociation constants in the carbonate system, and $\gamma_{\text{Ca}^{2+}} + \gamma_{\text{HCO}_3^-}$ are the activity coefficients of $\text{Ca}^{2+}$ and $\text{HCO}_3^-$. This equation is valid for the system $\text{CaCO}_3$-$\text{H}_2\text{O}$-$\text{CO}_2$, assuming that activities are equal to concentrations and $\text{pH} < 9$.

$$m^3\text{Ca}^{2+} = \frac{(p\text{CO}_2 K_1 K_{\text{calc}} K_{\text{CO}_2})}{(4 K_2 \gamma_{\text{Ca}^{2+}} + \gamma^2_{\text{HCO}_3^-})}$$

Concentrations of CO₂ in desert soils are often elevated well above atmospheric values, leading to increased calcite solubility. The elevated levels of soil CO₂ result mainly from CO₂ production by plant roots, and/or microbial respiration (soil respiration) associated with soil organic matter. In deserts that lack vascular plants and, hence, have relatively limited soil microbial populations, calcium carbonate dissolution and transport are inhibited. As a result, more soluble salts that only require small amounts of soil water for their dissolution and transport, such as gypsum, dominate B horizon development.

Studies of the micromorphology, mineralogy, and chemical composition of desert soils have shed light on other important soil-forming processes in deserts. For example, because much of the clay in desert soil B horizons commonly is composed of smectite, a clay mineral with shrink–swell tendencies, some desert soils expand and contract as moisture contents change. The small size and surface charge of smectite clay particles favor their translocation in suspension, and eventual accumulation in illuvial clay-rich B horizons. The ability of smectite to absorb large amounts of water is conducive to large volume increases and soil expansion during the rainy season, followed by contraction when the soil dries. These wetting–drying (expansion–contraction or swelling–shrinking) cycles, coupled with progressive increases in soil B horizon clay content, ultimately favor development of strongly expressed soil structure (e.g., subangular blocky or prismatic soil peds) as soil clay contents increase.

Smectite clays also play a key role in the formation of vesicular A horizons (McFadden et al. 1998). During sustained rainfall and infiltration events, some of the percolating water is absorbed by smectite, causing the minerals to expand. Then, when the soil dries, dehydration of smectite causes contraction and the development of an extensive system of polygonal cracks and, commonly, prismatic structure. Subsequent rainfall causes initially rapid infiltration through these cracks. Thus, the percolating water moves deeply into the soil, and because this water carries suspended clay, fine particles and solutes are translocated below the vesicular A horizon, potentially also promoting the development of Bt and Btk horizons. Periodic leaching also dissolves and removes some of the calcium carbonate near the margins of the blocks or prisms of the vesicular A horizon. The fine texture and strong matric potential of the vesicular horizon, however, draws some soil water into ped interiors. This process also likely drives the formation of vesicles, entrapping air in the horizon because the ped margins are sealed. Soil air expands as the soil warms and dries, which may cause expansion of voids, and hence, vesicle formation. The advance of the wetting front may also increase soil pore pressure in the sealed horizon, and has been suggested as another mechanism for vesicle formation (Dietze et al. 2012). With the passage of time, the vesicular horizon can thicken to 10 cm or more, and
SOILS OF DESERT LANDSCAPES

becomes increasingly clay and silt enriched and locally reddened, exhibits development of different stages of vesical formation and destruction, and is characterized by the accumulation of illuvial clay.

The development of a vesicular A horizon over initially highly permeable parent materials strongly affects soil development that follows (McFadden et al. 1998). For example, if a source of calcite is present in surface materials (e.g., limestone), the hydrologic behavior of the A horizon enables solutes derived by partial dissolution of these calcareous materials to precipitate as layers of calcite on the sides of large surface clasts that lie immediately below the soil surface. Upwardly diffusing CO₂ in the soil prevents precipitation of soil carbonate on the bottoms of embedded surface clasts that exist at slightly greater depths. This pattern of soil carbonate formation results in the development of “carbonate collars” on the near-surface clasts (McFadden et al. 1998). In this way, near-surface soil carbonate can accumulate well above the usually observed depth of carbonate accumulation in the B horizons of desert soils.

Many important discoveries concerning desert soil-forming processes have also emerged from studies of soil chronosequences. A chronosequence is a suite of soils that differ primarily in age (Jenny 1941). In essence, soil chronosequence studies involve soils associated with series of geomorphic surfaces of different ages, but with uniform parent materials and in a similar climate. Many are located on alluvial terraces, alluvial fans, eolian sheet dunes, loess sheets, and topographically smooth lava flows. Chronosequences enable investigations of how soils develop over thousands to hundreds of thousands of years.

One of the best and well-known examples of chronosequence-based research in a desert landscape is that of Leland Gile and his colleagues, associated with the Desert Project (Gile, Hawley, and Grossman 1981; McFadden, 2013). Conducted mainly from the 1960s through the early 1980s in southern New Mexico, their research showed that on alluvial fan and terrace surfaces ranging from late Holocene through Middle Pleistocene in age (0–790 ka), soils on older surfaces become predictably thicker and morphologically better developed. Increasing B horizon clay contents and reddening also are observed, but the most strongly time-dependent soil property is soil carbonate accumulation. A very small amount of soil carbonate is visible as early as only a few centuries, occurring mainly as coatings on the surface of gravel clasts or as small filaments in fine-textured parent materials (Figure 1). Carbonate accumulations increase predictably in older soils, and in most cases a petrocalcic (Bkm) horizon forms after approximately 100,000 years. The horizon continues to thicken for several hundred thousand years more. In addition to the complete cementation, or “plugging,” of soil materials by soil carbonate, older petrocalcic horizons also exhibit zones of nearly pure, laminated soil carbonate, typically at the top of the plugged parts of the horizon (Figure 4).

Using these observations, Desert Project scientists defined four time-dependent stages of soil carbonate morphology (Stages I–IV) (Figure 4). Subsequent studies suggested the addition of two more stages, V and VI, for soils that exhibit advanced soil carbonate morphologies. These last two stages extended the time range covered by this model to several million years (Figure 4). The use of this terminology has been nearly universally adopted by scientists in studies that involve carbonate-enriched desert soils.

Desert Project scientists (and others) have concluded that most soil carbonate reflects the incorporation and pedogenic alteration/translocation of eolian (wind-deposited) dust, rich in carbonate minerals, that becomes incorporated
into the soil via percolating water. Initially, this conclusion was inferred because of the rapid rate of soil carbonate accumulation in soils with parent materials with no, or only small amounts of, calcium-bearing minerals. These parent materials also showed little evidence of chemical weathering of the Ca-bearing minerals. The presence of substantial calcite in dust collected by dust traps since these studies were done has provided additional evidence supporting the role of dust in the formation of carbonate-rich desert soils. Calcium dissolved in rainwater provides
another “external” source of soil carbonate, but because the dissolved Ca is derived by dissolution of Ca-bearing dust in the troposphere, it also ultimately represents a dust source.

Recent research continues to demonstrate the eolian origin of many materials (Reynolds et al. 2006; McFadden 2013). Continent-scale, long-term, regional studies of dust flux and composition in the western United States, using specially designed dust traps, have shown that dust influx and composition readily account for the rapid accumulation of carbonates, sulfates, silicates, and silica in soils – the building blocks of calcic, gypsic, argillic, and duripan horizons. Other studies have used modeling and chemical mass balance approaches, as well as data on soil mineralogy and the isotopic composition of dust and soil carbonate to arrive at the same conclusion – dust is an important driver of desert soil genesis (Derry and Chadwick 2007).

Because the rate and magnitude of soil carbonate accumulation in many desert soils are primarily controlled by dust composition and influx, high influx rates can accelerate calcic horizon and Bt horizon development. In desert environments, the accumulation of dust-derived soil materials in soils is such a common and widespread process because of deflation and eolian sediment transport from extensive, barren surfaces (e.g., playas), sparse vegetation, frequently dry soil conditions, and seasonally high wind velocities. Suspended dust may be transported to high altitudes and carried great distances. It is delivered to the soils either by rainfall that scrubs the dust from the atmosphere or by entrapment that is favored by the effects of rough surfaces of gravelly alluvial fans, volcanic flows, or sparsely vegetated shrublands. Infiltrating water translocates this entrapped dust into the soil.

Studies of strongly dust-influenced soils associated with desert pavements in the Cima Volcanic Field of the Mojave Desert of southern California show that their development is markedly different from that proscribed by traditional models of soil profile development in humid regions (McFadden 2013) (Figure 5a). According to that model, A and B horizons develop mainly through biogeochemical weathering that entails loss of solutes by leaching. Progressive surface lowering of mineral soils is the inevitable consequence of this net loss of mass, despite some mass gains due to organic

![Figure 5](a) Classical soil development sequence for a desert environment. White areas in the Bk horizon represent segregated, illuvial soil carbonate. Modified from McFadden (2013) with permission of the Geological Society of America. (b) Similar diagram to Figure 5a, but in this instance the soil has formed by time-dependent accretion and inflationary profile (AIP) strain-dominated development. Light-brown, irregular shapes on soil surface could represent either rubble formed by initial physical weathering of bedrock (R), or coarse clasts in the parent material. Note how the soil surface is stable in Figure 5a, but grows upward here, due to accretion of dust. Modified from McFadden (2013) with permission of the Geological Society of America.
matter accumulation in O and/or A horizons, and gains in voids by bioturbation. Soils that develop beneath desert pavements, including the vesicular A and Bt horizons, however, form mainly through the process of *cumulative* soil development. This process is driven by the gradual additions, or accretion, of eolian materials. This material accumulates in the A and B horizons beneath the pavement and is variously altered by subsequent soil-forming processes (e.g., weathering of calcium-bearing minerals in dust and subsequent precipitation as soil carbonate). The accretion causes soil inflation driven by the cyclic generation of new soil void space via hydration–contraction processes. *Accretionary and inflationary profile (AIP)* development (Figure 5b) ultimately drives the “upward growth” desert pavements (McFadden 2013).

Maintaining a balance between dust entrapment and soil incorporation is necessary for continued AIP and the concomitant upward growth of an evolving desert pavement. This type of desert pavement formation profoundly contrasts with other models that entail losses of fine material and surface lowering thorough deflation and/or surface erosion, leading to concentration of a coarse gravel lag (the pavement layer).

Soil chronosequence studies have shown that AIP and desert pavement formation are favored on certain types of landforms (e.g., alluvial fans), mainly because they provide weathering–resistant rocks (Figure 6). AIP is also an important mode of soil profile development in semiarid regions where desert pavements cannot form and vesicular horizons are weakly developed or absent. Increased plant density, however, also promotes rates of dust entrapment necessary to favor AIP.

Besides hydration–contraction, other physical weathering processes play key roles in weathering and soil development in deserts. One is salt weathering, a process responsible for the disintegration of large subsurface gravel clasts. It has also been suggested as an important process driving the weathering of large surface clasts and ultimately the formation of desert pavements. Recent studies, however, have indicated that another weathering process is responsible for the initial fracturing of surface rocks. They show that stresses produced by nonuniform rock surface insolation are responsible for crack formation in surface rocks (McFadden et al. 2005; Eppes et al. 2010). The impact of insolation is demonstrated by a statistically significant pattern of generally north–south crack orientations, which can only reflect the systematic heating and cooling of the rock as it is subjected to directionally changing, diurnal insolation cycles (Figure 7). The subsequent introduction of salts or other eolian materials into these cracks may then favor additional crack extension and widening.

*Figure 6* Extensive areas of desert pavement on a piedmont in the western Andes Mountains of central Peru. Note the pale-colored boulders on the unpaved road across the pavement. Photo by L.D. McFadden.
Recent research that demonstrates the preferred orientations of cracks on surface rocks in Martian deserts, and modeling studies of asteroids and regolith on asteroids, have shown that insolation weathering is also an important weathering process on these surfaces as well (Abernathy, Eppes, and Willis 2013).

**Desert soils and plant communities**

With few exceptions, most deserts are vegetated, although the vegetative cover is typically sparse and often strongly spatially aggregated. The characteristics of the vegetation communities of deserts reflect climatic regimes ranging from hyperarid climates that support virtually no vascular plants, to semiarid climates that support denser communities such as piñon-juniper woodlands or shortgrass prairie communities. The character of desert biota reflects the overall aridity and unpredictability of precipitation, leading to low biotic productivity and, surprisingly, relatively high species diversity. Desert plants also must be adapted to climatic extremes. Obviously, water availability is the most critical factor limiting ecosystem processes in deserts. Consequently, soil properties that strongly influence water infiltration, available water-holding capacity, and overall soil water balance strongly influence most desert plants. For example, common desert shrubs of the Mojave and Sonoran Deserts, in the United States, such as creosotebush (*Larrea tridentata*) (one of the most spatially extensive and long-lived plants), are uncommon on soils with well-developed Bt horizons, because other plants such as white bursage (*Ambrosia dumosa*) have shallower root systems adapted to quickly utilizing soil water commonly held in the upper part of the profile. Another example is shown by the evolution of desert pavements and soils. Many vascular plants
SOILS OF DESERT LANDSCAPES

can recruit and become more easily established on recently deposited, well-drained gravelly alluvium. With increasing age, however, as surficial weathering and hydrologic processes progressively concentrate increasingly darkened surfaces of clasts above a vesicular horizon, the combination of high surface temperatures, high evapotranspiration rates, and fine soil textures inhibit the colonization and persistence of perennial vascular plants on the desert pavement soils. Variability in pavement packing, clast size, surface relief, and local burial of pavements by younger alluvial or eolian deposits may, however, influence the development of some hydrologically significant soil properties, locally increasing runoff and infiltration, thereby enabling plant recruitment and persistence (McAuliffe, Hamerlynck, and Eppes 2007).

Studies of desert soil carbonate show that its stable isotopic composition strongly reflects the photosynthetic pathway utilized by plants growing there (Sharp 2007). This relationship exists because of photosynthesis-driven isotopic fractionation in plant tissues; the $\delta^{13}C$ value in plant tissues is substantially decreased compared to its atmospheric value of approximately $-7$‰. The $\delta^{13}C$ value of plants that utilize the C$_3$ photosynthetic pathway, which characterizes woodland trees and high-latitude grasses, is $-23$ to $-33$‰. The $\delta^{13}C$ value of plants that utilize the C$_4$ photosynthetic pathway, used by many warm-season perennial grasses and a few shrub species, such as the saltbushes (Atriplex spp.), is $-16$ to $-9$‰. Desert soil-respired CO$_2$ thus possesses either a C3 or a C4 isotopic signature. The ratio of carbon isotopes in the soil carbonate precipitated in isotopic equilibrium with CO$_2$ molecules with these different isotopic values reflects a C$_3$ or C$_4$ value, or more typically, a value that reflects a composite value of a population of both C$_3$ and C$_4$ plants. Recent research focusing on incipient soil carbonate in soils associated with diverse plant communities in the northern Chihuahuan Desert of New Mexico (Breecker, Sharp, and McFadden 2009) revealed the relatively close relationship between plant types and the $\delta^{13}C$ values in the soil carbonate (Figure 8). Such studies, and studies of other stable isotopes in soil materials, elucidate the processes largely governing the timing of carbonate movement and soil carbonate precipitation. Such research shows, for example, that soil carbonate may not necessarily form annually during the growing season as many soil scientists had long believed. Instead, much soil carbonate may accumulate principally every few to several years after an especially strong drought.

Desert soils and climatic change

Worldwide, patterns of climate and its effect on soil water balance are closely associated with variations in the dominant types and density of plants. Consequently, climate variation in deserts also is associated with morphological variability. For example, climosequence studies show that as annual precipitation increases, the depth at which soil carbonate accumulates commonly increases. In transitional areas (desert to humid regions of ≥50 cm annual precipitation), carbonate may accumulate at depths greater than 100 cm, or soils there may be thoroughly leached and hence noncalcic. In marked contrast, in the driest and warmest deserts (e.g., <8 mm annual precipitation), accumulated gypsum or other soluble salts typically predominate shallow B horizon development, and soil carbonate accumulation is inhibited (Amit and Yaalon 1996).

