
The invention of the wheeled vehicle is more complex, involving the combination of the wheel, the axle, and the frame to create a vehicle with load-bearing moving parts. This form of transportation appeared around 4000 BCE, when Eurasian kingdoms reached a level of technical expertise and craftsmanship in the manufacturing of wooden and metallic objects. This device required precisely crafted parts to ensure that the wheels fitted through the nave, as well as calculating the correct size of the wheels and the vehicle to ensure that it could carry a particular load and travel at speed. Four-wheeled wagons were effective at carrying heavier loads on flat surfaces, while two-wheel carts where easier to pull and able to travel over more difficult terrains. It took centuries of experimentation in different areas to determine the right forms of vehicles to fit their respective transportation needs. Oxen were used to carry wagons with heavier loads over a flat surface, while horses were employed to pull lighter vehicles at a faster speed and in more difficult conditions. Incidentally, the introduction and diffusion of the wagon from 3500 BCE had significant impacts on the settlement pattern of farming communities in Europe, as it allowed individuals to carry manure out to the fields and to bring firewood and other supplies back home, and therefore reduced the need for cooperative communal labor beforehand.

Not unlike many other inventions in human history, some major transportation means were transformed into military equipment. Horse carriages, for example, were equipped with armor to become chariots and the horse was saddled by the cavalry. The military application of transportation significantly contributed to empire building around the Eurasian steppes. For instance, at the peak of their power around 1300 CE, the Mongol empire occupied most of the Eurasian continent, linking Europe to the Far East through what came to be known as the Silk Road, which had been established centuries earlier. Under the umbrella of Mongol dominance, exchanges of cargoes, scientific ideas, religions, and, more subtly, diseases between Europe, Central Asia, and East Asia reached unprecedented levels.

Besides the domestication of horses in temperate climates, camels and donkeys were also tamed from 4000 BCE in the savanna and desert regions of North Africa and the Arabian Peninsula as means of transport that were suited to these harsher environments. Their capacity to carry goods over difficult terrains unsuitable for wheeled vehicles made them the backbone of interregional trade that bridged parts of Eurasia separated by deserts.
TRANSPORTATION HISTORY

Roads and canals

Without roads travelers usually walked, rode, or drove to their destinations along the easiest paths using the shortest distances. The most frequented paths naturally became the first roads. To support empire building, road networks were artificially designed as an effective means to transport troops, collect taxes, trade, and deliver messages. In the major empires these systems usually focused on the imperial capital. For instance, by 500 BCE the Persians had built highways to link the many provinces of their empire. This legacy was surpassed by the Romans who created an extensive road system that is one of the hallmarks of their rule: the 113 provinces of the late empire were connected by 372 major roads, and one-fifth of the 400,000 km of Roman roads were stone-paved. In contrast, around 200 BCE, the first emperor of China, Ying Zheng (r. 260–210 BCE), constructed a network of very wide roads using the rammed earth technique. After prolonged use, the surface of the Chinese earthen roads would be eroded away by the wheels to form parallel ruts, which facilitated carriage transport with higher speeds and stability, so it became necessary for the imperial government to enforce a standardized cart gauge all over China. Many of the subsequent empires established post stations and hostels beside roads to enhance the convenience and security of traveling within the realm.

The earliest canals were built by the Egyptians around 2000 BCE to link the Nile River to the Red Sea. In Europe, the Dutch and the Venetians began to build canals during the Middle Ages to cope with the marshy terrain. These human-constructed water courses were implemented wherever an extensive river system was present and where their construction was justified by economic and political imperatives. Land transport was far more expensive than river transport. For example, it was estimated that the cost of land transport in China by ox wagon was 50 times that of river transportation. It is not surprising that China, from the seventh century onward, built the largest canal system in the world from south to north to connect most of its river systems flowing eastward from the Himalayas. The Grand Canal linked Beijing with Hangzhou over a total length of 1794 km, connected by a system of double-gate locks where barges could be raised or lowered to different water levels. Similar designs appeared in the Netherlands in 1373. Canal systems formed the backbone of inland transportation in many countries on different continents before the introduction of the railways in the nineteenth century.

The age of discovery

Prior to the eighteenth century, all transportation means were very slow by modern standards, and their main forms had remained unchanged for centuries. The major concern of premodern transportation was cost. Following the advancement of navigation technologies and the accumulation of travel experiences, safety and risks could be more accurately evaluated for long-distance transportation. Maps and log books were widely circulated. Celestial navigation tools were also employed alongside the compass to accurately estimate the location of ships.

“The age of discovery” is a Europe-centric interpretation of exploration activities that took place from the fifteenth century onward, when the rising colonial powers of Europe, either in competition or in cooperation with one another, began to build a global trade network. The Portuguese were the pioneers in exploring the Atlantic coast of Africa from 1418; the
The Industrial Revolution and modern transportation developments

New means and systems of transportation have emerged at a far faster pace since the Industrial Revolution started in the Great Britain in the eighteenth century. This involved greater speeds and capacities through the development of mechanical forms of propulsion. The steam engine was devised by the Scottish mechanical engineer James Watt to activate water pumps in mines, but it soon became evident that, by installing the engine directly inside a wheeled vehicle or ship and letting the steam power rotate the wheels or paddles, the steam engine could provide motion power for transportation.

There were many experimental forms of the steamship before the American Robert Fulton invented the first one used for regular passenger services in 1807. His design involved setting up a paddle wheel on each side of the hull. Since steam power was much more reliable than wind, sailboats began to be replaced by sailless steamships. This process accelerated in the second half of the nineteenth century when iron and steel were widely employed in ship construction. By 1838 the paddle wheels began to give way to the fan-shaped screw propeller which enabled faster and more stable propulsion. In the early twentieth century, the marine diesel engine superseded the steam engine, and almost all ships are now powered by petroleum.

To save on the cost of transportation, steam and diesel ships were built far bigger than the sailboats in the past, using stronger building materials and more powerful engines. The container ship was introduced in 1955 and has become the ubiquitous form of transportation, particularly because these standardized units can be carried by both inland and maritime transportation systems with great efficiency. The growing size of all types of sea vessels, including containerships, often necessitated the use of entirely new port sites outside the central business areas, where most ports had originally emerged. Many ports established on shallow sites during the age of sail were no longer adequate for the new giants. This changed the dynamics of ports toward sites that could handle larger cargo levels, and also transformed urban planning. Some traditional port cities in the past lost their importance; for
TRANSPORTATION HISTORY

example, Liverpool, once a major English port, declined with containerization.

The growing reliance on petroleum, particularly after World War II, created a huge demand for fossil fuels. The application of economies of scale in maritime shipping led to the introduction of large tanker ships carrying oil from producing countries to large consumption markets. The guarantee of sea routes for oil transportation became a national security priority of all industrial powers, and also a major source of conflict during and after the Cold War.

The first steam-powered locomotive was introduced in 1801 for road use, but turned out to be impractical as the roads at the time were too rugged for such machines, even though road conditions were improving in Great Britain through the construction of toll roads and the use of the macadamized process (1816) whereby roads were paved with single-sized aggregate layers of small stones, with a coating of binder as a cementing agent. The first practical steam-powered locomotive was invented in 1814 by George Stephenson who rested the engine on railways. The rail had been employed for moving coal from mines since the seventeenth century and was originally pulled by horses. Early forms of railways were made out of wood or stone, but from the 1760s they were replaced by cast iron plates. The low friction between steel wheels and rails enabled the mechanically powered locomotive to become efficient means for transporting people and freight at high speed and low cost.

Railway systems were soon established in many countries, and subsequently became the primary form of mechanized land transportation. Bridges and tunnels were constructed to facilitate the smooth operation of the system, and segments linking port cities, industrial regions, and resource extraction areas completely changed the landscape alongside them. Rail became a critical factor shaping urban systems and the urban spatial structure. For example, satellite towns linked by the railway could be built around major metropolitan areas, and the urban area thus expanded in line with the tracks.

The coal-fueled steam engine was first replaced by the diesel engine, which in turn was taken over by the electric engine on several rail segments, particularly on passenger trains. In environmental terms, the electric engine is much cleaner and can be used underground, which is better suited to subway systems supporting urban mobility in industrial countries. High-speed rail systems traveling at over 250 km per hour were first developed in Japan and Europe. Today there are huge high-speed rail construction projects in China and other emerging economies. In spite of its efficiency, the dominance of rail transportation was challenged by the automobile and the airplane in the second half of the twentieth century.

The first modern automobile was designed by the German inventor Karl Benz in 1885. Cars soon replaced horse carriages as a dominant form of individual transportation, especially after Henry Ford was able to mass-produce cars using the assembly line system in 1908, which made cars more affordable. After World War II the automobile became more affordable by the middle class and even the working class in some developed countries. In 2010 the number of automobiles had risen to over 1 billion; this figure is still increasing thanks to the rapid development of newly industrialized countries such as India. Highways and other roads were built to increase the connectivity and accessibility of nations, so that in theory almost any location can be reached by motor vehicle. The heavy consumption of petroleum by the internal combustion engine, however, constitutes a serious threat to the environment because of the air pollution and carbon emissions caused by burning fossil fuels, which are nonrenewable.
and will probably be exhausted within a few decades.

The airplane is perhaps the most innovative means of transportation. While only a dream before the Industrial Revolution, unlike the train, car, or steamboat, the airplane was not developed from any nonmachine-powered predecessors. Although hot air balloons existed in the eighteenth century, the diesel-powered plane was invented by the Wright Brothers only in 1903. Commercial airborne passenger travel became popular after World War II, with technical improvements making it faster, safer, and more cost-effective. In the 1950s air travel overtook the ocean liner as the dominant mode of long-distance passenger transportation.

**Conclusion**

Transportation history underlines the impacts of transport innovation on economic and social activities, notably their scale and frequency. It is undoubtedly a critical factor influencing all aspects of civilization past and present. Transportation development since the Industrial Revolution have changed the relative size of the world, and also imposed striking impacts on human social and economic activities. Our modern ways of residing, eating and even clothing are results of the new modes of transportation. Indeed, in the past two centuries transportation has turned out to be faster, safer, much cheaper and more comfortable, but nowadays pollution and sustainability have emerged as relevant serious concerns. Future improvement in transport technology will likely focus more on environmental issues: the greener the better.

Transportation planning

Eric A. Morris
Clemson University, USA

What is transportation planning?

Transportation planning manages the finance, politics, economics, design, construction, routing, and operation of transportation systems. Although there is considerable private sector involvement in transportation, typically “transportation planning” refers to the public provision of goods such as streets and highways, mass transit like buses and subways, maritime facilities such as ports, and air travel facilities such as airports and air traffic control systems. There is considerable overlap between the fields of transportation planning and transportation engineering; for example, both engineers and planners study travel behavior in the present and use it to predict travel patterns in the future. However, in general, transportation engineers are more focused on the design and construction of physical facilities, and on studying the mechanics of traffic flow. Planners focus more on issues like finance and economics, policy and politics, administration, public processes, transportation’s effects on the environment, and the two-way interplay between transportation and land use.

The early historical development of transportation planning

Transportation planning is not new. The city of Mohenjo-Daro in modern Pakistan, constructed in about 2600 BCE, had a gridded street pattern that is perhaps the first recorded instance of the conscious planning of a transportation system. However, a formal science of transportation planning would not emerge until the twentieth century (Brown 2006). At the beginning of this period, planning was dominated by “City Beautiful” principles. This movement was inspired by work such as the plan for Washington, DC, in the late eighteenth century, and particularly the plan for the reconstruction of Paris beginning in 1853, in which much of the dense, chaotic warren of streets that organically developed from the Middle Ages onward would be replaced by the broad, grand boulevards studded with monumental architecture that characterize Paris today. In addition to Washington, City Beautiful plans were implemented in Chicago, Cleveland, Detroit, Canberra, Melbourne, and many other cities.
TRANSPORTATION PLANNING

Transportation planning’s response to the automobile

However, growing motor vehicle traffic congestion ultimately led planners to shift their focus from aesthetics to improving the flow of traffic. Transportation planning transitioned to become a more “scientific” field, which used empirical data on travel demand and the movement of traffic. Early developments included innovations such as the stop sign, yield sign, pedestrian island, one-way street, pedestrian crosswalk, traffic circle, municipal traffic code, and, ultimately, the stop light. Next came the “Major Traffic Street Plans” that flourished in the 1920s. These plans focused on segregating different kinds of traffic (i.e., separating pedestrians, autos, and streetcars), creating street hierarchies that channeled auto traffic off of minor residential streets and onto major thoroughfares, and street widening, straightening, rationalization, and signalization.

The ultimate expression of this focus was the development of the freeway. It featured limited entrance and exit points, the elimination of at-grade intersections using over- and underpasses, and multiple wide lanes with gentle slopes and curves. Key milestones were the Italian Autostrada, the backbone of which was completed in 1926; Germany’s Autobahn, which saw its basic network built under the Nazis during the 1930s; and the American Interstate Highway System, on which large-scale construction began during the mid-1950s.

Transportation planning and the development of mass transit

Mass transit was introduced beginning with omnibuses, large horse-drawn carriages, in the 1820s. The next major milestone, which increased vehicle speed, safety, and capacity, occurred in the mid-1850s when the carriages, now called “horsecars,” were moved onto rail track embedded in the streets. In the 1890s, horses were replaced with electric propulsion (the electric streetcar), and, in the largest cities, “metros” were constructed with trains running in tunnels or on elevated track.

Transit systems in the United States were generally overseen, licensed, and sometimes financed by municipal governments, but they were typically owned and operated by private firms. Since their fares in the late nineteenth century were often beyond the means of the working classes and poor, transit was in the beginning a private enterprise patronized by the well-off as opposed to a public enterprise disproportionately patronized by the poor, as it is today. Although through World War II streetcar and metro systems thrived, competition from the auto, customer dissatisfaction, and the poor economic foundation of the industry resulted in hard times for mass transit in the postwar period; this was particularly the case in the United States, where mass motorization occurred several decades before it did in other nations. As a result, by the 1960s mass transit was suffering a severe loss of patronage and financial woes that threatened the survival of the industry. Its survival was guaranteed only by government ownership, which became widespread in the United States in the second half of the twentieth century.

The revolution in transportation planning

The government takeover of transit was an effect of a transformation in planning principles. This began in the late 1960s and early 1970s in part
due to widespread public opposition to the
disruption caused by the construction of urban
freeways, a growing environmental movement,
oil price shocks due to supply disruptions in
1973 and 1979, and the desire to arrest inner
city decline and check mass suburbanization
and sprawl. Moreover, at this time it became
increasingly clear that transportation planning
was prone to mistakes and improper strategies
that post ante revealed its fundamental flaws;
trying to control and predict traffic flows and
the nature of transport development was, and
remains, challenging, as was evidenced by the
ever-rising surge of traffic congestion which
seemed to defy all efforts to control it.

As a result of widespread dissatisfaction with
the state of transportation planning, a paradigm
shift took place in the field. Meyer (2000)
outlines the key points of this transformation in
transportation planning principles.

Transportation planning shifts from a
quantitative to a more qualitative focus

First, there has been waxing emphasis on qual-
itative planning principles as opposed to purely
quantitative ones. As in the past, transportation
planners today perform quantitative analysis of
present and future conditions. They conduct
large-scale surveys where respondents record
their travel behavior to inform complex fore-
casting efforts. The traditional method of such
forecasting is the “four-step” model. The first
step involves breaking a region into zones, and
calculating the number of trips each zone will
produce based on characteristics such as popula-
tion and the level of auto ownership. The second
step involves determining where the trips from
each zone will go, using the assumption that
each zone will tend to send more trips to zones
that are larger, denser, and closer. The third
step involves using “discrete choice” models to
predict the mode (e.g., auto, transit, walking)
that will be used for each trip. The fourth is
loading those trips onto a representation of the
transportation network to determine which
specific routes the trips will take.

The four-step model has been widely used for
decades, but it has long been known to have
deficiencies due to its abstraction, imprecision,
and inability to mimic many potential changes
in the transportation system. “Disaggregate
models,” which create idealized households
based on travel demand data, and attempt to
simulate these households’ actual travel patterns,
have long been recognized to be conceptually
superior. Disaggregate modeling is gradually
replacing four-step modeling, but this process
has been slow due to the appeal of the relative
simplicity of the four-step model, its ease of use,
and a degree of inertia among planning agencies.

However, given the complexity of the prob-
lem, it remains clear that even the best-informed
modeling is prone to error, and even willful
misrepresentation. Megaprojects such as urban
freeways and metro systems routinely and even
systematically come in over budget (Flyvbjerg,
Holm, and Buhl, 2003), and, in the case of
metro systems, nearly always have traffic levels
far below initial projections (Flyvbjerg, Holm,
and Buhl, 2005).

In response to this, and thanks to the recog-
nition of transportation’s broader impacts on
society, other “qualitative” concerns have begun
to share the stage with quantitative ones in recent
decades. For example, while the sole purpose
of modeling was once thought to be reducing
travelers’ time and monetary costs, planners
now consider a wider set of concerns such as
neighborhood cohesion and transportation’s
effects on social life, economic development,
public health, and so on. This change is generally
hailed by transportation thinkers, public officials,
TRANSPORTATION PLANNING

and the general public, though some question how concepts as vague as “livability,” which are difficult to define, let alone quantify, can reliably guide policy.

Planning focuses on alternative modes

Second, there has been a shift from an overwhelming focus on auto travel to planning for alternative modes such as mass transit, bicycles, and walking. For both financial and political reasons, the era of mass freeway building, at least in the developed world, has come to an end. At the same time, there has been a dramatic expansion of mass transportation, with the number of metro systems worldwide rising from 48 in 1970 to over 190 today, with 38 more currently under construction. The major reason for this has been the extension of government ownership of, and public subsidy for, mass transit. Virtually all metro systems in the world today are publicly owned and operated. This has dramatically increased transportation planners’ responsibility, resources, and influence, and enhanced their potential ability to produce more positive outcomes in terms of congestion and travel time, environmental impacts, quality of life, and much else. It has also, however, brought challenges to the field, as planners struggle to balance political, administrative, economic, financial, technological, engineering, and operational demands in running complex transportation systems. Moreover, efforts to persuade the public to substitute transit travel for auto travel have had mixed success.

In addition, transportation planners today work closely with land-use planners to create walkable and bikeable environments with higher densities, a mix of land uses (where a half century ago strict separation of land uses was considered the ideal), good pedestrian infrastructure, and appealing aesthetics. It is hoped that these areas will reduce auto trips, although how much they actually do so, and why, is a subject that is still being debated.

Transportation planning becomes integrated with land-use planning

Third, there has been increasing focus on using transportation to shape land use. In the past, city form was considered largely fixed, and transportation planners sought simply to accommodate anticipated future development. Today, there is a richer understanding of the symbiotic development of transportation systems and land uses. For example, cities such as New York and London, whose formative years were in the eras when walking and mass transit were dominant, have developed high densities and lively centers, while cities that developed when the automobile was the dominant mode, such as Atlanta, Phoenix, or Houston, grew with low densities and high levels of dispersion.

In light of this, transportation planning and land-use planning are now much more tightly integrated. Transportation and land-use models are now used in an iterative fashion, with transportation patterns predicting land-use developments, and land-use developments conversely predicting future use of the transportation system. Moreover, transportation and land-use planning are now more tightly coordinated, for example in the case of “transit-oriented developments” that aim to create dense, walkable communities around transit stops. On a larger scale, decision-makers increasingly build – or choose not to build – transportation facilities to channel growth into desired areas. For example, planners have increasingly eschewed building highways to outlying suburban and exurban areas in an effort to arrest urban sprawl.
Despite near universal acceptance that land use influences travel (Ewing and Cervero 2010), and that transportation systems shape land use (Giuliano 2004), the empirical evidence suggests that these links depend on context and have limits. For example, there is good evidence that new transit investments can powerfully stimulate growth in healthy central business districts with limited parking. However, to this point mass transit has not consistently shown the ability to reenergize blighted areas or cause new, denser development in low-density, outlying areas.

Transportation planners emphasize shaping travel demand

Fourth, planners now focus less on accommodating travel and more on managing it. Through the first two-thirds of the twentieth century, planning operated according to the “predict and provide” principle, presuming growing auto travel as a given and seeing the role of transportation planning as accommodating this growth. Today, transportation planning also emphasizes managing, and in many cases discouraging, auto travel. Europe has been in the lead in this campaign, with aggressive steps to heavily tax fuel and car purchases; levy tolls on autos in congested city centers; restrict parking, particularly in city centers; limit the construction of new highways; and so on. Transportation demand management programs, which attempt to change behavior by, for example, offering incentives to employees to share rides, take transit, walk, or telecommute, have also been tried, though with mixed success. At the same time, governments worldwide heavily subsidize public transit travel to promote it as an alternative to driving (as well as a means of promoting mobility for those unable to own and operate autos).

Transportation planning focuses on environmental impacts

Fifth, there is now intense interest in reducing transportation’s harmful effects on the environment. Transportation planners have always been cognizant of these, going back to the late nineteenth century when a pollution crisis developed due to reliance on horses in urban areas. However, a relaxed attitude toward the environment, plus ignorance about many of the detrimental impacts from emissions from motor vehicles, led to severe auto-generated pollution problems as early as the mid-1950s, when smog blanketed cities such as Los Angeles. These problems began to be addressed in the 1960s and especially in the 1970s. In the United States, the Clean Air Act of 1970 set in motion a chain of regulations that set limits on major auto-generated pollutants and penalized metropolitan areas for failing to meet standards. America’s Corporate Average Fuel Economy (CAFE) standards dramatically improved (and continue to improve) fuel economy and reduce emissions. Moreover, efforts to promote alternative travel modes such as bicycling, transit, and walking are often touted on the basis of their environmental benefits. By and large, tremendous progress has been made in reducing air pollution from autos and trucks, and smog levels have plummeted, at least in developed nations that have adopted high standards and are not experiencing rapid growth in vehicle use. However, it is unlikely that the question of transportation and the environment will ever be “solved,” if for no other reason than that past history shows that expanding knowledge of the environment and human health is perpetually resulting in the discovery of new hazards, such as ultrafine particulate matter from diesel engines and greenhouse gas emissions.
TRANSPORTATION PLANNING

Transportation planning exploits technology

Sixth, transportation planning increasingly focuses on developing and deploying technology to solve problems such as fuel consumption and emissions. Thanks to the CAFE standards, a new auto in the year 2025 will average roughly four times the mileage per gallon of its counterpart in the early 1970s. This is primarily being done with improvements in car body design, transmissions, tires, and the internal combustion engine; many believe that continued improvement in the near future will be dramatic thanks to the replacement of gasoline by electric batteries, natural gas, cellulosic ethanol, or hydrogen fuel cells. Since greenhouse gas emissions are proportional to fossil fuel use, all of these developments may ameliorate, though not solve, the problem of transportation’s effects on the climate. Also, new regulations are considerably reducing the emission of particulate matter from diesel trucks. Catalytic converters and lead-free gasoline have improved air quality to a great degree. Car safety has vastly improved, in part thanks to new technology like antilock brakes, airbags, stability control, rear cameras, and so on. Finally, many now believe that autos that drive themselves will ultimately have dramatic positive impacts on congestion and travel time, fuel consumption, crashes, air pollution, urban sprawl, and much else. It should be noted that these changes have not come about through market forces alone; for example, the evidence shows that automakers and their customers would not have sought out the current high levels of fuel economy without government regulation and the transportation planners who help craft it.

Despite considerable successes, however, the question of whether technology and the regulations that promote it will be sufficient for solving the problem of transportation’s negative impacts is a subject for debate. While one stream of thought is that the most severe problems caused by the auto can be addressed by improving it, another school of thought is that the auto is inherently deeply flawed, and that transportation planning should focus on replacing it with alternate forms of mobility and developing land-use patterns that reduce the need for auto travel. Undoubtedly, transportation planners in the future will reach some middle ground, depending on the context in which they operate.

The transportation planning process embraces public participation

Seventh, public participation has become a key element in the transportation planning process. At the time of the construction of the American Interstate Highway System, government had almost limitless power to displace homes and businesses, with compensation but with little possibility of appeal. Without these powers this massive system could never have been built, but in time citizens bridled as neighborhoods were riven by intrusive new freeways. In response to this, a “freeway revolt” movement began, setting in train a trend toward greater public input into the planning process. Today, planners in the developed world conduct extensive public outreach, seeking input on potential policies. This has great advantages in that it can prevent arbitrary, unjust, and counterproductive action on the part of planners. However, some maintain that not-in-my-backyard sentiment, ingrained aversion to change, and the ability of small numbers of passionate people to sway the process, coupled with the fact that most potential beneficiaries of transportation projects are too uninformed or apathetic to lobby, has sapped planners’ ability to develop needed transportation interventions. In short, some feel that the price
of checking overweening government may have been the creation of government paralysis. Still, few would prefer to return to an era where transportation planners ran roughshod over residents. In addition to working with the public, transportation planning also involves cooperation between numerous levels of government. The variety of arrangements for political control over, and funding of, transportation services and infrastructure varies considerably across the world, but typically it is a joint effort of national, state/provincial, regional, and local governments. As such, the transportation planning and finance system is often of great complexity, necessitating considerable political coordination and the navigation of daunting bureaucratic obstacles.

The future of transportation planning

Problems of political will can be simpler in developing nations, particularly those with less public input into the decision-making process, and this is where the demand for new transportation infrastructure is greatest. It remains to be seen what choices nations such as China and India will make. On the one hand, these countries have the opportunity to learn from the mistakes that developed nations made during their historical evolution, and they can adopt the latest technology and planning principles. On the other hand, the historical record shows that with rising wealth comes dramatic public demand for automobiles, highways, and suburban development, and in addition it is far from clear that transportation planning even in the developed world has “solved” many of the key problems. Given the developing world’s huge population and rapidly rising prosperity, developments in transportation planning there promise to have dramatic repercussions not just for those nations but for the world as a whole.

Travel geographies

Perla Zusman
Hortensia Castro
University of Buenos Aires, Argentina

Traveling may be defined as the movement of people from one place to another, while the experience of travel can involve a large range of voluntary and involuntary social practices, such as exile, pilgrimage, scientific exploration, and tourism. This movement across space involves a transformation of one’s subjectivity, one’s vision of the traveled to and visited places and societies, and one’s own place of origin, which, on return, may be perceived or experienced in a different way. The interaction between individuals and places new to them opens the door to the development of new ways of looking at and learning from places. The idea of traveling is also usually reserved for engaging in journeys that could shape an alien gaze; in this connection, the displacement that can occur in traveling involves an experience of discovery and invention of oneself and others (individuals, cultures, places). Within this framework, travel geographies can be understood as the study of the different practices connected with traveling and both the imaginary and the material geographies that are created through the displacement that travel can engender.

Traveling also creates travelers. Looking at how a relationship with a visited place is established, Todorov (2004/1989) identified a collection of types of travelers who represent variants of universal types. Among them he distinguishes: the assimilator, who wishes to change others so that they become similar to her/him; the tourist, a visitor usually in a hurry who prefers to engage with sites as opposed to human beings; the impressionist, who has more time than the tourist, and who extends her/his horizon to human beings and takes home not only photographic or verbal clichés, but also her/his own writings, sketches, or paintings; and the outsider, who makes a permanent comparison between her/his place of destination and her/his own country, and who may establish either a detached or an attached relationship with others.

Travel narratives in geography

Travel narratives, to the extent that they record and recreate a displacement experience, have historically been considered within academic geography as a source of objective information offering “true” empirical knowledge of visited places, especially in the case of texts generated by explorers, naturalists, and scientists. In the 1990s, with the influence of poststructuralism and the “cultural turn,” traveling and travel narratives started to be studied as a cultural product, contingent on historical and geographical factors, as both an expression and a means of representation of desires and fantasies. Critical approaches to travel entailed, in turn, an increase in the type of narratives under study. For example, in addition to canonical texts, such as those by the explorer Alexander von Humboldt (1769–1859) and the naturalist Charles Darwin (1809–1882), which express a relationship between traveling and scientific knowledge, there has also been a focus on
impressionistic or biographical narratives, such as those by the writers François de Chateaubriand (1768–1848) and Bruce Chatwin (1940–1989), and on narratives by women such as Mary Kingsley (1862–1900) (Blunt 1994). One focus in critical travel studies is the text itself, in terms of the forms of representation in narratives – a frequent object of interest being the narratives of Enlightenment naturalists: the knowledge strategies at stake, and the form and style in which these narratives were laid out. Conversely, other studies have turned their attention to the relationship between text and context, and delved into travel narratives as an active element of the production of knowledge about places.

Studies of travel narratives initially situated journeys in discussions that considered traveling as an individual practice, undertaken by “romantic travelers” whose narratives focused on impressions, desires, and inner needs, as opposed to traveling as a group (whether political, economic, cultural, and/or scientific) or on institutionalized ventures. For example, the early nineteenth-century exploration undertaken by Humboldt throughout South America, is frequently quoted as an example of a spirit of individual initiative, while his links to various institutional networks are ignored. And yet, in addition to being authorized by Charles V of Spain to travel across South American territories, Humboldt capitalized on the outcome of his trip by becoming a firm member and an important participant in French scientific and political circles.

Since the 1970s, travel literature has entered the fields of study of postcolonial geographies (in the anglophone world) and territorial formation (in Latin America), as well as of historical geography in general, enlarging the horizons of geographical knowledge. Accordingly, the political meanings attached to travel narratives became a focus of academic attention, particularly their role in the construction and reproduction of situations of domination. In examining political meanings, some scholars have focused on the deconstruction of travel narratives by naturalists and scientists in order to show that, under a “strategy of innocence” (Pratt 1992), such narratives could harbor political implications, which could in turn lend support to the creation of a consensus on imperial actions by Latin American nation-states against indigenous peoples. Literary critique, and in particular the texts by Said, Orientalism (1978) and Culture and Imperialism (1993), have contributed to the development of this perspective by proposing that travel narratives, in addition to texts by novelists and pictures or paintings from outside the European milieu, produce geographical representations that have supported the domination of colonized peoples. Said (1993) has shown how travel narratives have rewritten the history and geography of native populations, (re)constructing them from a perspective based on exoticism and curiosity in order to hide the most perversive effects of imperialism, namely oppression and violence.