During the Quaternary period, Earth’s climate changed substantially, varying between generally warmer interglacial (IG) periods, such as that represented by the Holocene epoch, and generally colder glacial (G) periods, such as the most
Figure 8  Profiles of carbon isotope values of soil and those predicted from measured soil-gas values, based on analysis of soils associated with four different biomes in arid and semi-arid areas of the northern Chihuahuan Desert, New Mexico. The key for all plots is shown in panel c. Results from both disturbed and undisturbed soil are shown at 92 cm for the Great Basin Shrubland. Dashed horizontal lines show the depth below which measured and predicted values can be directly compared. Equilibrium conditions were most closely achieved on May 4, 2008, and the profiles for this date are highlighted by enlarged symbols. VPDB – Vienna PeeDee Belemnite. Recent ice age of the late Pleistocene epoch. Results of these studies indicate that average annual temperatures change by as much as 4–5 °C from a glacial to an interglacial period, and that these changes were accompanied by substantial increases in precipitation in most desert areas. These types of dramatic climatic changes strongly affected the plant communities of deserts. For example, in the southwestern United States, areas now occupied by desert shrub vegetation were occupied by piñon-juniper woodlands during the most recent glacial period, equivalent to a shift in the average elevation of these biomes by 1000–1400 m. Global changes in climate during the Quaternary period were also characterized by other important environmental changes, such as strong variations in dust flux. Considering the strong relationships between
climate, vegetation, and dust on pedogenesis, it is easy to understand why these climatic changes also substantially influenced desert soil formation. From the 1960s through the early 1980s, Desert Project researchers, working in New Mexico, concluded that at least some of the features observed in pre-Holocene soils reflected these influences, rather than simply reflecting time-dependent changes. For example, they attributed the accumulation of desert carbonate in argillic horizons to a shift to drier climate and shallower depths of clay accumulation within a formerly noncalcic B horizon.

Desert pavement-forming processes also may have been inhibited during the cooler and effectively wetter climates of the last glacial period. Paleobotanical features such as the presence of microtopographic traces of former occupation by perennial plants (“plant scars”) on some desert pavements in the US Southwest likely reflect the shift from G to IG climate and the associated vegetation contraction. However, some older Pleistocene pavements and soils in some high desert areas seem to have persisted through the last glacial period. Possibly the influences of some features, such as dark pavements conductive to elevated soil temperatures and evapotranspiration rates, were sufficiently unfavorable to the recruitment and sustained colonization by plants, even during glacial periods. The presence of well-developed vesicular horizons, through their strong influence on soil hydrology, also can substantially decrease the depth of soil water movement and soil carbonate accumulation (McFadden et al. 1998). As a result, some desert pavements persisted through glacial periods and soil development continued (McFadden 2013).

Numerical modeling studies of soil carbonate accumulation can be used to study processes controlling its accumulation, and can help explain how Quaternary climate changes might have affected rates and depths of carbonate accumulation, as affected by changes in dust influx, soil water balance, plant canopy cover, evapotranspiration and soil respiration (McFadden et al. 1998). For example, it has been long hypothesized that G to IG climate changes should have caused a significant decrease in the average depth of soil carbonate accumulation, potentially resulting in a bimodal profile of soil carbonate concentrations with depth. Field studies of late Pleistocene desert soils show that such a pattern is common, and results of numerical modeling provide strong support for this hypothesis. Shifts in biotic communities of deserts, and, in many cases, the relative proportions of C_3 and C_4 plants, are also recorded in the isotopic compositions of soil carbonate in late Pleistocene and Holocene desert soils.

Desert soils and landform evolution

Chronosequence studies demonstrate the interdependent relationships between soils and associated desert landforms. They show, for example, that dust entrapment and accumulation on stable geomorphic surfaces promote the development of well-formed desert pavements and soil profiles in as little as a few thousand to a few tens of thousands of years (Wells et al. 1995). Once formed, a desert pavement can persist for hundreds of thousands or even several million years (Figure 6). Sustained pavement stability and dust accumulation rates promote continued AIP, and therefore also the continued subsurface accumulation of clay-sized soil carbonate, silica, and/or other salts, and leading to, respectively, increasingly thicker argillic horizons, petrocalcic horizons, and so on. Soils that thicken by AIP, however, cannot continue to thicken indefinitely. Eventually the destabilization of geomorphic surfaces is promoted by the presence of increasingly thicker, clay-enriched B horizons, which act to decrease...
soil infiltration rates and lead to increases in the proportion of surface runoff. Thus, erosion potential is increased. Erosion of most of the Bt horizon and decreased depths to a plugged and essentially impermeable subsurface horizon also would substantially decrease translocation of soil water to great depth, thereby favoring increased runoff. The progressive development of a network of drainage lines and channel incision on older desert piedmonts locally steepens surface gradients, further increasing erosion potential.

Once exposed by erosion, massively cemented, indurated soil horizons such as a petrocalcic horizon get exposed at the surface. These horizons are very resistant to weathering and erosion, enabling them to persist for millions of years (Figure 3). Accordingly, such horizons have been regarded as essentially “irreversible.” Studies in Australia indicate that some duripans can also remain as landscape elements for tens of millions of years. On some piedmonts in the southwestern United States, slow dissolution of the uppermost part of a petrocalcic horizon beneath a thin B horizon, combined with continuous channel incision, ultimately results in a convex-up surface form, known as a *ballena*. In other circumstances, however, rapid, deep channel incision has initiated instead cliff retreat enabled by the presence of the thick, indurated, locally silica-rich petrocalcic soil in southern Nevada (see Figure 3).

Much of the landscape in desert regions is hilly or mountainous. These surfaces typically generate considerably more runoff and thus have high erosion potential. Steeper, high-relief hillslopes also favor mass movements, such as landslides and debris flows. Together, these circumstances do not favor soil formation. Also, the limited magnitude of chemical weathering in deserts often means that weathering of hillslope materials and bedrock occurs mainly by physical weathering, leading to the production of mobile regolith (colluvium). This material can then accumulate as talus or mass movement debris at the bases of steep bedrock slopes. Steep, bedrock-dominated hillslopes in the arid and semiarid regions of the western United States are very commonly associated with well-cemented sandstones, welded ignimbrites, massive limestones, basalt flows, or other rock types (Figure 9a).

Interestingly, the typical hillslopes associated with marine mudrock-dominated formations such as the Chinle Group and the Mancos Shale in the American Southwest exhibit a very different hillslope form, with generally lower slope gradients and numerous rills and gullies (Figure 9a). Referred to as badlands, the associated sedimentary rocks lack the shear strength to support steep, high cliffs. Even minimal weathering can help to reduce the strength of mudrock. The high expandable clay content of these rocks also favors shrink–swell weathering and some creep-driven downslope transport. Saturation of the mudrocks during prolonged rainfall, however, can effectively seal the surface layer, substantially increasing runoff and erosion. The commonly high salt content of mudrocks also significantly inhibits colonization by all but very salt-tolerant plants, which also increases erosion potential. As a consequence of rapid erosion and slope retreat, as is the case for steep bedrock hillslopes, badlands usually lack soils.

In a famous paper, Gilbert (1880) argued that relatively steep, bedrock-dominated hillslopes form when the rate of regolith formation is exceeded by the rate of the downslope transport of weathered material. This situation is described as a *detachment-limited* hillslope. Such a slope typically exhibits variously developed soils (Figure 9a). Gilbert also proposed that, in a more arid climate where weathering processes are weak, detachment-limited hillslopes would be the most common hillslope type, particularly on rock types resistant to weathering, such as basalt. Recognizing the existence of smooth,
SOILS OF DESERT LANDSCAPES

soil-mantled hillslopes, Gilbert observed that they were generally prevalent at high elevations; the bedrock-dominated, detachment-limited hillslopes were at lower elevations. Gilbert hypothesized that the smooth form and commonly continuous vegetation mantles reflected higher magnitudes of weathering in a more humid climate. In these circumstances, formation of weathered material outpaces the rate of its erosion. The vegetation cover intercepts precipitation, limits erosion, and favors infiltration, all of which enhance the weathering of bedrock. The main form of downslope transport on such hillslopes is by abiotic and biotic-mediated creep processes, which lead to the formation of smooth hillslopes that become increasingly steeper downslope, accommodating transport of additional weathered material. These soil-mantled hillslopes are referred to as transport-limited (Figure 9b).

Transport-limited hillslopes are present but somewhat uncommon in desert regions (Figures 9b and 10). Soil geomorphic studies show that desert hillslopes are excellent dust traps, especially on the favorably oriented, windward aspects. Dust entrapped in bedrock cracks can increase the magnitude of physical weathering, thereby increasing the production of colluvium. In certain situations, dust entrapment may enable the formation of isolated areas of soil development that exhibit vesicular A, Bt, and Bk horizons. Locally continuous, thick soil mantles have formed, however, on some of the lower, piñon-juniper-covered foothill slopes of the granite-dominated Sandia Mountains (Figure 9b) (Persico et al. 2011). The slightly moister semiarid climate, generally windward orientation, and ample dust supply support a moderate vegetation cover here, which favors soil development. Most of the foothills of the Sandia Mountains exhibit bedrock-dominated corestone topography, implying that another factor also must locally favor soil development. In this area, the granitic rocks locally exhibit fine-grained dikes or small bodies composed of aplite, a rock that is resistant to chemical weathering. Physical weathering of aplite produces angular, joint-bound blocks that range from a single to a few decimeters in diameter. Unlike the much finer granitic grus, blocky aplite is far more resistant to erosion, accumulating instead as colluvium. Because relatively large, erosionally resistant bodies of the aplite eventually form the summit areas of hillslopes, aplitic colluvium buries granitic bedrock on lower hillslopes areas. The angular colluvial cover effectively entraps dust, and much of the dust is washed into the granite-mantling colluvium. Thus, despite the relatively steep hillslope gradient, remarkably thick, reddened Bt horizons have formed on these hillslopes, mainly by AIP, likely over tens of thousands of years.

Piñon-juniper woodland-mantled hillslopes also occur in other semiarid regions of the southwestern United States, including many areas of the Colorado Plateau. Some of these hillslopes are also smooth and have continuous soil mantles (Figure 10). These soils

Figure 9  (a) Detachment-limited hillslopes formed on Jurassic sedimentary rocks in the Grand Staircase National Monument, southern Utah. The uppermost, steep cliff-dominated hillslopes have formed in relatively well-cemented sandstones. The rilled (drainage lines) badlands that dominate the lower portions of these hillslopes have formed on mudrocks. Photo by L. D. McFadden. (b)
Figure 10  Steep, transport-limited hillslopes (S) with a southwest-to-west, relatively warm aspect contrast with the soil-mantled, transport-limited hillslopes (N) with an effectively more humid northern aspect formed on Jurassic sandstones, as seen in northeastern Arizona. Recent erosion on the steep, detachment-limited hillslopes on the left side of this image has removed all but a few isolated remnants of soil mantle, exposing bedrock. Decreases in the number of piñon and in the area of soil cover in the transitional, ecotonal region between these two hillslope areas are taken as evidence of ongoing hillslope transformation, likely occurring in response to climate change(s). Note the emerging, large sandstone concretions (C) and living roots (R) of cliffrose shrubs exposed by very recent soil erosion. Photo by L.D. McFadden.

are, however, relatively thin and have weakly developed A–C soil profiles. In northeast Arizona, these hillslopes have formed on regionally extensive sandstones of Jurassic age. Some Jurassic sandstones are cemented by clay, rather than calcite and silica cement. A significant fraction of the clay is smectite, and its weathering by cyclic hydration–contraction is conducive to the formation of a continuous, but weakly developed, soil mantle. The continuous vegetation canopy inhibits erosion, and consequently downslope sediment movement occurs by soil creep. Rapid soil creep and the lack of large, erosionally resistant rock fragments on the hillslopes minimize entrapment and accumulation of dust and, therefore, also the formation of thick, well-developed soils by AIP (McFadden 2013).

Smooth soil and vegetation-mantled hillslopes in this region of the southwestern United States are most prevalent on areas of northern aspect. Hillslopes with a warmer, effectively drier, southern aspect are generally steeper, with a much higher proportion of exposed bedrock (see Figure 10). Differences in topographically controlled, aspect-related microclimate diminish the magnitude of weathering and minimize soil formation on slopes with southern aspects, favoring the evolution of bedrock-dominated,
detachment–limited hillslopes. Aspect-associated
differences in average soil temperature are, how-
ever, not especially large, demonstrating the
sensitivity of these hillslope systems to relatively
small variations in topoclimate. In spatially
extensive hilly landscapes in the southwestern
United States associated with largely uncon-
solidated, noncohesive substrates, topoclimatic
variation also favors aspect-related difference in
hillslope form and vegetation cover. In these
circumstances, the exposure of the underly-
ing, noncohesive alluvium on southern aspect
hillslopes, rather than bedrock, causes the for-
mation of surface runoff-dominated hillslopes
with lower gradients than the soil-mantled,
north-aspect hillslopes (McAuliffe et al. 2014).
Hillslope soil, vegetation, and dendrologic
studies in the ecotonal areas between the
piñon-dominated northern and shrub-dominated
southern aspect hillslopes in the Colorado
Plateau study area show that the transformation
of soil-mantled, transport-limited hillslopes to
bedrock-dominated, detachment-limited hill-
slopes is very rapid (McAuliffe et al. 2014).
The transformation is achieved on timescales of
a few thousand years, or even centuries. The
change in hillslope form and soil–slope relations
is probably triggered by substantial reductions
in intercanopy grass cover caused by sustained
drought. Subsequent wetter climate, the reduced soil cover limits re-recruitment
and vegetation recovery. These hillslopes reflect
a landscape system that is highly sensitive to
changes in vegetation cover and soil thickness.
When a hillslope system threshold is reached,
subsequent erosion rates greatly increase, and
the result is the irreversible transformation of
hillslope vegetation communities, soils, and
hillslope form (Figure 10). Many well-known
areas in the Colorado Plateau with picturesque,
colorful sandstone weathering landforms are
likely the consequence of these types of process
interactions (Figure 11).

Conclusions

Soil geomorphic research over the last few
decades has revealed the critical roles played
by dust, parent materials, and vegetation in
the formation and evolution of desert soils and
associated landforms. On geomorphically stable
surfaces, prolonged dust entrapment and its
subsurface incorporation promote the formation
of thick, well-developed soils by AIP, over
long time spans. In drier deserts with very
sparse vegetation, these soils are commonly
associated with desert pavements and vesicular
A horizons. Thick well-developed soils also
form under dust-trapping plant communities
in semiarid regions. Even on geomorphically
unstable, steeper hillslopes, dust entrapped on
hillslopes associated with rock types that produce
dust entrapping colluvium, or the presence of
weakly cemented sandstone, is conducive to soil
development.

Understanding the relationships among the
diverse soil types and landforms in deserts
requires an appreciation of the sensitivity of
plants and certain rock types to climate. Whereas
some soils and landforms evolve slowly despite
having been subjected to major climate changes,
others have changed in profound ways. In
some desert settings, the rapidity of changes in
response to even relatively minor recent and
ongoing changes in climate is remarkable, and
such responses to predicted future global climate
changes are all but certain.

Soils of humid mid-latitude landscapes

Darrell G. Schulze
Purdue University, USA

Soil properties on a global scale are often discussed in terms of general soil regions, with climate being a defining characteristic, for example, “temperate soils” versus “tropical soils.” Although there are clear distinctions between soils in various climatic regions of the world that warrant their grouping into broad classes with similar soil properties and functions, only rarely are these classes formally defined. Therefore, to facilitate discussion and comparison of “humid mid-latitude soils” with respect to other soils of the world, the four global soil regions are first defined using criteria based on the soil temperature and soil moisture regimes of Soil Taxonomy (Soil Survey Staff 1999). These four groups, namely cold soils, arid soils, humid tropical soils, and humid mid-latitude soils, parallel entries with similar names in this encyclopedia.

Areas delineating each of the above groups (Figure 1a) were created utilizing maps of global soil temperature regimes (USDA 1997a) and global soil moisture regimes (USDA 1997b). Four mutually exclusive classes can be delineated according to the following criteria:

- Cold soils consist of all soils in the gelic, pergelic, and hypergelic soil temperature regimes. These are very cold soils that either contain permafrost, or have mean annual soil temperatures \( \leq 1^\circ C \) at 50 cm depth.
- Arid soils are all soils that occur in aridic soil moisture regimes. These soils are dry throughout the soil profile for more than half the year when soil temperature at 50 cm is >5°C, and moist for <90 consecutive days per year when the soil temperature is >8°C. In other words, they are dry during the warm growing season. They support xerophytic vegetation in their natural state, and must be irrigated if they are used for crop production.
- Humid tropical soils are soils that occur in iso-temperature regimes, that is, areas in which the mean summer and mean winter soil temperatures at 50 cm differ by <6°C. These soils have no distinct “cold season.” Most are warm throughout the year, although the few that occur at high altitudes, such as those on Mounts Kilimanjaro and Kenya in Africa or in the high Andes in South America, can be cooler. Note that soils already grouped with cold and arid soils are excluded from this category.
- Humid mid-latitude soils consist of all soils that are not previously defined as within the cold, arid, or humid tropical soil groups. Thus, they are a diverse group that can have xeric, ustic, udic, or perudic soil moisture regimes, and cryic, frigid, mesic, thermic, hyperthermic, and megathermic soil temperature regimes (Table 1).

In general terms, humid mid-latitude soils are those soils that (i) have sufficient moisture in normal years to support some sort of agriculture (as opposed to only grazing or pasture) without irrigation, (ii) have distinct seasonal temperature differences between summer and winter, with
SOILS OF HUMID MID-LATITUDE LANDSCAPES

plant growth limited by cool temperatures in winter, and (iii) are warm for long enough periods of time during the growing season to allow agricultural crops to reach maturity. As thus defined, humid mid-latitude soils comprise 27.4% of the Earth's ice-free land area (Table 2, Figure 1a and 1b), and most, 83%, occur in the northern hemisphere. More than half of the Earth’s population, 58.6% in the year 2000 (CIESIN and CIAT, 2005b) (Table 1; compare Figure 1a or 1b with Figure 1c), lives on and is supported by humid mid-latitude soils.

Most humid mid-latitude soils occur on various kinds of geologically young parent materials. Such sediment is usually rich in the weatherable minerals that impact the soils that

Figure 1  Continued
formed on them, and provides nutrients for the ecosystems and crops that these soils support. There are a number of reasons for the geologically young landscapes on which many humid mid-latitude soils occur. First, large areas in the Northern Hemisphere were glaciated during the Pleistocene epoch. Glacial ice obliterated the pre-existing landscapes, eroding uplands and filling valleys so that smooth, gently rolling plains remained after the glaciers receded. The sediments deposited by these glaciers were derived mainly from fresh bedrock, explaining

*Soil moisture regimes are defined on the basis of soil moisture, which is determined by the amount and distribution of rainfall and the temperature for all the moisture regimes except the aquatic regime, which is defined by soil morphological characteristics. The full definitions of soil moisture regimes and soil temperature regimes in *Soil Taxonomy* are lengthy and quantitative (Soil Survey Staff, 1999, 2014). The descriptions here are very generalized and based on Soil Survey Staff (2015).

†Further subdivided into hypergelic (≤10°C), pergelic (−4°C to −10°C), and subgelic (+1°C to −4°C) according to the mean annual soil temperature at lower levels of *Soil Taxonomy* (Soil Survey Staff, 2014).

‡The upper limit of the hyperthermic regime and the megathermic and isomegathermic regimes are defined by Eswaran et al. (1997).

why they are so rich in unweathered (primary) minerals. The soils on these formerly ice covered areas are no older than Pleistocene age (less than about 1.6 million years) and many are no older than 20,000 years. Pleistocene glaciers also impacted soils at considerable distances from the glacial margin. Meltwater carried freshly ground sediment from the glacial margin, depositing it as sandy and gravelly sediment called glacial outwash. Wind blowing across the dry floodplains in the winter picked up silt that was then deposited over large areas of the surrounding uplands as a deposit called loess. Loess often covers entire landscapes with deposits several meters thick. Even when thin, however, the loess adds fresh, unweathered minerals to older,
SOILS OF HUMID MID-LATITUDE LANDSCAPES

more weathered soils, adding divalent cations such as calcium (Ca\(^{2+}\)) and magnesium (Mg\(^{2+}\)), as well as silica and other elements, and initiating a new cycle of weathering and soil formation. Other areas of humid mid-latitude soils occur in tectonically active areas where erosion from mountainous areas provides fresh sediment to the surrounding lowlands. Finally, in some areas, volcanic activity provides fresh material, such as volcanic ash, for soil formation. For this reason, many of the older, more weathered soils like Ultisols and Oxisols are relatively uncommon across the humid mid-latitudes.

Types of humid mid-latitude soils

Soils of the humid mid-latitudes have been intensively studied; thus, it is no accident that they are represented prominently in all of the world's major soil classification systems. Eleven of the 12 soil orders of Soil Taxonomy occur in (or even dominate) humid temperate regions (Figure 1b, Table 3). Each order is summarized briefly here, in order of generally increasing pedogenic development.

Entisols are weakly developed and, hence, often very young soils. They have an ochric epipedon, which is a light colored and often thin surface horizon. Entisols lack subsurface horizons that have been significantly altered by soil forming processes. They are common on steep, eroding surfaces, as well as on floodplains and other areas that have only recently been exposed to pedogenic processes. They also include some very sandy soils and soils formed in parent materials that are resistant to weathering. Entisols make up 12.4% of the land area of humid mid-latitude soils (Table 3) and are distributed widely such that large contiguous areas do not stand out on small-scale maps (Figure 1b).

Like Entisols, Inceptisols usually have an ochric epipedon, but are slightly better developed in the lower profile. Inceptisols have a

*Includes small areas of shifting sands.
cambic horizon, which is a subsurface horizon that shows evidence of chemical or physical alteration, but lack increases in clay content or changes in other properties that define more developed subsurface horizons. Because of their weakly expressed horizons, both Inceptisols and Entisols resemble their parent materials more closely than most of the other, more pedogenically developed, soil orders. Many Inceptisols are on steeply sloping landscapes. They are widely distributed throughout the area of humid mid-latitude soils (Figure 1b) and are particularly common in mountainous areas (Figure 2a). They make up the largest area of humid mid-latitude soils (Table 3) and are particularly common in western Europe, the northeastern United States, and eastern China (Figure 1b).

Alfisols have an ochric epipedon overlying an argillic horizon, which is a subsurface horizon that has higher clay content than the horizons above it, along with evidence that clay has moved into the horizon from above. Alfisols have high content of base cations (Ca$^{2+}$, Mg$^{2+}$, K$^+$, and Na$^+$) and are defined as having >35% base cation saturation at the bottom of the profile. Alfisols make up 21.3% of the area of humid mid-latitude soils (Table 3). Because it takes several thousand years for an argillic horizon to form, Alfisols are found on landscapes that have been stable for at least that long (i.e., late Pleistocene) and in parent materials that contain ample amounts of clay and other primary minerals such as quartz, feldspar, and mica. Many Alfisols have formed under deciduous broadleaf or mixed coniferous–deciduous forest, although they occur under a variety of other vegetation types as well. Large areas of Alfisols occur south of the Great Lakes in North America, along a wide swath across northern Europe and northeastern Asia, and in Australia (Figure 1b). Alfisols are generally high in natural fertility and are responsive to good management. As a result, they are used widely for agriculture and forestry. A representative profile of an Alfisol is shown in Figure 2b.

Spodosols are often coarse-textured soils that have an ochric epipedon overlying a spodic horizon, which is a subsurface horizon with an accumulation of organic matter, usually also containing large amounts of poorly crystalline iron and aluminum oxides and hydroxides. An albic horizon, which is a bleached, sandy, light-colored horizon, often occurs between the ochric epipedon and the spodic horizon (Figure 2c). The most extensive areas of Spodosols occur in cryic and frigid temperature regimes along the northern edge of the humid mid-latitudes (Figure 1b), although smaller areas occur throughout the world, where they are usually restricted to coarse textured parent materials and wet sites. Spodosols are the typical soils of the northern boreal and mixed coniferous–deciduous forests and are extensive in southeastern Canada and on the Scandinavian Peninsula and adjoining areas of Russia, as well as in the northern Great Lakes region of the United States (Figure 1b).

Ultisols have an ochric epipedon overlying an argillic horizon or a kandic horizon. The kandic horizon is similar to an argillic horizon but contains clays that have lower cation exchange capacities (CEC). In contrast to Alfisols, Ultisols are more acidic and have <35% base saturation at the bottom of the soil profile. Ultisols are deeply weathered soils, usually associated with acidic parent materials; they occur on old and stable land surfaces. In areas of crystalline bedrock, the thick and deep soil profile may be underlain by several meters of saprolite above the hard bedrock. Because of the high content of low CEC clay minerals, Ultisols have low inherent fertility and most plant nutrients occur in the surface horizons due to biocycling. These soils usually support forest vegetation if they
SOILS OF HUMID MID-LATITUDE LANDSCAPES

Figure 2 Photographs of four soil orders and of an agricultural landscape representative of the humid mid-latitudes. The depth scales are in centimeters and photographs (a)–(d) have been sized so that the profile depths scales are similar for each photo. (a) An Inceptisol in the Carpathian Mountains of Ukraine near the Slovakia–Poland–Ukraine border. The top of the scale is at the interface of the approximately 10 cm thick O horizon consisting of leaf litter in varying stages of decay and the underlying mineral soil. An ochric epipedon occurs from 0 to approximately 25 cm, followed by a cambic horizon from approximately 25 to 110 cm. Unweathered rock occurs below approximately 110 cm. The stones in the cambic horizon are typical of soils in mountainous landscapes. Its great group classification as a Lithic Dystrudept indicates the soil occurs in an udic moisture regime, is well drained with no indication of a seasonal high water table, is acid throughout, and is shallow to bedrock.
Figure 2  (b) An Alfisol from eastern Lower Michigan, USA. This soil has an ochric epipedon approximately 15 cm thick, overlying an argillic horizon from approximately 15 to 50 cm. Unweathered, calcareous glacial till occurs below approximately 50 cm. Its great group classification as an Inceptic Hapludalf indicates that the soil is in a udic moisture regime, is well drained with no indication of a seasonal high water table, and is less developed than most Hapludalfs. (c) A Spodosol from eastern Upper Michigan, USA. This soil has a dark ochric epipedon from 0 to approximately 15 cm, an albic horizon from approximately 15 to 40 cm, a spodic horizon from approximately 40 to 70 cm, and unweathered, sandy parent material below approximately 70 cm. Its great group classification as a Typic Durorthod indicates that it is a typical, well drained Spodosol with no evidence of a seasonal high water table, but the spodic horizon is indurated. (d) A Mollisol from Illinois, USA. This soil has a dark mollic epipedon up to approximately 60 cm thick overlying a gray argillic horizon. This is the Drummer soil series typical of the wet prairies of Illinois and neighboring states in the Midwestern USA. Its classification in the Typic Endoaquolls great group indicates that it has a seasonal high water table, which is also reflected in the standing water at the bottom of this profile. These soils are usually tile drained and cropped extensively to corn and soybean. (e) A landscape in northwestern Tippecanoe County, IN, USA that is typical of many agricultural areas of the Midwestern USA. Center of the photograph is at latitude N 40.479°, longitude W 86.985°, WGS 84, and the view is to the northeast. The area is at the interface between soils formed under prairie and soils formed under forest. Wet Mollisols, as in Figure 2e, occur on the nearly level glacial till plain in the central part of the photo, while better drained Alfisols, as in Figure 2b, occur in the bottom and right side of the figure along drainage ways and more sloping areas. Rectangular wooded areas are remnants of the forest that covered parts of this scene prior to European settlement. Crops are predominantly corn and soybeans. Sources: 2a, 2b, and 2c reproduced from http://geo.msu.edu/extra/soilprofiles/; 2d reproduced from Natural Resources Conservation Service, http://www.nrcs.usda.gov/wps/portal/nrcs/detail/il/soils/?cid=nrcs141p2_030652; 2e Schulze, 2015. have not been cultivated. Ultisols are common in the southeastern United States and across southeastern Asia (Figure 1b). They make up slightly less than 10% of the area of humid mid-latitude soils (Table 3).

Mollisols are defined by the presence of a mollic epipedon, which is a thick, dark surface horizon (Figure 2d) that is high in organic matter and base cations. In addition to the mollic epipedon, base saturation must be ≥50% throughout the profile. Because they are classified mainly on the basis of the surface (A) horizon, Mollisols can have any of a variety of other subsurface horizons, including an argillic horizon or a calcic horizon, which is a horizon that contains an accumulation of calcium carbonate. Mollisols are the typical soils of grasslands. Thus, they are extensive on the Great Plains of North America and the Steppes of western Asia, where they occur between the Alfisols in the more humid climates to the east or north (Figure 2e), and the Aridisols of the more arid climates to the west or south (Figure 1b). Mollisols are also extensive in the Pampas of South America (Figure 1b). They have high natural fertility and are so extensively cultivated that in many areas few examples of their native grassland vegetation remain.

Vertisols are very clayey soils that shrink and swell upon drying and wetting. They have deep wide cracks that open to the surface when the soil is dry, but close when the soil wets up, usually in the wet season. These soils show evidence of shrinking and swelling throughout the profile. Many have dark surface horizons high in organic matter, although this is not a
SOILS OF HUMID MID-LATITUDE LANDSCAPES

defining characteristic. Vertisols form in neutral to alkaline parent materials that are either clayey initially, such as clayey sedimentary rocks or clayey alluvium, or that weather to clayey soils, such as mafic igneous rocks and volcanic ash. The shrinking and swelling of Vertisols damages houses, roads, and other types of infrastructure. Most Vertisols supported grasslands prior to cultivation and many remain under pasture today; when cultivated they are difficult to manage because the smectitic clays are sticky when wet and hard when dry. Vertisols make up about 3% of the land area of the humid mid-latitude soils (Table 3). The largest areas of Vertisols are on the Gulf Coastal Plain of North America, the Indian subcontinent, and eastern Australia, with smaller areas occurring in southern South America, southern Africa, and China (Figure 1b).

Histosols are soils that consist of approximately 50 cm or more of organic soil materials, such as peat and muck. They form in areas where organic matter accumulation exceeds organic matter oxidation. This situation occurs in areas that are saturated with water throughout much of the year, which is particularly common in cool, humid climates where precipitation frequently exceeds evapotranspiration. Histosols are most extensive along the northern fringes of the humid mid-latitudes, where they are associated with Spodosols in Canada and on the Scandinavian Peninsula (Figure 1b). Most of these areas of Histosols are in their natural state. Smaller areas of Histosols occur scattered throughout the upper Great Lakes Region of the United States, northern Europe, and western Russia, where they occur in association with Alfisols, and some Histosols occur in wetlands along the Atlantic and Gulf Coasts of the United States. Many of these areas have been drained for agriculture or forestry, while some are harvested for horticultural potting materials or mined for heating or electricity generation. Histosols store large amounts of reduced carbon and their use usually results in oxidation and release of carbon into the atmosphere.

Andisols are soils that have formed in volcanic materials such as tephra. Rapid weathering of the volcanic materials like glassy ash, pumice, and cinders results in the formation of poorly crystallized, high surface area, short-range-ordered minerals such as allophane, imogolite, and ferrihydrite that impart unique chemical and physical properties to these soils. For example, some Andisols may hold up to 200% or more water on a dry weight basis, and have a high capacity to fix phosphorus added as fertilizer. Nevertheless, Andisols that occur in the humid mid-latitude area are generally highly productive soils for agriculture and forestry. Andisols occur in volcanically active areas throughout the world at the edges of tectonic plate boundaries. They are common at various locations around the Pacific Rim, in Iceland, and in parts of Italy, but, because they make up only 1.2% of the humid mid-latitude soils (Table 3), they consist of only a few, barely visible areas on small-scale maps (Figure 1b).

Aridisols are the typical soils of arid regions. Their presence as up to 2% of the area of the humid mid-latitude soils (Table 3, Figure 1b) may be the result of cartographic error. Aridisols, however, can occur outside of arid climates if they contain a salic horizon, which is a horizon that is high in soluble salts. The dissolved salts in the soil water result in osmotic stress to plants like that of otherwise drier soils.

Oxisols are the world’s most highly weathered soils. They have low amounts of weatherable minerals and low inherent fertility and are typically associated with old, stable land surfaces in tropical climates. They are defined by their chemistry and mineralogy, not their climate. Thus, some Oxisols in the southern Brazilian states of Santa Catarina and Rio
Grande do Sul (Figure 1b) occur within the humid mid-latitudes as defined above, but they make up only 0.5% of the total area (Table 3).

Mineralogy of humid mid-latitude soils

Except for Ultisols and Oxisols, which together make up 10% of the humid mid-latitude soil area, the soil orders that cover the remaining 90% of the humid mid-latitude area (Table 3) are generally rich in weatherable primary minerals. These minerals are inherited either directly from the weathering of the igneous and metamorphic rocks themselves, or after previous cycles of erosion and re-deposition by water, wind, or ice.

The great majority of these weatherable primary minerals are the common minerals that make up most igneous and metamorphic rocks, for example, olivine, pyroxene, amphibole, mica, and feldspar group minerals, along with quartz. These minerals formed at high temperatures, and often at high pressures, either by the cooling and crystallization of a magma, or by metamorphism, usually deep below the Earth’s surface. They are far from thermodynamic equilibrium in the aqueous soil environment at the Earth’s surface. Thus, they slowly decompose and release their constituent elements to the soil. Primary minerals occur mainly in the sand (2 mm–50 μm) and silt (50–2 μm) size fractions. The majority are aluminosilicate minerals made up mainly of oxygen, aluminum, and silicon, with the remaining naturally occurring elements occurring in lesser quantities. As primary minerals weather, they release most of the nutrient elements (Ca, Mg, K, P, S, Fe, Mn, B, Zn, Cu, Cl, Co, Mo, and Ni) needed for plant growth, as well as the additional essential elements required by animals. Thus, in general, the presence of weatherable minerals is associated with young and productive soils, particularly when additional nutrient inputs are minimal.