Travel narratives and geographical imaginaries

A key topic dealt with by such studies has been that of the geographical imaginaries of colonized territories, in which territories were the other of imperial centers, presented as places of insecurity and disorder as opposed to those exemplifying the ideals of security and social and aesthetic order (Serjé 2005). For example, the idea of tropicality contributed to shaping the equatorial zones in America, Africa, and Oceania as environments that were supplementary to Europe and available to meet its needs and desires. They were represented as benign and prodigal, exuberant, and even paradisiacal places
in the narratives by Christopher Columbus (ca. 1451–1506), Louis Antoine de Bougainville (1729–1811), James Cook (1728–1779), and Humboldt, or as sick and hazardous places by Joseph Conrad (1854–1924) and Daniel Defoe (ca. 1660–1731). In Latin America, geographical imaginaries of the desierto (desert; a term used for areas with physically heterogeneous conditions such as Patagonia, or even fertile regions such as the Pampa) and the sertão (the Brazilian backlands) described these spaces as only inhabited by indigenous peoples with a social and economic system different from those of the West. Both of these imaginaries depicted these areas as “demographic vacuums” or “unpopulated lands” in an attempt to endorse their appropriation. In particular, throughout the process of the constitution of the nation-states of South America toward the end of the nineteenth and the beginning of the twentieth centuries, travel narratives shaped the Andes mountain range into a wall or barrier where it had traditionally been a space heavily crossed by exiles, guides, and shepherds (Hevilla 2007).

Imperial and nation-state networks could also give rise to dissimilar geographical imaginations for the same time and place. For example, travelers such as Ludwig Brackebusch (1849–1906), Eduardo Holmberg Jr (1852–1937), and Juan B. Ambrosetti (1865–1917), contracted by the Argentine government between the end of the nineteenth and the beginning of the twentieth century to survey the highlands of northwest Argentina, described in their texts the mineral wealth and potential oases in these areas. Other narratives, such as those by the American explorer Isaiah Bowman (1878–1950), who traveled across the same places, highlighted the harsh limitations imposed by extreme nature (particularly water scarcity) on the use of the environment and the population of these areas. Although it was such Western geographical imaginaries that became dominant, narratives and cartographies contained vestiges of representations from native populations. Such is the case in relation to indigenous toponomies, describing the perceptions and valorizations of native populations concerning their surrounding environment, the survival of which can be considered a strategy of resistance against dominant geographical imaginations.

Some authors have studied the ways in which local elites, seeking independence from the colonial power, gave new meanings to the imaginations of imperial travel narratives; however, this resignification did not imply a complete break with the European imagination. Several Spanish American authors writing from the end of the nineteenth century, such as Domingo Faustino Sarmiento (1881–1888) and Andrés Bello (1781–1865), used and adapted narratives from European travelers to advance claims for local autonomy that largely focused on the diversity and exuberance of South American “nature.” Nevertheless, their writings did not imply a rejection of the Enlightenment values and ideas of civilization that these elites shared with their European counterparts.

Other studies have shown how the ideas developed and disseminated through travel narratives produce and reproduce materialities. Such studies have focused on an analysis of the physical characteristics of the landscapes visited by travelers, as well as on their material forms of representation. Additionally, they have recognized the active role played by the ideas communicated through narratives on the transformation of places, as in the case of the export of quinine plantations to tropical India whose properties had been described by La Condamine (1701–1774) in his narratives on South America, or in the production of a “visibility space” around the Nile after the construction of platforms to secure panoramic views for
TRAVEL GEOGRAPHIES

Tourist consumption, which, based on romantic narratives, turned “an ancient Egypt” into “an exotic Orient” (Gregory 1999, 146).

Travel narratives and intersectionality

Geographical analyses of journeys and travel literature since the 1990s have also assumed that class, gender, and ethnic differences influence the ways in which a journey is envisaged, the type of routes followed, and the form of how a relationship with “others” is established, thus contributing to identity construction processes.

Concerning displacement as a mark of class distinction, research has been conducted on the Grand Tour, the trip undertaken by young European elites during the eighteenth and nineteenth centuries across ancient and Renaissance sites, including Greece, the south of the Italian peninsula, and also to South America (as in the case of Evelyn Waugh). Such journeys were conceived and implemented as an educational tool that reaffirmed the learned status of elite individuals, who went on to produce canonical pictorial representations of Mediterranean landscapes, particularly from Italy, such as the Coliseum, the Tivoli waterfalls, and Mount Vesuvius.

Literature produced by women travelers and their associated geographies awakened the interest of feminist geographers. In general, the emancipatory character of trips is recognized, even though, in some cases, an ambivalence is observed in connection with colonial discourses, which reveals the limits of emancipation. For example, the travel narratives of her trips through Argentina by the journalist Ada Elflein (1880–1919) in La Prensa – one of the most prominent newspapers in Argentina in the first decades of the twentieth century – invited women to abandon their homes and embark on adventure. The household space, however, was replaced in her narrative by the homeland space, a milieu containing the sense of safety similar to that inspired by home, to be praised only through direct contact with its breathtaking landscapes (Servelli 2014).

Globalization and less expensive travel costs have awakened a new interest in traveling and travel narratives. Today, many male and female travelers publish accounts of their experiences in journals, newspapers, or on the Internet, using canonical narratives to define their routes and to recreate their geographical imaginaries (or call them into question). Additionally, some intellectuals and scientists have recreated the experiences of past explorations to revisit sensations and imaginations. For example, the Paraná Ra’anga philosophic trip was organized in South America from March to April, 2010, by Graciela Silvestri, a landscape specialist, and sponsored by the Spanish International Cooperation Agency network of cultural centers. The term “philosophic trip” mirrors the name used in the age of Enlightenment to refer to travels designed to explore and “discover” the economic potential of colonial territories. Based on a river journey, the expedition attempted to follow the same route taken by the Spaniard Juan de Ayolas (1493/1510–1538) over the de la Plata, Paraná, and Paraguay rivers from 1536 to 1537, as described by the writer Ulrico Schmidl (1510–ca. 1580). A group of scientists, writers, and artists made this journey in order to reconsider the common “figures” (“figure” referring to one of the meanings of the Guarani word ra’anga (Silvestri 2011), such as external configurations or the appearances of things, the construction of which is shaped by anything from technical skills to feelings) representing the Paraná River as well as to stimulate discussions on current topics and problems concerning this river. From on the interactions that developed during this journey, knowledge exchanges were established between the different
actors living on the shore of the Paraná River and the members of the expedition.

There remains a need to deepen the search for and the study of narratives by subaltern populations that were part of the colonial encounter, whether these be represented by native populations or the people who accompanied travelers as guides, servants, or interpreters. The absence of these voices is likely to be explained by the small number of written narratives they produced, although these could be substituted for by a compilation of the oral testimonies of their descendants.

Images and discourses about places, originating in trips made during the eighteenth and nineteenth centuries, remain current today and are recreated by narratives of the present. Is it possible to overcome the exoticism embodied in these imaginations, which are so distant from current realities? Maybe a different kind of trip and traveler profile will unfold that can explore a horizontal and nonhierarchical relationship with visited people, which can produce a narrative reflecting a negotiation between the images that insiders and outsiders have of places.

An ecotone refers to a boundary or transition zone that is bracketed by more homogeneous vegetation types. Ecotones are created by environmental gradients that ultimately govern the physiological and reproductive range limits of species from adjacent ecosystems. Given the relatively high levels of stress imposed on species growing at or near the edge of what may be referred to as their bioclimatic envelope, the dynamics of ecotone boundaries are widely considered to be sensitive proxies for climate variability. The width of these biogeographical transition zones normally corresponds to how steep the local environmental gradients are, with more narrow ecotones approaching an abrupt line produced in environments with particularly sharp gradients and broader ones indicating a more gradual influence over space. In either case, however, the clear visual contrast provided by forest trees abutting communities of low-stature vegetation makes treeline ecotones one of the most easily recognized ecotones in existence.

Yet, considering the varying importance of environmental gradients in creating and governing tree regeneration and growth within these conspicuous vegetation boundaries or transition zones, this entry will be separated into two sections that deal exclusively with (1) arctic and alpine treeline and (2) savanna ecotones. These two categories of treeline environments occur in distinct biogeographic settings worldwide, and thus an individual rather than a group perspective can help articulate the processes responsible for maintaining their dynamic existence.

### Arctic and alpine treeline ecotones

#### Terminology and distribution

The arctic treeline (also referred to as the subarctic or polar treeline) is a very broad ecotone that forms a high-latitude circumpolar belt around the Northern Hemisphere between approximately 60°N and 70°N. It forms the low-elevation transition zone between the boreal forest biome to the south and arctic tundra biome to the north. The width of the arctic treeline ecotone demonstrates remarkable variability across relatively level terrain, as it ranges from a few kilometers to over 100 km. Although moderate relief can play a role in how wide these ecotones are, the fundamental reason for such expansive transition zones relates to the gradual decrease in temperature along a latitudinal gradient, particularly compared to the relatively sharp decreases in temperature found along steep elevational gradients. In addition, the southernmost boundary of continuous permafrost exerts a strong influence on the spatial extent of arctic treeline ecotones.

Alpine treeline (also referred to as upper treeline) ecotones form a high-elevation transition zone from subalpine forest to alpine tundra. Thus, arctic treeline ecotones form the northernmost extent of forests globally while alpine...
TREELINE ECOTONES

Treeline represents the highest elevational extent. Given that the main prerequisite for alpine treeline is a mountain that attains an altitude beyond which trees can successfully establish and reproduce, the geographic distribution is widespread, ranging in latitude from the subarctic to the tropics. Alpine treeline ecotones can vary in width but are relatively abrupt compared to the arctic treeline, especially on the steep mountain slopes characteristic of the European Alps and parts of the Rocky Mountains in the United States. In areas dominated by more gentle topography, the alpine treeline ecotone can span hundreds of meters and, generally speaking, limitations from permafrost are minimal and are confined to subarctic regions.

Terminology plays an important role in treeline ecotone research, although a cross-comparison of studies is often complicated by the fact that researchers do not adhere to a universally-accepted terminology in defining the spatial dimensions of a particular treeline environment. For instance, the term “timberline” normally refers to the northernmost or uppermost elevational extent of continuous forest where the treeline ecotone begins. Depending on how abrupt the transition from forest to tundra is and what species are present, this can be a challenging baseline to delineate in the field. This is especially true when the ecotone is composed of more open-grown species like pine (Pinus sp.) or larch (Larix sp.), compared to relatively dense stands of more shade-tolerant spruce (Picea sp.) and fir (Abies sp.). The “treeline” or “tree limit” then refers to the furthest extent of trees with an upright growth form, with the treeline ecotone existing between these two delineations. Another term used in treeline studies includes “tree species line,” which is intended to convey the existence of both krummholz and seedlings that may exist beyond the limit of upright trees. Krummholz is a German word and is used with reference to trees with a twisted or gnarled growth form that represents a phenotypic response to particularly harsh climate conditions often related to local wind and snow regimes. Distinguishing characteristics of krummholz also include a predominantly horizontal growth form resembling a large, multistemmed shrub rather than a single-stemmed upright tree.

Considered together, these terms are used to describe one of two main definitions used in treeline ecotone research. The first has roots in landscape ecological investigations of the treeline, and specifically defines the arctic and alpine treelines as the transition zone extending from closed subalpine or northern boreal forest (also called timberline or forest line) to the uppermost or northernmost extent of scattered and stunted individuals, regardless of their height. This definition of a treeline ecotone differs from the other commonly employed method where the uppermost or northernmost boundary of treeline is based on trees reaching a minimum height, such as 2 or 3 m. The rationale for confining ecotone boundaries to the elevational or latitudinal extent of trees with a given height instead of the point beyond which successful tree establishment occurs is typically based on the depth of winter snowpack in a specific environment and whether trees (seedlings and/or saplings) protrude above this protective layer or are sheltered beneath it. The basis for requiring a minimum height of 3 m, for example, also ensures the differentiation between tree crowns closely aligned with prevailing atmospheric conditions and low-stature vegetation, which are more capable of strongly modifying their microclimate. Potential arguments against using a specific height criteria when defining treeline ecotone boundaries relate to the tremendous variability in localized wind–snow interactions throughout alpine and arctic treeline landscapes, species-specific differences in vertical growth rates, and the pivotal
importance of understanding the spatiotemporal patterns of seedling establishment (e.g., growth to 3 m) within treeline ecotones. Moreover, this dichotomy in how a treeline ecotone is defined fits within a long-standing historical context, where observations and causal mechanisms were traditionally approached from one of two spatial scales: fine-scale local variability versus a more uniform broad-scale approach aimed at reaching a global perspective.

History of treeline research

Arctic and alpine treeline ecotones have captivated the research interests of geographers, ecologists, and naturalists alike for centuries. During the European Renaissance, for example, Leonardo da Vinci (1452–1519) observed that certain organisms were specific to a particular elevational belt on Monte Rosa in the Italian Alps. This rich history has in turn produced a remarkably extensive literature. Written descriptions of the alpine treeline ecotone date back to at least 1555, when Conrad Gessner (1516–1565) from Zurich published “description montis fracti” in which he attributed the elevational zonation of vegetation communities in the front ranges of the Swiss Alps to a decrease in temperature and growing season with elevation. This early period in treeline research extends through the time of the famous geographer (naturalist and explorer) Alexander von Humboldt (1769–1859). Humboldt was an unmistakably keen observer and, according to Körner (2012), he clearly viewed the alpine treeline as a life form boundary and common bioclimatological reference point, whereby the location of all other elevational vegetation belts were positioned relative to its occurrence. Moreover, Humboldt made some foundational linkages in the early nineteenth century (1805) regarding the global occurrence of the treeline and not only how the elevational position of the ecotone varied by latitude but how different vegetation belts were caused by shifting isotherms as elevation increases along a mountain slope. These insights strongly influenced his ideas of global plant formations and were instrumental in the eventual formation of biogeography as a viable subdiscipline of geography. Given that Humboldt’s observations remain valid today and because his understanding of alpine treeline linked observation with causality, he is perhaps the most distinguished of early treeline researchers. In summary, although this early period of treeline ecotone research lasted for over three centuries, its legacy is largely defined by observational insights derived from regional and local geographic studies.

Systematic treeline research began seeking to build on earlier observational work approximately 150 years ago. This transition period can be thought of as a time when an increasing number of observational studies hinted toward heat deficiency as the primary reason for the formation of arctic and alpine treelines. Collective efforts to prove this, however, often necessarily relied on the interpolation of meteorological data from weather stations far removed from treeline environments, especially in high-latitude areas of the Arctic, which in many instances, remains problematic today. During this time, climatological-based investigations identified the coincidental overlap between the arctic treeline boundary and the 10°C isotherm of the warmest month, July. Other increasingly systematic investigations centered on the mountain-mass effect in raising the elevational extent of the alpine tree-line and, correspondingly, the upper limit of the snow line, agriculture, and human settlements, along with early attempts to link precipitation with high-elevation treeline ecotones. Central to this transition into the more systematic modern period, however, was the work of Däniker in 1923, who was the first to pay special attention
TREELINE ECOTONES

to local ecological conditions when explaining the patterns he saw at the alpine treeline in the European Alps (Holtmeier 2009). What is perhaps most impressive about Däniker's work is that he had virtually no data, yet, through ecological reasoning based on comparison and plausibility, he reached the conclusion that a lack of sufficient heat limits tree growth at the upper treeline ecotone (Körner 2012).

Experimental approaches supplemented by the use of field instrumentation in the early 1930s marked a shift toward a more fine-scale understanding of the alpine treeline. This collective initiation of case studies identified a suite of governing mechanisms that may explain local-scale variation such as winter desiccation, but do not contribute further to a global understanding of the life form boundary that the alpine treeline represents (Körner 2012). Shortly thereafter, catastrophic avalanches in the Alps during the winters of 1951–1952 and 1953–1954 prompted the development of extensive research programs in Austria and Switzerland to assess the protective function of trees positioned within the alpine treeline ecotone which had been largely deforested for various land uses, including the creation of alpine pastures, mining, burning, salt works, and timber harvesting (Holtmeier 2009).

Another positive outcome of the avalanches was the visionary establishment of research stations in close proximity to the alpine treeline in 1953 (Obergurgl, Austria) and 1959 (near Davos, Switzerland) where experimental field studies on topoclimate, plant communities, soils, snow fungi, mycorrhiza, and species-specific reforestation efforts could be carried out and carefully observed (Holtmeier 2009). Similar field stations exist at far northern latitudes near the arctic treeline (e.g., Abisko, Sweden) that further underscore the ecological benefits of a permanent location to conduct fine-scale field experiments.

Deviations from the more fine-scale experimental approach during this period can be found in the broad-scale comparative approaches of Daubenmire and Troll who, in the opinion of Körner (2012), championed a biogeographical approach rooted in the Humboldt tradition that emphasizes the global nature of treeline ecotones. In both cases, this sort of treeline research focused on climate correlates that could explain the distribution of the alpine treeline. For example, Daubenmire (1954) meticulously plotted the elevation of the alpine treeline along the entire length of the American Cordillera and discussed the broad-scale variation within the context of temperature, wind, snow, and air mass climatology influences. Akin to previous work, his writing strongly hints at the likely overriding influence of heat in spite of the regional and local variations attributed to oceanic and wind/snow influences, respectively. Oceans influence the treeline through the trajectory of maritime air masses that lead to lower alpine treeline elevations because of cooler summer temperatures and normally shorter growing seasons because of heavier snow totals, in terms of both total accumulation and water content, especially compared to more continental settings, which have relatively dry, powdery snow. Troll (1973) was similarly placed within the context of bioclimatological studies, yet his global comparisons focused on high-elevation mountain environments in general rather than on the alpine treeline exclusively. As a result, it can be argued that his thorough consideration of periglacial processes in shaping the landscapes at or near the alpine treeline represents a precursor to more contemporary biogeomorphological studies. Either way, these broad-scale studies revived the global emphasis on treeline ecotones.

A later emphasis on more fine-scale studies accompanied the publication of Tranquillini's *Physiological Ecology of the Alpine Timberline*
(1979), which is widely considered a classic. This work represented a synthesis of Tranquillini’s experimental research on the ecophysiology of tree species growing at the alpine treeline in the Austrian Alps, in which he argued that the formation of the treeline is ultimately dependent on an increasingly unfavorable heat balance with gains in elevation or latitude. He supported this assertion with evidence of higher alpine treelines on south-facing slopes, which in the Northern Hemisphere receive more insolation than contrasting north-facing slopes, and the overall rise in treeline elevation when moving along a latitudinal gradient from the poles to the tropics. Tranquillini’s work also underscored how complex the effect of temperature is on plant physiological processes and that annual tree growth is likely limited by a minimum temperature threshold. These topics remain relevant in the literature today, including his understanding of how the dominating influence of temperature can in turn be modified by local variations in solar radiation, moisture, and wind. For those with ecophysiological interests, this book clearly reinforced the importance of studying tree growth (Körner 2012). However, the experimental work described by Tranquillini was discounted by others for the nontransferability of its results to distant treeline environments characterized by pronounced heterogeneous site conditions (Holtmeier 2009). Disagreements over the importance of Tranquillini’s pioneering ecophysiology work point to a natural divide within the treeline research community which, to a certain extent, remains evident today.

Context for modern treeline research

Global climate change and the burgeoning field of global change ecology have perhaps provided the strongest motivation for continued research efforts at both arctic and alpine treeline ecotones worldwide. This is because, in the presence of suitable substrate conditions for tree establishment, the location of arctic and alpine treeline ecotones is primarily controlled by heat deficiency. This means that the physiological processes responsible for tree growth and establishment at the uppermost or northernmost extent of the ecotone are temperature-limited and unable to occur successfully beyond a certain latitude or elevation. The onset and foreseeable continuation of warming related to global climate change is therefore expected to facilitate successful tree establishment in areas further north or upslope from where the arctic and alpine treelines currently extend. As a result, identifying the existence of and determining the causal factors for treeline advance have dominated the contemporary literature on both arctic and alpine treeline ecotones.

The premise for widespread treeline advance with warming is supported by paleoecological studies based on tree rings, radiocarbon dating of remnant wood in treeline ecotones, and plant macrofossil and pollen assemblages from lake sediment cores, which all demonstrate a relatively tight coupling between treeline extent and climate variability throughout the Holocene (ca. 10 000 years BP). During this time frame, treelines expanded beyond the present ecotone boundaries during a warming period initiated during the early Holocene (e.g., 10 000–6000 years BP in the Rocky Mountains) and returned to approximate positions comparable to the early twentieth century beginning around 3000 years BP. Although reconstructions focused on more recent changes in the elevational extent of the alpine treeline are possible using a variety of field and geospatial computer techniques, that treeline advance is confined to specific treeline types is underemphasized in the literature.
Climatic treelines essentially refer to environments where tree establishment and eventual treeline advance beyond the current ecotone boundary are unimpeded by local topography or geomorphological conditions, such as steep and rocky slopes, absence of soil development, or frequently disturbed avalanche tracks. Based on extensive field research in the Rocky Mountains in the United States, identifying mountain peaks with “climatic” treelines can be challenging because of the quantity of geologic treelines, where the uppermost extent of subalpine forest borders rocky landforms (e.g., talus slopes or sheer rock) that are incapable of supporting treeline advance, regardless of how amenable climate conditions become. Anthropogenic treelines also exist and refer to treeline ecotones impacted by human activities; these normally occur on more gentle terrain. Without knowledge of the previous land-use history of an ecotone, anthropogenic ecotones can visually resemble climatic treelines, especially on mountain peaks with a sizable expanse of palatable alpine species for grazing, as is the case in portions of the Sangre de Cristos in northern New Mexico. And, in some cases, the spatiotemporal patterns of tree establishment during the reforestation of a previously disturbed treeline resemble what one might expect from a climate-induced shift. Thus, a paradox can exist when climatic treelines are supposed to contain the most climatically sensitive trees positioned in relative disturbance-free environments, yet, because they are typically located along slopes or near peaks that are more traversable than those close to the geologic treeline, the influence of climate may be obscured by land-use legacies. Similar challenges arise at the arctic treeline when the influence of grazing reindeer and of climate on birch (Betula sp.) forests are juxtaposed. Local site histories are, therefore, important to consider when examining treeline advance, even when at climatic treelines.

Treeline advance is a term that has been linked to phenotypic and genotypic responses to climate. A phenotypic response refers to growth form changes, most notably when vertical leaders form on horizontally oriented krummholz in the presence of less severe climate conditions. This sort of treeline change or advance is most commonly reported in studies that define ecotone boundaries by minimum height, and has been a notable component of treeline change in the Scarps Mountains of Sweden and at the arctic treeline in eastern Canada. A genotypic response refers to successful tree establishment from seed beyond the current ecotone boundary and therefore typifies what is commonly thought of as treeline advance. Considering that both responses rely on favorable climate conditions, they are not mutually exclusive and may provide concurrent examples of treeline advance across a landscape or mountain slope.

The advancement of trees into tundra is often cited as evidence for the climatic sensitivity of trees within treeline ecotones. When treeline advance is considered from a regeneration standpoint, this process is contingent on several consecutive stages, beginning with the production of viable seeds. Although this ignores the likelihood of vegetative layering (e.g., root sprouting), which is common to certain treeline species such as black spruce (Picea mariana) at the arctic treeline and subalpine fir (Abies lasiocarpa) or quaking aspen (Populus tremuloides) at the alpine treeline, sizable treeline advance is contingent on the dispersal of viable seeds beyond the treeline boundary. Seed production alone is no guarantee of treeline advance without an ability to disperse effectively. Most seeds at the treeline are wind-dispersed (anemochorous), but some five-needle pines, including whitebark pine (Pinus albicaulis) in North America and stone pine (Pinus cembra) in Europe, have their highly palatable seeds cached by a specific subspecies.
of nutcrackers (*Nucifraga* sp.). Since birds cache multiple seeds in a manner that seems to facilitate establishment, these pines are often found in isolated spatial clusters well above the timberline boundary. Wind dispersal can spread seed rain up to a few hundred meters, depending on local wind regimes and topographic roughness; and, depending on the relative proximity of alpine treeline ecotones to bountiful seed sources at a lower elevation, dispersal can be more limiting to treeline advance at the arctic treeline (Holtmeier 2009).

Following successful dispersal, seeds require a suitable microenvironment for establishment, which can vary by species and in accordance with local climate and geomorphological conditions. A newly established seedling is highly susceptible to mortality and even a single year with extreme winter cold is capable of causing the dieback of seedling and sapling cohorts from several consecutive years. At the opposite end of the radiation spectrum, current trends and future projections of warming foretell the development of heat-induced moisture stress if rising temperatures are not accompanied by parallel increases in precipitation. The potential switch in dominant limiting factors, from the classic temperature-limited paradigm to one of moisture stress, has already been documented at various arctic and alpine treelines worldwide (e.g., the arctic treeline in Alaska and the alpine treeline in the Andes). Elsewhere, sharp rises in temperature triggered an abrupt regime-shift increase in tree establishment. A regime shift refers to the tipping point or measurable change stemming from an ecological threshold response, and results from external climate forcing and/or internal feedbacks more closely related to fine-scale biotic interactions. Considered together, these examples illustrate the meaningful impacts of climate variability exceeding critical threshold values and, as a result, either accelerating or retarding the pace and pattern of treeline advance.

**Considering spatial scale**

The relative role of climate in governing tree establishment is contingent on fine-scale, site-specific attributes capable of facilitating, modulating, or possibly overriding the influence of abiotic inputs. Examples of these more local-scale factors include slope aspect and corresponding soil moisture regimes, the structural form or spatial pattern of tree establishment, properties of soil and geologic substrate, geomorphic processes and landforms, herbivory, invasive forest pathogens, and land-use history. In spite of these wide-ranging factors to consider alongside climate, the expanding literature focused on studying tree establishment, and related treeline advance can be broadly classified into one of two categories: (i) climate–vegetation studies and (ii) process–pattern studies. Of course, neither approach is necessarily ideal; rather, each category often focuses on a particular scale of analysis. Combining these two categories, on the other hand, may help to form a holistic understanding of treeline ecotones that would otherwise be unattainable.

Climate–vegetation studies at the treeline have traditionally focused on broad regional scales where the influence of climate in general and temperature in particular are more easily discernible because governing factors increase in complexity when moving from broad to fine spatial scales. Conversely, process–pattern interactions have largely been restricted to local- and landscape-scale studies where the dominating influences on tree establishment are discussed from a bottom-up perspective. A central theme from this line of research that is relevant across
TREELINE ECOTONES

multiple spatial scales deals with positive feedback switches. Positive feedback in this case refers to the facilitative effects provided by the establishment and the sustained presence of a tree within the treeline ecotone, which in turn ameliorates locally harsh conditions and favors additional establishment. Krummholz patches, inanimate objects like boulders or terrace risers, and topographic depressions can also initiate positive feedback loops at both arctic and alpine treelines. Once formed, the neighboring biotic interactions of positive feedback can override the importance of climate inputs in particularly harsh treeline ecotones characterized by persistently strong winds or drought stress. This then creates a longer lag time in treeline response to climate compared to ecotones where positive feedback is not needed for treeline advance and trees are, in turn, more closely aligned with changes in the climate system.

Spatial scale is a historically relevant theme in treeline research that remains at the forefront of treeline advance studies rooted in landscape ecology or macroecology frameworks where cross-scale, process–pattern interactions are emphasized. Although considerable commonalities exist between these two frameworks, the latter can be distinguished by its stronger emphasis on broad spatial scales (e.g., regional or continental) and top–down climatic controls on process–pattern interactions operating at finer spatial scales (e.g., local). These linkages can be examined in a reciprocal manner as well, which provides the opportunity for a comprehensive understanding and synthesis through both a top–down and a bottom–up approach at spatial scales extending beyond the level of a landscape (e.g., mountain range). A macroecological framework is, therefore, useful for linking climate–pattern–feedback interactions across broad latitudinal gradients (e.g., Elliott 2011), which satisfies the reported need for treeline studies to address both regional and local-scale responses to climate variability while also permitting direct comparisons across large geographic areas.

Savanna ecotones

Tropical savanna ecotones exist in tropical and subtropical regions centered around the 30°N and 30°S latitudes (MacDonald 2003). They occupy the transition zone between wet tropical forests toward the equator and semiarid tropical steppes and deserts toward the poles. This broad ecotone is primarily located in Africa and contains the famous Serengeti Plains of Tanzania and Kenya, but can also be found in parts of South America (referred to as campos or llanos), South Asia, and Australia (referred to as brisalow). Globally, savannas occupy roughly 15 million km² or 40% of the terrestrial landmass. However, permanent land-use practices, such as grazing, are permanently removing savanna grasses and perpetuating the desertification of this biome while simultaneously facilitating the encroachment of the Sahara desert.

Mean annual temperature ranges from 20° to 30°C with an approximate 10°–15°C seasonal range between summer and winter (MacDonald 2003). Total annual precipitation varies from 50 to 150 cm given that the latitudinal position of tropical savannas generally corresponds to the position of subtropical high-pressure cells. These are warm and dry, moisture-limited environments with a winter dry season up to seven months long. The wet season is therefore short in comparison and is initiated when the migrating equatorial cyclone belt referred to as the Intertropical Convergence Zone (ITCZ) arrives and forces air aloft through surface convergence. The pronounced wet and dry seasons of the Serengeti dictate the migration routes for an
unparalleled number of mammal fauna in general and ungulates (hoofed mammals) in particular, with over 90 different species present. Rainfall patterns dictate not only animal migration routes but also areas where trees can exist.