The mineralogy of the clay fraction (<2 μm) also plays a critical role in defining the properties of humid mid-latitude soils and, with some exceptions, most humid mid-latitude soils have clay fractions with high surface areas and, thus, high chemical activity potentials. In all soils, clay minerals form from the elements released by the weathering of primary minerals. The majority of the clay minerals present in many soils, however, reflect the complex history of the parent materials from which the soils formed, as much as they do the current pedological conditions. Nevertheless, some generalizations are possible.

First, phyllosilicate clay minerals tend to be the most abundant secondary minerals in soils of the humid mid-latitude regions. The 2:1 phyllosilicates, represented mainly by smectite, vermiculite, clay-sized mica or illite, and various intergrades between these end member minerals, tend to be the most abundant clay minerals in Alfisols, Mollisols, Inceptisols, Entisols, and Vertisols. These 2:1 phyllosilicates have a net negative charge on their layers that is balanced by divalent and monovalent cations, predominately Ca$^{2+}$, Mg$^{2+}$, K$^+$, and Na$^+$, along with smaller amounts of other cations, that are loosely held and can be exchanged for other cations. The high surface area and net negative charge of 2:1 phyllosilicates results in the high cation exchange capacities (or nutrient holding capacity) that are common in humid mid-latitude soils and explains why these soils are highly productive. Alfisols, Mollisols, Inceptisols, and Entisols often have a mixed clay mineralogy in which no one phyllosilicate mineral predominates. Vertisols, on the other hand, are characterized by high contents of smectitic clay. The swelling and shrinking of the smectitic clay at the molecular level as it wets and dries imparts the macroscopic properties
SOILS OF HUMID MID-LATITUDE LANDSCAPES

that define the Vertisol order, namely, slickensides and deep, wide cracks when the soil is dry.

The 1:1 phyllosilicates, mainly kaolinite and halloysite, make up the other major group of phyllosilicate minerals. Kaolinite and halloysite have very low charge on their layers and, as a result, they have very low cation exchange capacities and little ability to hold nutrient elements against leaching. Thus, soils dominated by these types of clay minerals often lose fertility over time. The clay fraction of both Ultisols and Oxisols are dominantly kaolinite, and thus, both soil orders are inherently less fertile than those rich in 2:1 phyllosilicate minerals.

Poorly crystalline and short-range-ordered minerals such as the minerals allophane, imogolite, and ferrihydrite occur in Andisols. These minerals account, in part, for the low bulk densities, high organic matter contents, high water holding capacities on a dry weight basis, high phosphorus fixation capacities, low cation exchange capacities, and other properties of Andisols that make them unique.

Human impacts on humid mid-latitude soils

Human land use activities are transforming large portions of the Earth’s surface, often at the expense of the environment (Foley et al. 2005). Such impacts can be locally dramatic, such as when surface mining for coal completely transforms a landscape and begins a new cycle of soil formation, or they can be less obvious but perhaps more significant, such as when excess nitrogen and phosphorus from agricultural areas results in eutrophication of lakes and marine environments. Human pressure on the global environment shows no signs of abating. World agricultural production will need to roughly double in the future to keep pace with population growth, changes in diet, and increased use of bioenergy (Foley et al. 2011), placing increasing pressure on the environment in general, and soils in particular.

Agricultural land uses occupy about 38% of the Earth’s land surface, with about 12% in croplands and 26% in pastures, making agriculture the largest use of land globally (Foley et al. 2011). Almost one-quarter (22.5%) of the land area of humid mid-latitude soils is in cropland, while 12.3% of the land area of tropical soils, and 6.8% of the land area of arid soils, is cropped (Table 2, Figure 1b). Additional expansion of agriculture by extending croplands and pastures to new areas still in natural ecosystems will have serious impacts in reducing biodiversity, increasing greenhouse gas emissions, and depleting ecosystem services. Most of the recent expansion and resulting environmental impacts have occurred in tropical areas, while adding relatively little to the global food supply (Foley et al. 2011). Rockström et al. (2009a, 2009b) suggest that croplands should occupy no more than 15% of the Earth’s ice-free land. Most of the recent gains in agricultural production have been achieved through intensification of agriculture by managing lands to be more productive by using fertilizers, irrigation, and biocides, and by mechanization and improved management practices (Foley et al. 2011). Much of this intensification has occurred on soils of the humid mid-latitudes, and this trend is likely to continue.

The amount of fertilizer applied to crops is one measure of how intensively soils are managed for agriculture. Using this metric, humid mid-latitude soils clearly stand out (Figure 1e). The mean rate of nitrogen fertilizer application for humid mid-latitude soils is 2.68 kg ha⁻¹, roughly five times the mean fertilizer application rates for humid tropical soils and arid soils (Table 2). Rates for phosphorus fertilizer
show similar trends (Table 2). Regions with the most highly fertilized soils include eastern China, northern India, Western Europe, and the Midwestern United States. These high rates of fertilization result in high crop yields, but not without environmental costs. Loss of nitrogen and phosphorus through runoff or leaching to surface or groundwater results in the eutrophication of lakes and marine ecosystems, with serious human and ecological consequences.

Agriculture is the largest source of excess phosphorus and nitrogen in waterways and coastal areas (Foley et al. 2005). Rockström et al. (2009a, 2009b) argue that the flow of new reactive nitrogen into the environment has already greatly exceeded its “planetary boundary,” and suggested that this flow should be limited to 25% of its current value. As a start, targeting “hotspots” of low fertilizer use efficiency could significantly reduce nutrient pollution from intensive agriculture. Roughly 32% of the global surplus of nitrogen and 40% of the global surplus of phosphorus come from only 10% of the world’s croplands (Foley et al. 2011), and most of these losses occur from soils in the humid mid-latitudes. The challenge will be to develop and implement sustainable agricultural systems that reduce nitrogen and phosphorus runoff and leaching from agricultural soils, while still maintaining high levels of production.

Conclusions

Defined by the broad forces of geology that made most humid mid-latitude soils geologically young and inherently fertile, and climate that has provided the moisture and temperature conditions conducive to agriculture, soils of the humid mid-latitudes have supported human civilizations for thousands of years. Because of the great variety of parent materials and climates across the humid mid-latitudes, soils here display remarkable diversity. The challenge in the future will be to sustainably manage these soil resources so that they continue to provide the food, fiber, fuel, shelter and other resources for a still growing population, while preserving and enhancing their ability to provide equally essential ecosystem services.

University of Savoy, France

Characteristics of mountainous landscapes

Mountain areas cover, depending on which definition is applied, roughly between 22 and 27% of the Earth’s total land area (Grabherr and Messerli 2011). A common definition of mountains is highlands and elevated ice shields above 2500 m, along with hilly areas below this altitude. Mountain areas play an essential role for life on this planet, but they also have vulnerable ecosystems that are complex and fragile. Soils are intimately linked to these ecosystems and consequently exhibit similar traits. This vulnerability – or the rate and direction of change – is fundamentally dependent on the composition of the parent material in which the soils are developing, as affected by the five soil-forming factors. Although not new, the principle that soils are a function of independent state factors such as time, climate, topography, vegetation, and parent material has become widely accepted, and it highlights and helps us to understand soil formation and the problems of soil wastage better (Figure 1).

Mountain landscapes are generally associated with relatively steep slopes that have a high energy potential. Furthermore, mountains frequently exhibit a high variability of forms. Morphodynamic processes related to the high-relief energy create specific habitats such as screes, landslides, and avalanches that further contribute to the richness of species and landscape elements. Owing to the great differences in environmental conditions within relatively short distances, mountain areas are often hotspots of biodiversity. The wide variety of areas at different elevations gives rise to the coexistence of several major climate zones and biomes from the mountain base to the summit. These altitudinal vegetation belts (orobiomes) that follow the climate zones, show the types, habits, and strategies of plants that are adapted to a particular water and energy balance (Burga, Klötzli, and Grabherr 2004). The following altitudinal sequence can usually be observed in many mountains: footslope (planar-collineate), montane, alpine, nival, or glacial zones (Figure 2). Along such an altitudinal sequence, the soil characteristics are clearly determined by the changing climate and vegetation.

Only geologically young (i.e., formed during the alpine orogeny; 100 Myr BP to present) areas actually occur as high mountains. Examples include the Himalayas, the Rocky Mountains, the Andes, the New Zealand Alps, and the Alps (Burga, Klötzli, and Grabherr 2004). A large part of the variscan (ca. 400–280 Myr BP) and Caledonian (ca. 570–390 Myr BP) mountains were eroded and smoothed during the Paleozoic and Mesozoic eras. Examples of the variscan high mountains are the Scottish highlands, the northern Appalachians, southeastern Australia, Newfoundland, eastern Greenland, and so on. Examples of mountains produced by the Caledonian orogeny are the Urals, southern Appalachians, north-eastern Australian mountains, and many others (Burga, Klötzli, and Grabherr 2004). The alpine orogeny occurred during the Cretaceous and Tertiary periods and is still ongoing in many places. These mountains reach relatively high altitudes, have steep slopes, and have a high potential for erosion. Landslides,
rock falls, debris flows, or avalanches are typical geomorphic processes in young, high mountains. Clearly, the age and type of the mountains has a strong influence on their ecosystems and soils.

A number of climate characteristics in mountain areas reflect regional or even local, rather than global, patterns. This climatic setup complicates explanations of mountain ecosystems and soils. Consequently, a typical mountain climate does not exist (Burga, Klötzli, and Grabherr 2004). Nonetheless, some generalities about mountain climates can be provided. With increasing altitude, temperature decreases in all mountain systems. The lapse rate of atmospheric temperature varies in general between 0.4°C in the more continental climate regions and 0.8°C per 100 m in the more oceanic regions. A decrease of 0.6°C per 100 m seems to be the best estimate for both temperate and tropical mountains. Mountain belts also experience considerable fluctuations in temperature between day and night, with frequent night frost at high elevation sites in tropical as well as in temperate zone mountains. The snow regime and distribution helps to prevent soil and plant exposure to these low temperature extremes. Winds also impact mountain climates because of their potential cooling, warming, and desiccating effects.

Figure 1 Model of the process interplay among mountain soils, in relation to soil formation processes and factors of soil formation with a given parent material.
Soils of Mountainous Landscapes

The amount of precipitation and its annual distribution are important for plant growth. The most common observation in mountain areas is an elevational increase in precipitation. However, in some mountain areas, precipitation tends to increase with elevation, but then to decrease above a mid-altitude maximum (e.g., in some subtropical areas such as Tenerife). Several investigations (e.g., Egli, Norton, and Dahms 2014) showed that the presence of moisture plays a crucial role in soil formation even in cold environments. Periodic extreme moist situations in soils may occur because of snowmelt, which has the same effect as heavy rainfall and results in a rapid passage of soil water. This flush of water produces much increased rates of leaching in soils and regolith.

Mountain soils: processes, evolution, major characteristics, and threats

Slope processes strongly influence the fate and evolution of mountain soils. The mass balance of a soil is the result of the relationship between soil material production and erosion (Figure 3). For all soils, changes in soil material mass can be expressed by (Egli, Norton, and Dahms 2014):

\[
\frac{\partial (\rho_w h_w)}{\partial t} = \rho_r Q_{UA} - \nabla \cdot (\rho_w \vec{Q_D})
\]

\[
= \phi - \nabla q_e - \nabla q_w
\]

(1)

where \(\rho =\) bulk density (\(w:\) soil; \(r:\) parent material), \(h_w =\) soil material thickness, \(Q_{UA} =\) soil material mass production rate per unit area, \(Q_D =\) denudation mass flux rate per unit area,
SOILS OF MOUNTAINOUS LANDSCAPES

Figure 3 Schematic overview of the evolution of a soil profile. Symbol $e$ refers to the interface between bedrock (or parent material) and soil; $h$ is soil thickness. The transformation rate is given by $P_{\text{soil}}$. $A$, $E$, and $W$ correspond to atmospheric input, erosion, and chemical weathering (solute output), respectively. Reproduced from Egli, Norton, and Dahms, 2014. © Elsevier.

$\phi = $ soil production rate, $q_e = $ soil erosion rate per unit area, and $q_w = $ chemical weathering rate per unit area. Due to steep slopes and in many cases extreme climate conditions, mountain soils may experience particularly high rates of erosion and chemical weathering and, consequently, production rates.

In mountain soils, chemical and physical weathering and mineral transformation contribute to progressive soil development, whereas erosion and deposition of unweathered materials lead to regression. In general, erosion leads to a rejuvenation of the soil surface by exposing less-weathered minerals, enhancing chemical weathering. Changes in soil-forming factors in mountain soils, across space, might be very abrupt, either by catastrophic and natural events or by the influence of humans (land-use change, intensification of agriculture). Thus, on a spatial level, mountain soils often show a high variability within very short distances. Soil evolution is, thus, best regarded as discontinuous over time and conceptualized by “progressive” or “regressive” process phases (Johnson and Watson-Stegner 1987). Because of the sloping nature of mountains, their soils are prone to lateral fluxes of water, matter, and solutes between soils. This tendency leads to strong dynamics in the spatial extension of soil domains.

The active nature of erosion and accumulation gives rise to the existence of (i) thin and constantly rejuvenated soils in the erosion zone and (ii) thick soils in the accumulation areas. Such events may lead to the successions of paleosols in the latter (Figure 4).

Due to geomorphologic activities and the minimal human impact, many mountain landscapes offer unique opportunities to study and model soil development pathways and rates. Chronosequences are particularly useful for estimating rates of soil formation and weathering (e.g., Föllmi et al. 2009) as well as for ecosystem development.

Because of their young age and high rock fragment content (Figure 4), mountain soils have

Figure 4 (a) A soil showing several buried paleosols, in the Anterne catchment, French Alps, 2100 m above sea level (photo J. Poulenard). (b) Typical soil in the Italian Alps, having a relatively high content of rock fragments (Entic Podzol (Episkeletic)). Photo reproduced with permission from M. Egli.
long been considered weakly developed. To many, weathering seemed to be almost nonex-
istent. However, recent studies have shown that soil formation and weathering rates in moun-
tainous areas – even in cold alpine regions – can be very rapid. Studies in mountain regions
have demonstrated that young soils weather intensively, even in areas of continuous seasonal
snowpack (Egli, Norton, and Dahms 2014; Figure 5).

Data on physical erosion and weathering
rates in mountainous regions have become
more widely available through cosmogenic
nuclide techniques (e.g., Riebe, Kirchner, and
Finkel 2004). Surveys in mountain areas using
cosmogenic nuclides ($^{10}$Be) and the chemical
depletion factor have indicated that physical ero-
sion and chemical weathering are, to a certain
extent, coupled (Riebe, Kirchner, and Finkel
2004; Dixon, Heimsath, and Amundson 2009;
Figure 6). Beryllium-10–derived estimates of
soil production and erosion rates show that
soil production rates increase with increasing
catchment-averaged erosion rates, a relationship
that enhances soil-cover persistence. A transition
to landslide-dominated erosion in steeper, more
rapidly eroding catchments results in thinner,
patchier soils and rockier topography.

Although subject to controversy, there are
increasing amounts of evidence that soil mois-
ture (rather than temperature) controls the
rate of soil formation in mountains, and that
this relationship holds even in cold alpine
environments (see e.g., Egli, Norton, and
Dahms 2014). As a consequence of microcli-
matic differences, more water is available in
soils with northern exposures (in the north-
ern hemisphere). Due to cooler conditions at
north-facing sites, evapotranspiration is lower
there and as a result soils may dry out more
slowly. This leads to a higher amount of water
percolating the soil and, subsequently, a higher
net export of elements. Weathering rates of
silicates depend on the action of water (together
with dissolved acids and organic and inorganic
ligands) on minerals. At north-facing alpine
sites more organic ligands seem to be present in
the percolating water, and these stimulate the
leaching of elements from soils and enhance
mineral dissolution and transformations. Con-
sequently, soil formation proceeds faster and
weathering processes are often more intense
on north-exposed slopes, even in cold alpine
environments.

Similarly, soil biological properties are influ-
enced by aspect. Although soil biota usually
show complex responses to environmental
settings, several differences in soil biological
properties can be related to local thermal dif-
ferences, caused by differences in aspect. Ascher
et al. (2012), among others, found that species
richness of microannelid assemblages was higher
under warmer conditions (south exposure; lower altitude) in alpine areas and that micro-
bial biomass (total phospholipid fatty acid) was
higher at cooler sites. Lower decomposition rates
were detected at cooler sites resulting in a lower respiratory loss and accumulations of weakly decomposed organic materials.