Savanna ecotones are composed of xerophytic vegetation that has evolved to minimize water loss. Within these dry ecotones, the proportion of tree cover varies dramatically depending on moisture availability, competition with grasses, herbivory, and fire. This leads to some areas with only sporadic tree growth and woody shrubs within a broader grassland matrix. In other, more moisture-rich areas, such as riparian zones and well-drained uplands, tree density can resemble a closed canopy forest. Still elsewhere, vast expanses of treeless grassland can exist. Grasses grow quickly once the rainy season starts and can grow to 2 m in height, which shades out tree seedlings of a much smaller stature. Once trees establish, however, they develop a deep tap root to access groundwater because surface rainwater is typically consumed by grasses with more shallow root systems. Trees are characteristically flat-topped in savannas, and this expanded horizontal canopy helps reduce grass cover by shading out the grass understory, which reduces competition for water and the accumulation of highly flammable fine fuels. In Africa, trees are deciduous and shed their leaves in response to drought stress. Outside of Africa, however, trees and shrubs are primarily evergreen with sclerophyllous leaves, indicating a leathery or waxy texture to help prevent water loss through transpiration (MacDonald 2003).

Disturbance is common in savannas and tree cover is often related to grazing, browsing, and fire interactions. Fires occur on an annual basis, and their destructiveness to trees depends on whether they occur at the beginning or end of the dry season, with early-season fires shown to improve tree cover compared to late-season ones, which burn more intensely and in turn kill trees. Trees are equipped with thick bark to protect against both water loss and fire, but the intense heat produced by late-season burns can override this adaptation. African savannas are unique with respect to supporting both grazers, which feed primarily on grasses and forbs, and browsers, which prefer woody vegetation (Holdo, Holt, and Fryxell 2009). Wildebeests are a common grazer and, according to Holdo, Holt, and Fryxell (2009), elephants are a particularly destructive browser because of how quickly they can reduce tree abundance by toppling canopy trees and preventing shorter ones from reaching full size. In addition, the loss of trees creates an opportunity for grasses to expand, which, owing to the competitive advantages of grasses, creates a bottleneck for further tree establishment while concurrently creating more highly flammable, fire-prone grasses. This leads to more widespread fires and tree loss across the landscape unless wildebeests are able to remove enough fine fuels through grazing and thus modify the impacts of fire (Holdo, Holt, and Fryxell 2009).

TREELINE ECOTONES

Further reading

A hurricane is a tropical cyclone over the Atlantic Ocean with maximum sustained winds of at least 74 mph (33 m s$^{-1}$ or 64 kt). In this entry the discussion of hurricanes will serve as the basis for a broader exploration of tropical cyclones. Large-surface low-pressure systems are classified as tropical, extratropical, or subtropical. A tropical cyclone is a low-pressure system that forms over tropical or subtropical oceans. It has a well-developed cyclonic (i.e., counterclockwise in the Northern Hemisphere or clockwise in the Southern Hemisphere) circulation at the surface and a warm core in the middle and upper troposphere. Tropical cyclones are driven by the release of latent energy, and the strongest winds occur relatively close to the center. Frontal boundaries are not attached to a purely tropical cyclone. An extratropical cyclone is a low-pressure system that develops over oceans or land in the middle and high latitudes. It generally forms along existing frontal boundaries and has a cold core in the middle and upper troposphere. Extratropical cyclones are driven by the baroclinic conversion of gravitational potential energy to kinetic energy as cold, dense air moves under warmer, less dense air. The strongest winds may occur at a large distance from the center of an extratropical cyclone. A subtropical cyclone exhibits some characteristics of tropical cyclones and some of extratropical cyclones. It forms over subtropical or tropical oceans and has some deep convection. However, it lacks a central core of convection and it gets energy from baroclinic conversion and the release of latent energy. A subtropical cyclone may have a cold core in the upper troposphere and the strongest winds may occur at an intermediate distance (i.e., several hundred kilometers) from the center.

Tropical cyclones are given various classifications according to their geographic locations. Tropical cyclones are designated as tropical depressions, tropical storms, or hurricanes over the Atlantic, Eastern North Pacific, and Central North Pacific Oceans. Similar low-pressure systems are called tropical depressions, tropical storms, or typhoons over the Western Pacific Ocean. Designations of depressions and cyclonic storms are used over the Northern Indian Ocean, while similar systems are categorized as tropical depressions, tropical storms, or tropical cyclones over the Southwest Indian Ocean.

Formation of hurricanes

Formation of a hurricane requires a pre-existing disturbance, sufficiently warm sea surface temperatures (SSTs), and light winds in the upper troposphere. The pre-existing disturbance may be of tropical, subtropical, or extratropical origin. The original disturbance consists of an area of low pressure at the surface and it may contain some regions of convection. The low serves as a focus for convergence and as a source of low-level vorticity (the tendency for air to rotate cyclonically). As air at the surface flows over a warm ocean, evaporation transfers large amounts of latent energy into the air. The SST in a tropical
ocean has to be at least 26°C to provide enough energy to support the development of a hurricane. When the air converges in the low-pressure system, it begins to rise. Condensation in deep convective clouds converts latent energy into internal energy. Enough latent energy is released to warm the temperature in the middle and upper troposphere, and light winds in the upper troposphere allow for the formation of a warm core over the center of the system. The warm core enhances upper-level divergence, which pumps mass out of the developing cyclone and allows the pressure at the surface to decrease. As the pressure decreases, the pressure gradient force increases and accelerates the air into the center of the developing storm. Stronger winds cause more evaporation and extract more latent energy from the ocean. A positive feedback intensifies the developing low-pressure system. It is classified as a tropical depression and given an alphanumeric designation when a well-organized closed circulation at the surface is identified. A tropical storm is given a name when the maximum sustained wind speed reaches 39 mph (17 m s$^{-1}$ or 33 kt). It becomes a hurricane when the maximum sustained wind speed is greater than or equal to 74 mph (33 m s$^{-1}$ or 64 kt).

Several different weather systems may serve as the initial disturbance for the formation of a hurricane. A tropical disturbance is any discrete area of organized convection that forms and moves over the tropics or subtropics and persists for more than 24 hours. Tropical (easterly) waves are elongated troughs of low pressure in the lower troposphere that are generated as tropical easterly winds flow around mountains in eastern Africa. Tropical waves are characterized by an inverted-V shape that appears in the surface isobars and may be apparent on satellite images. The waves form every one to four days during the summer and early autumn. They move westward across sub-Saharan Africa and emerge over the Atlantic Ocean. Approximately 10–20% of tropical waves develop into tropical cyclones over the Atlantic Ocean. The majority of tropical waves dissipate without becoming a tropical cyclone, but some of them cross into the Eastern North Pacific Ocean and intensify into hurricanes. The southern end of some tropical waves interacts with the Intertropical Convergence Zone (ITCZ) and a cluster of thunderstorms breaks off from the ITCZ. A few of these ITCZ disturbances emerge into the easterly flow at low latitudes and intensify into hurricanes over the Atlantic Ocean. In portions of the world with well-developed monsoonal circulations, such as the Western North Pacific Ocean, a monsoon trough or gyre may be the initial source of low-level convergence, convection, and vorticity.

Extratropical and subtropical weather systems can make a transition into tropical cyclones during cooler seasons. Nearly stationary frontal boundaries, old extratropical cyclones, midtropospheric cutoff lows, mesoscale convective systems, and subtropical cyclones have transformed into hurricanes. These weather systems initially have a cold core at some levels in the atmosphere, a large low-level circulation, and scattered convection at some distance from their center. It can take days for them to be transformed into a tropical cyclone. When they move over the ocean and sit over relatively warm SSTs, evaporation increases the latent energy in the air. An additional transfer of internal energy from the warmer ocean into cooler air reduces horizontal temperature gradients and existing frontal boundaries weaken. Latent energy is released in convection and starts to warm the atmosphere in the middle and upper troposphere. If convection is generated near the center of circulation, a warm core develops and the system exhibits a more tropical cyclone-like structure with the strongest winds located closer
to the center. This tropical transition results in the low being reclassified as a tropical cyclone. In some years, typically when El Niño conditions exist, nearly half of tropical cyclones over the Atlantic may develop as a result of this type of tropical transition.

Structure of hurricanes

Hurricanes exhibit a structure that is distinct from most other types of cyclones. Showers and thunderstorms are organized in bands of rain that spiral cyclonically around the center of circulation. Local regions of convergence in the low-level wind flow generate enhanced rising motion and create the bands of precipitation. Air sinks in a broad area outside of these rainbands and in a narrow region just inside the band. The pattern of vertical motion creates relatively precipitation-free zones between rainbands. A larger primary or principal rainband may spiral into the center of a tropical cyclone. The strongest horizontal winds may occur within the primary rainband of a tropical depression or tropical storm. When rising air reaches the upper troposphere, it diverges anticyclonically and spreads a canopy of cirrus clouds over the tropical cyclone. As a tropical storm intensifies into a hurricane, the primary rainband may wrap around the center of circulation. Subsidence, possibly associated with convection, creates a clear eye at the center of the hurricane. The subsidence does not extend to the surface and the lower one or two kilometers of the eye are comprised of moister air and may include low clouds. The eye is surrounded by a circular eyewall of strong convection. The tallest clouds and the strongest winds in a hurricane are typically found near the inner edge of the eyewall. The average diameter of an eye in an Atlantic hurricane is 46 km, but hurricane Wilma (2005) had an eye with a diameter of 3 km and some hurricanes have exhibited eyes with diameters of over 100 km.

In more intense hurricanes a rainband may wrap completely around an existing eye and eyewall to create concentric eyewalls. Willoughby, Clos, and Shoreibah (1982) presented a conceptual framework to explain eyewall replacement cycles. Initially the strongest winds and convection occur in the original, inner eyewall, and a secondary wind maximum is present in the new, outer eyewall. A clear area caused by subsidence between the two eyewalls is called the moat. As more air converges and rises in the outer eyewall, convection weakens in the inner eyewall. This causes the wind speeds to decrease in the original eyewall and the hurricane weakens temporarily and the radius of maximum winds (RMW) expands to the outer eyewall. As the inner eyewall dissipates, the outer eyewall begins to contract and the hurricane begins to reintensify. If the eyewall replacement cycle continues uninterrupted, eventually the outer eyewall will move to the previous radius of the original inner eyewall and the hurricane will regain its prior intensity.

Knaff, Kossin, and DeMaria (2003) identified a group of annular hurricanes. These hurricanes have large eyes surrounded by a symmetrical ring of convection. The eyes in annular hurricanes have an average diameter of 86 km, which is almost twice the size of eyes in average Atlantic hurricanes. Convection in outer rainbands is much less active than in other hurricanes and annular hurricanes have a “truck tire” or “donut” appearance on satellite imagery. It is still not clear what causes hurricanes to develop an annular structure, but it has been suggested that mesovortices inside the eye may mix energy and momentum until a balanced axisymmetric structure is generated. Annular hurricanes tend to maintain a steady intensity longer than other hurricanes and can pose a challenge for forecasters.
Motion of hurricanes

Many tropical cyclones develop in easterly flow located on the equatorward side of the subtropical high-pressure systems. The easterly flow extends throughout most of the depth of the troposphere and initially steers the storms toward the west. A hurricane will begin to move more poleward as it nears the western end of the subtropical high. As the hurricane moves toward higher latitudes, it begins to enter the zone of westerly flow in the middle and upper troposphere. The westerly flow causes the hurricane to recurve back toward the east. The forward motion of a hurricane will often accelerate as it moves poleward. The precise steering level for a specific tropical cyclone will depend on the intensity of the storm and its thermal environment. Strong storms over the warm SSTs in the tropics will have deep convection and will be steered by the winds throughout the troposphere. An average of the winds between 850 hPa and 200 hPa may give a good estimate of the short-term motion of these hurricanes. The convection in a storm over cooler SSTs will not be as tall and those hurricanes are more likely to be steered by the winds in the middle troposphere (e.g., 500 hPa). Tropical cyclones that are weaker and exhibit mainly shallow convection are steered by the winds in the lower troposphere (e.g., 850 hPa). When the winds at the steering level are weak, a hurricane may become stationary or complete several loops before resuming a steadier forward motion.

Dissipation of hurricanes

Since the primary source of energy for a hurricane comes from evaporation of water from the ocean, movement over land greatly reduces the energy supplied to the storm. Increased friction over land contributes to the weakening of the circulation and movement over mountains can quickly dissipate a hurricane. However, cases have been documented where tropical cyclones maintained their intensity or reintensified modestly when they were well inland. Andersen and Shepherd (2013) performed a global analysis of inland tropical cyclones. They identified a small group of cases they called tropical cyclone maintenance/intensifying (TCMI) systems. The TCMI systems were most prevalent over Australia. They also reported another group of cases they labeled neutral/hybrid that occurred mainly over the United States, China, and India. It is hypothesized that large upward fluxes of latent and internal energy from the surface maintained the circulation and warm core of the inland tropical cyclones.

When hurricanes move poleward over the oceans, cooler SSTs result in less evaporation and hurricanes begin to weaken. Stronger upper-level westerly winds and a more baroclinic environment may cause a hurricane to make an extratropical transition into an extratropical cyclone as it moves poleward. Some hurricanes are sheared apart when they move into a region where there is a large difference in the winds in the lower and upper troposphere. The increased vertical shear can result from an increase in the low-level easterly flow caused by a surge in the trade winds, or from a rapid increase in the flow in the upper troposphere. In either scenario the low-level circulation may become detached from the upper-level warm core and it dissipates in two or three days.

Geographical distribution and frequency of tropical cyclones

Globally, an average of 86 named tropical cyclones form each year. Around 47 tropical cyclones reach hurricane intensity each year. Although there is some year-to-year variability,
the average global frequency of tropical cyclones is relatively stable. A large area of warm SSTs, known as the Western Pacific Warm Pool, contributes to a favorable environment that results in the formation of more tropical cyclones over the Western North Pacific (WNP) Ocean than over any other basin. Approximately 26 named tropical cyclones originate each year over the WNP. The second most active basin is the Eastern North Pacific where an average of 17 named tropical cyclones and nine hurricanes form in a year. The highest frequency of tropical cyclone formation per unit area occurs over the Eastern North Pacific. An average of 12 named tropical cyclones and six hurricanes form annually over the Atlantic Ocean, Caribbean Sea, and Gulf of Mexico. There are an average of 11 named tropical cyclones near Australia, nine over the Southwest Indian Ocean, seven over the South Pacific Ocean, five over the Northern Indian Ocean, and one over the Central Pacific Ocean in a year. For a long time it was thought that hurricanes did not occur over the South Atlantic Ocean. However, in March 2004 a low-pressure system east of Brazil underwent a tropical transition and struck the Brazilian state of Santa Catarina with hurricane force winds. This storm was subsequently given the name Hurricane Catarina and it represents the first documented instance of a tropical cyclone over the South Atlantic Ocean. In rare instances small intense low-pressure systems form over the Mediterranean Sea that have a structure and some characteristics similar to those found in tropical cyclones.

**Hazards accompanying hurricanes**

High winds associated with hurricanes present a danger to life and property. In the strongest hurricanes winds may approach 200 mph (90 m s\(^{-1}\)) and can do damage to even well-constructed buildings. Strong winds blowing toward the shore can create a rapid rise of water level called a *storm surge*. The storm surge can increase water levels by several meters in weaker tropical cyclones and by 10–15 m in the strongest hurricanes. Indentations in the coastline associated with bays or rivers may funnel water into particular locations and cause locally higher water levels. Storm surges are the greatest hazard at the coastline and have been responsible for some of the greatest loss of life in tropical cyclones. A storm surge associated with a hurricane killed thousands in Galveston, Texas, in 1900, which is the largest loss of life in the United States from a hurricane. A storm surge with a tropical cyclone over the Bay of Bengal killed over 100,000 people in Bangladesh in 1970. Heavy rainfall and the flooding it causes is often the greatest hazard in inland locations. Rainfall rates can approach a meter per day in large slow-moving tropical cyclones. Steep topography and deforestation increase the speed of surface runoff and increase the potential for flooding of rivers and streams. Floods caused by Hurricane Mitch killed over 10,000 people in 1998. Some hurricanes spawn tornadoes when they make landfall. Increased friction at the surface slows the wind and it changes direction, while the winds initially are less affected several thousand meters above the surface. The vertical wind shear created by the differences in wind speed and direction causes rotation in the updrafts of some thunderstorms in the rainbands around a hurricane. In some cases this rotation is strong enough to spin up a tornado. Most tornadoes generated in hurricanes are relatively weak and short-lived. However, they are capable of doing damage and causing casualties. Many hurricanes create only a few tornadoes, but several have produced large numbers of tornadoes. The circulation around Hurricane Ivan generated 117 tornadoes.
when it made landfall in the United States in 2004.

Hurricane and tropical cyclone warnings and classifications

The World Meteorological Organization (WMO) has assigned the responsibility for monitoring the oceans and issuing warnings for tropical cyclones to Regional Specialized Meteorological Centers (RSMCs). Each RSMC has the responsibility for a designated area of the Earth. The National Hurricane Center (NHC) monitors the North Atlantic and Eastern North Pacific Oceans, The Central Pacific Hurricane Center (CPHC) monitors the Central Pacific Ocean, the Japan Meteorological Agency (JMA) covers the Western North Pacific Ocean, the Indian Meteorological Department (IMD) handles the North Indian Ocean, and Météo France issues warnings for the South West Indian Ocean. In addition, Tropical Cyclone Warning Centers provide warning information for smaller regions, and national meteorological agencies may provide specific advisories for their countries.

Each RSMC may use a different system for classifying tropical cyclones based on their maximum sustained wind speed. The NHC and CPHC designate tropical cyclones as tropical depressions, tropical storms, or hurricanes. Those RSMCs also use the five categories of the Saffir–Simpson Scale to specify the intensity of hurricanes based on their maximum sustained wind speed. Category 1 and 2 storms are sometimes considered to be minor hurricanes while Category 3, 4, and 5 hurricanes are considered to be major hurricanes. The JMA classifies tropical cyclones as tropical depressions, tropical storms, severe tropical storms, or typhoons. The IMD uses a classification system that includes depression, deep depression, cyclonic storm, severe cyclonic storm, very severe cyclonic storm, and super cyclonic storm. Météo France’s classification scheme ranges from tropical depression through moderate tropical storm, severe tropical storm, tropical cyclone, and intense tropical cyclone to very intense tropical cyclone.

Climatological cycles of hurricane activity

Hurricane activity appears to vary on timescales running from intraseasonal to decadal. Attempts have been made to link the variability to other known atmospheric cycles. Maloney and Hartman (2000) postulated a link between the frequency of hurricanes over the Eastern Pacific Ocean and the phase of the Madden–Julian Oscillation (MJO). The MJO is a 30–60–day oscillation in convection and outgoing longwave radiation that moves west to east across the tropics. In one phase of the MJO, enhanced low-latitude westerly winds in the lower troposphere increase the vorticity around tropical disturbances and upper-level divergence may contribute to the development of tropical cyclones. The North Atlantic Oscillation (NAO), which is a function of the pressure difference between the subtropical high near the Azores and low pressure near Iceland, has been linked to changes in the location of formation of tropical cyclones and their subsequent tracks. Elsner, Liu, and Kocher (2000) concluded that when the subtropical high is located farther south and west, the NAO will be negative and hurricanes will take more westerly tracks across the lower latitudes of the Atlantic Ocean. If the subtropical high is located farther north and west, then the NAO will be positive and
hurricanes are more likely to recurve before they reach the East Coast of the United States.

Gray (1984) presented observational evidence that the El Niño Southern Oscillation (ENSO) phenomenon in the tropical Pacific Ocean had an impact on the formation of hurricanes over the Atlantic Ocean. An El Niño is associated with above normal SSTs over the tropical Central and Eastern Pacific Ocean. Enhanced convection associated with the warmer SSTs pumps mass into the upper troposphere and strengthens the westerly winds occurring in that portion of the atmosphere. Those stronger westerly winds flow across the Atlantic Ocean and produce increased vertical wind shear, which inhibits the formation of tropical cyclones. The frequency of hurricanes also seems to exhibit a longer multidecadal cycle associated with the Atlantic Multidecadal Oscillation (AMO). It has been hypothesized that the AMO represents a multidecadal oscillation of SSTs in the North Atlantic and thus modulates hurricane activity on the same timescale. There has been a significant increase in the frequency of hurricanes over the Atlantic Ocean since 1995, which may be associated with the active portion of the AMO.

Climate change and hurricane activity

The possible impact of climate change on hurricane activity has been a subject of some debate. Early research which focused on an increase in SST suggested that warmer SSTs would produce more and stronger tropical cyclones. However, the situation is more complicated than that and a number of environmental factors affect the development and intensification of hurricanes. Some coupled global atmosphere/ocean models have produced a reduction in the worldwide number of simulated tropical cyclones when the concentration of carbon dioxide and the SST were increased. The greatest decrease occurred in the Southern Hemisphere and the changes in hurricane activity over the Atlantic Ocean were less clear. In some models a decrease in the humidity in the middle troposphere and a reduction in upward motion were linked to a decrease in the number of tropical cyclones over some basins.

There has also been a suggestion that a warmer climate could lead to a reduction in the speed of the upper-level westerly winds in the middle latitudes. This would be consistent with the concept that the upper-level westerly winds are partly a function of the pole-to-equator temperature difference. If those westerly winds were weaker, there would be less wind shear, which could potentially result in stronger hurricanes at higher latitudes. Less cold air in the middle latitudes could also result in tropical cyclones moving further poleward before extratropical transition occurs. Any changes to the global wind pattern could also alter the origin and types of disturbance that produce tropical cyclones and the paths of those storms. Much more research needs to be done before a definitive statement can be made about the impact of climate change on future hurricane activity.

Tropical geography

Daniel Clayton
University of St Andrews, UK

In his 1947 primer *Les pays tropicaux*, the French geographer Pierre Gourou envisioned tropical geography as a disciplinary specialism dealing with the physical and human geography of the tropical zone – usually understood as the region of the Earth around the equator between the Tropic of Cancer (23° 26′ 16″ N) and the Tropic of Capricorn (23° 26′ 16″ S), and distinguished from surrounding (temperate and polar) regions in cosmographic, environmental (climatic and biogeographic), and sometimes ethnographic terms. But Gourou asked a profound question which pushes what he had in mind into a much wider critical frame: Does “the tropics” augur a certain way of seeing or style of inquiry; or should the idea of “tropical geography” be conceived more restrictively, as a branch of geographical inquiry that deploys (and if need be adapts) conventional disciplinary tools to tropical settings?

Gourou went down the latter route, and during the 1950s and 1960s tropical geography emerged as a distinct research area within geography, most evidently in those countries that had (or once had) tropical colonies – America, Belgium, Britain, France, Germany, and Portugal. Significant – although, with the exception of Bordeaux, never sizeable – ‘schools’ and ‘laboratories’ of tropical geography were established in these Western countries, and in West and East Africa, Brazil, and South and Southeast Asia. Gourou, Paul Pélissier, Gilles Sauter, Orlando Ribeiro, and Robert Steel (to name only some of the most prominent figures) undertook fieldwork. By the 1970s there were also a number of textbooks on tropical geography besides Gourou’s (which became a staple of university geography courses on the subject).

Gourou adapted the regional paradigm in French geography pioneered by Vidal de la Blache (with its chiefly rural focus on “man and milieu”) to the rice-growing peasant civilization of the Tonkin Delta in French Indochina, and his regional monograph (the product of six years of fieldwork) is still considered one of the finest in this tradition. Gourou was also a vehement critic of environmental determinism, which imbued early twentieth-century American and German geography, and viewed the field-based analysis of what he termed “techniques d’encadrement” (local landscape molding techniques), and the cartographic analysis of population densities, as keys to unlocking the nature and mysteries of tropical geographies. However, tropical geography was conceived in other ways. Gourou’s *Les pays tropicaux* advocated a zonal understanding of the tropics, and geographers (such as Charles Fisher, Dudley Stamp, George Kimble, and Gourou himself) also produced works on “monsoon Asia,” “tropical Africa” and “Amazonia.” Most works in tropical geography proceeded (as was customary in regional geography) from an analysis of physical geography to that of human geography. But this research niche was also sometimes deemed to lie at the interface between a “regional” and a more “systematic” (or integrated) geography (although the conceptual difficulties surrounding these competing claims to know in unique and general ways were hardly explored), and it had strong links with the
TROPICAL GEOGRAPHY

subfields of population geography and economic geography.

Furthermore, American, British, and Portuguese geographers generally had a more utilitarian concern with the economics of tropical development than their French counterparts, who tended to focus more on land-use practices. Much postwar tropical geography was thus palpably “applied,” and, in tandem with other fields (especially agronomy), cultivated the tropics as a laboratory within which new forms of scientific management and academic expertise could be brought within the armature of the late colonial state and newly independent governments. Indeed, some of Gourou’s work on the Far East was commissioned by the French ministry of foreign affairs, and his postwar fieldwork on tropical Africa was funded by the Belgian government. His expertise was also sought by the United Nations (Bowd and Clayton 2016). These imbrications of knowledge and power in this era of decolonization extended a much longer imperial history, stretching back to the Spanish and Portuguese in the Amazon, and British and Dutch in the East Indies, in which scientific deliberations and aesthetic reactions to the tropics were bound up with commercial and political objectives (Driver and Martins 2005). However, by the 1970s radical geographers inspired by Marxism and feminism, and concerned with issues of dependency and underdevelopment, deemed tropical geography conceptually staid and politically reactionary, and since the late 1970s the appellation has for the most part been supplanted by others that resituate “the tropics” in alternative critical frames (development geography, political ecology, environmental management, postcolonial studies, and globalization).

But let us backtrack to the 1950s. For it is in the overlap between geography and decolonization, and Western intellectual inquiry and Western dominance that the other side of Gourou’s question comes into view: the equation of the tropics with the “exotic,” and the priming of an exotic tropical world for material and intellectual appropriation. Since the start of modern European empire-building in the fifteenth century, tropical climate and vegetation — a warm, moist climate year-round, albeit with rainfall distributed unevenly in wet and dry seasons in monsoon regions, and falling more evenly through the year in rainforest and subtropical (savannah) ecosystems — have been lodged in Western perception and experience as potent emblems of environmental otherness, and out of this has come a close and enduring set of connections between tropical geography and power. It has been argued that “the tropics” solicited a particular set of Western sensitivities: ones revolving primarily, and in the most visceral of ways, around the senses (particularly sight, but also sound) and the vulnerability of the human body and mind to heat and humidity, and inimitably tropical diseases (Driver and Martins 2005).

David Arnold (2000) and now geographers have used the term “tropicality” to describe these sensitivities and the imaginative geography (akin to Edward Said’s idea of Orientalism) they install. Tropicality is not simply a Western style of imagining the tropics — as the West’s unruly environmental other; as the opposite of a temperate (regular, moderate, and composed) Western nature. It has also served as a way of “handling” (as Said put it in relation to the Orient) the tropics — licensing exploitation and “intemperate” behavior. Furthermore, since many of the figures who have been extolled as modern geography’s intellectual forebears (explorers and naturalists such as James Cook, Alexander von Humboldt, and Charles Darwin) focused their energies on the tropical belt, contemporary geographers with postcolonial critical sympathies have found it at once important and difficult to disentangle
their discipline’s heritage and public image from a long history of tropical othering and its strong imperial overtones (Driver and Martins 2005).

However, tropicality is an ambivalent construct and its connection to geography’s imbroglio with empire can be overplayed. In Gourou’s work and a much greater swathe of Western experience and learning, the tropics have been exoticized in both positive and negative terms: on the one hand, as edenic, picturesque, fecund, alluring, and promiscuous (Paul Gauguin’s Tahiti paintings in many ways the epitome of this vision); and on the other hand, as stifling, disease-ridden, deceiving and degenerative, a green hell, savage wilderness, land of illusory riches, “the heart of darkness” (to draw on Joseph Conrad’s modern fable about Western civilization lapsing into primitivism in the jungle peripheries of the capitalist and colonial world). Gourou’s work provides a good example of this ambivalence. He romanticized the rice-growing delta areas of the Far East as beautiful and harmonious, but represented equatorial Africa in pejorative terms, as “suffering from a certain number of inferiorities” (Gourou 1947, 176). Critics accused him of casting a stifling geographical spell on the tropics. At the same time, he was skeptical about the benefits of colonialism and Western style development in the tropics. He identified poor soils and deleterious agricultural practices as inherent sources of tropical backwardness; yet he also saw them as “problems” that had been exacerbated by colonial and development practices (see Bowd and Clayton 2016). In other words, while it is in some ways easy to wield a postcolonial critical agenda which situates the tropics and bodies of work like Gourou’s in a Western imperial imaginary, and see tropical geography as part of geography’s maleficent and lingering Eurocentrism, the story of tropicality and its relation to tropical geography is complex.

Work on tropicality has added an important environmental dimension to critical debates about the development of Western science, medicine, and colonial power, and encouraged critical and historical reflection on the categories and practices of tropical geography. However, negative tropicality is being given a new lease of life in the work of prominent public intellectuals, such as Jeffrey Sachs, who are talking again about “tropical backwardness” and the humanitarain “curse” of the tropics. The annals of The Malayan Journal of Tropical Geography (launched in 1953 and renamed the Singapore Journal of Tropical Geography in 1980) provide a rich record of (especially anglophone) research in this area, and in recent decades has published essays on tropicality and the place of the tropical world in a broader postcolonial geography.

Tropical geomorphology

Avijit Gupta  
University of Wollongong, Australia  
National University of Singapore

Tropical geomorphology is a branch of geomorphology that studies landforms and processes in the tropics and subtropics. The tropics may be perceived as an area of radiative surplus between the two anticyclonic circulations near the latitudes of 30°N and 30°S. This is an area over which the Hadley Cell operates, giving rise to easterly trade winds which converge at the equator. The tropics are considered a climatic region but the only common meteorological component across this belt of low latitudes is temperature. Considerable climatic variations are found across the tropics, primarily in rainfall. The annual total, the seasonal distribution, and occasional synoptic disturbances all vary across the tropical zone which, depending on the amount of moisture available, can be divided into two basic units: the humid and the arid tropics. About half of the surface of our planet lies in the tropics. The tropical oceanic expanse is huge and plays an important role in influencing the world climate. A number of geomorphic processes operate in the tropics over a range of rock types and geological structures, resulting in a wide variety of landforms. The processes are similar in kind to those found in other regions, but in the tropics they operate at different rates and with varying intensities.

In the geologic past, the present tropical landmasses (South and Central America, Africa, the Indian subcontinent, Southeast Asia, and Australia), a number of islands, and the cold continent of Antarctica constituted a single landmass known as Gondwana or Gondwanaland. Gondwana, located in the cold southern latitudes, was the southern part of a single world continent, Pangea. Pangea broke up about 200 million years ago, and the different parts of Gondwana drifted slowly towards the present warmer locations via plate tectonics to create the present distribution of land and sea in the low latitudes. This entire history is reflected in the tropical landforms: the origin from Gondwana, the break-up, the drifting of individual landmasses towards the equator, the impact of geomorphic processes after reaching the tropical zone, and currently, the changes caused by anthropogenic activities. The tropics exhibit a wide variety of landforms, and no single representative template exists.

Traditional tropical geomorphology

We know very little about the geomorphological knowledge that existed before the arrival of Western maritime powers in the tropics. From the last decade of the eighteenth century, Western scientific explorers including Alexander von Humboldt, Alfred Russel Wallace, and Charles Darwin visited the tropics with great astonishment, enthusiasm, and insight. They were revolutionizing biological sciences, but they also left perceptive accounts of regional geology and geomorphology. Our knowledge was further extended by geologists such as Sapper, Passarge, and Bornhardt from Germany and Dana from the United States. However, even up to the 1970s, the landforms and operating
TROPICAL GEOMORPHOLOGY

Geomorphic processes in the tropics were considered to be primarily controlled by climate. The work of Peltier, De Martonne, and Büdel was associated with this period. At the same time, the teaching and research carried out in the tropical countries used textbooks based on extra-tropical examples. Two concepts were heavily used: the Davisian cycle of erosion and the concept of climo-morphogenetic regions (Gupta 1993).

Modernizing tropical geomorphology

The climate-based approach of tropical geomorphology changed from the second half of the twentieth century. The writings of L.C. King in South Africa emphasized the role of geological history and rock types in understanding the ambient landscape. A number of excellent case studies, such as Ruxton and Berry on granite weathering in Hong Kong, Simonett on earthquake-generated slope failures in New Guinea mountains, and Coleman’s account of the Brahmaputra River in Bangladesh, highlighted the new process-based approach. Several regional collections of case studies were published, and accounts of tropical landforms and geomorphological processes became easily available, reducing the exoticness of tropical geomorphology. This was also the time of diffusion of modern mainstream concepts and techniques to geomorphologists of tropical residence (Gupta 1993 and references therein).

The diffusion of the new concepts of process geomorphology resulted in a rapid increase in the quantity and quality of research. Several textbooks in geomorphology with a tropical slant were published. Examples from the tropics were no longer considered unusual, and even used as background information for theory building. The Andes and Himalaya were studied repeatedly as sediment sources, and the Amazon and Ganga-Brahmaputra river systems monitored in order to determine sediment storage and transfer in large river systems (Dunne et al. 1998; Kuehl et al. 2005; Meade 2007). Mainstream geomorphic processes were seen to operate in the tropics but at different rates. For example, denudation rates were found to be unexpectedly high in many areas.

Although climate acts as an important control in both humid and arid tropics, landforms and operating processes are dependent also on other factors. Gardner et al. (1987), writing about certain locations in Central America and the Caribbean, highlighted three items from a long list of regional geomorphic processes and landforms. These are karst, alluvial fans, and tectonism along convergent plate margins, being the most characteristic of the region and representing the dominance of lithology, a rapid fluvial depositional process, and neotectonics. In other parts of the Caribbean, the local landforms demonstrate the dominant role of hurricanes or volcanoes. The fascination and challenge of tropical geomorphology lies in the recognition of such diversity within the region.

A number of world maps on suspended sediment yield, published since the 1980s, demonstrate the rapidity and efficiency of tropical geomorphic processes (Milliman and Syvitski 1992 and references therein). These show very high rates for most of the humid tropics, especially in high-relief areas. Milliman and Syvitski interpreted relief as a surrogate for tectonism, and suggested that large sediment yields from active orogenic belts are due to “the entire tectonic milieu of fractured and brecciated rocks, oversteepened slopes, seismic and volcanic activity” (Milliman and Syvitski 1992, 539–540). The high sediment yield is also due to intense tropical rain falling on the tectonic mountains.

Source: Based on Gupta (2011), p. 10, Table 1.1.

The natural geomorphic processes, however, are not necessarily the only ones in operation. Parts of the tropics have a long history of human occupation, leading to modification of the natural landscape. Such alterations accelerated from the 1950s, and natural landforms and processes became progressively less extensive in areal coverage. The destruction of tropical rain forest has increased the annual sediment yield from less than $10^2$ t km$^{-2}$ to more than $10^3$ t km$^{-2}$ in Southeast Asia. Transfer and storage of such increased volume of sediment sequentially affect hillslopes, gullies, rivers, and coastal forms. Thus, erosion and sedimentation in the tropics is a function of relief, climate, and land use: all three.

Tropical geomorphology combines scientific research with the application of its findings for the betterment of people (Gupta 2011). Recent research in tropical geomorphology highlights three areas (Table 1):

1. the major controls in tropical geomorphology: geology, landforms, climate, and land use
2. the operating geomorphic processes (mainly dealing with the passage of water and sediment from the mountains to the coast), and inherited Pleistocene changes
3. anthropogenic alteration of the natural rates and processes, including the effect of climate change

Major controls in tropical geomorphology

A variety of landforms occur across the tropics, depending on their history. Part of the tropics are inherited from Gondwana, forming uplands or basins at various levels, underlain by old metamorphic rocks that are difficult to erode such as found in the Brazilian Shield. The old uplands are also formed by flood
basalts and granitic bodies which give rise to flat-topped plateaus (Deccan Plateau of India) and steep-sided rounded hills (Main Range of Malaysia), respectively. Convergent plate boundaries, and the active sides of the moving continental plates, created mountains such as the Andes and Himalaya. Sediment from such mountains filled large structural downwarps to form wide plains such as the valleys of the Amazon and Ganga. Sediment then traveled to the passive side of the continental plates to build coastal plains and deltas over the shallow continental shelf. Geological structures and rock types induced small-scale landforms against this background (Gupta 2011).

Active mountains, positioned by plate tectonics, are eroded heavily to become primary sediment sources for large rivers such as the Amazon, Ganga, Brahmaputra, and Mekong. More than 90% of the Amazon’s sediment is derived from the Andes and its foothills, and carried along its 6000 km length to the South Atlantic (Meade 2007). Short streams that drain the mainly volcanic steep slopes of the islands of Southeast Asia and the Indian and Pacific Oceans may carry a very high sediment load. The annual contributions from their basins have been estimated to be 3000 tkm$^{-2}$.

In contrast, little sediment is carried by short steep streams flowing down the drier western slopes of the Andes. Ancient and metamorphosed stable rocks of most of tropical Africa produce very little sediment. In tropical Africa, rivers that drain the high relief associated with rifting in East Africa transfer higher sediment discharges, but not high by world standards. Old rocks of South Asia or Brazil also produce a low volume of sediment.

Climatic characteristics do affect geomorphology in the tropics but not as deterministically as was presented in the past. For example, the warm and wet climate of the humid tropics accelerates the process of weathering, and the high-intensity rainfall gives rise to slope failures and flooded rivers in the humid tropics.

Over the oceans, the easterly trade winds operate throughout the year with minor latitudinal shifts and small variations in intensity, bringing rain primarily to the eastern slopes of islands and land masses. In the higher tropics, an alternating wet and dry season operates over the continents and coastal waters due to a seasonal reversal of wind systems known as the monsoon. Rainfall from moisture-bearing winds is triggered by orographic lifting, convergence, and atmospheric disturbances. Depressions bearing heavy rain tend to arrive embedded in the monsoon system of winds. Arriving in the middle of the wet monsoon, when the soil is already saturated and rivers high, these events frequently cause slopes to fail and rivers to flood. The general pattern of rainfall in the tropics is periodically disrupted by the El Niño Southern Oscillation (ENSO), causing certain years to be wetter or drier, and causing floods or droughts.

Tropical cyclones (also known as hurricanes or typhoons) are large atmospheric disturbances which develop from depressions over warm oceans in summer. These huge revolving storms are carried in the trade winds, traveling west from their area of origin over oceans. They are associated with very strong winds, spiralling clouds, heavy rainfall, and storm surges. Daily rainfall in a tropical cyclone may reach several hundreds of millimeters. If the tropical cyclones slow down or confront orographic barriers, the cumulative rainfall over several days may reach very high totals. Such storms, associated with extensive slope failures, massive floods, and catastrophic coastal damage, are recognized as high-magnitude, low-frequency events capable of causing large-scale landform alteration in days.

Tropical rainfall can be strikingly erosive. Hudson (1971), examining the erosive nature
of rainfall, mentioned that rainfall intensity seldom exceeds 75 mm per hour in temperate countries but intensities double that amount are common in the tropics. The surface of the land used to be protected by the extensive cover of tropical forests. Significant destruction of natural vegetation began with the start of agriculture at the beginning of the Holocene, and within a few thousand years forests were being depleted at a fast rate. From the mid-twentieth century, deforestation was accelerated by demand for timber and for land for pasture or plantations of rubber or oil palm. Land surface exposed to the direct impact of the rain became subjected to accelerated slope erosion and enhanced deposition of sediment in rivers and coastal waters.

Geomorphic processes in the tropics are influenced by three types of climatic variations. Near the equator it is nearly always warm and humid, weathering is advanced, and unless the natural vegetation has been removed, a deep soil cover is in place. A seasonal component exists away from the equator resulting in variations in streamflow and arrival of floods. Weathering and soil formation are limited in the arid tropics where rivers carry water only for a short period after a rare rainstorm.

Operating geomorphic processes in the tropics

A range of geomorphic processes, the majority of which also occur elsewhere, operate at varying rates in the humid and arid tropics. The following description highlights processes that operate efficiently in the tropics, giving it a characteristic landscape. Weathering operates differently between the arid and the humid tropics. Rocks break up physically into a shallow layer of small clasts in the arid sector whereas the hot and humid climate of the humid tropics accelerates chemical changes in minerals. The thick weathered layer near the equator, the reddening of soils on igneous rocks and limestone, and the characteristic layers in weathered granite with sand and clay on top and large corestones in depth, all are very characteristic of the humid tropics due to intense chemical weathering (Figure 1).

Deep soft weathered layers fail as a rotating mass following rain, the process being called rotational slides or slumps. The thickness of the weathered zone, however, is frequently interrupted by impervious layers of precipitated material. The generic term for such layers is “duricrust,” but they are also specified by the constituent material and called silcrete, calcrite, ferricrete, and so on. This impermeable layer allows the weathered mass above it to store water, become saturated, and fail. Such failures are translational or planar slides which also happen at the contact between the weathered mass and the hard rock underneath.

Many types of mass movements may happen on tropical slopes but the common ones are creep, planar and rotational slides, and debris flows and debris slides. Weathered material tends to creep in the rain forest. Slides are common on slopes, and debris flows occur on hillslopes following high-intensity rain. In the humid tropics, the failures are moisture driven, and slopes fail in the wet season when a rainfall event acts as a trigger to the antecedent moisture already stored in the weathered material. In contrast, slope failures are episodic events in the arid tropics, happening only after earthquakes or rare heavy cloudbursts.

Slope failures in tropical mountains contribute most of the river sediment, irrespective of the scale of the basin. Larsen and Torres Sánchez (1992), working in a small river basin in eastern Puerto Rico, calculated that 81% of the total
sediment transported out of the basin originated in mass movements. The pattern is similar in very large basins including the Amazon (Meade 2007).

The sediment is transported to the coast by rivers. Rivers of the humid tropics follow the general rules of fluvial geomorphology that determine their size, shape, slope, and channel pattern. The rivers in the seasonal tropics, however, may need to adjust also to (i) seasonality in discharge and (ii) episodic large floods. These floods, often driven by tropical cyclones or disturbances, periodically affect river systems in selected regions, such as the Indian subcontinent, the Caribbean, or tropical Australia (Wohl 1992; Gupta 2011). Such rivers display a nested set of channels of different sizes in order to adjust to floods and seasonality. Working in Australia, Pickup and Rieger (1979) showed that regional channel forms result from a series of discharges rather than a single one. This nested pattern has been reported for other rivers of the seasonal tropics. The largest one carries the episodic high-magnitude flood, the middle one the wet season high flow, and the small one the dry season flow. The sediment and the channel forms are stored inside the banks of the largest channel, and are eroded and removed in high-magnitude floods and rebuilt in the interflood period (Figure 2). This may not happen if seasonality is not pronounced, the river carries only fine sediment, or it is geologically controlled.
A large amount of sediment is carried by rivers of the humid tropics, giving rise to characteristic depositional forms. These include big alluvial fans called megafans at the highland-lowland contact of tectonic mountains in the seasonal tropics, wide river valleys filled with sediment (Figure 3), and large deltas. Climate and biological activities provide tropical coasts and wetlands with a distinct appearance with the presence of mangroves, dry salt flats (sabkhas), and coral reefs.

A number of features, such as star-shaped depressions (cockpit karst), cone-shaped rises, and towers, are characteristics of the limestone topography in the humid tropics, and occur along with the karst features found elsewhere. The tropical features are attributed to high temperature and precipitation, dense vegetation, and high production of organic acids. Good examples occur in South China, Sarawak, Yucatan, Jamaica, and other places (Gupta, 2011 and references therein).

Nearly half of the tropics is semiarid or arid. Wind action and sand dunes cover about half of the arid tropics; the other half is in rock, often under a thin veneer of gravel, sand, and riverine silt. Extremely variable rainfall translates into episodic sheetflows and stream discharges, and the dominant geomorphic process on rock is flowing water, in spite of the general aridity. The channels and depositional forms reflect a nested arrangement related to the past flood history.

Tropical geomorphology also carries a Quaternary past. Tropical landforms and geomorphic processes were affected mainly by enhanced glaciation in the mountains, repeated climate change, and repeated changes in sea level. Such events in the Pleistocene explain the presence of relict alluvium in tropical river valleys, paleo-channel of major rivers, and the origin of deltas and coastal plains.

**Anthropogenic alteration of the natural rates and processes**

Anthropogenic transformation of the physical environment modifies landforms and processes. Case studies such as Rapp *et al.* in Tanzania, Dunne in Kenya, and Douglas *et al.* in Danum Valley, Sabah, indicated a remarkable increase in runoff and sediment yield following the removal of or change in vegetation cover. With removal of vegetation, soil and regolith are restructured, natural slopes altered, a dense network of gullies established, and erosion rates and sediment yields significantly increased. A combination of anthropogenic alteration and fragile landforms
locally gives rise to very high sediment yield. The resulting erosion and sediment transfer not only impact proximal slopes and rivers but also distal deltas, coasts, and coral reefs. This may happen both episodically and cumulatively.

Dams are barriers to the downstream passage of water and sediment, forcing rivers to adjust their morphology and behavior below dams. A large number of dams, some huge, have been built across tropical rivers since the mid-twentieth century. Aswan High Dam on the Nile, Kariba Dam on the Zambezi, and Xiaowan Dam on the Mekong are examples. The practice is still continuing, although dams are now hardly being built in the developed world. Without these impoundments, the blocked sediment would have built bars and floodplains downstream, and ultimately reached the coast. Rivers below dams need to adjust to a decrease in sediment and a controlled water release. This alters their form and function, and results in a negative impact on riverine ecology.
Anthropogenic alterations have occurred in the tropics for a very long time. However, since the middle of the twentieth century, high population and economic development have strikingly modified landforms and geomorphic processes. This suggests that the tropical geomorphologist may possess a problem-solving capability in environmental management. This is well illustrated in two areas: urbanization and climate change. Urbanization often degrades the physical environment by enhancing flood frequency, slope failure, and subsidence in cities (Gupta 2011). Furthermore, a number of tropical cities are located in or have spread to hazardous areas. A knowledge of geomorphology is crucial in managing such settlements (Gupta and Ahmad 1999). The present ongoing climate change will affect landforms and geomorphic processes in the tropics. Anticipating such changes and finding the ameliorating techniques could be the most fascinating part of tropical geomorphology in the future.

Defining a tropical rainforest

The term “tropical rainforest” (tropische Regenwald), was first used by A.F.W. Schimper in his classical Plant Geography (Schimper 1898) to describe “the climax, or potential natural vegetation” found in humid equatorial climates (Richards 1996). In the broadest of definitions, a forest must include the following attributes to be considered a tropical rainforest.

2. Receive rainfall regularly throughout the year (200–1000 m or more per year).
3. Remain warm and frost free all year long (mean temperatures are between 70° and 85°F, 21°C and 31°C) with very little daily fluctuation.

However, for anyone who has ever visited, studied, or even heard the term tropical rainforest, what comes to mind is a dense evergreen forest of large, extremely tall trees, interspersed with vines and epiphytes, teeming with all sorts of faunal life, from insects and birds to primates and large carnivores. Essentially, we think of a place synonymous with the word jungle. Noted evolutionary biologist Charles Darwin gave an account of what it is like to behold a tropical rainforest for the first time during his first shore visit from the Beagle to the Atlantic coast forest in Salvador, Brazil, on February 29, 1832. In his journal he wrote: “Delight … is a weak term to express the feelings of a naturalist who, for the first time, has wandered by himself in a Brazilian forest. The elegance of the grasses, the novelty of the parasitical plants, the beauty of the flowers, the glossy green of the foliage, but above all the general luxuriance of the vegetation, fill me with admiration … The noise from the insects is so loud, that it may be heard even in a vessel anchored several hundred yards from the shore … To a person fond of natural history, such a day as this brings with it a deeper pleasure than he can ever hope to experience again.” (in Whitmore 1998)

The occurrence of tropical rainforest ecosystems

Tropical rainforests occur on all three of the continental land areas that fall within the boundaries of the tropics (Figure 2). About half of the total global land area (4 × 10^6 km^2) is found in the American and neotropical rainforests, which comprise about one-sixth of the total broadleaf forest area in the world. The rainforests occurring in the Americas are divided into three discrete areas, the largest being that of the Amazon and Orinoco basins. The second extends from the Pacific coasts of Ecuador and Colombia, through Central America to the northernmost boundary in the southern state of Veracruz, Mexico. The smallest (and most disturbed) area includes the Atlantic coast of Brazil, which has by some accounts been over 99% destroyed (Whitmore 1998).
Figure 1. Photos of rainforests. Clockwise from top left: lowland Madagascar rainforest canopy; vines and canopy emergent in Corcovado National Park, Costa Rica; slash and burn agriculture in eastern Madagascar; deforestation in eastern Madagascar; giant epiphytes in eastern Madagascar; stream in primary rainforest, eastern Madagascar. Photos taken by the author.
The second-largest area of rainforest in the world occurs across tropical Asia. Centered on the Malay Archipelago, the land area included covers about $2.5 \times 10^6\text{ km}^2$. This includes Indonesia, whose total forest area is second only to Brazil. The Malay Archipelago, also called Malesia, extends northward to continental Southeast Asia, Burma, Thailand, and Indochina. The extent to which tropical rainforests extend into the southern Himalayas in upper Burma, Assam, and southern China is under debate as there is not a clear line. At the southern end of the boundary are the coastal rainforests of Queensland, Australia.

Africa has the smallest land area of tropical rainforest: about $1.8 \times 10^6\text{ km}^2$, centered on the Congo River Basin (Whitmore 1998). Cameroon and the Central African Republic are located at the northern limits of tropical rainforest in this region. Gabon, Equatorial Guinea, Congo, and the Atlantic Ocean comprise the westernmost boundary. The Democratic Republic of the Congo has the largest land area of African tropical rainforests. To the east, Madagascar and the associated islands of Reunion, Mauritius, the Comoros, and the Mascarenes are located at the eastern edge of the region’s rainforests. These rainforests have been extensively destroyed over the past 40 years, with
TROPICAL RAINFOREST ECOSYSTEMS

only 7–8% of intact forest remaining (Green and Sussman 1990).

Though tropical rainforests now occur in these three regions, this was not always the case. Paleo scientists believe that tropical rainforests began evolving prior to continental drift. Since all present-day tropical rainforests lie on lands that once made up Gondwanaland, biogeographers highlight the significant role continental drift played in determining the ranges and patterns of species distribution among tropical rainforests. With the major evolution of flowering plants occurring before Gondwanaland began to drift apart, today upwards of 334 genera (59 families) of flowering plants are essentially pantropical (Whitmore 1998). The timing of the shift in continental locations also played a role in speciation of tropical rainforests. Madagascar, for example, was separated from Africa about 160 mya and remained part of present-day India until about 80–90 mya when it began to drift into its current location. Scientists believe that it is for this reason that Madagascar’s rainforests are more like Malasian rainforests than African rainforests in stature and species richness (Grubb 2003; Armstrong, Shugart, and Fatoyinbo 2011). Madagascar has unparalleled levels of endemism as a result of the long period of isolation that occurred from when it broke off from India and drifted back toward the African continent. Upwards of 85% of floral and faunal species are found nowhere else on planet Earth (Goodman and Benstead 2003).

Similarities in flora that occur between the three regions of tropical rainforest do so because they were all once part of Gondwanaland. High levels of species diversity are thought to have evolved across tropical rainforests in part because the tropics did not experience the mass extinctions that occurred in ecosystems at higher latitudes during periodic ice ages. The location of the landmasses that support present-day rainforests, in addition to the timeline of continental drift, is the source of many of the complexities of floral distribution, evolution, and interaction that have occurred across time and space. Some genera, such as Campnosperma, have a typical Gondwanan distribution, meaning that they are found in present-day Panama, Colombia, Brazil, Madagascar, and the Seychelles, and from India to Micronesia. Their absence from continental Africa is thought to be due to mass extinctions that occurred during periods of drying out that happened in more recent geologic history. Climate influences have given rise to both distinctions (like that of Campnosperma) that exist between rainforest regions and similarities of species distributions along climatic gradients within the regions. Geography, continental drift, climate, and local environmental gradients are all important factors when relating to tropical rainforests worldwide.

Characteristics of the tropical rainforest ecosystem

An important universal feature of tropical rainforests is that they have a multistory canopy structure. Unlike forests at higher latitudes, rainforest tree species vary significantly with respect to maximum potential height. Most tropical rainforests are comprised of three to four canopy layers including: the canopy emergents, the main canopy, the understory, and the forest floor (the latter two are considered together in some forests). However, multiple variations in layering can exist and some forests may have as many as five or six distinct canopy layers, while others have as few as three. The significance of distinct layers is that the vertical complexity gives rise to a larger variation in microenvironments or habitats than is found in temperate or boreal forests. Spatial complexity in both the vertical
and the horizontal directions leads to an increase in diversity of niche space, resulting in high levels of species biodiversity.

Tropical rainforests are known to have some of the most nutrient-poor soils on planet Earth. While this may seem counterintuitive with regard to the abundance of vegetation types that are supported by these soils, it follows that the majority of nutrients found within these ecosystems are stored in the vegetation. As the tropics were not subjected to the glaciation that occurred during the ice ages, tropical rainforest soils have been subjected to millions of years of weathering. In addition, heavy rains have leached most of the nutrients out of the soil. Furthermore, nutrients that are present in these soils are often in forms that are not accessible by plants. High humidity and warm year-round temperatures result in rapid decomposition rates. Thus, soils of tropical rainforests contain significantly less organic matter than those of temperate forests. The nutrients that are released into the soil by rapid decomposition following a treefall are quickly taken up by nearby trees.

Ecologists have long recognized soils as an important feature in rainforest environments. As noted above, nutrient cycling in forested ecosystems is characterized by a set of direct and indirect feedback mechanisms between soil and vegetation (Brand and Pfund 1998; Castellanos et al. 2001). Biogeochemical cycles in forests involving successive transfers of nutrients among compartments or pools (i.e., canopy, litter, humus, soils, etc.) have been shown to vary greatly depending on soil type (Schlesinger 1997; Vagen, Andrianorofana, and Andrianorofana 2006). Major essential nutrients include: carbon (C), nitrogen (N), phosphorus (P), calcium (Ca), and potassium (K). Iron (Fe), aluminum (Al), magnesium (Mg), and sodium (Na) are considered secondary nutrients that are often important components of cycling of many of the primary nutrients. Recent research on overall patterns of mineral cycling in soils of tropical rainforests clearly indicates that patterns of nutrient cycling in tropical forests are as diverse as they are complex. Forests growing on nutrient-poor, acidic soils — such as those often found in tropical rainforest ecosystems — tend to exhibit tightly closed nutrient cycling in which the forest subsists almost entirely on the stock of nutrients circulating through the soil, biomass, and litter (Richards 1996). Soil texture has been shown to strongly influence nutrient availability and retention, particularly in highly weathered soils of tropical rainforest ecosystems (Silver et al. 2000). As defined by percentage of sand, silt, and clay, texture can affect the ability of a soil solution to retain carbon, water, and nutrients, thus greatly impacting many hydrologic and biogeochemical processes in forest ecosystems (Jenny 1980; Silver et al. 2000).

Vegetation formation in tropical rainforest

Physical environmental variables including elevation, climate, and soil dictate which types of trees and plants are able to grow, compete, and adapt to change within different landscapes. Tropical rainforests are a broad category of forests encompassing a range of physiognomic properties with respect to size, stature, density, tree species, and presence of vines and epiphytes. A combination of physical and physiognomic properties dictates how rainforests are subdivided into four rainforest types, including: semi-evergreen rainforest, lowland evergreen rainforest, lower montane rainforest, and montane rain forest. There are an additional nine other types of forests found in the tropics, but as they do not fit the criteria mentioned above, they are not considered to be rainforests.
TROPICAL RAINFOREST ECOSYSTEMS

Tropical lowland rainforests

Tropical lowland rainforests occur in humid climates where water stress is intermittent or absent, and at a range in elevation from sea level to 1200 m. Some of the highest tree species diversity worldwide is found in lowland rainforests (Table 1). Lowland rainforests are characterized by the presence of dense closed canopy stands of evergreen trees in at least three layers, with a canopy often exceeding 30 m and emergents exceeding 45 m in height. The majority of canopy emergent trees are uncommon species that individually do not contribute more than 1% of the total number in a given forest (Whitmore 1998). In addition to a multilayered canopy, a common feature of lowland forests is a lack of plant species diversity; ground vegetation is often sparse and mainly made up of tree seedlings. Some of the largest trees may be deciduous or semi-deciduous, but with staggered leafless periods that do not affect the evergreen nature of the canopy as a whole. Trees with buttresses are common; other structural features such as prop roots may be present but less common. Other common tree features include: cauliflory and ramiflory, tree species with pinnate, mesophyll leaves, woody vines that are both free hanging and bole hugging, and both sun and shade epiphytes (Richards 1996).

In addition, there is a relatively low diversity of large-leaved monocots, a feature that has been commonly attributed to acclimation or adaptation to poor soils and low soil-water supply (Grubb 2003). Palms and pandan species are found in varying levels of presence depending on location. For instance, there are 130 species of palms (Palmae) found in Madagascar lowland rainforests, with 11 of the 19 genera endemic (the seven remaining genera contain one species each). Similarly, the pandan (Pandanaceae) family is well represented with 70 species found mostly in the eastern forests of Madagascar (Goodman and Benstead 2003). This is in contrast to the large areas of tropical East Africa, where there are fewer than 20 species of palms and pandans combined, and they are confined to topographically constrained wet sites (Grubb 2003).

Tropical montane rainforest

Montane rainforests are subdivided into lower and upper forest formations. Occurring between elevations from 1200 m to 1500 m, tropical lower montane rainforests exhibit different structure and physiognomy than lowland rainforests. These forests are characterized by a lower stunted, often paler-colored, but more even canopy. Trees tend to be more slender, with gnarled limbs and dense subcrowns. Buttresses are uncommon or small, cauliflory and ramiflory is rare, leaves are mesophyllic, vines are highly uncommon, but nonvascular and vascular epiphytes are abundant. The canopy height is usually between 15 and 33 m, depending on the topography and soil strata, with very few emergent trees that are up to 37 m tall.

From 1500 m to the treeline (ca. 4000 m), upper montane rainforests ecosystems are distinctly smallest in stature. Canopy height decreases with increasing elevation, and ranges from 1.5–18 m. Emergent trees are not usually present; when they do occur they usually only grow to a maximum of about 26 m tall. In general, the forest is characterized by a smaller dense canopy of microphyll leafed tree species that may be heavily swathed in bryophytes and filmy ferns. Cauliflory is absent, very few or no vines exist, and the occurrences of epiphytes are frequent and abundant.

On small mountains, lowland rainforest neighbors upper montane rainforest. However, on large mountains, lower montane rainforest occurs in between and defines a broad ecotone
between lowland rainforest and upper montane rainforest. The Eastern tropical forests are very mountainous and many studies exist of the extensive zonation of these forests. The Andes also exhibit strong zonation, though less area has been fully characterized and described. The most comprehensive studies of elevational zonation in tropical rainforest types exist for the forests of Jamaica. By contrast, montane rainforest systems are least prevalent in Africa, where they only occur in Cameroon and on the eastern edge of the Congo River Basin (Whitmore 1998).

**Tropical semi-evergreen rainforest**

The African continent has the most extensive seasonally dry or semi-evergreen rainforest on the planet. Semi-evergreen rainforests are tall closed canopy forests with emergents upwards of 45 m in height. The canopy is comprised of a mixture of evergreen and deciduous trees. Though deciduous tree species may make up about 30% of the main canopy tree species, they are not all necessarily leafless at the same time. Species richness is high, but second to that of lowland rainforests. Trees with buttresses and other structural features are common in both evergreen and deciduous tree species. The height of both the canopy and emergents tends to be slightly less than in lowland rainforests. Tree bark tends to be thicker, and cauliflory or ramiflory is rarer. Woody vines and epiphytes with ferns and orchids tend to be very abundant, though varying regionally. In addition, bamboos are often present.