Organic matter is the most active and vital component of these soils because of its role in chemical, physical, and biological processes. Very high carbon stocks and sequestration rates can be found, even in (young) mountain areas (Figure 7); common carbon stocks values for the Alps range from 20 to 25 kg C m$^{-2}$. But these partially high stocks are under threat due to climate and – often increasing – land-use changes. The sequestration rates of organic C and N in soils of the European Alps, the Rocky Mountains (Wind River Range) and many other areas can reach very high values in young soils (up to 10–100 g m$^{-2}$ year$^{-1}$ for C and 0.5–5.5 g m$^{-2}$ year$^{-1}$ for N), whereas in old soils ($>20$ kyr) sequestration rates are several orders of magnitude lower ($<1$ g C m$^{-2}$ year$^{-1}$ and 0.01 g N m$^{-2}$ year$^{-1}$, respectively).

It is known from palynological and pedoanthracological studies that the altitudinal belts of vegetation in the mountains have shown considerable variations during the Holocene for reasons related to climate changes and/or in connection with human activities and land-use change. Studies of paleosols (Figure 4), soil charcoal, or lacustrine sedimentary archives (Mourier et al. 2010) have confirmed the succession of progressive (especially during the first part of the Holocene; Figure 8) and regressive phases of soil genesis phases in these mountain areas. In the European Alps, the tipping point between the two phases seems to be between 5000 and 2500 year BP and coincides with a stronger
human impact (agricultural use) on mountain environments.

In large parts of the mountainous landscape, grazing is the main traditional, human-induced, land-use activity. The distribution of pastural herds during periods of summer has significantly impacted the nutrient reserves in the soil and the spatial distribution of soil properties. There are, thus, very strong spatial variations in nutrient stocks in soils (predominantly P and N but also K, Ca and Mg) across mountains. High nutrient stocks are encountered when the contributions from animal droppings are higher than can be exported. In some areas, this situation can even lead to a dominance of nitrophilous plant species when the conditions are extreme. In areas where

Figure 7  Average carbon and sequestration rates (over the time considered of each single profile) in alpine areas. Reproduced from Egli et al. 2012. © Elsevier.
Figure 8 A conceptual soil evolution model (upper), showing progressive and regressive phases (Johnson and Watson-Stegner 1987), as compared to the dominant soil evolution pathway in the subalpine belt during the Holocene (lower). The model was developed by the author, from lacustrine sediment data. Created by author, using data from Johnson and Watson-Stegner 1987.
the output of nutrients (due to grazing) is higher than the input, nutrients are depleted from the soils. As a consequence, strong acidification occurs in these soils. Such spatial differences are much more pronounced in naturally acidic environments (crystalline rocks) than in environments having calcareous parent materials.

Mountain soils play a major role in the functioning and conservation of unique ecosystems and the hydrology of mountain belts. Thus, a change in alpine soil properties due to land use can raise concerns about their fertility and associated services. Traditional, human-made alpine pasture near the tree line has been common in mountainous regions for at least 7000 years. In parts of Europe, the abandonment of such pastures is starting to affect soil dynamics. In many other parts of the world, mountain soils are subjected to increasing grazing pressure, which leads to a rapid degradation and erosion. Acid deposition is another important threat to mountain soils in regions with silicate parent material and low buffering capacity. High mountain ecosystems are furthermore considered to be particularly sensitive to climate change. Overall warming and associated changes in precipitation patterns and snow cover will distinctly influence mountain vegetation as well. Climate change can influence both carbon balance (C mineralization versus C sequestration) and mineral balance (weathering versus erosion), although its effect is still not clear. Lastly, heavy rainfall events (due to global warming) will likely become more frequent, and erosion of mountain soils is likely to be enhanced in the future.

Soils of the United States

Patrick J. Drohan
Pennsylvania State University, USA

The diversity of US soils (Figure 1) is arguably one of the nation’s most important assets. This is especially so given the commodities produced from soil and the influence of soils on the nation’s social, economic, and political history. The genesis of soil is the result of many surficial processes, some acting independently but many working synergistically, with erosion/deposition, biocycling, pedogenesis, and, recently, the actions of humans being key drivers of soil development and change.

Understanding soil distributions necessitates a larger and more holistic understanding of landscape evolution through time. Soil genesis, or pedogenesis, is typically first dependent on the parent material from which soil forms. The resulting soil horizons reflect the degree that other soil-forming factors (climate, time, topography, and organisms; Jenny 1941) and processes (additions, removals, translocations, and transformations; Simonson 1959) have had on the parent material. These concepts are used widely by academics and within the US Soil Survey program. They emphasize dominant differences in the state factors of soil, and the resulting effects that these state factors have had on soil morphology (color, texture, structure, etc.; see Figure 2).

A hierarchical classification system, Soil Taxonomy (Soil Survey Staff 1999), uses our accumulated knowledge of pedogenic processes to place the various soil morphologies into categories with similar pedogenic backgrounds (Table 1). Although all soil-forming processes are potentially active anywhere on Earth, their effect on pedogenesis can be limited by the complex interaction of the soil-forming factors. For example, translocation of soil materials downward in the profile is greatly limited in Gelisols, in comparison to other soil orders, owing to the cold climate where Gelisols occur. However, such processes are very common in many other soil orders.

Since 1894, when the United States Department of Agriculture (USDA) created the Division of Agricultural Soils, the United States has led the world in mapping and interpreting soils, in soil conservation, and in improving agricultural productivity based on soil science. Nearly all US soils have been mapped in considerable detail, and hundreds of thousands of soil samples have been analyzed by the federal government, land-grant universities, and other academic institutions. This effort has resulted in greater understanding of soil-forming processes and how they (and the resulting soils) vary across the landscape.

The Soil Survey was developed from a need to better support and guide agriculture, and thus in most instances their data products include soil information derived from a depth of only a meter or two. In addition, the complex nature of soil genesis has often been simplified so that the products can be effectively used by conservation agencies and the public. However, the reality of soil genesis is that virtually all soils are far thicker than depicted in the Soil Survey, and most soils are polygenetic in origin, having resulted from multiple periods and processes of soil formation.

Regional trends in soil characteristics across the United States

The size of the United States and its complex topography can make conveying soil patterns based solely on abiotic variables such as temperature or precipitation challenging. Nonetheless, the effect of climate on soil is described in part by the Soil Survey via soil moisture and temperature regimes (Figure 3; Figure 4). These data are also used at various categorical levels in Soil Taxonomy and infer conditions affecting soil development and agricultural practices. Soil moisture regimes describe classes of soil moisture conditions, whereas soil temperature regimes describe classes of soil temperature.

As one moves from the colder and wetter regions in northeastern North America (Figure 2) to the warmer, drier southwest deserts (Figure 4), the effects of precipitation and temperature on vegetation and soil morphology change. Climatic conditions limit aboveground vegetation in northern latitudes; hence, permanently frozen soils with weak development (Gelisols) are common (Table 1). Gelisol subsoil horizons may be frozen (Cf horizon) or mixed by freeze–thaw processes (Bwj horizon). Farther south, coniferous vegetation becomes common, in addition to young, sandy soils
formed in sediments deposited by Pleistocene glaciers. Cold temperatures and precipitation totals that exceed evapotranspirative demand in these soils often result in rapid, deep leaching and eluviation of soluble substances and clay minerals (Figure 2). Excessive leaching in an environment with few base cations (Ca, Mg, etc.) often leads to the development of acidic soils known as Spodosols (Table 1). Spodosols have a subsoil horizon with high contents of organic matter, aluminum, and often iron (Bs or Bhs horizons). Inceptisols (Table 1) can be common in such areas too, but they often occur on more unstable landscapes, on resistant parent materials, or where soil formation is somehow limited. The limited time of soil development results in weak color changes or soil structure development (Bw horizons) relative to parent materials (Figure 1).

Moving toward the east central United States, many soils had more time to develop on the older landscapes. Hence, subsoil clay and iron accumulations are greater (Figure 2). Warmer temperatures have increased the rates of chemical reactions, aiding weathering reactions and producing more clay minerals. Precipitation is less than at the northeast end of the transect; this difference in precipitation results in dry
periods of the year that allow for the stabilization of weathering products transported via soil water. Stabilized weathering products accumulate in the subsoil in the B horizon as secondary silicates and iron/aluminum oxides, that is, clay minerals (Bt or Btx horizons). Clay-rich, often reddish-colored, soils that have not been extensively weathered are Alfisols. Where leaching has been excessive or the parent material was low in base cations to begin with, Ultisols form (Table 1).

In the Midwestern United States, near the 100th meridian, precipitation totals drop further (Figure 4). Vegetation changes from forest to mostly grassland. The high belowground organic matter production from grassland environments that preceded modern agriculture has resulted in thick, dark A horizons rich in organic matter (Figure 2), typical of Mollisols (Table 1). Because precipitation can still exceed evapotranspiration, especially in the eastern parts of the region, carbonates (Bk horizons) and salts do not persist in the upper soil profile. Instead, they are leached to the subsoil or to the water table. However, west of the 100th meridian, decreasing amounts of precipitation result in carbonates becoming more common at increasingly shallow depths.
Figure 4  (a) Soil moisture and (b) soil temperature regimes in the contiguous United States (see SCS 1994 for an explanation of classes; see also Newhall and Berdanier 1996).
SOILS OF THE UNITED STATES

Across the far southwestern section of the transect (Figure 2), soil moisture deficits are common, as the climate becomes increasingly desert-like. Exceptions occur at higher altitudes, which are cooler and wetter. Entisols, Aridisols, and Mollisols are common orders across this section of the transect (Figure 1; Table 1). Relative to other portions of the United States, the limited precipitation and associated leaching result in high concentrations of salt and/or carbonate precipitates at the surface and in the subsoil (Bkk or Bkm horizons). Soils here can also contain substantial amounts of ash from past volcanic eruptions, which can persist in a relatively unweathered state because of the dry conditions. Vegetation in the southwestern United States has evolved to tolerate dry conditions and/or soils dominated by salts and carbonates. Where vegetative production is high, organic matter can accumulate in the soils, but not to the extent one finds in the central United States, under grassland or even forest. In this area, like many others, increasing altitude often results in a sequence of soils and vegetation similar to moving north in latitude.

Landscape evolution and its influence on the distribution of US soils

We begin by examining the distribution of lithologies and geomorphic surfaces on which soils form, using the United States Geological Survey (USGS) physiographic divisions and provinces as a guide (Fenneman 1928; Fenneman and Johnson 1946) (Figure 5). The states of Alaska and Hawai‘i will be examined separately.

Appalachian Highlands division

The Appalachian Highlands (Figure 5; Table 2) are dominated by sedimentary rock from
Pennsylvania south across the division, and crystalline rock from New England through the Piedmont and Blue Ridge provinces (Fenneman 1928). The division’s northern end (roughly bisecting Pennsylvania and the upper half of New Jersey) has experienced numerous glaciations, with the effects of the last glaciation still evident (Ciolkosz et al. 1989). North of the glacial boundary, till, outwash, and loess are common parent materials, and many soils are wet owing to high water tables. Moving south along the region’s major tributaries that were fed by Pleistocene glaciers (the Susquehanna and Delaware rivers, for example), outwash and loess become the most common parent materials. Virtually all backslopes and footslopes in the division are mantled by mass weathering deposits known as colluvium (Ciolkosz et al. 1979). The division’s soil moisture regime is mostly typic udic with some aquic areas in lowlands. The soil temperature regime is thermic in the south, mesic in the center of the division, and frigid in the north (Figure 4).

Throughout the Adirondacks and New England (Figure 5), the effects of glaciation are ubiquitous. Glacial sediments are thus the primary parent material. An exception is in the Adirondacks where, mainly due to glacial erosion, igneous and metamorphic rocks of the Canadian Shield are exposed (Fenneman 1928). Spodosols are common in these provinces, especially on sandier sediments. Inceptisols occur on terraces, steeper slopes, resistant parent materials, or where bedrock is shallow. Entisols occur on the least stable landscapes (floodplains, very steep slopes) or very sandy parent materials. Histosols are common in very wet areas such as bogs and swamps. Forests cover much of the region, but pasture and some row crop agriculture are other land uses (USDA–NRCS 2006).

Across the Appalachian Plateau, Blue Ridge, and Piedmont provinces (Figure 5), Inceptisols, Ultisols, and Alfisols are the most common soil orders. Inceptisols occur on backslopes in colluvium and along floodplains, that is, on young landscapes. Ultisols can form on stable backslopes and footslopes, or in valley locations. Ultisols in this area form on base cation-poor, or very weathered, parent materials. Alfisols have also formed in lowlands, but from parent materials that are base cation-rich, such as limestone or calcareous shale, weakly metamorphosed or crystalline rocks, and some glacial tills in the north. Spodosols have formed on stable Appalachian Plateau landforms in sandy soils, and where precipitation drives deep leaching in porous materials. Timber production is extensive on the Appalachian Plateau, but there is also a mineral resource extraction economy and some row crop and pasture agriculture. Across the Blue Ridge and Piedmont provinces, row crop and pasture agriculture are more extensive. Recreation is a common land use in both provinces (USDA–NRCS 2006).

Atlantic Plain division

Along the Atlantic Plain (Figure 5; Table 2), soils have formed largely in sediments eroded off the continent. However, along the Mississippi River, thick and extensive loess deposits can be found. The soil moisture regime inland is typic udic, but aquic conditions occur near coastal areas, along some major rivers, and on low relief areas of uplands (Figure 4). The soil temperature regime is mesic in the north of the division, thermic in the south central, and hyperthermic in the south (Figure 4). Because many soils have poor drainage, organic materials accumulate, resulting in the formation of Histosols. Entisols occur on young deposits along floodplains, and on unstable beach deposits. Adjacent areas of higher elevation have a cover of Inceptisols and Mollisols. Mollisols, derived under former

soils of the united states

grasslands, are most extensive across Florida, and currently produce a wide variety of agricultural crops. The division’s Spodosols occur in very poorly drained to moderately well-drained conditions, and dominantly in sandy but wet parent materials (Harris 2000). Where sediments are less sandy and time has allowed for more weathering, clay minerals have accumulated in B horizons. Such soils fall within the Alfisol and Ultisol orders and often occur on terraces or wet areas of floodplains or depressions. Ultisols occur inland on stable landscapes that are old and weathered, or on base cation-poor parent materials. Alfisols form on base cation-rich sedimentary rocks, provided the mineralogy does not have the shrink–swell capability of Vertisols. Vertisols are common in the southwest of the division, where clay-rich, calcareous parent materials occur, commonly derived from sedimentary rock or unconsolidated sediments. The mineralogy of these parent materials imparts a high shrink–swell capacity to the soils, as they dry and wet, respectively. Where soils are not too wet, crop production is diverse (corn, sorghum, cotton, bean, rice, hay, truck crops, and citrus). Rangeland is present in the southwestern parts of the division, and timber production is extensive in the south and southeast (USDA-NRCS 2006).

Interior Highlands division

The Interior Highlands (Figure 5; Table 2) is a remnant of the Ouchita–Ozark Highlands; the northern end of the division is the Ozark Plateaus province and the southern end is the Ouchita province. The division’s topography originates from the dissection of an old plateau, resulting in slight to steep relief. Carbonate and sedimentary rock (sandstone and shale) predominate. Although soils are often residual and, hence, relate closely to their local lithology, soils in the northern Ozark Plateaus province often have formed in 1–5 m loess that was derived from the Missouri and Mississippi rivers or their major tributaries (Bettis et al. 2003).

The division as a whole has a typic udic soil moisture regime, and in general spans the boundary between mesic and thermic soil temperature regimes (Figure 4). Across the Interior Highlands, approximately half of soils are Alfisols (most in the Ozark Plateaus province) and half Ultisols. Alfisols and Ultisols have formed on stable landscapes underlain by limestone and cherty limestone. Mollisols occur in the western or southwestern sections, on terraces or broad open meadows within forests. Deciduous forest predominates here, but coniferous forest can be found at high elevations. Agriculture is most successful where topography is least limiting; hence, pasture (versus cropland) is the more common agricultural practice (USDA-NRCS 2006).