Whereas zones of lowland and montane tropical rainforests are defined by altitude, regular annual periods of moisture stress differentiate semi-evergreen rainforests. Because moisture stress can be influenced by rainfall seasonality,
particular local soil conditions, and microclimate effects, semi-evergreen forest stands can appear in a less ordered degree of zonation than what appears on a mountainside, for instance. Semi-evergreen rainforest occupies the lower Amazon and most of the African forest block, including the entire Congo River Basin. It forms as outlier buffer forests around the edges of many lowland rainforests in the Eastern rainforest block, as well as in India and most of the Australian tropical rainforest. It probably was also the most prevalent rainforest type in continental Southeast Asia, but this area in general has been reduced to almost nonexistence by human activity. Heterogeneously mixed evergreen and semi-evergreen forest stands are thought to comprise the rainforests of the middle Americas. Given the predicted drying out of the tropics as a consequence of global climate change, semi-evergreen forests with their deciduous tree species may prove to be a successful adaptation strategy that will lead to their expansion into previously evergreen rainforests in the future.

Tree species patterns and diversity

The structural complexity of tropical rainforest ecosystems worldwide and the discerning of underlying environmental factors that shape community interactions within them have long been considered important topics of study among ecologists. In many cases, the relationships investigated between environmental conditions and plant communities have provided a basis for explaining vegetation patterns, but mostly at local and occasionally regional scales (Holdridge 1967; Box 1981; Smith and Huston 1989; Clark and Clark 2000; Leigh et al. 2004). In 1982, noted rainforest ecologist T.C. Whitmore asserted “that forests of the world are fundamentally similar, despite great differences in structural complexity and floristic richness, because processes of forest succession and many of the autecological properties of tree species, worked out long ago in the north temperate region, are cosmopolitan. There is a basic similarity of patterns in space and time because the same processes are at work” (Whitmore 1998).

Whitmore’s conclusion, that the fundamental patterns of succession in forests have evolved in a similar manner globally despite their varied development through geographic space and time along broad environmental gradients, has become a widely accepted tenet in ecosystem ecology. Because all trees and plants rely on the process of photosynthesis to grow and survive, they are all constrained by the same basic needs of light, water, and nutrients. Thus, there is a certain amount of homogeneity of growth and competition processes that exist in forests around the world.

In rainforest ecosystems, species richness has given rise to differing competitive strategies among cohorts of trees and fine-scale patterns are often constrained by local environmental processes such as nutrient limitations. High levels of biodiversity and year-round growing seasons cause patterns in gap recovery phases and larger-scale environmental processes to be increasingly difficult to decipher in tropical rainforests. High biodiversity in tropical rainforests is thought to be caused by a combination of the following attributes: (i) the absence of mass extinction events during the ice ages that affected higher latitudes and resulted in forests that are millions of years old; (ii) year-round growing seasons; (iii) the absence of water and temperature limitations; (iv) nutrient limitations that vary spatially and are extreme in some forests. These attributes have resulted in large variations in competitive strategies and niche differentiation.
Biodiversity is measured in numerous ways. Two common ways to quantify species diversity in a given forest are: (i) by calculating the importance value, and (ii) by relating the Shannon–Wiener index with evenness. In the first, species richness and abundance for each species is used to calculate an importance value index (Curtis and McIntosh 1951; Kent and Coker 1994). An importance value index is often used because it is a better measure of biodiversity than frequency and dominance calculations alone. It combines and quantifies the three most commonly used vegetation descriptors.

A second way to enumerate overall species diversity in a given forest site, the Shannon–Weiner index makes the two assumptions that: (i) individuals are randomly sampled from an infinitely large population, and (ii) that all the species from the community are included in the sample (Kent and Coker 1994). In quantifying vegetation descriptors such as species diversity and forest structure variables, scientists attempt to discern patterns of species distribution across forests and relate them to other rainforests. The commonalities that exist among rainforest trees shed light on our understanding of how rainforests have grown and evolved over millions of years, and perhaps give us insight into how they can be conserved and protected in the face of our changing planet.

The imperiled future of tropical rainforests

The importance of tropical rainforest ecosystems with respect to the health of the entire global ecosystem cannot be understated. In addition to the unparalleled species diversity as discussed above, tropical rainforests are in many ways an untapped resource of information about everything from the evolution of genetic diversity and fundamentals of the planet’s past ecosystems to understanding the role this diversity plays in an ecosystem’s resilience in the face of natural disturbance. From the human perspective, the genetic diversity in tropical rainforests remains a reservoir of information about uses for forest products, from medicinal knowledge about plants to high-yield energy foods. Currently, hundreds of species of trees and plants are currently used in thousands of pharmaceuticals worldwide. Information reported by the US National Cancer Institute states that 70% of plants found to be useful in the treatment of cancer are found only in tropical rainforests (www.cancer.gov). Yet, only a fraction of a percent of rainforest species have been analyzed for their potential use in drugs or products.

Human product potential only encapsulates a small amount of the importance of tropical rainforests. By some estimates, as much as 50% of the terrestrial species on planet Earth are found in rainforests, and this figure does not include migratory birds that winter in the tropics. Fundamentally, tropical rainforests help maintain global rain and weather patterns by providing important intermediate water storage; much of the water that evaporates from the trees returns in the form of rainfall. This intermediate storage provides a buffering capacity against floods, droughts, and erosion in these regions where annual rainfall amounts are so high.

At the forefront of the global climate change discussion is the increase in carbon dioxide and greenhouse gases in the Earth’s atmosphere. Rainforests store a significant portion of the Earth’s carbon, while producing a substantial percentage of the planet’s oxygen (Figure 3). Saatchi et al.’s global carbon stock assessment from 2011 estimates that 247 gigatons of carbon – more than 30 years’ worth of global emissions of fossil fuel burning at the current annual rate – are stored in the tropical rainforests.
TROPICAL RAINFOREST ECOSYSTEMS

located across Latin America, Africa, and South-east Asia (Saatchi et al. 2011). Carbon dioxide given off into the atmosphere from deforestation constitutes 20% of total annual anthropogenic greenhouse gas (GHG) emissions.

Yet, as our knowledge of the importance of tropical rainforests has increased over recent decades, so too has the rate of deforestation of these ecosystems on a global scale. Rainforests are in trouble; deforestation worldwide was measured to be 5.44 million ha per year between 2000 and 2005 (Hansen et al. 2008). Deforestation rates have varied regionally across space and time, however. Brazil’s deforestation rate was measured to be 3.1 million ha per year (2000–2005), which amounts to a 1% loss per year. This annual rate was approximately 18% higher than in the previous five years. The worst year of deforestation on record was 2004, when 27 000 km² were lost. Following 2004, rates declined steadily until 2012, when a 28% rise in deforestation area was recorded (BBC 2013). Upwards of 70% of the deforestation occurs as a result of the land being converted to cattle pastures. Previously that percentage was as high as 91% (between 1970 and 2000); however, in recent decades Brazil’s farmers have increasingly converted rainforest to cropland (Barreto et al. 2006; Melillo et al. 1993). Brazil is currently the world’s second-largest producer of soybeans (behind the United States).

The second-largest rainforest in the world, Congo’s rainforest has the lowest human density surrounding the forest as compared to other rainforests worldwide. In addition, the area has been checkered by conflict in recent decades. This instability has insulated the ecosystem from large-scale commercial logging and agriculture, but smaller-scale slash-and-burn agriculture and illegal logging operations persist. Between 1990 and 2000, Congo’s deforestation rate remained relatively constant at about 311000 ha (roughly 0.20%) annually. Since 2000, satellite imagery has shown this rate to decline by one third (FAO 2011). In addition, West African and Madagascan rainforests have shown similar decline in deforestation rate, with Africa’s overall rate dropping from 592000 ha per year in the 1990s to 288000 ha per year during the past decade. Mayaux et al. (2013) note that

![Figure 3](image)

**Figure 3** World biomass map in (tonnes of carbon per hectare). Saatchi et al. 2011. Reproduced by permission of the National Academy of Sciences.
Africa’s rate of deforestation is a product of its circumstances, including “the almost complete absence of agro-industrial scale clearing,” which accounts for more than half of tropical forest loss worldwide.

Indonesia has the third-largest area of tropical rainforest on the planet and the second-highest deforestation rate, of approximately 1.9 million ha annually between 2000 and 2005, and 1.17 million ha in 2008 (Indonesia UN-REDD National Joint Programme Document 2009). With 68% of its landmass classified as forest (131.3 million ha), this deforestation rate is equivalent to a loss of 0.9% each year (Ministry of Forestry 2008). A 2010 report by the National Council on Climate Change suggests that 85% of Indonesia’s GHG emissions stem from land-use activities, with 37% due directly to deforestation (National Research Council 2001). Whereas the majority of deforestation in the Amazon has been for conversion to cattle pasture, and in the Congo for subsistence agriculture, in Indonesia over the past 20 years deforestation has been driven predominantly by agricultural expansion of oil palm plantations (Singh and Bhagwat 2013).

Conservation tools: ecological modeling, remote sensing, and REDD+

The scientific tools available to measure and track rainforest species spatial extent has advanced considerably in the past few decades. With studies on the onset and impact of climate change for tropical rainforest ecosystems ever increasing, so too are the strategies to conserve them. The ability to accurately assess aboveground biomass and associated carbon stocks across tropical rainforest landscapes is a topic at the forefront of current scientific investigation and methodological refinement. Two important tools in the advancement of carbon assessment and monitoring globally are those of high-resolution forest modeling and high-resolution satellite imagery. Ecological models have the ability to incorporate fine-scale in situ vegetation measurements. When these models are run with datasets from high-resolution satellite image data, scientists are developing improved larger-scale estimates of rainforest biomass and reducing uncertainties in our overall understanding of tropical rainforest dynamics.

Ecological forecasting has become an essential tool used by ecologists toward understanding the dynamics of growth and disturbance response in threatened ecosystems such as rainforests. The application of growth and process models for forest ecosystems has been widely studied in temperate forest ecosystems since the 1980s. However, there are some inherent difficulties that exist in the development of rainforest-specific modeling frameworks, including: (i) the immense tree species diversity in tropical rainforests (upwards of 500 species per ha in some forests); (ii) the fact that the ages of trees within a rainforest are often not known and are difficult to measure due to the inability to apply methodologies such as dendrochronology or monospecific plantation measurements and to the absence of long-term datasets; (iii) the fact that the lifespan of tropical trees is very long, as compared to temperate trees, and can vary widely among species with similar light requirements; and (iv) the fact that there is a lack of long-term monitoring data relative to the age of the forests and for existing datasets (the observation period is usually under 20 years) (Whitmore 1998; Richards 1996; Huth and Ditzer 2000).

Individual-based gap models, which simulate the growth and process of every tree, provide the most accurate virtual depiction of a rainforest ecosystem; however, they are often restricted to local spatial scales by processor limitations. Gap models are hierarchical in that the higher-level
patterns observed (i.e., population, community, and ecosystem) are the result of the integration of plant responses to the environmental constraints defined at the level of the individual (Shugart and Woodward 2011). Recent increases in the capability of remote sensors to detect some of the patterns generated by individual tree processes has increased the potential to apply these gap models over larger areas of rainforests through tree demographic averaging. The use of remotely sensed datasets to inform ecological models brings a new level of application to both; models can now be steered by datasets to track actual landscapes (rather than virtual) through time, and modeled data can be used to predict and validate landscape change signatures in areas where satellite images previously had high uncertainty.

Repeat satellite observations of vegetation patterns in two dimensions have revealed much about the state and dynamics of the global biosphere. In tropical rainforests, satellite imagery has provided unprecedented access to previously underexplored areas too remote to monitor extensively. Coarser grain products such as MODIS (Moderate Resolution Imaging Spectroradiometer) and Landsat are used in conjunction with ground-truthing datasets to make accurate maps that classify land cover by forest health and land use. The high periodicity of measurement makes the large-scale tracking of land-use change, deforestation, and biomass flux quantifiable at multiple scales from the 1980s to the present.

The more recent application of higher-resolution datasets such as LiDAR (Light Detection And Ranging) is considered the most accurate and consistent measurement of vegetation height and structure on the scale of the individual tree. The shape of the LiDAR waveform is a function of canopy height and vertical distribution of foliage, trunks, twigs, and branches at varying heights within the LiDAR footprint. A number of studies have shown that LiDAR metrics describing the waveform are proportional to forest biomass over a range of ecosystem types (including high-biomass tropical forests), although biomass accuracy varies with forest types and terrain slopes (Drake et al. 2002; Lefsky et al. 2005; Anderson et al. 2009). In addition, tree height can also be measured with radar data using a technique known as Interferometric Synthetic Aperture Radar (InSAR) (Graham 1954). Scientists can also integrate Landsat, L-band Synthetic Aperture Radar (ALOS/PALSAR), and LiDAR (GLAS/ICESat) to develop a spatially explicit approach to modeling carbon stocks across a gradient of forest disturbance (from mature forest to recently disturbed) (Simard et al. 2006; 2008). Recent advances in remote sensing technology allow viewing the biosphere in three dimensions, and provide refined measurements of horizontal as well as vertical structure of forests.

The availability of satellite imagery, and to a lesser extent data models, has provided an accessible monitoring capability to private entities, corporations, universities, and governments. A combination of this data access, an increasing awareness of the link between greenhouse gas emissions and tropical rainforest deforestation, and the catapulting of the imminence of climate change into the global consciousness by the Intergovernmental Panel on Climate Change’s (IPCC) 2007 report has led to a number of programs that combine environmental science with an economic-based approach toward mitigating rainforest deforestation (IPCC 2007). While still relatively new in both scope and implementation, these programs provide economic incentives to governments and private entities toward conserving rainforest ecosystems worldwide. Born out of the concept that many of the nations that contain the world’s rainforests
TROPICAL RAINFOREST ECOSYSTEMS

are developing and trying to enter the global marketplace, the Reducing Emissions from Deforestation and forest Degradation (REDD) program aims to create an incentive for these countries to protect, better manage, and wisely use their forest resources, ultimately contributing to the global fight against climate change. The program was launched in 2008 and is a multi-organizational collaboration of the Food and Agriculture Organization of the United Nations (FAO), the United Nations Development Programme (UNDP), and the United Nations Environment Programme (UNEP). The UN-REDD program’s goal is to make forests more valuable remaining intact than they would be if cut down. By creating a financial value for the carbon stored in trees, UN-REDD creates a market out of carbon storage. Once the carbon is assessed and quantified through forest inventory and scientific measurement, the final phase of REDD involves developed countries paying developing countries carbon offsets for their standing forests. Further, REDD+ is a climate change mitigation solution that goes beyond UN-REDD strategies to incorporate the role of conservation, sustainable forest management practices, and in some cases enhancement of forest carbon stocks toward reducing greenhouse emissions (www.un-redd.org).

Conclusions

Anthropogenic factors driving deforestation in the tropics are causally linked to the economic livelihoods of the cultures living within them. As noted by the World Bank’s 2011 Economic Prospects report, the majority of the world’s tropical rainforests are located in countries that are classified as “less developed” or “least developed” in terms of gross domestic product (GDP), infrastructure, industrial potential, and other indices (Figure 4). As shown in Figure 4, the majority of the world’s remaining rainforests occur in developing nations, many of which have a majority of their populations living in rural areas where pressure on forest resources is extremely high. With the increasing awareness of the linkages between deforestation, local livelihoods, and in many cases globalization of commodity markets, however, the green activist “Save the rainforest!” campaigns of the 1980s have evolved into a more holistic conservation approach.

Whereas the campaigns of the latter part of the twentieth century were aimed at increasing international awareness, today organizations such as Conservation International (CI) and World Wildlife Fund (WWF) combine a scientific approach in discerning target areas called hotspots with a more collaborative relationship at the local and government levels. In addition, market-based strategies such as REDD+ provide economic incentive-based protection mechanisms to threatened ecosystems. Even so, deforestation rates in the Amazon River Basin, for instance, match those of the 1980s, and government-based programs aimed at protection remain difficult to enforce at both the local and the international level.

Equally important in our understanding of how best to manage and conserve the world’s remaining tropical rainforests is an appreciation of the dynamic relationship that exists between the endemic flora and fauna at the ecosystem level. Comprehensive ecosystem studies that include species inventories, structure, growth, diversity information, and comparisons to other rainforests worldwide provide a foundation for future research toward understanding both floral and faunal patterns of existence and interaction. In addition, scientific research serves to provide a basis of comparison to future studies grounded in wider-scope, cutting-edge techniques such as remote sensing of forest extent, 3-D structure,
TROPICAL RAINFOREST ECOSYSTEMS

Figure 4  This figure depicts the income disparity between developing and developed nations according to annual GDP. The size of the red (developed nations) and blue (developing nations) spheres relates to the remaining forest in 2014 in square kilometers of forest. The annual GDP (in thousands of US dollars) in 2014 for 55 countries is shown with the percentage of the total population living within rural areas for each nation. The blue spheres represent the majority of the world’s tropical forests and include (in order of forest size): Brazil, Democratic Republic of the Congo, Indonesia, Peru, Mexico, Colombia, Angola, Bolivia, Zambia, Venezuela, Tanzania, Mozambique, Papua New Guinea, Myanmar, Gabon, Republic of the Congo, Malaysia, Laos, Guyana, Thailand, Suriname, Zimbabwe, Vietnam, Ecuador, and Madagascar. The red developed nations, only one of which contains tropical rainforest (all others contain other forest types), include: Australia, Austria, Canada, Denmark, Finland, France, Germany, Ireland, Israel, Japan, Netherlands, New Zealand, Norway, Sweden, Switzerland, United Arab Emirates, United Kingdom, United States, Iceland, and Belgium. University of Western Australia

Coverage

Savannas are a major component of the world’s vegetation, covering 20% of the land surface in the lowlands of tropical and subtropical latitudinal zones between 30°N and 30°S. They are generally found in a transitional zone between evergreen tropical rainforest and mid-latitude deserts. A large proportion of savannas are located in Africa, with an estimated 15.1 million km², or 50% of the African continent. This is followed by South American savannas, which cover 2.1 million km² and are mostly located in Brazil, Colombia, Venezuela, and Bolivia. Australian tropical savannas are the third-largest tropical savannas, covering nearly 2 million km², or 25% of the country. Savannas are also found in other parts of the world in small pockets, such as in India, Southeast Asia, Central America, and Pacific islands. Some distinct formations of savannas also occur in temperate (Southeast Australian temperate savannas), Mediterranean (oak tree savannas in California), and montane eco-regions.

Definition

Savannas are ecosystems in seasonal tropics comprising a distinctive dual canopy system. The understory vegetation consists of mainly herbaceous cover, whereas overstory plants are comprised of trees and/or shrubs with varying proportions of canopy cover (Hill, Román, and Schaal 2011). Based on overstory tree crown cover, savannas can be classified as (i) savanna woodland (50–80% of crown cover), (ii) open savanna woodland (20–50%), (iii) open savanna (5–20%), (iv) isolated trees (0–5%), and (v) pure grassland (crown cover 0%). Savannas have a distinct composition of trees and grasses, with contrasts in functional types (e.g., C₃ trees and a C₄ herbaceous layer). As such, the trees and grasses compete for water resources and interact with each other in a way that eases water stress (competition/facilitation mechanisms) and allows coexistence and maintenance of the spatial structuring of this ecosystem.

Seasonality of rainfall (pronounced dry and wet seasons in a year), hot temperatures, and high solar radiation determine the structure and vegetation composition of savannas. In the dry season, water deficit in the soil causes the understory vegetation to dry out and senesce, leaving only the overstory trees to contribute to productivity. Increased rainfall in the wet season encourages the growth of herbaceous vegetation that forms a more or less continuous understory canopy cover.

Savannas generally grow in nutrient-poor soils that are: (i) highly leached, often sandy and

lateritic soils (Oxisols or ferralitic soils), and (ii) base-rich montmorillonitic black clay soils (Vertisols). Generally, these soils are frequently disturbed through fire and herbivory and thus have low cation exchange and very low phosphorus and nitrogen concentrations but are high in iron and aluminum.

**Carbon cycle in savannas**

The carbon budget of savannas consists of the following processes (Figure 1).

1. Gross primary productivity (GPP) is defined as the sum of photosynthesis by all leaves at the ecosystem level (Chapin et al. 2006). CO₂ fixed by trees, shrubs, and grass species in savannas through photosynthesis directly supports savanna growth and produces organic matter. GPP is the primary conduit of carbon transfer from the atmosphere to the plants on land. The energy used in fixing carbon in plants is consumed by animals (grazing) and soil microbes in the ecosystem.

2. Net primary productivity (NPP) refers to the net primary production after accounting for autotrophic respiration (Rₜ). Organic matter produced by plants in savannas through photosynthesis is released back to the atmosphere through Rₜ, which converts carbohydrates into CO₂ and releases energy that is used for growth and maintenance of plants. NPP also refers to the annual plant growth. Globally, the average NPP of savannas is estimated to be 7.2 ± 2.0 tC ha⁻¹ year⁻¹ (average 95% confidence interval) (Grace et al. 2006), which is approximately 64% of the NPP of rainforests (Grace et al. 2006). Savannas account for approximately 66 Pg of the global carbon stored in biomass (13% of all terrestrial carbon).

3. Net ecosystem exchange (NEE)/net ecosystem production (NEP). The instantaneous net exchange of carbon between the atmosphere and the ecosystem is known as NEE and the net accumulation over days or longer is termed NEP. NEE/NEP is calculated as the difference between GPP, Rₜ, and Rₜ (heterotrophic respiration). Rₜ refers to the respiration by nonphotosynthetic organisms such as decomposers (bacteria and fungi) and herbivores. NEP and NEE are widely used as indicators of the amount of carbon accumulated or lost (medium-term storage) by an ecosystem. Generally, root carbon stocks of savannas tend to be slightly higher compared to the above-ground carbon. Soil carbon stocks are high compared to those of the vegetation.

4. Net ecosystem carbon balance (NECB). The amount of carbon remaining after accounting for longer-term disturbance regimes is NECB. Carbon stored in savanna ecosystems is also released to the atmosphere through disturbances such as fire (see section “Fire,” below), herbivory, storms, cyclones, and fluvial transport of dissolved organic carbon (DOC), dissolved inorganic carbon (DIOC), and particulate organic carbon (POC) (see section “Other disturbances,” below). Savanna fires are estimated to contribute CO₂ emissions of between 2 and 4 Pg C year⁻¹ (Bowman et al. 2009). The carbon lost due to disturbance is mostly regained during the subsequent period of plant regrowth, unless the area is converted to pasture or grazing land for cattle (Grace et al. 2006), and savannas are considered to act overall as carbon sinks, taking up an estimated 0.5 Gt C year⁻¹ (Scurlock and Hall 1998).

5. Net biome productivity (NBP). NECB integrated spatially across a biome is termed
TROPICAL SAVANNA ECOSYSTEMS

Figure 1  Schematic diagram showing the typical carbon cycle processes in savannas.

NBP and it is representative of the long-term biome carbon balance. Estimates of NBP show that tropical savannas and grasslands are a sink for carbon.

Factors controlling carbon cycle in tropical savannas

A comprehensive review on the environmental determinants of savanna productivity was given in Kanniah, Beringer, and Hutley (2010) and they identified the major environmental drivers as radiation, rainfall, temperature, and nutrient availability (discussed below) which is then modified by disturbance and longer-term climate change (discussed in the following sections).

Radiation

Radiation is the primary driver of productivity in ecosystems, and savanna regions are typically found in lower latitudes where radiation is plentiful. Nevertheless, in Australian savannas it has been shown, through a land surface model sensitivity analysis of leaf area index (LAI) and soil moisture content inputs, that modeled GPP was limited by light interception rather than water availability. Radiation may be modified by cloud or aerosols (Kanniah, Beringer, and Hutley 2010) from frequent burning, and both may impact on vegetation productivity. Although a reduction in radiation can decrease plant productivity, it has been shown worldwide that the concomitant changes in diffuse radiation can enhance photosynthesis/productivity because diffuse radiation can illuminate light-limited understory vegetation canopy more evenly by penetrating multi-layer canopies (Kanniah et al. 2012; Figure 2).

For savannas, the quantity of solar radiation is more critical for photosynthesis in the wet season, especially when cloud cover is high, although generally this area receives a higher level of radiation compared to many other ecosystems (Kanniah, Beringer, and Hutley 2013a). However, enhanced light-use efficiency (LUE) under cloudy skies can be counterbalanced by the decline in total radiation. In Africa, Le Roux (2006) indicated that solar radiation was potentially a limiting resource for savanna growth, especially at the end of the fast growing season in July and August (wet season) when cloud cover was high.

Rainfall

The intensity, duration, and changes in patterns of rainfall can affect the structure, composition, and primary production of savannas both spatially and seasonally. During the wet season, topsoil moisture is available for any plant species.
Grasses and trees compete for topsoil moisture, but the deeper water is available only to deep rooted species such as the evergreen trees. Herbaceous plants with shallow roots dominate the superficial horizon of soil substrate, and thus have high productivity in the wet season when soil water is high. After the wet season ends, the topsoil water content drops and can remain low during the dry season. The deeper soil water content also drops, but the rate is slower, therefore it maintains higher soil water potential for longer periods in the dry season. In the dry season, soil water deficit causes the herbaceous layer to diminish, but trees with deep roots are able to extract groundwater, and hence become photosynthetically active.

The highly seasonal pattern of available moisture in savannas is reflected in a strong seasonal cycle in productivity. During the wet season months of February and March in northern Australian savannas, average NEP has been recorded as 3 gC m$^{-2}$ day$^{-1}$ (Figure 3), when LAI was at its peak of around 2.3 due to the rapid growth of C$_4$ grasses (grass LAI approximately 1). Wet season fluxes (December to April) were responsible for 72\% of the mean annual NEP of 3.6 tC ha$^{-1}$ year$^{-1}$. In the dry season, a net uptake of 1 gC m$^{-2}$ day$^{-1}$ was maintained by the ecosystem, largely due to evergreen trees accessing deep soil water, and hence driving photosynthesis.

The length and intensity of the wet season also determine the structural composition of savanna vegetation spatially. Long-term moisture availability is a critical driver of ecosystem structure and composition. For example, along the North Australian Tropical Transect (NATT) Eucalyptus and deciduous species dominate in the wetter regions (12.50°S, where rainfall was 1622 mm year$^{-1}$) and there is a transition to Acacia spp.
Figure 3  A strong seasonal response to rainfall on the seasonal patterns of savanna gross primary productivity (GPP), net ecosystem exchange (NEE), and respiration. Solid triangles show fire events. Beringer et al. 2007, 7. © John Wiley & Sons, Ltd. Reproduced by permission of John Wiley & Sons, Ltd.

in lower rainfall regions (17.73°S, where mean rainfall was 643 mm year⁻¹). At the same time, the grass stratum changes from tussock grasses with ephemeral leaves to hummock grasses with evergreen and sclerophyllous leaves. In these lower rainfall regions the amounts are smaller, with high interannual variability due to isolated convective storms. Such changes are an evolutionary response that enables vegetation in drier sites to withstand drought via water-conserving strategies. Changes in structure, composition, and water use have a profound effect on the spatial and interannual variation in productivity.

Analysis of carbon accumulation by different vegetation types within the savanna region in the Northern Territory, Australia (Kanniah, Beringer, and Hutley 2013b), showed that closed forest occurring in wet and often fire-proof environments assimilated (GPP) 4–6 times more carbon than grasslands and Acacia woodlands that grew in arid environments (<600 mm annual rainfall). Annual rainfall and interannual variability in rainfall was found to
TROPICAL SAVANNA ECOSYSTEMS

exert a significant influence on GPP for different vegetation types. Arid ecosystems had a higher interannual variation in GPP (>20%) compared to woodlands and forest (5%).

Rainfall also strongly influences woody plant cover of savannas, especially in arid and semi-arid regions that receive mean annual rainfall of <650 mm. In these regions, woody cover and tree-grass coexistence are determined predominantly by rainfall. Although rainfall was found to influence tree basal area (surrogate for woody biomass) of savannas in the continents of Africa and Australia, in South America there was no relationship between rainfall and tree basal area, which could be due to the narrower range of rainfall that savannas occupy.

Rainfall and evapotranspiration together drive the available soil moisture, which is also an important driver of soil respiration and soil carbon storage in arid and semiarid savannas. The arrival of the first rains at the beginning of the wet season can cause savannas to become a strong source of carbon for a short period of time due to high ecosystem respiration (Beringer et al. 2007).

Temperature

Generally, savannas receive plenty of solar radiation and thereby maintain higher annual mean and minimum temperature. In Australian savannas, the daytime temperature is more than 25°C in the wet season; meanwhile, the optimum temperature for savanna photosynthesis (tree species) in southern Africa is 30°C. Nevertheless, high temperatures due to climate change may decrease the productivity of savannas. For instance, at Mongu, Africa, the daytime canopy carbon flux of Kataba forest was seen to be reduced by 50% when air temperature was above 27°C (Scanlon and Albertson 2004).

Temperature can also influence fire in savannas. At warmer sites, such as in Australia and Africa, temperature can cure fuels faster, thus facilitating frequent fire. High temperature can also promote the photosynthesis and growth of C₄ pathway grasses and thereby large accumulation of biomass for fire.

Nutrient availability

Savanna ecosystems are largely driven by the interactions between water and nutrients (nitrogen, phosphorus, and calcium). Due to the low fertility of Australian soils, many native trees such as Eucalyptus have an array of nutrient-conserving mechanisms, such as the ability to extract almost all nutrients from dying leaves. Consequently, there is a low decomposition rate of litter. In South American savannas the acidic and infertile soils constrain the distribution and structure of savanna vegetation.

Nutrients are cycled by termites in savannas, especially in the dry season when microbial decomposition almost stops. In African savannas, nitrogen and clay content in the soil affect woody plant cover negatively, probably due to increased growth of the grass layer under increased levels of nitrogen availability. This has significant implications for savanna structure under future environmental change (i.e., nitrogen deposition), where woody savannas may change into grassy savannas.