Interior Plains division

The Interior Plains (Figure 5; Table 2) form an extensive portion of the conterminous United States, including the Great Plains, Central Lowlands, and the Interior Low Plateaus. The division as a whole has low relief (except near river valleys) and consists largely of sedimentary rocks derived from sediments eroded off the Rocky Mountains to the west, and the Appalachian Mountains and Ozark–Ouachita Mountains to the east and south, respectively (Fenneman 1928). The Interior Low Plateaus has the most varied relief, with steep to gently rolling topography. Because it was never glaciated, its topography is reflective of differential erosion of the sedimentary rocks. The Great Plains province has been extensively glaciated in the very north, as was the upper half of the Central Lowland province. As a result of glaciation, the topography of these two provinces is flatter than
SOILS OF THE UNITED STATES

the Interior Low Plateaus. Loess is an extensive parent material across the division (Bettis et al. 2003; Schaezl and Attig 2013). Great Plains loess deposits can be >20 m thick in Nebraska, along the Iowa–Nebraska border, and along the Mississippi River and its tributaries, but across the Central Lowland and Interior Low Plateaus, these deposits typically are <5 m thick. Across central and northwest Nebraska is the Sand Hills region. This unique area features Quaternary sand dunes derived from the underlying bedrock.

The division’s soil moisture regime varies from typic udic in the east to ustic aridic in the west. The temperature regime ranges from frigid in the north, mesic in the center, to thermic in the south (Figure 4). Mollisols are associated with stable landscape positions where prairie ecosystems existed prior to European settlement. Alfisols have formed on stable landscape positions, typically on sites of former forest and where parent materials are base cation-rich. Ultisols occur on the older soils of the Interior Low Plateaus on stable landforms. Entisols occur where soil-forming materials are young, for example, on floodplains and areas of steep slope. Inceptisols are common on young but stable landscapes. Aridisols occur in the Great Plains province where landforms are stable and the soil moisture regime is aridic. Agriculture is the division’s primary economy and consists of diverse cropland and grassland (USDA-NRCS 2006). Native prairie grassland is much less extensive today than prior to European settlement. Mineral, oil, and gas production are extensive in various parts of the division’s northern and southern ends.

Intermontane Plateau division

The rugged Intermontane Plateau division (Figure 5; Table 2) consists of the Basin and Range province, and the Colorado (Arizona, New Mexico, Colorado, and Utah) and Columbia (Oregon, Washington, and southern Idaho) Plateaus provinces. Topography across the Basin and Range and Colorado Plateaus provinces is the product of tectonic uplift and subsequent erosion, while the Columbia Plateaus province is derived from extensive lava flows. Catastrophic water release from Pleistocene glacial lakes dramatically shaped some of the division’s topography and parent materials. Examples include the breach of Glacial Lake Bonneville (northern Utah), which drained northwest into the proximity of the present-day Snake River of southern Idaho, and that of Glacial Lake Missoula in western Montana, which drained into Glacial Lake Columbia out of northern Idaho into eastern Washington and northern Oregon. This complex geomorphic and geologic history has resulted in soils forming from a variety of materials.

The Columbia Plateau province consists of broad areas of flood basalt, bordered to the west by the Cascade Mountains and to the east by the Rocky Mountains. Most upland soils are shallow to bedrock. Valley alluvial sediments are deep and can be composed of volcanic, metamorphic, and igneous sediment derived from the weathering of the surrounding mountain systems (Fenneman 1928). Loess is extensive along the major river valleys and tributaries of the Columbia River, especially in the Palouse and Nez Perce Prairie areas to the east of the province, and along the Snake River to the south. Glaciofluvial and glaciolacustrine parent materials can also be found. The soil moisture regime is dominantly xeric to xeric aridic, with some small pockets of aquic and typic udic. The soil temperature regime is mostly mesic, but frigid to cryic at higher elevations (Figure 4). Mollisols are common along floodplains and terraces, but most common at high elevations under
SOILS OF THE UNITED STATES

Tree and shrub communities. Aridisols occur on stable landscapes at low elevations where the soil moisture regime is aridic. Smaller extents of Alfisols, Entisols, Inceptisols, and Andisols occur. Alfisols occur at elevations above Aridisols and below that of higher-altitude Mollisols. Although Andisols are not extensive, volcanic ash occurs in varying amounts across the province’s soils. Agriculture is a mix of grazing and cropland, and forest and mineral/gas extraction are also important. Recreation is an important use of forested areas (USDA-NRCS 2006).

Rugged, deeply incised river valleys dominate the Colorado Plateau province. A classic example is the Colorado River’s Grand Canyon. Although sedimentary rocks predominate, volcanic rock associated with lava flows is also common (Fenneman 1928). Like much of the western United States, the province’s soil moisture and temperature regimes vary with altitude. The driest soil moisture regime, typic aridic, is found at low elevations, with soil moisture increasing with elevation (Figure 4). The soil temperature regime is mesic at low elevations and frigid to cryic at higher elevations (Figure 4). Entisols predominate across young geomorphic landscapes but extensive areas of Aridisols are common on stable landscape positions, given the aridic soil moisture regime. Mollisols are found at higher elevations under tree, shrub, and some grass cover. Alfisols occur on stable landscape positions (Table 2) and at higher elevations than Aridisols. The occurrence of Alfisols is, in many places, attributed to a past, wetter period of soil formation, during the Pleistocene. Under the present drier conditions, many of these soils have accumulated calcium carbonate in their B horizons. Much of the region is rangeland used for cattle grazing. At high elevations, forest and shrub cover are more common. Much of the land is used for timber, oil and gas production, and recreation (USDA-NRCS 2006).

The Basin and Range province consists of rugged topography with dramatic changes in elevation, with north–south trending mountains (some with summits >3200 m) and broad valleys of similar orientation. Although sedimentary rocks predominate, volcanic materials are common (Fenneman 1928). During the Pleistocene, a vast system of lakes existed across the province; Utah’s Great Salt Lake is an example of a modern remnant of the former Pleistocene Lake Bonneville. Today, many of these former lakes are dry or ephemeral lakebeds called playas. The province’s basins consist largely of alluvium derived from the adjacent mountains, but in playas, salty lake sediment is found, often covered with isolated sand dunes. Soil development is strongly tied to the age of the landform (Peterson 1981); thus older landforms have older, better developed soils with increasingly rich CaCO3 or Si subsoil accumulations. Soil morphology frequently reflects the former, usually wetter, soil-forming environment.

The Basin and Range province supports several types of deserts; their differentiation is based on differences in moisture and/or temperature, topography, and resulting flora and fauna. Deserts of the province’s southern end consist of the Mojave, Sonoran, and Chihuahuan, and across the province’s central and northern area is the Great Basin Desert. The Basin and Range province’s current soil moisture and temperature regimes vary with altitude. The driest soil moisture regime, typic aridic, is found at low elevations, with increasingly wetter conditions at higher elevations (Figure 4). The soil temperature regime is hyperthermic and thermic at the lowest elevations in the Mojave Desert of southern Nevada and California, and mesic at low elevations in the province’s center. Frigid and cryic soil temperature regimes occur at higher elevations, which along with the additional moisture provided at altitude support
SOILS OF THE UNITED STATES

forest cover more typical of northern locations in Montana, Wyoming, or Idaho. Aridisols make up nearly half of the province’s soils and occur on stable, older landscape positions. Some of the oldest soils in the United States are Aridisols found in the Mojave Desert, on Mormon Mesa near Mesquite, Nevada (Brock and Buck 2009). Entisols are common on unstable, recently deposited sediments across steep slopes, or on floodplains. Mollisols can be found at higher elevations (see Tables 3 and 4, below), where soil moisture is greater and cooler temperatures persist, but they can occur along river systems on terraces or floodplains as well. Alfisols are largely a product of the Pleistocene and occur at higher elevations. Due to the current dry climate, calcium carbonate accumulations are common in the upper B horizons of some Alfisols. At high elevations, Alfisols may currently be forming (Elliott and Drohan 2009). Inceptisols occur at higher elevations or along major river systems on terraces, but lack the marked clay accumulation in B horizons that are common to Alfisols. The province’s Vertisol extent is limited to stable landscapes and base cation-rich parent materials. At low elevation, rangeland for grazing is prevalent, along with oil and gas production, recreation, and some row and truck crop agriculture. At high elevations, forest and shrub cover are more common, fueling timber extraction and recreational land uses (USDA-NRCS 2006).

Laurentian Upland division

The Laurentian Upland division (Figure 5; Table 2) is a low relief area that spans northern Wisconsin and Minnesota; its sole province is the Superior Upland. Nearly the entire division was glaciated during the Pleistocene, and thus most parent materials are glacially derived, unless bedrock is exposed. The area is the southernmost extension of the Canadian Shield, which consists mainly of igneous and metamorphic rocks (Fenneman 1928). Glaciation filled in many former bedrock valleys, resulting in a low relief, rolling landscape. Glacial geomorphology (outwash plains, drumlins, moraines, etc.) and associated parent materials (till, outwash, lacustrine deposits, loess, etc.) set the stage for soil formation across the division, and thus soils that have formed in multiple, stacked, parent materials are common (Schaetzl 1998). The generally level terrain has led to the formation of many areas with wet soils, commonly in bogs and swamps. The division’s soil moisture regime (Figure 4) is mainly typic udic, but aquic conditions are found in lowlands. The soil temperature regime (Figure 4) is frigid. Spodosols are common in the division and form in a number of sandy to loamy parent materials (e.g., alluvium, loess, outwash). Alfisols form across a range of parent materials, textures, and drainage classes, with the one common feature being a stable landscape that has allowed enough time for development of clay accumulations in the B horizon. Unless the parent material consists of finer materials to begin with (e.g., silt-sized loess or glaciolacustrine materials), the clay contents

of soils in this division are lower than in Alfisols typical of the midwestern or eastern United States. Entisols have typically formed in sandy glaciofluvial deposits on floodplains. Inceptisols can occur in loamy deposits on ground moraines or end moraines, but also in sandy deposits on terraces (Table 2). Histosols are found in bogs and swamps (Table 2). Forestry and recreation are the most extensive land uses across the region (USDA–NRCS 2006).

Pacific Mountain System division

The Pacific Mountain System (Figure 5; Table 2) has extensive relief. Tectonic and volcanic activity continues to shape this landscape. Three provinces encompass the division: the Pacific Border (coastal and running north to south), the Cascade–Sierra Nevada Mountains (inland and running north–south), and Lower California in the far south. The Cascade Mountains consist of volcanic rocks, whereas granitic rocks dominate the Sierra Nevada Mountains. Alpine glaciers existed in the Sierra Nevada Mountains during the Pleistocene, with Yosemite National Park being the most prominent example. Glaciofluvial deposits and loess can be found along major rivers, especially the Columbia River. The Pacific Border province (the largest of the three) is very diverse. Along its northern end, in the Oregon Coast Range, volcanic rocks dominate, but sedimentary rocks and marine terraces occur along the coast, and glacial parent materials occur widely around Puget Sound. In the south central part of the province are the California Coast Ranges (generally north–south trending mountains) and the Los Angeles Range (east–west trending mountains). Soils in coastal areas can be formed in weathered sedimentary rocks and/or on marine terraces. Coastal valleys are often filled with unconsolidated coastal sediments or sediments derived from the adjacent mountains. Lithologies are a mix of metamorphic, granitic, and sedimentary rocks (Fenneman 1928). Many soils near areas of volcanic activity have volcanic ash parent materials, and soils near the Columbia River in the northern end of the division can be derived from loess or have some loess influence.

The division’s soil moisture and temperature regimes are complex and generally drier to the
SOILS OF THE UNITED STATES

south, with hot and dry summers throughout (Figure 4). Soil diversity reflects the division’s complicated physiographic history (Table 2). Entisols are on the youngest landscapes and steep slopes. Inceptisols are most common where landscapes are relatively young, for example, on fluvial or colluvial sediments. Mollisols occur in valleys on the coastal side of the division’s mountain ranges. Andisols are found in areas of recent volcanic activity, most commonly in the Cascade Sierra province. Alfisols are far more common than Ultisols and occur on a wide range of base cation-rich parent materials. Ultisols occur mostly in the northern end of the division, in colluvium or residuum derived from sedimentary and basic igneous rocks. Volcanic ash is found in most soils, and most recently came from the eruption of Mount Mazama (presently Crater Lake, Oregon), nearly 7700 years ago.

The division’s soil moisture and temperature regimes are highly diverse and vary greatly across even short distances. Higher-elevation areas tend to be cooler and wetter, and lower-elevation areas drier and hotter (Figure 4). Mollisols are most common where former grasslands existed at lower elevations, or at higher elevation under shrub and tree communities. Inceptisols are extensive across the division’s steeper but stable landscapes, especially in the Northern Rocky Mountains province where clay accumulation has not been extensive. Entisols form on young or unstable landscapes, such as on the steep slopes and floodplains. Alfisols form on base cation-rich parent materials across stable landscapes, and Aridisols are found at the lowest elevations on stable landscapes, but in an aridic soil moisture regime. The division’s soils are frequently influenced by volcanic ash, but not necessarily enough to always result in Andisols. Andisols form where volcanic materials predominate, as in the Northern Rocky Mountains. Some Spodosols occur on sandy parent materials where precipitation is substantial. Rangeland is extensive and hay and row crops can be supported, often with irrigation. Forested areas are important for timber and for recreation (USDA-NRCS 2006).

Rocky Mountain System division

The Rocky Mountain System division (Figure 5; Table 2) is composed of steep, formerly glaciated mountains, often consisting of sedimentary rocks; however, granitic (especially volcanic rocks) and metamorphic rocks are most common. Alluvial sediments and a variety of glacial deposits (lacustrine, till, glaciofluvial, etc.) can also be locally important parent materials. Volcanic ash is found in most soils, and most recently came from the eruption of Mount Mazama (presently Crater Lake, Oregon), nearly 7700 years ago.

The division’s soil moisture and temperature regimes are highly diverse and vary greatly across

Alaska

Alaska has a highly diverse geomorphic history, with both active glaciation and volcanism. Pleistocene glaciers covered many, but not all, areas of Alaska (Fenneman 1928; USDA-NRCS 2006). Where erosion and/or the burial of glacial deposits has occurred, colluvium and alluvium are the main parent materials. Glacial deposits that persist are varied and include lacustrine and glaciofluvial sediment, loess, and till. Holocene volcanic activity has contributed much ash to the landscape, and Holocene wind action has reworked dry stream sediments across the landscape. Glaciers still persist
in Alaska, and permafrost can occur but is typically not continuous. Across the coldest areas, periglacial features, for example pingos, gelifluction lobes, and patterned ground, are common.

Soil patterns across Alaska (Table 3) are perhaps best explained by patterns of temperature, length of winter (Walker et al. 2004), landscape stability, and vegetative production. Gelisols dominate in the far north, where soil processes are severely limited by cold conditions. Permafrost can cause significant cryoturbation, resulting in convoluted subsoil horizons. Where temperatures are not so low and vegetation production is not limited, organic matter can accumulate in soils, leading to the formation of organic-matter-rich Gelisols. Central Alaska’s complex soil temperature regime results in an intermixture of Gelisols, Inceptisols, and Spodosols. Although Gelisols occur in the coldest areas, where permafrost is absent but landscapes are quite young and/or precipitation is limited, Inceptisols dominate. Where precipitation is ample and temperatures support forest across sandy parent materials, Spodosols dominate. Where landscapes are persistently wet and organic matter production is high, Histosols can be found; the colder temperatures help reduce organic matter decomposition. Volcanic activity in southern Alaska can result in Andisols where volcanic ash is dominant. However, where volcanic ash is less prevalent and frozen soil conditions are absent, high precipitation totals, coniferous vegetation, and sandy parent materials result in the formation of Spodosols. Agriculture is diverse but constrained owing to cold temperatures, high precipitation, or terrain. Pasture or hay production is common, but timber production is predominant (USDA-NRCS 2006).

Hawai’i

Hawai’i’s volcanic islands have some of the nation’s most fascinating soils and soil patterns (Figure 1). Despite its small size, Hawai’i contains 10 of the 12 soil orders (Deenik and McClellan 2007). Given that the parent material of the islands is a constant (basalt), climate and topography are the main drivers of pedogenesis. The youngest island, Hawai’i (ca. 500,000 years old), has substantial areas of nonsoil (bare bedrock) owing to recent volcanic activity. Across all the islands, rainfall is highest on the windward – north and northeast – sides, with much less precipitation on the leeward sides. Precipitation also varies with altitude and is typically lower on the coast and increases with elevation (USDA-NRCS 2006).

Andisols are the most common soil order in Hawai’i (Table 4) and form near former volcanic vents. These soils are most common on the younger Hawaiian islands of Hawai’i and Maui (Macdonald, Abbott, and Peterson 1983). Windward or lower elevation areas on several islands sustain higher organic matter production, and if supported by low to moderate precipitation, produce Mollisols. Interestingly, the island with the smallest extent of Mollisols is Hawai’i. Could this suggest a minimum time period for Mollisol establishment? Wet or wet and cool areas of the islands can support Histosols, and the greater the precipitation the more acidic the Histosols tend to be. Many Histosols occur on the island of Hawai’i, over shallow lava flows that perch water. Oxisols can form either on low-elevation dry areas, or on high-elevation wet areas. Oxisols are more common on the older islands. The amount of rainfall determines the amount soil development in Oxisols, and thus, the level of fertility. Older soils are generally less fertile. Entisols are common in coastal areas and develop often from coral limestone. They also are found in drier areas where alluvium is
The soils of the United States are one of the country’s most important resources. It depends on them for food, water filtration, fiber production for clothing and manufacturing, wastewater filtration, and ecosystem support. An increased need for greater crop production and the development of physical infrastructure to meet a rapidly growing human population places substantial pressure on soils worldwide. Although anthropogenic disturbance has not been specifically separated out in this entry as a driver of soil genesis, it is often a dominant soil-forming factor; human actions often result in a change in soil character. A substantial challenge facing the United States will be improved conservation measures to prevent further degradation of soil properties, so as to meet the needs of an ever-growing population.

Soils of tropical landscapes

S.W. Buol
North Carolina State University, USA

All soils perform functions critical to shaping both natural and human ecosystems. They provide a rooting medium to physically support plants. Soils acquire temperature and natural moisture characteristics closely related to the climatic conditions at that location. In addition to carbon, oxygen, and hydrogen acquired from air and water, soils provide the other essential nutrient elements required for physiological functions of plants and animals. Most of these elements, except nitrogen, are derived from minerals in the soil and taken up as inorganic ions. Although plants obtain nitrogen from the soil, it is derived from the air by either micro-organisms symbiotically associated with leguminous plants or free living in the soil. It is available to plants as inorganic ions in the soil as the micro-organisms and plant residues decompose. Many tropical soils contain few nutrient bearing minerals.

Contrasts between tropical and temperate latitude soils: what makes tropical soils unique?

Minimal seasonal variation in soil temperatures is universal throughout soils in tropical latitudes. Only a 6°C or less temperature difference exists between the average soil temperature of June, July, and August and the average temperature of December, January, and February for almost all soils in the tropics (USDA Natural Resources Conservation Service 1999). This nearly uniform soil temperature regime contrasts with temperate latitudes where natural vegetation and agronomic practices have to accommodate much colder winter temperatures and utilize warm summer months for crop production. At the highest elevations in the tropics where mean annual soil temperatures are below 10°C the growing of almost all food crops is precluded. At somewhat lower elevations with mean annual soil temperatures of below about 15°C plants are subject to sporadic freezing, limiting production of many food crops and certain natural species.

A significant proportion, but not all, of the soils in the tropics are formed in materials that have been on the land surface for longer expanses of geologic time than in temperate latitudes. During the extensive exposure to water enriched with organic acids, and repeated cycles of erosion and deposition, almost all of the more soluble minerals have decomposed and their by-products removed, leaving behind soil parent materials enriched in quartz, iron and aluminum oxides, and kaolinite clay. Soils formed in such materials are nearly devoid in minerals bearing elements necessary for plant growth.

Another less commonly recognized feature of most soils in the tropics is their lack of silt-sized particles, so prevalent in the loess-derived soils in the Midwestern United States and in Eastern Europe. Silt-rich soils retain approximately 0.2 cm of plant available water per centimeter of soil depth, whereas silt-poor soils retain half that much. As a result, plants growing on silt-poor tropical soils are more adversely affected by droughts during the growing season.
Soils of Tropical Landscapes

Soil moisture regimes in tropical landscapes

Weather conditions vary from year to year in the tropics, but the climatic probability of rainfall dictates the probable amount and duration of plant available water in the soil. Probable soil moisture is a characteristic of individual soils because each soil has a fixed geographic location and topographic position in the landscape. Soils are thus classified by the rainfall and potential evapotranspiration conditions at their location in normal years, as well as the seasonal depth to the ground water table (USDA Natural Resources Conservation Service 1999). Aquic soil moisture regimes identify soils that are periodically saturated with water; engineered drainage is required for growing most food crops. Aquic conditions are present in localized landscape depressions within upland areas and near rivers and lakes. Aridic soil moisture regimes identify soils with less than three consecutive months of adequate plant available soil water, making the growth of most food crops without irrigation impossible. Ustic soil moisture regimes identify soils where normal rainfall patterns provide plant available soil water for the growing of one or two food crops annually. Most of these areas have a single reliable wet season extending from three to nine months each year, although notable contrasts are present in parts of eastern Africa where two short growing periods, separated by a dry season, occur. Udic soil moisture regimes identify soils that annually have less than three months that are too dry for growing food crops; two crops are usually possible each year. Perudic soil moisture regimes identify soils where precipitation exceeds potential evapotranspiration each month of the year. Lack of a dry season in which to harvest grain limits food production on these soils to fruits and nuts and human populations are low (see Van Wambke 1981, 1982, and 1985 for soil moisture regime location maps).

Soil chemical, physical, and mineral properties of soils in the tropics

The mineralogical, chemical, and physical properties of soils are in large part determined by the geologic composition of materials in which they form. Perhaps the most common generalization of soils in the tropics centers on the characteristics of Oxisols (USDA Natural Resources Conservation Service 1999) or ferrasols (IUSS Working Group WRB 2006). Oxisols, sometimes known by other historical names such as latosols and laterites, dominate landscapes in about 24% of the tropics (Van Wambke 1991, 343). Oxisols are loamy or finer textured, physically friable soils of low bulk density. They contain mainly quartz, kaolinite, gibbsite, and iron oxide minerals. Most are various shades of yellow or red in color and contain only sparse amounts of minerals containing elements necessary for plant growth. They have nearly uniform texture with depth and a strong granular structure that permits rapid percolation. Most are on level to rolling landscapes with slopes of less than 10%.

Oxisols are present in all soil moisture regimes in the tropics. Extensive areas of Oxisols are present in central Brazil and the lower portion of the Amazon basin. They are also extensive in the central portion of the Congo basin and other interior basins in Africa, parts of tropical Asia, and northern Australia. In South America, most are formed in nutrient poor sediments, often several meters in thickness deposited during the warm, humid climate of the Cretaceous period and early Cenozoic era (Orme 2007) (Figure 1).

Most Oxisols are some of the least fertile soils in the tropics (Buol 2007). Being formed in largely inert parent materials, these soils have
few morphological features indicative of present climatic conditions (USDA Natural Resources Conservation Service 1999; Buol et al. 2011). However, not all Oxisols are naturally infertile. Some, formed in ancient sediments derived from basic rocks like basalt, have a high base cation saturation percentage; in moist areas these soils usually support lush forest vegetation. Many of these more naturally fertile Oxisols have been cultivated for food crop production. The least fertile Oxisols naturally support only savanna vegetation so deficient in calcium and phosphorus that grazing mammals cannot maintain proper bone structure and it is impossible to grow food crops without additions of externally derived sources of plant essential nutrients. Historically these areas have been almost devoid of human populations. However, in recent years one of the most extensive areas of the least fertile Oxisols in central Brazil, known as the Cerrado, has experienced extensive agricultural development utilizing modern methods of fertilization and mechanization (Lopes 1996). Initially large amounts of phosphorus are required to overcome the phosphorus fixation capacity of these soils. However, after a one-time capital investment in phosphorus and lime is made, agricultural production is sustainable and profitable with annual increments of fertilizer. Then, annual fertilizer needs to replace nutrients removed by the grain harvest, and lime to combat acidity, are no greater than in other soils. The remarkable commercial agricultural development ongoing in Brazil (Figure 2) attests to the huge potential for increased human food production in South America, Africa, and elsewhere in the udi and ustic soil moisture regimes of the tropics. Commercial market infrastructure is necessary for modern agriculture to fully utilize these soils.

Throughout the tropics, soils formed on sediments containing nominal amounts of weatherable minerals, or directly from underlying rock and on slopes less than about 15%, have loamy to sandy topsoil overlying finer textured subsoil horizons. These soils classify as Alfisols and Ultisols. On slopes greater than about 15%, most soils are either shallow or have nearly uniform texture with depth. These soils classify as Entisols and Inceptisols and are very similar to many such soils in temperate latitudes. Chemical differences among these soils are determined by the composition of the parent material. Ultisols and relatively infertile Inceptisols and Entisols are formed in acidic parent materials. Alfisols and more fertile Inceptisols are formed over basic rocks or sediments. In udi and ustic soil moisture regimes these soils are most often naturally forested. Here indigenous humans commonly practice slash-and-burn, that is, shifting cultivation.

**Indigenous land uses in the tropics**

Slash-and-burn land use practices consist of cutting, drying, and burning native vegetation to volatilize the organic carbon, thereby converting...
The plant essential elements contained to plant available inorganic forms. Slash-and-burn practices locally differ in detail but all provide the high concentrations of nutrients necessary for food crops. Most food crops grow in less than 100 days in the tropics, requiring much more rapid uptake of nutrients than do native species. Burning also kills weed seeds near the soil surface. After one to three crops are harvested, the fields are abandoned and slow-growing native plants invade. It takes about 20 years, or more, in the least fertile soils for enough natural regrowth to accumulate sufficient plant-essential elements to nourish a reasonable food crop after again cutting and burning the vegetation. In many remote areas indigenous humans continue to utilize shifting cultivation for subsistence food crop production (Figure 3). In tropical Asia and elsewhere, thicker soils on steep slopes are often terraced for water management and fertilized for sustained growing of food crops.

Aquic soil moisture regime (seasonally saturated) Inceptisols and Entisols are present in major delta areas and smaller areas in river flood plains throughout the tropics. Proximity to river transportation and the possibilities for irrigation have attracted the development of civilizations in these locations. Frequent flooding is a hazard but the renewal of essential nutrients (obtained from the eroded topsoil deposited during floods) maintains soil fertility. Human intervention has largely removed native vegetation from these areas, and paddy rice production is extensive. Many of these areas, especially in Asia, have reliable infrastructure, and farmers supplement the natural soil fertility with commercial fertilizers to support the genetic potential of improved cultivars.
Thick, clayey textured soils composed primarily of smectite clay (Vertisols) on nearly level landscapes are rather extensive in India and Sudan, with smaller areas scattered throughout the tropics in old lake beds. These soils expand when wet and shrink when dry, forming deep, wide cracks. Most Vertisols have natural savanna ecosystems, and are chemically fertile. Thus, despite the undesirable physical properties, humans have used them extensively for food production and livestock pasture. If they can be kept moist via irrigation, they are good sites for paddy rice.

Andisols, soils formed in volcanic ash, comprise only a small portion of the tropics. Most Vertisols have natural savanna ecosystems, and are chemically fertile. Thus, despite the undesirable physical properties, humans have used them extensively for food production and livestock pasture. If they can be kept moist via irrigation, they are good sites for paddy rice.

Organic soils (Histosols) are present in small, level, swamp areas throughout the tropics. The most extensive areas of Histosols are on the north coast of Sumatra and in parts of Borneo. Most areas have largely been avoided by indigenous peoples, except for paddy rice growing. Engineered drainage is needed for cultivation of most other crops.
SOILS OF TROPICAL LANDSCAPES

Sandy soils with a subsoil (B) horizon of amorphous materials composed of organic matter and aluminum (Spodosols) are of little agronomic value. Such soils are scattered in small areas throughout the Amazon Basin, with a rather extensive area present in the Rio Negro watershed. In Africa an area of southwestern Zambia is dominated by Spodosols.

Soils with an aridic soil moisture regime, mainly Aridisols but also some Oxisols, Andisols, Entisols, and Vertisols, receive insufficient rainfall to grow most food crops without irrigation. Only low intensity grazing is possible. The most extensive aridic soil moisture regimes in the tropics are south and east of the Sahara Desert in Africa, the Arabian Peninsula, and the west coast of South America in Peru and northern Chile.

Summary

Minimal seasonal soil temperature variation is the only characteristic common to all soils in tropical latitudes. The majority of soils in the tropics have other physical, chemical, and mineralogical properties comparable to many soils in temperate latitudes. Only one major order of soils, Oxisols, is not found in temperate latitudes; they occupy only about 24% of the tropical land area. Viable technologies that greatly increase food production in the tropics are available. Lack of infrastructure to implement these technologies, not insurmountable soil properties, relegates farmers to low yielding subsistence farming in many tropical areas.

Soils of urban and human-impacted landscapes

Jeffrey L. Howard  
Wayne State University, USA

W. Lee Daniels  
Virginia Polytechnic Institute and State University, USA

Many soils of urban and human-impacted landscapes have been so modified by human activity that the original soil remains only as a buried profile, or has been so drastically changed that it is no longer recognizable. Often these soils have unique characteristics that lie outside the range of indigenous soil series. Such soils have been labeled by various adjectival terms, for example “anthropomorphic,” “anthropic,” and “anthropogenic.” To facilitate discussion, the term “Anthrosol” is used informally here for any soil formed or profoundly modified by human activity (IUSS Working Group 2006). Anthrosols may be formed from human-transported materials (anthropogenic deposits) or human-altered natural parent materials.

In this entry, we recognize four distinct types of Anthrosols based on geographical setting and historical context: (i) agricultural, (ii) archaeological, (iii) mine-related, and (iv) urban. Agricultural Anthrosols differ from plowed and other soils normally found in agricultural settings in that they have been modified so profoundly by human activity that they require reclassification as a different type of soil. These changes are usually caused by long-term additions of soil amendments (manure, fertilizer, etc.), or by a fundamental change in soil drainage brought on by irrigation. Agricultural Anthrosols can be classified into two distinct subtypes: (i) Plaggenic, and (ii) Anthraquic. Plaggenic Anthrosols are characterized by an artificially overthickened A horizon called a plaggen in Europe, or a plaggen epipedon in the United States (Soil Survey Staff 2010). A plaggen epipedon is a surface layer ≥50 cm thick produced by long-term additions of manure or other organic materials. It often contains artifacts (objects of anthropogenic origin) such as charcoal, bone, brick, and pottery, and may contain included chunks of subsoil churned up by digging or tilling. In northwestern Europe, where plaggen are widespread, it was common practice during Medieval times to spread forest litter, heath-turf, or grass sod on the floors of barns and stables. These materials, along with the droppings compacted by earthmoving equipment, and are sometimes formed in parent materials that were imported from offsite. Urban and archaeological Anthrosols are unique in that they often contain abundant artifacts (objects of anthropogenic origin) which may be comprised of substances not found in nature. Anthrosols are also associated with suburban settings, streets, highways, and utility line or pipeline construction areas.

Agricultural Anthrosols

Agricultural Anthrosols differ from plowed and other soils normally found in agricultural settings in that they have been modified so profoundly by human activity that they require reclassification as a different type of soil. These changes are usually caused by long-term additions of soil amendments (manure, fertilizer, etc.), or by a fundamental change in soil drainage brought on by irrigation. Agricultural Anthrosols can be classified into two distinct subtypes: (i) Plaggenic, and (ii) Anthraquic. Plaggenic Anthrosols are characterized by an artificially overthickened A horizon called a plaggen in Europe, or a plaggen epipedon in the United States (Soil Survey Staff 2010). A plaggen epipedon is a surface layer ≥50 cm thick produced by long-term additions of manure or other organic materials. It often contains artifacts (objects of anthropogenic origin) such as charcoal, bone, brick, and pottery, and may contain included chunks of subsoil churned up by digging or tilling. In northwestern Europe, where plaggen are widespread, it was common practice during Medieval times to spread forest litter, heath-turf, or grass sod on the floors of barns and stables. These materials, along with the droppings
of livestock, were then collected and strewn onto sandy fields under cultivation. European plaggen may be 1 m or more in thickness as a result of many centuries of these types of activities. Plaggenic Anthrosols are common in England, Ireland, Holland, Belgium, and Germany.

Anthraquic Anthrosols are a special kind of aquic soil in that they are affected by excess water introduced by flood irrigation, often associated with paddy rice cultivation. Anthraquic soils are affected by continuous or periodic saturation for three months or more resulting in chemical reduction. They are often characterized by a tilled surface layer with redoximorphic features lying directly above an impermeable horizon (Soil Survey Staff 2010). During a wetting event, \( \text{Fe}^{2+} \) may be released to solution by protonation and then adsorbed onto the exchange sites of clay minerals and organic matter. Basic cations are desorbed and undergo hydrolysis generating \( \text{OH}^- \) anions. During a subsequent drying event, sorbed \( \text{Fe}^{2+} \) is oxidized to form ferrihydrite and \( \text{H}^+ \). This cyclic process was referred to as ferrolysis by Brinkman (1977), who thought that excess \( \text{H}^+ \) generated by this process could eventually cause dissolution of clay and a reduction of cation exchange capacity in these soils.