Disturbances

Fire

Fire and land clearing are major natural (lightning in late dry seasons) and/or anthropogenic (prescribed burning) activities in savanna landscapes that can modify the structure and physiological function of savannas. In Australian savannas, up to 75% of the landscape burns annually.
The direct impact of fire on the savanna carbon cycle includes the emission of CO$_2$ (including trace gases) from biomass burning. Over the period 1997–2013, Australian tropical savanna fires have been estimated to contribute 0.088 Pg C year$^{-1}$ to this total (through all gases), which represents an average of 0.46 tC ha$^{-1}$ year$^{-1}$ across the entire Australian savanna biome (Beringer et al. 2014; Figure 4).

Indirectly, fire reduces productivity following scorching due to the loss of functional leaf area and the high respiration associated with canopy rebuilding. Fire mainly consumes the understory herbaceous or grassy vegetation and scorches the overstory canopy in the dry season, when the soil water content is reduced dramatically. Consequently, canopy leaf area, canopy photosynthesis, and evapotranspiration are reduced and savannas switch from a small carbon sink into a carbon source following fire.

The effect of fire is most prominent in mesic savannas because increasing moisture availability promotes grass production and tree basal area. Consequently, wetter areas are capable of supporting more frequent, high-intensity fires by providing fuel load. Although moisture can increase tree basal area to a maximum value, fire prevents the accumulation of tree basal area and maintains it at a lower value. Thus, mesic savannas are more likely to be fire dependent (tree-grass coexistence) than savannas in arid regions. The role of fire in reducing savanna woody cover at the global scale is well documented. In African and Australian savannas, continental-scale analysis showed that fire emerged as the second-most important predictor (after rainfall) of woody cover. The effect of fire on savanna vegetation is dependent on many factors, such as the seedling and sapling growth rate, fire resilience traits, and fire intensity. A recent review (Beringer et al. 2014) elucidated the impact of fires on savannas from leaf to ecosystem scale on long-term regional carbon budgets (Figure 4).

Although fire can cause a loss of carbon from savanna, over the longer term it could contribute to soil carbon storage through the production of slowly decomposing black carbon. Grace et al. (2006) estimated an accumulation of black carbon of approximately 0.07 tC ha$^{-1}$ year$^{-1}$ in the soil of savanna ecosystems. If savannas were protected from fire, they could store more carbon in biomass due to the encroachment of woody species, whereas complete fire control can replace savanna species with forest trees. Fire suppression has resulted in an increase in tree density.

Other disturbances

In addition to fire (largest disturbance pathway), savannas are also subjected to carbon loss due to disturbance processes by herbivory (termites, insects, and grazers), extreme storm and cyclone events, and fluvial transport of DOC, DIOC, and POC. In Australian savannas, carbon may be lost due to grazing by native and feral animals, although grazing pressure is generally low.

Climate change impacts on savannas

Atmospheric CO$_2$ concentration

An increase in atmospheric CO$_2$ concentration is expected to enhance woody plant cover in savannas compared to grasses due to their low CO$_2$ saturation levels ($C_3$ photosynthetic pathways). Preliminary findings of the investigation of the impact of CO$_2$ enrichment on the savanna carbon cycle in Australia show a rapid (103%) increase in above-ground grass NPP for 550 ppm CO$_2$ relative to ambient controls in the first full growth season (Stokes et al. 2005). This increase was believed to be a short-term enhancement of growth and water-use efficiency (WUE) in
TROPICAL SAVANNA ECOSYSTEMS

**Figure 4** The net biome productivity (NBP) for Australian savanna (tC ha\(^{-1}\) year\(^{-1}\)). Evapotranspiration (ET) and precipitation (P) are in mm year\(^{-1}\). Uncertainties of the estimates are shown as * low, ** medium, and *** high (based on expert’s opinion). Beringer et al. 2014. Reproduced by permission of John Wiley & Sons, Ltd.

Response to the initial application of the CO\(_2\) treatments. However, long-term studies have revealed limited impacts on soil carbon sequestration in Southern African C\(_4\) grassland (Stokes et al. 2005). Nevertheless, increasing temperatures under high levels of CO\(_2\) may reduce the sink strength of savannas by enhancing heterotrophic respiration (i.e., loss of soil carbon to the atmosphere). In a worst case scenario, tropical forests are expected to be encroached by savannas and grasslands are to be replaced by arid systems as a consequence of warming and reduced WUE.

**Woody thickening**

Woody thickening, the increase in standing biomass of woody species, is a global phenomenon that is most commonly observed in arid and semiarid regions and therefore has been observed in savannas and shrublands. Impacts of woody thickening on biogeochemical cycling and C stocks are regionally substantial and globally significant. Thus the conversion of grasslands to closed woodlands could represent an increase in terrestrial carbon sink. The causes of woody thickening include changes in land-use practice, changes in fire regime and grazing and cessation of clearing and abandonment of formerly managed grass and cropland. Changes in climate and in atmospheric CO\(_2\) concentration may also drive woody thickening.

**Climate change and multiple factors**

The current and future links between climate, biomass, and fire interactions of trees and grasses can be explored using dynamic vegetation models. A study by Scheiter et al. (2014) modeled the effect of precipitation seasonality, fire return interval, and fire timing on carbon stocks under a scenario where, by 2100, CO\(_2\) concentration increased to approximately 700 ppm, air temperature increased by 4°C, and mean annual precipitation increased by 13%. Under that scenario, both tree and grass biomass increased, by 18.6 and 0.7 tC ha\(^{-1}\) year\(^{-1}\), respectively. Factorial simulations that varied climate drivers
showed that most of the increase in tree biomass was due to the CO₂ concentration increase, whereas grass biomass increased due mainly to the temperature increase. Increasing the seasonality of precipitation shortened the growing season and decreased biomass in both trees and grasses, with a feedback to lower fire intensities due to lower fuel loads. Changing fire timing to occur in the early dry season or reducing fire frequency both increased the tree biomass, by 20.3 and 4.9 tC ha⁻¹ year⁻¹, respectively. Increases in tree biomass were due to woody thickening, and competition between trees and grass resulted in slightly decreased grass biomass. The fire intensity increased with longer return times (due to increased fuel loads) but decreased in early dry season fires (due to higher fuel moisture content).

From the existing studies, it is clear that future climate change will have a large impact on the structure and function of savannas. Appropriate management is therefore essential if we are to prevent degradation of these resources. Managing the savannas for the best outcomes for sequestering greenhouse gases is also becoming increasingly important.

Description and purpose

The Association of Tunisian Geographers (ATG) is a scientific association founded in 1977 by young geographers working in university and public departments in the field of land planning and regional development.

The main objectives of the association are: the promotion of geographical research and knowledge in Tunisia; the dissemination of geographical knowledge within academic and general public; ensuring the participation of Tunisian geographers in international events; and the promotion of Tunisian geography at the international level.

The ATG’s main initiatives are: editing the periodical “Géographie et Développement”; several events planned per year, including an international congress, Arab congresses, and national conferences and meetings; scientific fieldtrips inside and outside of Tunisia; and workshops on methodologies and techniques in geography.

Journals or major publication series

Geographie et developpement

Current activities or projects

Activities of the association of the last few years were: the 31st International Geographical Congress “IGC-Tunis2008”, held in August 2008 with the main theme as “Building Together our Territories”; the 7th International Olympiads of Geography “IGEO Carthage 2008” held in Tunis in August 2008; the 9th Colloquium of Maghrebine Geography held in Sfax in April 2007; regular meetings of geographers from the Maghreb Region (Algeria, Libya, Mauritania, Morocco and Tunisia), with a main theme of “Dynamics of Coastal Spaces”; 12e Journées Scientifiques du Réseau Télédétection de l’A.U.F.-Tunisie 2010, held in Monastir in November 2010 with the main theme of “Télédétection, Changements Climatiques et Environnements”; and regional geographical days held in Medenine in October 2011 with a main theme of “L’espace local dans les régions arides: Connaissance, Aménagement et Développement.”

Turkey: Türk Coğrafya Kurumu (TCK) (Turkish Geographical Society)

Founded: 1941
Location of headquarters: Istanbul
Website: www.tck.org.tr
President: Ahmet Ertek

Description and purpose

The society aims to promote and improve the study and research of geography in Turkey and other places, to facilitate geographical surveys of Turkey using appropriate scientific methods, and to enable Turkish geographers to remain in touch with global geographical development.

Journals or major publication series

Turkish Geographical Review: it is published twice a year and has been granted national reference publication status.

Current activities or projects

The society regularly hosts professional workshops for academicians and training courses for geography teachers as well as annual national geographical congresses at various locations around the country. It organizes geography field excursions for geography teachers and international trips to different continents. In September 2011, the society celebrated its 70th anniversary with a geographical congress in Istanbul where national and international organizations participated. The society participates at international geography Olympiads, such as Koln 2012 and Krakow 2014. TCK is the host organization for the 34th International Geography Congress (IGC) of IGU 2020 in Istanbul, Turkey.

Brief history

In June 1941, the Turkish Ministry of Education pioneered the first formal gathering of Turkish geographers that led to the founding of the Turkish Geographical Society, established as a non-government organization through a decision ratified by the Council of Ministers. The headquarters of TCK was in Ankara from 1943 to 1988, but then relocated to Istanbul. TCK has been a member of the International Geographical Union (IGU) since 1949 where it represents Turkish geographers.

Description and purpose

The Turkish Association of Geographers (TAG) was established in 2012 by a group of Western-influenced young academics with a view to bringing Turkish academic geography in line with the international geographical world. The main purposes of the association are to improve the status of geography, to disseminate geographic research and knowledge, and professionalize the discipline. Although it is a young nongovernmental organization (NGO), it is the largest geographical association in the country. The association holds annual meetings, educational programs, and runs national and international projects. It publishes the Turkish Journal of Human Geography, Turkish Journal of Physical Geography, and the Turkish Journal of Geographical Education in addition to a biannual bulletin.

Journals or major publication series

Beseri Coğrafya Dergisi (Turkish Journal of Human Geography). www.cd.org.tr/?bcd&changelang=EN

Current activities or projects

The Turkish Association of Geographers coordinates or participates in national and international projects that aim at advancing geographic knowledge (www.cd.org.tr/?projeler), publishing books, newsletters, journals and reports (www.cd.org.tr/?dergiler), and providing training activities for its members (www.cd.org.tr/?kariyer). TAG also organizes annual meetings in different places throughout Turkey where scientific exchange takes place. One of the priorities of TAG is to internationalize Turkish geography through participation in international meetings, developing international projects, and cooperation with international geographical bodies such as the International Geographical Union (IGU), the European Association of Geographers (EUROGEO), and the American Association of Geographers (AAG). The association has just finalized the Piri Reis project (http://pirireis.dicle.edu.tr) which will connect Turkish geographers with European colleagues.

Brief history

As scientific geography initially developed in Turkish universities in the early 1900s with the efforts of first generation of geographers educated in the West or by Western geographers who migrated to Turkey for several reasons. They established academic geography, started geographic research activities in universities, and institutionalized the discipline with a number of
TURKEY

activities. However, the practice of geography did not develop further for decades after that initial brilliant start and the Turkish academic geography was until recently characterized by traditional, descriptive regional geography.

When the Turkish government decided to establish a number of universities in the 1990s, funding was provided for geography students to seek graduate education abroad resulting in a number of students moving to the United States, United Kingdom, and Germany. These students received their graduate degrees and returned to Turkey in the early 2000s to take up posts in these new universities. They, together with some local geographers who were aware of the shortcomings of traditional geographic practice, decided to reform Turkish geography and the establishment of the TAG was one of the results of that reformation movement. The TAG works to bring contemporary approaches and issues into the agenda of Turkish geographers by meetings, conferences, workshops, educational programs, new books, and journals.

Description and purpose

The institute is the leading Ukrainian institution that provides advanced geographical research. There are six departments in its structure: Landscape Science, Paleogeography, Geomorphology, Human Geography, Nature Management and Sustainable Development, and Cartography.

Its activities include fundamental and applied research; PhD students’ training; development and revision of standards, laws, plans for governmental authorities, and public administration; and conferences. The institute sponsors research in GIS and atlas mapping, sustainable development, neotectonics and morphostructures, paleogeography of the late Cenozoic, landscape research and planning, and urban and regional development. The institute is the head office of the National Committee of Ukrainian Geographers and the Association of Ukrainian Geomorphologists.

Journals or major publication series

Current activities or projects

As an academic organization, the BGN/PCGN focuses on fundamental and applied research, supporting 10 to 20 projects annually. Its current projects focus on issues of modern and paleo landscapes’ assessment, multipurpose GIS mapping and modeling, urban spaces, regional development, spatial planning, and measures of sustainable development. Among the most significant projects in recent years have been the “Atlas of Natural, Technological, Social Hazards and Risks of Emergency in Ukraine,” “Landscape Planning in Ukraine,” and “A Sustainable Development Strategy.” The institute also supports international and national activities through its publications (monographs, Ukrains’kyi Heohrafichnyi Zhurnal), conferences, and scientific exchange programs.

Brief history

The institute was established in 1964 as the Scientific Department of the National Academy of Sciences (NAS) of Ukraine and received its new name – the Instytut Heohrafiyi NAN Ukrayiny – in 1991, although work in the sphere of geographic research had been carried out within the NAS of Ukraine beginning in 1918. During its complicated history the institute and its members have been recognized frequently for their achievements and outstanding accomplishments, including awards, thousands of
UKRAINE

publications, and hundreds of successful projects. In 1993, the institute received its first State Prize in the field of science and technology for the series of monographs “Geographical Foundation of Regional Nature Use in Ukraine.” In 2009 it was awarded its second for the National Atlas of Ukraine, published in 2007. The Atlas is an encyclopedic work prepared in response to a decree of the president of Ukraine to summarize the state-of-the-art spatial information needed by executive and legislative agencies of government to formulate the policy development of the state.

In accordance with its mission – to make geography an important part of administration and public life – BGN/PCGN have been collaborating with similar national and foreign institutions, ministries and governmental agencies of Ukraine, regional authorities, and NGOs.

Current activities or projects

The society’s main event is held every four years. The 11th annual conference was held in Kiev in 2013 with the theme on “Ukraine: Geography of goals and opportunities,” and with 200 participants.

In recent years the society’s activities have focused mainly on the development and publication of the national atlas of Ukraine; the national collection of nautical maps and the oceanographic atlas of the Black and Azov Seas; the historical atlas of the Ukraine; the comprehensive atlas of Lviv; the completion of a set of local studies (in particular, the publication of a series on the “native places of Ukrainians,” “anthropogenic landscapes of Podillia,” etc.); the promotion and improvement of the teaching of geography courses; personnel training and retraining; the celebration of the anniversaries of prominent geographers (N. Miklouho-Maclay, P. Chubynskyy, etc.); the submission of proposals to state and local governments for the development of geographical science and education, regional policy and administrative reform, the development of tourism and resorts, and so forth; and the systematization of geographical terminology.

Brief history

The Ukrainian Geographical Society traces its origin to the South-Western Department of Imperial Russian Geographical Society founded in 1873 in Kiev. The Ukrainian branch of
UKRAINE

The Geographical Society of the USSR was organized in 1947. The first meeting of the Society was held in Kiev in 1964. In the 1950s and 1960s it focused on the problems of physical and economic-geographical regionalization, thematic mapping of Ukraine, integrated water management, the impact on atmospheric processes, environmental protection, training of geographical personnel, and improvement of teaching of geography. In the 1970s and 1980s, the issues of the planning of economic development, rational environmental management, and spatial planning were important.

The Geographical Society of Ukrainian SSR was renamed the Ukrainian Geographic Society in 1992. From the 1990s to the present conference themes have been: “Think about the future. Take care of nature,” “Ukraine and global processes: the geographical dimension,” “Geographical problems of sustainable development,” and “Geography in the information society.”

Uncertain geographic context problem

Stephen A. Matthews
Pennsylvania State University, USA

Across the social, behavioral, and health fields there has been interest in the effects of broader social and geographic contexts on human behavior. Perhaps the best known conceptual framework in the social sciences is Bronfenbrenner’s (1979) ecological systems theory of child development. In his theoretical model, Bronfenbrenner introduced a perspective and a typology consisting of multiple, overlapping, individual, and environmental contexts relevant to a child’s development. That is, variables and processes relevant to the development of the child were seen to operate simultaneously at multiple levels. In refinements to the ecological systems theory, Bronfenbrenner also made more explicit the temporal processes and the variability in the influence of multiple contexts over a person’s lifespan. Similar models and theoretical frameworks that pertain to understanding the contextual effects on individual behavior exist in other fields too. For example, a multilayered perspective on the influence of place – or geographic context – is reflected in the socioecologic model, a model that has emerged as a dominant theoretical framing in the epidemiology and public health fields (Glass and McAtee 2006).

The renewed interest in geographic context has been fueled by the recognition that scientific explanations for the human condition based solely on individual-level data may be insufficient. Health researchers, in particular, have long suspected that where you were born, where you have lived, and where you currently live matters, and the general scientific interest in health effects of place dates back at least over two millennia to the writings of Hippocrates (Macintyre, Ellaway, and Cummins 2002). “Putting people into place” (Entwisle 2007) and utilizing analytical approaches that attempt to shed light on the processes by which place “gets under the skin” (Taylor, Repetti, and Seeman 1997) have led to a proliferation of multilevel studies across the social, demographic, and health sciences. Indeed, open almost any social science, demographic, and health journal within the last decade and the reader will likely find several articles on multilevel modeling applications exploring the relations between individual-level outcomes and attributes of a geographically defined context. Interestingly, the majority of the multilevel studies to date link an individual to a single geographic context, most typically the individual’s current residential neighborhood (variously defined; see below). Moreover, the relative lack of data on residential histories means that many of these studies are by design cross-sectional and as such can only examine the relationship between individual outcomes and the attributes of their current residence or geographic context (Kemp 2011).

It is the use of just one representation of place and the lack of attention to the temporal duration individuals spend within places that may result in either an over- or an underrepresentation of actual exposure to the geographic context or contexts where individuals live, work, and play (Basta, Richmond, and Wiebe 2010; Chaix et al. 2009; Cummins et al. 2007; Matthews 2008; Rainham et al. 2010; Zenk et al. 2011). The potential inability to detect what Diez Roux and

Mair (2010) refer to as “true causally relevant” geographic contexts is the crux of the uncertain geographic context problem (UGCoP), introduced and labeled by Kwan (2012a) (see also Kwan 2012b).

In the seminal paper on UGCoP, Kwan identified and focused on two sources of contextual uncertainty: (i) the uncertainty associated with the spatial configuration of geographically defined contexts, and (ii) the uncertainty about the timing and duration of exposure to these contexts (expanded on below). Briefly then, the effects of geographic contexts on individual behaviors may be affected by how these geographic contexts are geographically delineated and the extent to which these areal units deviate from the true geographic context relevant to the processes and outcomes being studied. Kwan’s paper is a timely addition to the literature and while only recently published we can anticipate that the UGCoP will help generate more careful decision-making about how researchers across the social and health sciences might measure contextual exposures in space and time.

It is important to note that the conceptual and methodological issues and the challenges associated with the UGCoP can be traced back to critical discussions within several disciplines, including geography (e.g., time-geography) and epidemiology (e.g., the socioecologic model), as well as public health, sociology, demography, and other disciplines that have all embraced place-based multilevel modeling applications (see Glass and McAtee 2006). However, even though the discipline of geography has a long-established literature on fundamental spatial concepts, spatial behavior, and time-geography (Golledge and Stimson 1997; Hägerstrand 1967), and multilevel models and spatial data usage continue to proliferate across the health sciences, there is a clear need to provide improved guidance on spatial thinking, spatial concepts, and spatial theories. As noted earlier, there are several theoretical models of health and society that explicitly incorporate multiple, hierarchical, and nonhierarchical levels, and many of these (e.g., the socioecologic model) are adopted as a theoretical backdrop to the study of say a health or wellbeing outcome. It is ironic, then, that closer scrutiny of such multilevel theoretical frameworks uncovers a disjuncture between the processes being modeled and how these same processes may act in the real world. That is, while socioeconomic models make frequent reference to distal factors such as social structure, social environments, social/political/economic conditions, policy, and environmental resources and constraints, it is rare that the level or geographic context is defined as anything other than a neighborhood or community. Moreover, rarely is the definition of a neighborhood or a community specified. Kwan’s research, arguably more than that of any other researcher, has helped promote greater awareness of the UGCoP and has further reinforced the need to take geographical contexts seriously.

Implications of the UGCoP

The choices researchers make regarding both geographic contexts and exposure to geographic contexts are not benign. Kwan argues that the lack of association between the contextual variables and the individual outcome in a multilevel model might be due to a failure to account for the mismatch between the observed and the true geographic context relevant to the individuals under study. As Kwan states “[T]he spatial uncertainty and dynamics of geographic context associated with the UGCoP greatly complicate any examination of the effect of contextual influences” on individual outcomes (Kwan 2012a, 962). As shown in Figure 1, adapted from

**Figure 1** Inferential errors due to the UGCoP. Source: Adapted from Kwan (2012a) with the permission of the Association of American Geographers, www.aag.org.

Kwan (2012a, 962), being unable to identify and measure the true geographic context might lead to inconsistent results and inferential errors. While the true and observed contextual effects can be in broad alignment, Type I errors (false positives) can arise when the contextual variable of interest has no effect on the outcome variable but a significant, and ultimately spurious, association between them is observed. Similarly, Type II errors (false negatives) will arise when the association between the contextual variable and the individual outcome exists but is not observed. For many research applications the true geographic context is not known (i.e., unobserved) but it has been most often assumed to operate at the local level, often the smallest administrative or aggregate level, at which data are most easily available.

Important questions arise as a result of thinking about the potential for Type I and II errors associated with the UGCoP. Frumkin (2006) among others has suggested several questions that deserve attention: What theoretical model should underlie definition and measurement of place? By what mechanism(s) does place affect health? How far does place extend? How should the relevant qualities of place be defined and measured? Kwan also would likely add questions associated with the measurement of the movement of people across geographic
context and the measurement of the dynamics of geographic context. Ultimately, perhaps the most fundamental question, especially relevant to the goal of generating a better understanding of how place “gets under the skin,” is quite simply, whether all variables of interest, and the processes and mechanisms they represent, operate at the same level, and do so consistently across time. That is, are the processes related to the individual outcomes we seek to understand adequately captured by the definitions of geographic context – or place – that are typically used in our analytical models?

Conventional geographic contexts and the UGCoP

In much empirical research that explicitly analyzes individual outcomes within a geographical context – demographic and health outcomes related to fertility, risky behaviors, morbidity, mortality – the measurement of place is conceptually naïve. The adoption of a naïve view of place is in part because the approach fits the available data and analytical models. Data availability and data format are arguably the most important reasons why the majority of the published empirical research examining the role of geographic context uses the residential neighborhood (typically defined by a postal or census unit; in the United States as a ZIP code or a census tract). This is the conventional approach within sociology, demography, and other social sciences; indeed, there has been somewhat of a fetish for the residential census tract to be used as the single correct scale in the study of neighborhood effects. Interestingly, even though researchers may be studying the same individual outcome of interest (e.g., obesity), other disciplines, especially in the health sciences, are increasingly using alternative definitions of geographical context. In recent years we have seen the emergence of both distance- and network-based buffers being used to define a person-centered or egocentric local residential neighborhood (Chaix et al. 2009). Given the variability in definitions of place, and by extension the measurement of attributes within those places, it is perhaps not surprising to find inconsistent results across studies (Feng et al. 2010). What both the administrative and the egocentric views of geographic context have in common is the use of discrete bounded areas, whether defined as a census tract or a buffer, and as such they reduce individuals to actors who cannot escape the “local trap” (Cummins 2007). The discrete view of the world is reinforced by geographically based contexts and multilevel data structures; these ignore the exposure to places traced out by people as they navigate their complex lives in continuous space.

Functionally useful geographic contexts

Before moving on to discuss the complexity of measuring spatial behavior and contextual exposure, it is important to note that multilevel models are appropriate tools in specific nested and discrete contexts; in Figure 1 this is represented by the two cells in which the contextual units are appropriately defined and as such the inferences are likely to be correct. For example, multilevel modeling in the social sciences grew out of their application to education outcomes, typically studying school children within classrooms within schools. The context of the classroom and the school is perfectly appropriate and also the levels follow a strictly nested relationship. Similarly, others have used multilevel methods to look at economic, social, and political organizations such as when
examining employee performance within firms or individual beliefs within congregations and denominations. Again the higher-level context is relevant to the outcome being investigated.

Moving beyond organization or group contexts it is important to note that appropriate discrete geographic contexts also can be identified. Policymakers and social scientists are often interested in policy environments and as such some geographical contexts make analytical sense. At one extreme, the modern nation-state provides one of the clearest examples. The nation-state has well defined legal boundaries, within which all citizens and visitors are bound to the laws and regulations of the geographic context. Below the nation-state there are jurisdictions also that retain an element of control over local policies and practices (e.g., US states). In the United States, state-level policy can determine the broad parameters associated with access to and provisioning of welfare and health-care services, levels of taxation, or whether same-sex couples can marry, to name but a few. Similarly, it can also be argued that some geographic contexts also have an intuitive appeal vis-à-vis individual behavior. In the latter, one might consider fairly coarser-scale units of analysis such as labor and housing market areas as being appropriate for the study of employment and housing outcomes. Moreover, researchers argue that several finer-scale functionally meaningful units of analysis exist (Siordia and Matthews 2016). For example, counties, minor civil divisions, census-defined urban places, and school districts are in many instances highly salient – or functionally relevant – geographic contexts. It is within these local government-related geographic contexts that both service provision (revenue spending) and financial obligations (taxation) relationships exist between individual residents and the place of residence.

### Contextual exposures in continuous space: short-term mobility

As implied by the UGCoP, a major challenge for researchers is the need for flexibility in allowing for individual exposures across different spatial and temporal scales. The lack of attention to the boundaries of geographic contexts and how they invisibly dissect everyday life is particularly curious given what we already know about movement and mobility in everyday life (e.g., over short timescales, commuting to work and journeys for food shopping typically take the individual out of their residential tract). Individuals’ exposure spaces are typically bimodal in time and space, with clusters of time and activities around specific hubs or nodes (such as home and place of work, or for children, home and school), and some activities cluster around journeys and routes between the main nodes. As research in behavioral geography (Golledge and Stimson 1997) has repeatedly shown us, we live in a continuous world, not one bounded by arbitrary boundaries (Chaix et al. 2009; Matthews 2011). Kwan (2012a), in her discussion of recent literature, also identifies the pervasiveness of nonresidential movements, whether the studies utilize census data, travel surveys, or ethnographic materials. Indeed, in the last decade Kwan has been the leading proponent of activity space research, initially based on the use of transportation survey data (Kwan 2000) then later in mixed-method research and qualitative geographic information systems (GIS) (Kwan and Ding 2008).

In Kwan (2012a) the way to address the UGCoP focused on the use of GPS and wireless technologies to help identify the daily activity space of the individuals in question, that is, to actually measure an individual’s exposure to the multiple places they might visit during a typical day (i.e., both the local residential area and
UNCERTAIN GEOGRAPHIC CONTEXT PROBLEM

extra-local places). This is important as attributes calibrated for experienced exposure areas may be less correlated with each other than at the residential or local neighborhood level, potentially allowing researchers to differentiate among potential mechanisms (Zenk et al. 2011). Kwan (2012a) suggests examining the potential effects of UGCoP by using sensitivity analysis methods to assess how different delineations of contextual units might affect the measurement of contextual variables and study results. Researchers in physical activity research, more so than in geography (see Shoval et al. 2014), are beginning to use GPS data to create person-specific activity space summary measures (i.e., convex hull, standard deviational ellipses, buffers, and kernel density estimation) to define environmental or place-specific exposure. The analysis of activity space environments will allow researchers to think in a more spatially sophisticated manner about the linkages between inequality and the conditions of contextual environments: namely, how the conditions within one’s activity space shape both exposure to risks and access to resources and opportunities.

It is also worth noting that paralleling the focus on objectively measured activity spaces, using GPS, researchers might, where possible, collect information on perceptions of place(s); that is, measuring environmental features within a perceptual space may offer a more accurate and comprehensive characterization of environmental exposures than one based solely on an administrative unit (see Vallée et al. 2010). Within sociology, researchers have observed that individuals living in close proximity to each other and sharing similar socioeconomic and demographic characteristics do not necessarily share a common definition of their residential neighborhood (for a review see Matthews 2008). Interestingly, an individual’s own definition of their residential neighborhood also may change over time as length of residence increases but also across an individual’s lifespan as the utilization of resources and services changes with age; what was once an important feature of the local neighborhood as a child may lose significance during adolescence or as an adult as spatial knowledge and boundaries expand (or even contract).

In the social sciences and other fields, often lacking GPS data, researchers may examine adjacent or proximal census tracts, compare multiple definitions of place, or explore clustering techniques to create homogeneous geographic contexts (see Matthews and Yang 2013). In one of the most well-cited and innovative studies of recent years, Inagami, Cohen, and Finch (2007) examined extra-local effects – in neighborhoods where people shopped – as well as simultaneously examining local residential neighborhood effects. Inagami and colleagues’ work was based on the Los Angeles Families and Neighborhood study which collected geocoded activity location data spanning a narrow range of basic activities and locations.

Contextual exposures in discrete space: long-term mobility

The importance of time and dynamics is relevant for both tracking the individual and for measuring change or dynamics in the attributes of geographic contexts. Kwan (2012a) focuses on the use of GPS to track movement over comparatively short periods of time. The focus on UGCoP (Kwan 2012a) lies mainly with short-term temporal coverage and the collection of data on activity spaces over comparatively short periods of time: periods of up to 7–10 days (occasionally an intervention study might collect GPS data before and after the intervention or perhaps at multiple intervals to examine temporal effects such as seasonal influence on spatial
behavior). One problem with GPS data, perhaps more so in the first generation GPS studies, was the inability to necessarily show that the observation window of a few days captured all of the relevant geographic contexts an individual might visit. As GPS battery and storage capacity have improved, the collection of longer sequences of days, say 14 or more, likely provides a much more complete picture of typical movements and activity spaces. As tracking expands across temporal scales, researchers may need to adapt and think differently about the implications of UGCoP. It is worth noting that the possibility of compiling data on exposomes—a set of exposures experienced over an individual’s lifetime—may not be so farfetched (Wild 2005). Wild seeks better precision in the measurement of individual exposures coupled with spatial and temporal precision. This will not be an easy task given known constraints on resources and available data, but scientific practice is changing rapidly and we can begin to envision ever more detailed data being gathered that will facilitate the tracking of human movement and exposure from cradle to grave. In a world of “big data,” “volunteered information” (e.g., Facebook, Twitter), biomarker data, real-time tracking, surveillance and other sensor data, and smartphones, this idea of compiling intensive longitudinal data on individuals over extended time periods is increasingly possible; this is especially the case in studies of movement, networks, and interactions (see González, Hidalgo, and Barabási 2008; Raento, Oulasvirta, and Eagle 2009; Palmer et al. 2013).

While technological developments in wireless tracking devices and new social media place increasing emphasis on fine-scale temporal and spatial units of analysis, it is worth noting that in the social sciences there is a tradition of collecting longitudinal data, including long-running birth cohort studies or longitudinal panels of adolescents, working-age, and older adults. As researchers begin to think about UGCoP they might be well served by other literatures and disciplines in the social sciences with a research tradition that focuses on the individual and on the sequencing of events they experience (e.g., migration histories), the durations of events or exposures to specific circumstances (e.g., job retention, housing tenure, cancer survivorship), and on transitions (e.g., entry into marriage, the labor market, or retirement). Within the United States, the ability to utilize linked administrative records at secure research data centers will also enhance the ability to study exposure to sequences of places over a lifetime or part of a lifetime. Similarly, Scandinavian countries have an established record of collecting detailed migration data associated with all residential moves. In these latter examples, the temporal and spatial specificity may be crude (annual data and at the scale of the housing market) but these types of data structures can inform the calculation of lifetime exposure via the reconstruction of detailed residential histories.

Measuring attributes in discrete and continuous contexts

As stated earlier, it is important to note the tendency to use relatively small geographic units to define context (e.g., census tracts), and in the analytical model, to use variables based on these areas (e.g., the unemployment rate) to examine associations between contextual variables with an individual outcome (e.g., teen pregnancy). However, let us briefly consider the unemployment rate of a census tract. Most fundamentally, the unemployment rate in a specific census tract does not occur in a vacuum and thus embedding of an individual within a single tract disregards the absolute and relative positioning of the
tract and the patterning of unemployment at other higher-level contextual scales. That is, census tracts are embedded in nested and even non-nested larger geographical regions, and the processes or drivers of unemployment can emerge from macro-level factors that may be operating at the level of the labor market areas, which are in turn embedded within regional and national economies. Residential neighborhoods are not isolated islands, rather they are connected to other neighborhoods and they are embedded within larger contexts that typically remain undefined, unmeasured, and unexamined.

Some of the contextual variables we use are more complex than unemployment. Consider race/ethnic segregation, a critical component of any study of racial inequality and racial health disparities. Race/ethnic segregation can be measured in multiple measures, as many as 20 different indexes, grouped into five key dimensions of segregation: evenness, exposure, concentration, centralization, and clustering. Moreover, as in the case of unemployment, we know that segregation exists at multiple scales simultaneously, embedded in local, urban, regional, and national contexts. Race/ethnic segregation is typically calibrated from a single common source, in the United States, from data available from the US Census Bureau. However, other variables can be calculated, and calculated in different ways, from a variety of data sources and for different geographical contexts. A good example of this concerns the myriad of ways in which the food retail environment or food availability can be measured (see NCCOR 2014). Briefly, some data sources provide counts, densities, and other aggregate attributes of food store types (variously defined) for different geographical contexts, typically units such as a ZIP code or census administrative unit. Increasingly, researchers on food environments are also working with point data; the data on food stores comes as a geocoded point. With this format the analyst can aggregate and generate density scores or measures of the diversity of different store types for almost any geographic context they wish, or generate density and/or accessibility surfaces, the latter being yet another data format. In theory, point data enhances flexibility, but the aggregation of such data and manipulation to match areal units also can potentially lead to the calculation of different scores for input into a model.

These are just a few examples of the complexity of variable measurement, how they vary by measure and geographic context, to say nothing of utilizing such data for calculating change scores for examining dynamic contexts.

Moving from monadic contexts to dyadic and polyadic contexts

The patterns of association among different individuals and groups of people with place suggest that the use of restricted definitions of place (i.e., residential neighborhoods) is missing part, and often significant parts, of the narrative on the connections between people and place. If researchers are to better understand social and health outcomes they need also to think more creatively about the complexity and heterogeneity of human mobility, and about individual exposure to risks and access to resources across time and space. This kind of perspective is increasingly necessary as the human scale of activity no longer appears to coincide with the local scale of the residential neighborhood (Cummins 2007; Basta, Richmond, and Wiebe 2010; Zenk et al. 2011). Indeed, one of the potential reasons why neighborhood effects are found to be small may be due to the heterogeneity in spatial behavior of individuals living in the same context (Chaix et al. 2009; Matthews 2011). As where and when people spend their time will vary across individuals, new
notions of context, and by extension contextual exposure, are increasingly likely to be operationalized through individualized measures that allow exposure levels to vary even for individuals within the residential context. Kwan’s UGCoP could not be a clearer statement on this issue.

Place and health are intertwined, but conventional approaches typically adopt somewhat limited views of the complex relationship between people and place, and more specifically places. The UGCoP challenges researchers to move research away from single exposure or monadic perspectives. A dyadic perspective or framework would see researchers focus on an examination of exposure at two primary places, such as work and home, or borrowing from both spatial and multilevel modeling might examine exposure to adjacent geographical contexts (via estimation of, for example, spatially lagged variables) or examine exposure at processes and measures calculated for two higher levels, either nested or non-nested (e.g., individuals within tracts within counties, or individuals within nonhierarchical geographies such as school districts and health service areas; complex multilevel models can handle both nested and non-nested multiple membership models). A more complete perspective on contextual exposure would adopt a polyadic framework, seeking to examine exposures to multiple places. GPS data collection represents one form of data required for a polyadic perspective where the focus is on short-term measurement periods. Similarly, data from a longitudinal study such as a birth cohort also could fit under the polyadic umbrella, as migration histories could be reconstructed to examine the timing, sequence, and duration of residence and thus exposure to multiple contexts across a longer time period: the human lifespan. While there are examples of three-level data structures (e.g., nested predefined units such as people within census tracts within counties), it is still rare that researchers explore linking individuals to multiple, hierarchically nested or hybrid places.

Examining the effects of multiple places, specifically extra-local or nonresidential places, is an emerging area of research that lies at the intersection of multilevel analyses, geospatial data, and spatial analysis. We will inevitably see more use of wireless technologies and tracking devices to capture human spatial behavior, but so too in the next decade we will read about the adoption and use of other analytical techniques that can help model an individual’s exposure to multiple contexts. Nonspatial disciplines will use techniques such as multiple membership models that permit assigning individuals to multiple non-nested contexts, and this will help unpack UGCoP-related issues.

Uncertainty

Stephen C. Guptill

US Geological Survey (Retired)

A digital spatial dataset represents a model of geographic reality. These models incorporate both the locational and the nonlocational aspects of the phenomena of interest. An observation describes a property of these phenomena. However, every observation is subject to some uncertainty. The uncertainty of the observation is the error that is associated with the result or value of that observation. Taken in total, the uncertainty of the observations conveys information about the quality of the dataset.

Although the real world of geographical variation is infinitely complex and often uncertain, it must be represented digitally in a discrete, deterministic manner. In one method of organizing or describing geographic reality we think of the world as a space populated by objects or features of various kinds. Features have attributes that serve to distinguish them from each other. Buildings, bridges, roads, streams, grassland, and counties are examples of features. Any point in the space may be empty or occupied by one or more features. Feature data models use graphic elements (points, lines, and polygons) to describe the geographic location and extent of the phenomenon under study. These features may exist in one combined database, or may be separated according to a theme or variable into a number of layers or classes. Most digital map data are in this form.

Instead of describing discrete geographic objects, geographical phenomena can be represented and organized by recording the locational pattern of one variable over the study area – that is, as fields of data. When the spatial interval of this spatial sampling is regular (e.g., square), the resulting matrix of observations is called a raster data structure. Locational information is embedded in the data structure; each cell of raster data is located at a unique position. The value of an observation at the cell location is recorded for each and every cell in the area. Digital terrain models, digital images, and land-cover maps (derived from remotely sensed data) are typically stored in this structure.

Whether organized as objects or fields, it is the set of observations that hold the information. An observation tells us about a property of a feature of interest at a specific point in time. Observations can be made with measuring instruments resulting in scalar results, such as locations, elevations, or reflectance values. Or observations can be the result of human or algorithmic interpretation of a feature of interest, resulting in nominally valued objects, such as roads, streams, or buildings. The number of observations about an object can be quite large, and may include information about the various characteristics of the feature of interest (e.g., the number of lanes of a highway) and their relationships to each other (e.g., directional flows on streams, or turn restrictions in road networks). However, for every observation there is always a margin of error or doubt.

Axes of uncertainty

Uncertainty in geographic data is measured along at least four different conceptual axes, including space (location), time, theme (content...
UNCERTAINTY

characteristics), and logical consistency. The space axis characterizes positional accuracy; the time axis indicates temporal accuracy and validity; the theme axis reflects semantic ambiguity, delineation ambiguity, and attribute accuracy; and the logical consistency axis concerns conformity to a data model, internal consistency, and completeness. These qualities are not independent, however. Indeed some data quality aspects, such as logical consistency, directly refer to the interrelationships of elements measured on the other three axes. Not all of these quality elements have well-defined quality metrics associated with them. Metrics of semantic accuracy, for example, are not well understood and some of the measures used for other quality elements may be inadequate.

Location

Uncertainty along the space axis usually concerns the accuracy of geographic coordinates in two- or three-dimensional space. These scalar measurements can be collected directly with a wide variety of instruments, such as global positioning system (GPS) receivers (of varying accuracy and precision), surveying instruments, and geodetic recorders. Many of these instruments have been tested and calibrated and the uncertainty values associated with the measurements are known. However, some locational data is not collected directly, but results from a secondary process. For example, the elevation at a particular location may be calculated from a stereopair of aerial photographs. The final elevation value is the result of complex series of photogrammetric calculations that take into account camera positions, lens distortions, and relief displacement, along with other factors. Each of these elements has an uncertainty factor associated with it, and estimates of the total error introduced in the process can be made. In another example, the geographic coordinates of linear geographic features such as roads might be collected by tracing that feature from a paper map or orthophoto image. Uncertainty in the coordinate values can be introduced by the accuracy of the tracing device, the skill of the operator doing the tracing, the locational accuracy of the feature on the source material, and a myriad of other factors. In such cases, it is difficult to estimate the amount of error introduced by each step of the process, and the uncertainty is usually determined by testing the values in the end product.

Time

The time axis appears straightforward; simply record the time when the observation was made. The first source of uncertainty involves the granularity of the time measurement to associate with the observation. GPS timings are measured in nanoseconds, but a date may be sufficient for describing a land-cover condition. The second confounding factor is that a geographic dataset is usually comprised of a collection of objects, each of which may have a separate “observation” time associated with it. The variance of these times could be measured in months or years. Furthermore, the dataset takes time to produce and assemble, and the final product might not be released until some later time. For example, consider what appears to be a seamless, uniform, cloud-free image of a large geographic area, such as a county or state. The question arises as to what time stamp would be provided with this product. This product is a mosaic made up of a number of separate images, collected at different times, processed and merged together before being published. Typically, all that is provided is the date of publication or release. Clearly, this single date does not accurately represent the temporal characteristics of the product. To
compound the problem, a person might trace a road segment into a database using this image. The question then arises as to what temporal stamp is associated with this road segment. A third aspect involves the concept of temporal validity and whether an observation made at time $x$ is still valid or useful at a later time $y$. Often, observations are assumed to be valid until replaced by newer ones: for example, when users get a new edition of a road database for their car navigation system. However, there are many instances using historic or time series data where all of the observations are required, not just the ones that are currently valid. It is incumbent on data producers to associate sufficient temporal attribution and uncertainty measures with the spatial data that they provide. Determining the temporal uncertainty of a dataset after the fact by an independent data quality evaluation is difficult.

Theme

The theme axis reflects the uncertainty with respect to the content of the dataset: what the phenomena being observed are, and what observations are being made on those phenomena. For users to understand the nature of the data there must be a complete specification of the phenomena being described. Comprehensive data specifications include the definition of the observed phenomena as well as definitions of their attributes and attribute values. Consider the simple example of a geographic dataset consisting of towns and temperatures, such as shown on a weather report. First, we need a geographic location for the named town, for example, “Washington, DC,” second, the measurement scale for the temperature value (Fahrenheit or Celsius) is needed, and third, the question must be asked as to whether the temperature value represents the current temperature (in which case we need the time of the reading), or the maximum or minimum value from yesterday, or a prediction for the future temperature. Lacking any specific guidance, a user will make assumptions about each of these items, but clearly there is a degree of uncertainty associated with each of them.

The term “uncertainty,” in a scientific sense, implies that we can quantify the amount of doubt about each of the observations. Along the theme axis, the items of concern are difficult to quantify. It is less about the uncertainty value of a given observation, but rather more about the ambiguity of what phenomena are being observed (semantic ambiguity). This dilemma is particularly acute when describing phenomena modeled as geographic features or objects, and so deciding what is really meant by terms such as “forest,” “marshlands,” “residential land,” or “bridge.” Consider features labeled with a common place term, such as a stream/river (which we define as a body of flowing water), and whether a database of features called “streams” contains or distinguishes the following: a perennial stream (it contains water throughout the year except for infrequent periods of severe drought); an intermittent stream (it contains water for only part of the year, but more than just after rainstorms and at snowmelt); or an ephemeral stream (it contains water only during or after a local rainstorm or heavy snowmelt). Additional source of ambiguity stems from defining the boundaries of the objects being described: for example, where the edge of a wetland or forest is, or the shoreline of a lake. Even “hard-edged” objects, such as a road, have a level of ambiguity (e.g., whether or not the gravel shoulder is part of the road; where the gravel ends and the dirt begins). Clearly, additional information is required for a complete understanding of the data. Hopefully, the definitions and specifications of the data producers
Uncertainty

(which are not always publicly available) match to some degree the expectations of the user.

To help solve this data-definition problem, a feature data specification can be used to provide a detailed definition of each feature and how it is modeled. This technique is used by national mapping agencies and commercial spatial data producers. The feature data specifications define the domain of features that may be represented in a spatial database. For each feature in the feature data specification, a domain of attributes is defined. Each attribute is assigned a value, taken from the domain of values specified by the attribute definition authority. In addition to the definitions, guidance is given on how a given feature is delineated, when it is collected, and how it is represented in the spatial data model. However, user-contributed or volunteered geographic information is usually collected and provided without regard to adherence to a set of specifications and procedures. As a result, this increases the level of ambiguity and uncertainty in datasets comprised of such data.

Logical consistency

Logical consistency issues concern the degree of conformance to a specified data model. For example, geographic features are often represented by point (or node), line (or edge), and polygon (or face) geometric elements. The relationships between the nodes, edges, and faces are called topological relationships. In simple terms, the topological relationships are that edges start and end only at nodes, and that faces are enclosed by a series of edges. Attention is given to neighboring geographical entities when coding edges. For instance, the topological description of each arc includes not only the starting and ending bounding nodes but also the left and right designations of the co-bounding regions. In this way an edge is directed: that is, the first coordinate is that of the start node and the last coordinate that of the end node. Each face record might also include the identification of any interior islands or, if the polygon is itself an interior island, the identification of the single exterior polygon. This data structure not only accommodates the natural pattern of mapped features efficiently, but also provides the information needed to model networks and to facilitate automated editing and manipulation of the database. Computer algorithms can check to see if the data conform to the specified set of topological relationships.

Another aspect of consistency deals with the consistent, complete collection of all instances of the phenomena (and their associated attributes) that are specified in the data model definition—for example, if the data specification includes driveways that serve two or more houses as a part of the database, or whether all instances of such driveways have been collected. Incomplete collections or collections that do not strictly adhere to the collection specifications add a great deal of uncertainty to the quality of the data.

Other specific relationships, termed “semantic relationships,” are used to express interactions that occur between features that are otherwise difficult to represent with locational data, topological relationships, or feature descriptions. Such relationships can include the following: to flow, the relationship that occurs among the two-dimensional features composing a river system; to connect, the relationship that occurs (at junctions) among the two-dimensional transportation features composing a road network; to bound or to be bounded, the relationship that occurs between the perimeter of a city and its city limits; to be composed of, the relationship that occurs between a designated route of travel and the transportation features that compose it, or between the stream and pond features that comprise a watercourse; and to be above, the
relationship that occurs between the features in an overpass or underpass of a freeway interchange. The intent of all of these relationships is to model the interactions between features sufficiently to support geographic information system (GIS) applications and automated cartographic-product-generation requirements. Failure to provide information about these interactions among the data elements could increase the uncertainty level of the information that is provided.

Evaluating uncertainty

To evaluate uncertainty, a variety of evaluation procedures can be used. Data quality evaluation methods are divided into two main classes: direct and indirect. A direct evaluation method evaluates the quality of a dataset based on a comparison of the items within the dataset with reference information. The direct evaluation methods are classified as internal or external. Internal direct data quality evaluation uses only data that reside in the dataset that is being evaluated. For example, topological consistency checking of the road network is an example of an internal data quality evaluation. External direct quality evaluation requires reference data that are external to the dataset being tested. The reference data are accepted as representing the “ground truth.” In this case, an example would be that the positional accuracy of United States Census Bureau TIGER (topologically integrated geographic encoding and referencing) roads might be evaluated by comparing the roads visible in high-resolution orthoimagery, or field personnel with high-precision GPS devices could retrace the road segment. For both external and internal evaluation methods, one of two inspection methods may be used: full inspection or sampling. A “full inspection” tests every item in the population and is most appropriate for small populations or for tests that can be accomplished by automated means. Sampling tests are performed on subsets of the geographic data.

An indirect evaluation method infers or estimates data quality using information about the data, such as lineage information. This type of external knowledge may include, but is not limited to, data quality overview statements or other quality reports on the dataset or data used to produce the dataset. It may be estimated from knowledge about the source, tools, and methods used for capturing the data and evaluated against procedures and specifications that represent the “best practice” for this product. If indirectly evaluated data quality has been reported, it should be accompanied by a description on how it was determined. In some cases it might be misleading or not even possible to report indirectly evaluated data quality as quantitative results. In those cases the data quality may be described in textual form using a descriptive result. As such, it is often subjective. For these reasons, direct evaluation methods are preferred to indirect evaluations.

Data quality evaluation procedures can be applied at various points in a product’s life cycle. At the production stage, the producer may apply quality evaluation procedures as part of quality control. The description of the applied quality evaluation procedures, when used for production quality control, may be reported as lineage metadata including, but not necessarily limited to, the quality evaluation procedures applied, the conformance quality levels established, and the results.

A quality evaluation process might be used upon completion of production to report data quality results. These results may be used to determine whether a dataset conforms to its product specification or not. If the dataset passes inspection (composed of a set of quality
UNCERTAINTY

evaluation procedures), then it is considered to be ready for use. Most data producers apply quality evaluation methods as part of data processing procedures. However, formal documentation of these quality processes and results are usually not available.

Uncertainty in geographic analyses

Geographic information systems utilize spatial data to provide a wide variety of analytical results. However, it is not standard practice to utilize uncertainty information (should it exist) in the algorithms used to generate results: for example, in determining the level of uncertainty that can be placed on a set of routing instructions from a navigation product, or how often the identified road will not exist, an illegal turn will be specified, or an erroneous destination will be provided. Each of these probably results from errors in the underlying data. Data producers should have knowledge about the uncertain levels in their data and could tell the user that there is, say, one chance in a thousand that the driving instructions contain an error.

Many GIS-processing algorithms utilize multiple sets of often disparate data, each with their own uncertainty characteristics. However, the results of GIS analyses have often been presented as definitive to decision-makers (e.g., this is the best site for the municipal water well), with little or no qualification. One would expect that decision-makers would insist on qualifying statements on any results presented to them. The methods for doing this are not well understood. For example, due to the cumulative effects of error, it has been conjectured that, as the number of datasets used in a GIS analysis increases, the accuracy of the result decreases. This runs counter to common practice, where multiple datasets are used with little regard for whether they are contributing more to the information content or to errors in the result.

Formal characterization of spatial data quality

The ISO (International Organization for Standardization) Technical Committee 211 Geographic information/Geomatics (ISO/TC211) has developed a series of standards, the ISO 19100 series, which deals with standardization in the field of digital geographic information. The standards contain a detailed set of terms, definitions, procedures, and organizational hierarchies to describe and report the various aspects of spatial data quality, including measurements and observations. These terms are used in the section that follows to provide a formal characterization of the elements of spatial data quality.

The information on data quality, which is encapsulated in metadata records, can be applied at varying data granularities, from individual feature instances to entire databases. A quality description can be applied to a dataset series, a dataset, or a smaller grouping of data located physically within the dataset sharing common characteristics so that its quality can be evaluated.

The quality of a dataset is described using the following components: data quality elements, data quality sub-elements, and data quality overview elements.

Data quality elements and sub-elements

Data quality elements and sub-elements, where applicable, are used to describe aspects of the quantitative quality of a dataset. The completeness element describes the presence and absence of features, their attributes and relationships. It has sub-elements of: commission – excess data
present in a dataset; and omission – data absent from a dataset.

The logical consistency element characterizes the degree of adherence to logical rules of data structure, attribution, and relationships (data structure can be conceptual, logical, or physical). It has sub-elements of: conceptual consistency – adherence to rules of the conceptual schema; domain consistency – adherence of values to the value domains; format consistency – the degree to which data is stored in accordance with the physical structure of the dataset; and topological consistency – correctness of the explicitly encoded topological characteristics of a dataset.

The positional accuracy element details the accuracy of the position of features. The sub-elements include: absolute or external accuracy – closeness of reported coordinate values to values accepted as or being true; relative or internal accuracy – closeness of the relative positions of features in a dataset to their respective relative positions accepted as or being true; and gridded data position accuracy – closeness of gridded data position values to values accepted as or being true.

The temporal accuracy element reports the accuracy of the temporal attributes and temporal relationships of features. It has sub-elements of: accuracy of a time measurement – correctness of the temporal references of an item (reporting of error in time measurement); temporal consistency – correctness of ordered events or sequences, if reported; and temporal validity – validity of data with respect to time.

The thematic accuracy element describes the accuracy of quantitative attributes and the correctness of nonquantitative attributes and of the classifications of features and their relationships. The sub-elements include: classification correctness – comparison of the classes assigned to features or their attributes to a universe of discourse (e.g., ground truth or reference dataset); nonquantitative attribute correctness – correctness of nonquantitative attributes (e.g., correctness of attribute values such as “road name” or “pavement type”); and quantitative attribute accuracy – accuracy of quantitative attributes.

Additional data quality elements may be created to describe a component of the quantitative quality of a dataset not addressed in the ISO 19100 standards.

Data quality overview elements

The data quality overview elements are used to describe the nonquantitative quality of a dataset. The overview elements are: purpose – describes the rationale for creating a dataset and contains information about its intended use; usage – describes the application(s) for which a dataset has been used; and lineage – describes the history of a dataset and, in as much as it is known, recounts the life cycle of a dataset from collection and acquisition through compilation and derivation to its current form.

Lineage may contain two unique components. These are: source information describing the parentage of a dataset; and process step or history information describing a record of events or transformations in the life of a dataset, including the process used to maintain the dataset (whether continuous or periodic), and the lead time.

The ISO 19100 standards can be used when identifying and reporting quality information, evaluating the quality of a dataset, developing product specifications and user requirements, and specifying application schemas. The quality of a dataset is described using a combination of data quality elements and data quality overview elements.

Data quality elements, together with data quality sub-elements and the descriptors of
UNCERTAINTY

data quality sub-elements, describe how well a dataset meets the criteria set forth in its product specification, and provide quantitative quality information about the dataset. Data quality overview elements are critical for assessing the quality of a dataset for a particular application that differs from the intended implementation. Theoretically, a dataset (from the data quality perspective) may be as small as a single feature or feature attribute contained within a larger dataset. When data quality measures are applied to collections or aggregates of individual features, those measures tend to serve as screens or filters. In other words, for example, all of the features in this collection have a positional accuracy greater than 3.5 m, or all of the features have passed a logical consistency check.

The ISO standards recognize that quantitative and nonquantitative information may have associated quality and the analysis of quality information may include a measure of confidence or reliability. This type of information is then recorded in a quality evaluation report.

Underclass theories

Bradley S. Gardener
Middlebury College, USA

The underclass, a concept popularized in the United States in the mid- to late twentieth century by social scientists and journalists, describes persons living in the most severe poverty. Historically, the underclass, referencing the Marxist concept of the *Lumpenproletariat*, is black and urban, and lives in the inner city. Underclass theories are mainstays in US and UK policy circles, and have helped produced a retrenchment of state policies related to public assistance and affirmative action. Originally contrived as a way to identify Americans, regardless of race or geographic location, who lacked class mobility, underclass theories have largely been positioned as a part of a larger discourse that blames the victim for their state of impoverishment.

Underclass theories and debates are enlivened by the following questions: Who are the poorest of the poor? Where do they live? Why do they continue to stay in poverty? And perhaps most importantly, what are the policy solutions for eradicating this kind of poverty? In brief, according to most variations of underclass theory, these answers are found in identifying the poorest of the black poor, and more recently Latinos in the United States (in an international context this can refer to any number of racialized minority groups). Here, if poverty is pathology, the welfare system encourages people not to work. Thus, the best solution is to cut the safety net and force the poor to find legitimate employment. Out of a need to survive, it is reasoned, this poor population will be forced to take the attitudes and norms associated with mainstream society. Only then will they be able to escape from what supposedly traps them, a vicious cycle of poverty.

Early uses of the term underclass are attributed to Swedish social scientist Gunnar Myrdal, who is best known for his studies of race relations and assimilation in the United States. Myrdal first used the term underclass in a series of lectures he made at prominent US college campuses between 1962 and 1963. These lectures were eventually collected into a book called *Challenges to Affluence*. In a society characterized by wealth and social mobility, particularly among white European immigrants and their offspring, Myrdal was concerned about Americans who were relegated to multigenerational poverty (Myrdal 1963).

Myrdal’s focus, like that of many of his successors, would be on employment or waged labor in the formal economy. He concentrated on several categories related to work in his definition of the underclass, which included the unemployed, the underemployed, and the unemployable. Although he identified structural conditions as the primary cause of poverty, he still focused on problematic attitudes around legitimate work, a keystone of future behavioral-centered theories of the underclass.

Around the same time Myrdal lectured about the underclass, Oscar Lewis, an anthropologist and ethnographer, wrote a book about his research with poor Mexican families. While Myrdal focused on the nation as a whole, Lewis studied the behaviors and attitudes of individuals and families living in poverty. His...
book *The Children of Sanchez* demonstrated that culture greatly influenced the cyclical nature of intergenerational poverty (Lewis 1961). His primary point was that the kinds of behaviors people adopt in order to cope with poverty often prevent them from escaping from it. The findings of his research would be debated heavily in the years following its publication. The culture of poverty is very influential to behavioral variations of underclass theory.

In the early 1980s journalists such as Ken Auletta, who first started using underclass in the highbrow magazine *The New Yorker*, further advanced behavioral strands of underclass theory. Drawing comparisons to Jacob Riis, Auletta sought to reveal everyday realities of the underclass (Auletta 1982). His New York research identified the underclass as being black, poor, and urban. Auletta stressed the values of the underclass, distinguishing them from other impoverished people based on what he saw as aberrant or antisocial behavior. Auletta also wrote a book on the subject, *The Underclass*, which would appear side by side with a plethora of similarly themed magazine articles and news programs, most of which made a racialized spectacle out of extreme poverty.

More than any other scholar, William Julius Wilson is credited for framing the debate around the underclass in academic circles (Wilson 1987). His classic book, *The Truly Disadvantaged*, published in 1987, produced hundreds of follow-up studies. Through a sociologist's lens he documented and explained the most concentrated African American poverty in Chicago. He argued that large-scale changes in the economy having to do with the location of jobs and the disappearance of legitimate work were strongly related to the antisocial behaviors of ghetto residents, which included having children out of wedlock, welfare dependency, and criminal activity.

Key to his argument was the increased social and spatial mobility of African Americans in the post-Civil Rights period. He argued that black ghettos suffered a brain drain. Civil Rights legislation allowed the most educated members of the community to migrate into more integrated neighborhoods, leaving those left behind with fewer connections to legitimate work.

Perhaps the most useful concept to come out of Wilson's work for geographers is “spatial mismatch,” a term that continues to be a focus of geographers who do work on poverty. In this case, poverty is partly a function of the geographic distance between jobs and skill sets. As Rust Belt cities deindustrialized, manufacturing jobs that provided opportunities for social mobility disappeared. This theme gave a geographical dimension to the underclass, as Wilson focused on the lack of legitimate job opportunities in areas of concentrated poverty. Feminist geographers have used Wilson's concept to analyze gender, space, and employment.

Political scientist Charles Murray focused on the behavioral side of Wilson's argument. Unlike Wilson, he deemphasized the economic causes of the underclass related to globalization, and instead concentrated on the excesses of the welfare state. In his influential book *Losing Ground: American Social Policy 1950–1980* he created a series of laws about human behavior that prefigured his later work with Richard Herrnstein, *The Bell Curve*, where he argued that intelligence was related to race and geography (Herrnstein and Murray 1994). In *Losing Ground*, Murray argued that the state and what he described as generous welfare programs were responsible for creating and reproducing the underclass (Murray 1984). To eliminate the underclass, he suggested that public assistance programs such as welfare should be severely cut or eliminated. His research and recommendations foreshadowed significant policy changes in the United States and the
United Kingdom. Murray is particularly relevant in the UK context, as he was invited there to do research about poverty and the underclass.