Well drained sandy agricultural Anthrosols also may be characterized by an agric horizon, that is, an anthropogenic illuvial horizon lying directly beneath a plowed A horizon. An agric horizon is \( \geq 10 \) cm thick with illuvial humus, silt, and clay comprising \( \geq 5\% \) of the horizon by volume. It is typically characterized by abundant earthworm burrows (krotovina) and clay lamellae (Soil Survey Staff 2010). This horizon develops because the plowing disturbance facilitates translocation of fine particles into the zone immediately underlying the plow layer. Over time, illuvial particles form lamellae, or coatings in worm burrows and on ped surfaces. Examples of agric horizons are found in Belgium, and in India on the floodplain of the Ganges River.

Archaeological Anthrosols

Archaeological Anthrosols are developed on agricultural, habitation, ceremonial, and burial sites. They are commonly found as buried soils in tells and burial mounds. Archaeological Anthrosols differ from native soils because they have been altered drastically by additions of organic matter derived from plant and animal wastes, or charcoal, along with mineral material in the form of ash, bone, and shell. Four types of archaeological Anthrosols can be distinguished (Holliday 2004): (i) Plaggenic, (ii) Dark Earth, (iii) Terra Preta, and (iv) Midden. As noted above, plaggen result from the intentional addition of manure and other wastes, although they also frequently contain archaeological artifacts dating back to the tenth century or earlier. “Dark Earth” Anthrosols are common throughout Europe, and in Britain they may date back to the late Roman Empire. They are referred to as “urbic Anthrosols” in the World Reference Base classification (IUSS Working Group 2006). Dark Earth Anthrosols are somewhat similar to plaggen in that they are an overthickened A horizon, perhaps 70 cm thick or more, containing brick, mortar, pottery, bone, shell, and other artifacts. However, they are morphologically more homogeneous than plaggen, and Dark Earth Anthrosols are thought to represent former occupation sites (Holliday 2004). Terra Preta Anthrosols are also thick, black, artifact-bearing topsoils which have been artificially enriched in organic matter. These soils are characteristic of the Brazilian Amazon basin, where the thick, black topsoil is in striking contrast to the underlying reddened Ultisol horizons. Their origin appears
to be complex. Scientists today are unsure whether Terra Preta were formed intentionally, unintentionally, or both (Lima et al. 2002). A midden is an organic-rich topsoil formed in the classic sense by dumping of “kitchen” wastes at archaeological sites. Kitchen middens were the inspiration for the anthropic epipedon as originally defined in Soil Taxonomy. A midden is basically a mollic epipedon containing elevated levels of phosphorous, commonly due to the incorporation of bones or organic substances that are rich in phosphorous. Shell middens are common in coastal, estuarine, or lacustrine settings, which are in proximity to sources of shellfish. Burned rock middens are common in Texas. They are essentially an anthropic epipedon containing charcoal, and burned or fire-cracked rock representing a former fire pit.

Mine-related Anthrosols

Mine-related Anthrosols differ from native soils in that they are formed on anthropogenic (human-created) landforms, whose surface and subsurface hydrological characteristics have been drastically altered. These soils also have formed from parent materials that have been artificially sized by blasting and mixed together in an unnatural way by mechanized equipment. Mine-related Anthrosols are particularly widespread in areas surface-mined for coal and aggregate (sand and gravel), but large land areas have also been disturbed by metal and aggregate mining and associated waste dumps.

Of all mine-related Anthrosols, Appalachian (United States) coal mine spoils, and resultant topsoil-substitute mine soils, have been studied most extensively. They differ from natural parent materials because they are often characterized by a considerable amount (20–40%) of soil-sized (<2 mm) material coupled with a large proportion of hard rock fragments. They tend to be highly compacted by earthmoving equipment, and highly variable in both physical and chemical properties (Haering, Daniels, and Galbraith 2005). In contrast, large areas of coal mine soils in the central United States have been reconstructed from pre-existing agricultural soil materials and, as a result, more closely resemble their native counterparts in texture and bulk soil chemistry.

Coal and associated carbonaceous shale often contain pyrite, possibly in great abundance. In an oxidizing environment, pyrite weathers rapidly to generate sulfuric acid, which can in turn drastically lower the pH value of the soil, as well as solubilize iron and various toxic trace metals within it. Mine-related Anthrosols formed from pyritic parent materials are typically characterized by a sulfuric horizon, that is, a horizon ≥15 cm thick comprised of mineral or soil material with a pH ≤3.5. If calcareous parent materials are present, sulfuric acid can react with calcite to produce gypsum. Coal mining also generates a large volume of coal-processing wastes (coal refuse) that are usually much coarser, more acidic, and more carbonaceous than other mine spoils. Pyrite and toxic trace metals are often concentrated in coal refuse. Mining of sand and gravel, and minerals containing valuable trace metals (e.g., titanium, zirconium), has disturbed large areas of land in various parts of the world. A wide range of hard-rock mining activities for metals, aggregate, and carbonate rock has also generated large areas of waste rock dumps and/or tailings that contrast strongly with native parent materials, resulting in a wide variety of mine-related Anthrosols with unique properties.

Urban Anthrosols

All soils in an urban setting are affected by environmental changes of anthropogenic origin
SOILS OF URBAN AND HUMAN-IMPACTED LANDSCAPES

(i.e., anthropogenic soil-forming processes) such as elevated soil temperature resulting from the urban heat island effect, deposition of wind-blown soot and coal ash, runoff containing deicing salt, acid rain deposition, and so on. However, urban Anthrosols differ from urban native soils because they have been modified so profoundly by human activity that they require reclassification as a different type of soil, or the native soil remains only as a buried profile. Urban Anthrosols often contain large volumes of artifacts, and are sometimes characterized by layers of concrete, asphaltic pavement, and so on, which seal off part or all of the soil from the effects of more “natural” soil-forming processes. To facilitate discussion, urban Anthrosols are classified into two types depending on whether they were formed in: (A) human-altered material (modified native parent materials), or (B) human-transported material (anthropogenic deposits). Human-altered parent materials are formed in place either by deep mixing, excavation and replacement from a single pedon, or truncation and removal of the surface soil. Human-transported parent materials are formed by excavation of material from one pedon and mixing with materials from other pedons, or by moving material horizontally onto a pedon from other sources, usually with the aid of hand tools or mechanized equipment.

Type A urban Anthrosols are characterized by a profile similar to that of native soil, but with a thicker, darker A horizon created by human additions of organic substances other than manure. They often contain artifacts (Figure 1a) and show some evidence of human disturbance by digging. This type of anthropogenic A horizon may or may not have elevated phosphorous levels (from animal bones), but otherwise usually meets the current requirements of an anthropic epipedon (Soil Survey Staff 2010). The darkening of the topsoil may be the result of human additions of organic substances (char, charcoal, coal ash, etc.), or perhaps soot and coal-ash contamination, as a legacy of fossil fuel combustion. Artifacts are typically household items or trash.

Type B urban Anthrosols are characterized by a weakly developed soil profile (Figure 1b) developed in an anthropogenic deposit, often overlying buried native soil (Figure 1c), or resting directly on native parent materials. The anthropogenic deposit is typically the result of construction or building demolition. The parent materials are comprised of an artificial mixture of artifacts and earth materials (rock, sediment, soil, etc.), often imported from offsite. The anthropogenic deposit is usually massive, highly compacted, artifact-rich, lithologically heterogeneous, and laterally discontinuous. Such deposits may be comprised of a single massive layer, or multiple layers, and occasionally have a complex microstratigraphy. Artifacts in such soils are often waste building materials (wood, glass, brick, mortar, concrete, plaster, nails, etc.) or coal-related wastes (soot, fly ash, cinders). They may be comprised, at least in part, of artificial substances (e.g., coal tar, plastic) not usually found in rocks and native soils (Figure 1d). They can range in size from gravel to sand or finer, and may represent waste materials simply left onsite, or comminuted by the demolition process (Howard, Dubay, and Daniels 2013), and then incorporated into earthy backfill materials during grading. Glass and glass-bearing artifacts (brick, coal cinders and ash, steel-making slag) can be expected to have good preservation potential based on their resistance to chemical weathering. There is also a high probability of preserving organic artifacts comprised of bituminous materials or black carbon (coal, asphalt, black carbon, tar) because they are relatively recalcitrant to biodegradation.

Urban Anthrosols which have experienced excessive compaction are usually characterized by greatly reduced infiltration, excessive dryness, and possibly anaerobic conditions. A perched
Figure 1  Urban Anthrosols at former demolition sites in Detroit, Michigan: (a) Type A soil characterized by anthropic epipedon formed in human-altered material; (b) Type B soil 24 years old with weakly developed A horizon formed in human-transported material; (c) Type B soil 68 years old with human-transported material overlying buried native soil; (d) Type B soil comprised of coal-related wastes overlying buried native soil. Scales in cm. Pick handle is 67 cm long. ^A denotes anthropogenic horizon; u, artifacts; b, buried; d, densic; g, gleyed; k, calcic; w, cambic. water table (episaturation) is common, but the hydraulic conductivity of the underlying restrictive layer may also be significantly enhanced by the presence of vertical worm burrows. Urban Anthrosols are structureless and may contain elevated levels of iron oxide and manganese oxide and carbonate as a result of the presence of weathered ferruginous and calcareous artifacts. The organic fraction often contains a mixture of soil organic matter (produced by humification), black carbon (e.g., charcoal, soot, and coal ash), and various types of carbonaceous substances derived from geogenic materials (e.g., coal, coked coal, coal tar, asphalt, carbonaceous shale). Soil pH and exchangeable calcium levels are typically elevated as a result of weathered calcareous artifacts. Exchangeable sodium levels may also be elevated in urban soils which have received excessive runoff from pavement carrying de-icing salts. Measured carbon/nitrogen ratios and pH values show significant decreases, and soil organic matter contents substantial increases, in urban soils over the course of about a century of soil development in Detroit, Michigan (Howard, Dubay, and Daniels 2013). Microbial biomass appears to be very low initially in anthropogenic fills, but rebounds with increasing humification and nitrogen accumulation such that microbiological activity in urban soils may be comparable to that of native soils in less than 100 years. Anthrosols similar to those termed “urban” for this discussion may be present in suburban and even possibly in rural geographical settings.

Genesis and classification of Anthrosols

Plaggenic Anthrosols (and certain archaeological Anthrosols) are known to have required as much as 600 years or more to form, and there are Anthraquic paddy rice soils in southeastern Asia which have formed as a result of 1000 years of cultivation. However, an A horizon is usually the first feature to develop during
pedogenesis. Weakly developed A horizons have been observed to develop relatively rapidly (about 15–30 years) in mine-related (Haer- ing, Daniels, and Galbraith 2005) and urban (Howard and Olszewska 2011; Howard, Dubay, and Daniels 2013) Anthrosols. In contrast, except for some weak signs of structure, B horizons require centuries to form. Thus, the typical Anthrosol is characterized by an A/C profile. Where compaction by earthmoving equipment has occurred, mine-related and urban Anthrosols often have a densic (Cd) horizon which cannot be penetrated easily by plant roots and has a bulk density \( \geq 2.8 \text{ g/cm}^3 \). Mortar and other calcareous artifacts in A horizons may show significant weathering within a few decades and, accompanied by leaching, may form a calcic (Ck) horizon at depth. Despite excessive compaction, krotovina (burrows) produced by earthworms such as *Lumbricus terrestris* may become prevalent in urban Anthrosols, especially at sites that have remained vacant for decades.

Anthrosols first appeared on the revised legend of the Food and Agriculture Organization–United Nations Educational, Scientific and Cultural Organization soil map of the world in 1990, and are still recognized as a major grouping in the soil classification systems of some countries (IUSS Working Group 2006). In the case of agricultural Anthrosols, human influence is mainly restricted to surface layer, and several categories of “anthric horizon” have been recognized. Anthric horizons are generally similar to mollic or plagggen epipedons in the US Soil Taxonomy system. Early efforts to apply the US system of Soil Taxonomy to urban soils showed that they were typically classified as Entisols, but because of their unique properties, they did not conform to the central concepts of existing Entisol suborders. Several early proposals for modifying Soil Taxonomy to account for disturbed soils were eventually presented and widely debated. It was proposed that all eastern US mine soils could be classified as various subgroups (e.g., Calcic) of a new Great Group called Udispolents, emphasizing their “mine spoil” components. Much wider revisions at the suborder level (Garbents for garbage, Urbents for urban soils, etc.) and lower categories were also proposed. The International Committee for Anthropogenic Soils was first convened in 1995 to help formulate revisions to Soil Taxonomy pertaining to the classification of Anthrosols. Although much discussion followed about the possible creation of an Anthrosol Order, it now appears Anthrosols will be classified as Anthropic Subgroups of existing Great Groups. Efforts are still underway to update the definitions of buried soils, artifacts, human-altered and human-transported parent materials, the anthropic epipedon, and other anthropogenic features.

Historically, county-level soil surveys in the United States mapped urban and human-impacted soils simply as “made-land” or “urban-land” before the 1970s, and as various subgroups of Udorthents in more modern surveys. However, in recent years urban land areas have been delineated as newly created anthropogenic soil series, or as soil complexes comprised of an existing native soil series and undifferentiated urban land. A problem commonly encountered during urban soil mapping is that anthropogenic landscapes have often been leveled, and thus the standard approach of using slope to delineate genetic map units is ineffective. Another problem encountered in the mapping of urban soils is that the high level of variability and the presence of abundant artifacts make it necessary to obtain an inordinately large number of auger borings. As a result, remote sensing techniques using geophysical methods (e.g., electrical conductivity mapping) may be more effective for mapping Anthrosols.
Reclamation and revitalization of Anthrosols

Reclamation of coal mine-related Anthrosols in the United States is now mandated by the 1977 Surface Mining Control and Reclamation Act. One requirement of this law is that mine operators post bond monies which are not returned until the disturbed land has been revegetated. Hence, a great deal of research has been carried out in the United States with the objective of developing cost-effective strip mine reclamation techniques. Similarly, revitalization of urban Anthrosols has become a target of study because large tracts of vacant urban land produced by building demolition have attracted considerable interest for urban gardening and agriculture, green infrastructure (e.g., for groundwater recharge or wildlife habitat), and as a repository for wastewater from combined sewer overflow. Unfortunately, mine-related Anthrosols and Type B urban Anthrosols are rendered biologically unproductive, and have severely limited infiltration and hydraulic conductivity rates, as a result of excavation and backfilling processes.

Mine-related Anthrosols are strongly influenced by local geological and soil conditions, coupled with mining and reclamation methods (Figure 2). Revitalization of these soils is commonly limited by excessive potential acidity (from acid mine drainage), compaction, high rock fragment contents, low water-holding capacities, low plant-available nitrogen and phosphorous contents, and saline-sodic conditions. Coal-processing wastes are particularly difficult to reclaim because of acidity, and large piles of coal refuse are prone to mass movements (Daniels and Stewart 2000). Assuming that issues with pyrite are managed via application of appropriate acid-base accounting procedures, application of organic waste materials (sewage sludge, biochar, etc.) is still the most common approach for strip mine reclamation.

Demolition site soils are in need of revitalization because of low organic matter contents, compaction, excessive artifact contents, and various forms of other contamination, particularly by lead. Reconditioning techniques for urban soils include promoting air, water, and nutrient infiltration into the soil in order to enhance biological activity, application of amendments to alter soil chemistry, addition of compost, and removal of artifacts and tilling to reduce bulk densities (USEPA 2011). In some cases, it may be advantageous to leave calcareous and ferruginous artifacts in the soil because their weathering products act as immobilizing agents for certain toxic trace metals (Howard and Olszewska 2011).

Conclusions

Anthrosols are widely distributed in agricultural, archaeological, mine-related, and urban geographical settings. They are an important natural and historical resource, and have become a topic of considerable interest for geologists, geographers, and soil scientists over the last few decades. The fact that Anthrosols have characteristics outside the range of native soil series has important implications for their use and management. Hence, more study is needed of anthropogenic processes, anthroscapes, and techniques better suited for the mapping and classification of Anthrosols. As reclamation techniques improve, mine-related and urban Anthrosols may eventually reach their full potential as a repurposed natural resource for agricultural and other types of land use. Many earth scientists now believe that we are living in a new geological epoch, the Anthropocene, based on the fact that human activity has altered the Earth’s surface to such an extent that the uppermost part of the geological

column is profoundly different from that of the Pleistocene and Holocene epochs. Hence, the societal need for a better understanding of Anthrosols is expected to continue growing in importance because the rates of world population growth, and associated land disturbance by humans, are increasing exponentially.