Underclass theories are relevant because of their widespread adoption by policy circles. In academic and political discourse, the underclass became a signifier for a type of place and person, one that was poor, not because of structural reasons, but rather, because of flawed culture or individual behavior. This ideological shift towards individual behavior and responsibility led Prime Minister Margaret Thatcher famously to say, “There is no such thing as society.” Murray’s theory of the underclass prefigures and influences what scholars call the Neoliberal turn.

Around the same time that the underclass concept became popular, actor Ronald Reagan ran for president of the United States. In his campaign speeches he promised to decrease the size of government and punish the undeserving poor. He popularized the welfare queen, a gendered and racialized character who cheated tax payers by spending food stamps on alcohol, buying luxury items with welfare checks, and having kids with multiple men in order to exploit government programs. Reagan’s assault on the undeserving poor, coupled with claims that affirmative action gave jobs and seats in universities to people of color based on skin color, and not merit, provided a wave of support to hamper gains made through the civil rights movement, and the Great Society, a set of programs launched by President Lyndon B. Johnson in the mid-1960s to fight social inequality.

In the United States these debates culminate in a significant restructuring of the welfare system in what is popularly known as the “End of welfare as we know it.” In the early 1990s, Republican politician Newt Gingrich and others conspired to change the way the American public thought about welfare and the role of the state, creating a series of words, expressions, and concepts that were antithetical to leftist solutions to poverty (Peck 1998). Their efforts successfully reconfigured debates around welfare. Being pro-welfare in any capacity became a political faux pas. Along with the support of President Bill Clinton, the welfare system was hampered.

Today, the social science literature on underclass theories reveals two major schools of thought. The structural theory argues that the underclass cannot compete in the formal economy because good jobs for unskilled laborers have relocated from cities to suburbs and overseas due to revolutions in transportation and communication technology, and the automation of work has deskillled workers to create a bifurcation between the rich and poor. Coupled with multiscalar forms of racism, the underclass is trapped in poverty because of forces beyond their control.

Alternatively, the behavioral theory of underclass tells variations of the following narrative. Poor blacks reside in ghettos where they live in opposition to mainstream norms. They engage in irresponsible sexual activities producing single female heads of households, depend on welfare and government assistance for basic needs making it disadvantageous for them to find legitimate work or develop a good work ethic, and lack the ability to think towards the future, practicing instant gratification. These behaviors are part and parcel of a culture that glorifies crime and antiestablishment behavior. This culture reigns supreme and keeps underclass groups in an endless cycle of poverty. Individual behavior and flawed culture are the primary reason why the underclass is not socially mobile.

In both cases there is a geographic or spatial aspect to renditions of the underclass. The underclass lives in highly concentrated urban areas, primarily in Rust Belt cities where formal economic opportunities have diminished. Scholars also use the concept of geographic isolation to explain the persistence of the underclass. Spatial
separation from mainstream norms, education, and jobs creates a potent culture of poverty, a set of behaviors that make it very difficult to escape poverty. In *American Apartheid*, Massey and Denton argue that underclass conditions are produced by high rates of segregation between blacks and whites (Massey and Denton 1993).

For geographers, there is a special emphasis on the spatial strategies that are used to deal with dangerous or at-risk populations, such as those identified as underclass. Kay Anderson’s seminal work on Vancouver’s Chinatown demonstrates how space is used as a tool to manage groups seen as a threat to the health of a city or nation (Anderson 1989).

The underclass and its geographical correlate, the inner city, fall into this paradigm. Critical scholars identify public housing, urban renewal, and the ghettoization or warehousing of African Americans in the United States as spatial strategies for dealing with the underclass. Parks, highways, and bodies of water often naturalize boundaries between urban neighborhoods and highlight the otherness of the people who live in these areas. One spatial strategy used to deal with the underclass is to destroy the neighborhoods where they live. In Chicago, the infamous Robert Taylor Homes were demolished less than 50 years after they were built.

The underclass concept travels well in academic, journalist, and policymaking circles. Its wide and varied use means that the definition of underclass largely depends on the context in which it is deployed. It has been used by social scientists on the left to decry structural racism and inequalities wrought by global capitalism, and on the other hand, by the right, to lobby for the end of welfare. The malleable nature of the underclass concept has allowed it to jump to the international scale, where it has frequently been used to question the behavior of what are perceived to be unruly minority groups. That being said, the scholarly evolution of underclass theories is well documented.

Leftist academics have taken issue with the term underclass, and have attacked the presuppositions on which behavioral versions of underclass theory are based, primarily that deficient behaviors produce poverty. The most direct critique of this underclass theory was from Loïc Wacquant, a French student of William Julius Wilson. He took an ethnographic approach to studying the underclass. Wacquant’s critique of underclass theories mirrored other scholars who saw it as a clumsy term that unfairly grouped all urban African Americans into a negatively valued category. He worried about the implication of placing a diverse group into a narrow category, arguing that poor African Americans in Chicago did not see themselves as part of an underclass. Rather, he saw that academics and state actors were unfairly placing this category upon them from above.

The underclass concept has also been critiqued for not actually referring to a class, lacking a common economic relationship or the capacity for enacting collective social action. Marx’s writing about the *Lumpenproletariat* was a precursor for this argument. In the *Eighteenth Brumaire*, Marx attempted to calculate the political potential of this group, and found little hope (Marx 2005/1852). By most accounts, Marx saw them as a heterogeneous group of thieves, pimps, and ragpickers, who lived off the detritus of the current political economic order.

Another critique of the underclass concept has to do with heavy policing and incarceration. Scholars of the prison industrial complex have long pointed to the devastating effects of removing men from urban communities.

Although debates over underclass theories dimmed in the early 2000s, there has been a shift in the terrain on which it is discussed. The largely urban and black character of the
underclass has been expanded to include Latino groups, particularly undocumented Mexican workers, spawning the social science term “the rainbow underclass.” The expansion of the underclass category reflects anxieties around undocumented workers (Cameron, Cabaniss, and Teixeira-Polt 2012). The location of racialized poverty has changed from the inner city to the border. Although the geography and groups identified as underclass have changed, the link to individual behavior has not. The underclass now also refers to “illegals,” who it is claimed receive undeserved medical and financial benefits of living in the United States, not because they refuse to work, but rather because they do not pay taxes.

Popular talk-show hosts and right-leaning intellectuals have recently taken up underclass theories in reference to the proposed amnesty of undocumented Mexican migrants. Rush Limbaugh, for example, recently said that the Democratic Party wants to give voting privileges to 11 million illegal immigrants because they need a permanent underclass to stay in power. Defending the research of Jason Richwine, who argued in his doctoral dissertation that the IQ of immigrants is below that of white Americans, Pat Buchanan is concerned that Hispanics threaten to become a permanent underclass in the United States because of their lack of intelligence.

To conclude, it is appropriate to talk about indigenous resistance to underclass theories. What have the people that the underclass targets, primarily people of color living in urban areas, done to resist claims that they have a flawed culture?

Scholars see hip hop as a form of indigenous resistance, as it communicates injustices to the world outside underclass areas, and helps solidify locally based resistance against the retrenchment of the welfare state associated with underclass research and policy recommendations.

Currently, a popular hip hop concept is “work.” Although it has different meanings depending on context, one popular iteration has to do with work as drugs. “Pushing work,” is another way of discussing the sale of illicit drugs. In underclass theories, selling drugs is seen as the antithesis of work. In this case, selling drugs is work. The illegitimate becomes legitimate. By reappropriating the concept of work, youth of color are talking back to social scientists and politicians who think they are lazy.

In the black community, the link between behavior and poverty is a highly contested issue. These debates center around the role that parenting, behavior, culture, and role models play in class mobility. Right-leaning African Americans such as Bill Cosby feel that poor African Americans have dishonored the civil rights tradition by not holding up their end of the bargain, engaging in behavior such as buying their kids expensive sneakers, being poor role models, not emphasizing academic achievement enough, and even giving their kids African names. Hip hop artists such as Ice T and scholars such as Michael Eric Dyson have trenchantly critiqued Cosby’s link between behavior and poverty, trying to shift the debate about the underclass towards issues of job availability, economic realities, and institutional racism.

Unemployment and “underclass”

Michael Samers
University of Kentucky, USA

The persistence of severe unemployment in the world’s poorest countries, the last 40 years of stubbornly high unemployment in much of the European Union (EU), and the global repercussions of periodic economic and financial crises have all ensured that unemployment remains high on the agenda of political institutions and publics around the world. Higher unemployment in especially the wealthier countries over the last six years has also seemed to increase concerns about a continual “underclass,” which in the twenty-first century is sometimes referred to as “the precariat.” Unemployment may be an “invention” of economists and others, relative to changing understandings of work since the nineteenth century (Salais, Baverez, and Reynaud 1986), it may also be implicitly coded in negative and moralistic terms, but it affects millions with significant consequences for individuals’ physical and psychological wellbeing. Similarly, the underclass or the precariat may be the creation of social thinkers of various political stripes but both describe conditions and processes that affect countless numbers of people across the globe.

Though unemployment is calculated differently in different countries, and even within countries depending on political winds, it is usually defined by the number of people actively seeking work who cannot find work. If an individual has given up seeking formal work, or is self-employed, then s/he cannot be considered as unemployed. It is typically measured by direct surveys (such as the Current Population Survey in the United States) or by other estimations. Unemployment statistics are often broken down into further categories: by age (e.g., “youth unemployment”) or other social categories (such as disability, ethnicity, gender, or “race”); in spatial terms (e.g., national unemployment or local and regional unemployment); temporally (e.g., temporary unemployment, long-term unemployment, cyclical, seasonal); or by other qualities (e.g., frictional, hidden, and structural). Official unemployment statistics notoriously do not measure the unemployment of undocumented migrants (which is one element of hidden unemployment) although estimates or surveys may fill in the void. In poorer countries, unemployment is not only difficult to measure because of inadequate or heavily manipulated survey and reporting practices, but it may explain very little about people’s actual economic activity, since the extent of informal employment is so considerable.

The reasons cited by economists for increases in unemployment change over time and space. In the 1970s and 1980s, for instance, it became a common argument that slow growth and structural unemployment (“Eurosclerosis”) plagued the European Union, not just because of industrial restructuring, but also because EU labor markets suffered from “labor market inflexibilities” relative to especially the United Kingdom and the United States. In contrast, the United States (and to a less extent the United Kingdom) appeared to produce innumerable low-wage service sector jobs owing significantly to highly flexibilized labor markets. Dunford (1996) argued against what he saw as this
limited “Eurosclerosis” argument, and instead underlined how labor market regulation and the conditions of reproduction shaped different levels of regional productivity and thus employment levels in certain European regions. More generally, explanations for unemployment in the wealthier countries have tended to stress some mixture of “human capital” variables (e.g., levels of education), flawed macro-economic policies, the role of family support systems, welfare policies, and other gender-inflected labor market institutions, as well as racial discrimination and disadvantage. Since the mid-2000s and certainly after 2008, other explanations for high unemployment in at least the wealthier countries have surfaced, including the crisis itself, insufficient nationally oriented mass consumption owing to income inequality and the globalization of consumption; technological innovation in destroying “moderately paid” clerical and manufacturing jobs, international competition (e.g., the debated impact of “offshore outsourcing”), and a heavily disputed “skills gap” or “mismatch” between the skills required by new jobs and the skills of jobseekers.

In poorer countries, there is a significant difference between explanations for unemployment by economists and those of other social scientists, including geographers. For the former, quantitative analyses focus mainly on the effects of trade liberalization, (real) exchange rates, and government policies. For other social scientists, it is more common to explain unemployment by referring to crises (e.g., the Asian financial crisis) or to “neoliberal” structural adjustment policies beginning in the late 1980s – in many ways this terminology reflects a more critical stance that emphasizes the unequal effects of trade liberalization on poorer countries in terms of poverty and unemployment, but also structural adjustment’s impact on declining state resources for antipoverty, pro-employment programs. Furthermore, considerably more attention by noneconomists is accorded to whether declining employment in rural areas and rural to urban migration has an effect on (un-)employment in cities. This is often combined with both critical reflections on the significance of “human capital” (e.g., the inability of formal educational credentials to ensure employment or acceptable employment), and on the differentiated social impacts of unemployment, especially the relationship between gendered work expectations, the division of labor, and unemployment differences between men and women. Finally, over the last 15 years especially, there is far more research on youth unemployment, especially in African and Latin American countries.

Beyond the macro-economic arguments that seek to explain global, macro-regional, or national differences in unemployment, many geographers and sociologists (along with economists) have contributed to understanding subnational geographical differences in unemployment, especially in the wealthier countries. Such explanations are diverse. Some have interrogated the so-called spatial mismatch hypothesis (e.g., Holloway 1996), or neighborhood effects to analyze (un)employment. The spatial mismatch hypothesis refers to the gap between the location of available jobs in the suburbs and the location of the poor and the jobless, especially in the United States. The debate evolved into whether there is in fact a spatial mismatch, a skill mismatch, or even an “automobile mismatch.” Outside the United States, for example, in the United Kingdom, Houston (2005) notes a reinforcing relationship between a skills and a spatial mismatch. The question remains to what extent such debates are still relevant in the United States in particular, with the revival of some central cities. Other explanations for local (un)employment include insufficient or deficient social networks, local labor market institutions, and the need for specific forms of often locally
oriented “cultural capital” at the point of hiring, which some immigrants may lack (Bauder 2006).

In the 1980s, socially and spatially concentrated unemployment and poverty in US “inner cities” led to adoption of the term “underclass.” Some viewed this as a racialized and pejorative term which stereotyped the African American urban poor as “work-shy.” Others believed the term accurately reflected a “class” of people below the “working classes,” chronically or permanently divorced from the world of work. Wilson (1996) argued that the concept could be legitimately mobilized, provided that one viewed the underclass as a structural problem associated with deindustrialization and unemployment in US cities, and not strictly a behavioral problem associated with a particular group of people. Since the 1980s, the seemingly growing mass of long-term unemployed, chronically (under-)employed, or informally employed with diminished social benefits soon gave rise to another concept: the precariat. This frequently amorphous term is not without critics, and recalls the nineteenth-century formulations of Marx, namely the “reserve army of labor” and the lumpenproletariat, or more recently “the socially excluded” (in the EU). The choice of terms is always political, but probably most social scientists agree that the explanations for, and the often dire consequences of, severe unemployment vary over space and time.

Uneven regional development

Jamie Peck

University of British Columbia, Canada

Uneven development is a foundational concept in political economy, especially its Marxian variants, where it denotes asymmetrical and exploitative relations between classes, companies, and countries, all of which are understood to be endemic, not transitory, features of capitalist development. When referring to the subnational scale of cities and regions, uneven development signifies an out-of-equilibrium economy, characterized by the dynamic coexistence of regionalized growth and localized decline, by “slash and burn” logics of political-economic colonization and abandonment, by unequal interactions and asymmetrical power relations between cores and peripheries, and by qualitatively variegated forms of dis/connection to the matrix of transnational economic development. Specific patterns and forms of uneven regional development are always historically and conjuncturally contingent, but the production of uneven regional development itself, as a generalized condition, is a recurring and indeed systematic phenomenon. Political economists recognize this to be a defining (necessary) feature of capitalist development. Orthodox economists, while they use neither the term nor the concept, have found it increasingly necessary to accommodate the fact of uneven spatial development (albeit in the more depoliticized terms of agglomeration economies and path dependence).

It was Leon Trotsky who first invoked the notion of uneven development, which was central to his understanding of “permanent revolution.” Trotsky rejected simplified stage models of capitalism (and socialism) for their “pedantic schematism,” insisting instead that “[u]nevenness [is] the most general law of the historic process” (Trotsky 2008/1932, 5). This called attention to the complex (and mutually constitutive) relations between leading and lagging economies, connecting the advanced (or accelerated) political-economic development of some regions to the exploitative underdevelopment of others. Ernest Mandel (1979, 34) suggested that this “innovating idea” was later “widely assimilated,” including into more orthodox scholarship, but as Neil Smith and others have since reflected, the notion that (geographical) difference is everywhere is easily trivialized, sometimes purporting to account for practically everything while actually explaining almost nothing. The concept of uneven development, Smith (2006, 180) pointed out, had been “subject to a remarkable lack of serious analysis” in the half-century after its premature inauguration as a “law” of Marxist theory in the 1920s: for all its enigmatic allure, the idea seemed to have “passed into arcana.” Jon Elster (1986, 56), for his part, took the view that the concept belongs to that “class of Marxist notions whose suggestiveness is equaled only by their elusiveness.”

Elster had failed to take account of developments in radical geography, however, where much more was being made of this suggestive concept, especially by those who had since the late 1970s been working to “spatialize” various currents of Marxian theory. Among other things, this line of work was opening up questions of uneven development at scales other than the national. Specifically, the notion of
UNEVEN REGIONAL DEVELOPMENT

uneven urban and regional development, which was treated no more than obliquely in the founding texts, would be the focus of sustained (and productive) attention (see Harvey 2006/1982; Dunford and Perrons 1983; Massey 1995 Smith 2008/1984). This included fundamental work on spatial divisions of labor and the fast-changing geographies of industrial restructuring; on the extra-regional causes of “regional problems” like structural unemployment and long-term economic decline; on gentrification, suburbanization, and metropolitan transformation; and, in more abstract terms, on the contradictory logic of capital switching, devaluation crises, and the dialectics of fixity and motion in the accumulation process.

In economic geography, in particular, the idea that political-economic transformations, capitalist and otherwise, are necessarily and inescapably characterized by uneven spatial development would later acquire something approaching foundational status, even if this was (sometimes) observed no more than implicitly, as a condition of existence for studies of localized economic formations, processes, and practices. Here, the received view that (real-world) economies vary significantly (and sometimes systematically) across space – rather than tending toward a convergent, universal, or transhistorical form – is broadly shared, not to say axiomatic. The widespread utilization, across this field, of urban and regional (i.e., subnational) case studies and units of analysis, of network-based understandings of distantiated-yet-connected nodes and modes of development, and of now-basic concepts such as the spatial division of labor, with its implications for moving landscapes of profitability, employment patterns, social regulation, wealth, and socioeconomic calculation – all can be seen to reflect a generalized ontological presumption of uneven development, and a geographically differentiated world of distinctive “local” economies with constitutive outsides, variously positioned in relation to one another.

This loose consensus around the issue of uneven spatial development (either as an active analytical proposition or as a “background” condition for localized studies) is one that holds across most of the heterodox and eclectically pluralist field economic geography today, although it tends to occupy a more awkward (and relatively marginal) position in orthodox economic theory (as it does, for that matter, in neoliberal policymaking). In the latter, more mainstream discussions, despite considerable evidence to the contrary, there is continuing faith in the universal reach of singular economic “laws” and market forces, in equilibrating tendencies and long-term dynamic efficiencies, and in the role of global integration as a source of (upward) convergence, typically married to a commitment to remove political “obstacles” and institutional “barriers” to what should otherwise be a freely functioning market economy. Empirically, uneven regional development must be acknowledged, of course, but it is understood to reflect a transitory state, linked to inherited (or natural) endowments, which in the long run will be eroded (away) by competitive tendencies for the equalization of factor returns and convergence toward more “balanced” and efficient development. Geographically inclined economists are now exploring the economics of spatial agglomeration and “clustered” forms of (industrial) development, although they tend to do so by relaxing only some of these orthodox assumptions.

In comparison, where they are embedded in political-economic theorizing, notions of uneven regional development are more disruptive, more unsettling; they index conflict and contradiction, inconstancy and inequality, discontinuity and divergence. They also raise a host of political questions, about imperialism and colonialism, about the interconnections
between wealth creation and poverty generation, about the problems of “external control,” about exploitative or “dependent” modes of development, about the causes and consequences of localized “underdevelopment” and the (re)production of “regional problems,” about the role and responsibilities of global cities, about free-riding suburbs and bankrupt inner cities, about unsustainable environmental exploitation, about the distributional outcomes of different growth models or policy paradigms, and about sociospatial equity and global social justice. In contrast to the empty promises of competitive convergence through market exchange and lift-every-boat models of neoliberalized growth, this is anything but a smooth ride.

Unevenness in theory

Critical of Stalin’s notion of “socialism in one country,” Trotsky’s ideas about what he called “uneven and combined development” positioned trajectories of socialist revolution within the context of capitalism’s emergent world system. Contrary to the view that transitions to socialism were more likely to emerge from (political conditions in) “advanced-stage” capitalist countries, propelled by deepening economic contradictions and prompted by the limits of reformism, Trotsky argued that the volatile circumstances of so-called backward countries like Russia were potentially more conducive to revolutionary change. (He saw no common evolutionary pattern, and no universal stage model that could be applied to each and every society.) The progressive but uneven integration of the world capitalist system meant that different countries (or regions) would exhibit qualitatively distinctive trajectories of development, their political and economic prospects being shaped through mutual interdependencies and interactions of various kinds (for example, involving trade, geopolitical relations, technological diffusion, and cultural ties), both with one another and with the emergent totality of the world system, duly reflected in particularized patterns of class power and politics. Nonlinear “leaps” and orthogonal turns are consequently (always) possible, if rarely predictable.

Capitalism … prepares and, in a certain sense, realizes the universality and permanence of man’s [sic] development. By this the repetition of the forms of development by different nations is ruled out. Although compelled to follow after the advanced countries, a backward country does not take things in the same order … Savages throw away their bows and arrows for rifles all at once, without traveling the road that lay between those two weapons in the past. The European colonists in America did not begin history all over again from the beginning … The development of historically backward nations leads necessarily to a peculiar combination of different stages in the historic process. Their development as a whole acquires a planless, complex, combined character. (Trotsky 2008/1932, 4)

These conditions were held to bestow an ironic “privilege of historic backwardness” on some countries with a “slow tempo” of development, in the sense that lagging economies, those “coming along at the tail end of the European nations,” might find themselves in the vanguard of a stage-hopping leap from capitalism to communism (Trotsky 2008/1932, 5, 74). Even if some of Trotsky’s formulations sound crude today, and even if their political context may strike some as idiosyncratic or even anachronistic, they appeal to a sophisticated, dialectical understanding of uneven development as a relational phenomenon. Countries (and regions) have their own, distinctive trajectories and histories, often combining the old with the new, but these are shaped through mutual interaction and
UNEVEN REGIONAL DEVELOPMENT

long-distance connectivities with other places. And they occupy conjuncturally specific positions within (while at the same time recursively shaping) the evolving world system, understood as an emergent totality rather than a pre-formed container, or source of top-down determination.

Trotsky’s first-hand observations on the historical geographies of Russia at the turn of the twentieth century were instrumental in shaping this understanding of uneven and combined development. At the time, the country contained a few islands of relatively advanced industrialization, mostly confined to the big cities (and often linked to various forms of military production, financed by European powers). Yet these were located in a sea of feudal underdevelopment, as Russia remained a largely peasant society, its relatively weak bourgeoisie existing as an adjunct to the Czarist state. This conjuncture was characterized as an unstable “amalgam of archaic with more contemporary forms,” the combination of “backward cultures” and uneven capitalist integration prompting alternating surges and setbacks, festering political-economic tensions, and all manner of contradictory frictions, further stressed by the “whip of external necessity” (Trotsky 2008/1932, 5). Under these conditions, Trotsky reasoned that social transformation would be led not by Russia’s nascent capitalist class, by virtue of its lack of political independence from the autocratic state, but by a revolt originating in the urbanized workforce. (It was the sprawling Putilov works in St Petersburg – a complex of railway, artillery, and steel factories which employed more than 20000 workers – that duly became the epicenter of a wave of strikes, organized by the Petrograd Soviet, that were the seedbed for the Russian Revolution of 1917.)

The Petrograd Soviet retains its place in history, in the pantheon of “urban-based class struggles,” from the Paris Commune of 1871 to the wave of civil-rights, anti-capitalist and antiwar protests in 1968, and from the Prague Spring to Occupy Wall Street (Harvey 2012, 115). These highly uneven geographies of localized insurrection are hardly predictable, needless to say, but neither is their spatiality entirely random. Historically, cities have served as vital basing points for the intertwined territorial (re)organization of capital accumulation, social reproduction, and state capacities; they are also sites where the pressures of intensified growth and restructuring periodically reach boiling point. These concerns have been central to David Harvey’s long-term project of constructing an historical-geographical materialism, grounded in Marxism but at the same time amplifying and elaborating what he sees as the distinctive spatialities of capitalism – uneven development being understood to be, simultaneously, a motor of the system, an expression of some of its most dogged contradictions, and a trigger for both reformist policies and disruptive politics. If the period 1898 to 1917, and the purview of Trotsky’s initial analysis, might be regarded as “the birth of uneven development proper in the global political economy” (Smith 2006, 185), the experiences of the following century would lay to rest the notion that geographical unevenness was merely the disorderly residue of a pre-capitalist past, subject to erosion into historical irrelevance by the modernizing diffusion of market relations. As the work of David Harvey, Neil Smith, and others has demonstrated, (historically) new forms of uneven spatial development were being produced by capitalism itself, layered on top of inherited spatial inequalities, and not by accident or happenstance, but in accordance with the “moving contradictions” of profit-driven accumulation (Harvey 2014).

It was Harvey who first worked out a “capital logic” understanding of uneven development in his Limits to Capital (2006/1982). Here, he
demonstrated that, through the ceaseless ebb and flow of the accumulation process, the mass of fixed capital tends to build up over time, relative to circulating capital, piling up in places in the form of relatively fixed infrastructures, such that the conditions for profitable expansion in one phase may hamper development in the next. In a précis of his argument, Harvey (2014, 155) has explained:

Capital has periodically to break out of the constraints imposed by the world it has constructed. It is in mortal danger of becoming sclerotic. The building of a geographical landscape favourable to capital accumulation in one era becomes, in short, a fetter upon accumulation in the next. Capital therefore has to devalue much of the fixed capital in the existing geographical landscape in order to build a wholly new landscape in a different image ... Capital creates a geographical landscape that meets its needs at one point in time only to have to destroy it at a later point in time to facilitate capital's further expansion and qualitative transformation. Capital unleashes the powers of "creative destruction" upon the land.

Capitalism was birthed into a world of uneven development, in the prolonged transition from feudalism, but it would inhabit and remake this world, increasingly, in its own image. Having originally encountered a "variegated geographical environment ... encompass[ing] great diversity in the munificence of nature and in labour productivity," the forces unleashed by capitalism would "attack, erode, dissolve and transform much of the pre-capitalist economy and culture" (Harvey 2006/1982, 416). These sources of inherited (or "imported") uneven development had been earlier explored by Rosa Luxemburg, who maintained that capitalism was destined to remain contradictorily codependent on its "outside," those extra-capitalist (socioecological) worlds that precede and exceed the accumulation process, while at the same time providing a less than completely manageable source of raw materials, labor, and markets for a crisis-prone accumulation system. Increasingly, imperialism would become the primary means to annex the noncapitalist world, Luxemburg believed, the ravages of which marked out not only the "new frontiers" of production but ultimately the final frontier of capitalism (like Lenin, she saw imperialism as the highest, but also terminal, stage of capitalism). Any "leveling" effects of capitalism would, for Luxemburg, be attenuated by the fact that the accumulation system must live off and through its "noncapitalist surroundings" (Luxemburg, quoted in Smith 2006, 184).

It has been Harvey's distinctive contribution to reveal how uneven geographical development is "actively produced" by forces intrinsic to capitalism, in the sense of being integral to both the logic and the contradictions of the value form: just as the "accumulation of capital and misery go hand in hand, concentrated in space," so also the fastest-growing cities and regions are prone to rising costs, negative externalities, and restive class politics, generating (counter)tendencies for spatial dispersal (Harvey 2006/1982, 416, 418), wherein the nonrepeating cycle continues. On the basis of a searching examination of these interrelated dynamics of capital deepening (in place) and dispersal (through space), Harvey proposed his "third cut" theory of crisis formation, which recognized the systemic normality of relentless restructuring, place-specific devaluation, and localized capital flight, revealing that bust in one location and boom in another are both manifestations of the same macro dynamic.

These are drivers of creative destruction as a geographical process. Capital's insatiable need for "spatial fixes" results in a susceptibility not only to inertia but to stagnation, against which ever more violent "switching crises" seek to effect an exit from despoiled locations, where profit
uneven regional development

and productivity growth had hit their limits, opening up new fronts of accumulation. “Crises build, therefore, through uneven geographical development,” being not so much alleviated as displaced, “mov[ing] capital’s systemic failings around from place to place” (Harvey 2006/1982, 431; emphasis added; 2014, 161). Outward displacement consequently reflects, but does not suspend, inherent crises in the value form; the problems may be moved around, from region to region, resulting in temporary fixes, but the contradictions go all the way up.

If Harvey always regarded his spatialization of Marxian theory in *The Limits to Capital* as “incomplete,” he would credit his student, Neil Smith, with taking the next steps. Smith’s *Uneven Development* sought comprehensively to resuscitate the titular concept, cutting a new theoretical path between a Marxian tradition that had come to rely on underdeveloped (if not bourgeois) conceptions of space, and received approaches in “academic geography,” which acknowledged spatial differences but had a habit, at the same time, of evacuating these of meaningful historical and political content. His would be a sustained theorization of uneven geographical development, not as the fount of deterministic laws, but as a contradictory driver-cum-dynamic of the accumulation process. “Uneven development,” for Smith (2008/1984, 206), was “social inequality blazoned onto the geographical landscape,” a condition that was not simply encountered by an always-expansive capitalism, but which was systematically exploited by and reproduced through capitalist social relations. His analysis entailed, in particular, an understanding of the *scaled* nature of uneven spatial development (from the regional and the intra-local to the global and the international) as a vital dimension of capitalist development. Echoing Harvey, Smith maintained that uneven spatial development could not be reduced to a transitory stage, en route to competitive convergence, as in “flat Earth” versions of the orthodox globalization narrative, and it was also much more than a mere byproduct, or unfortunate side-effect, of capitalist growth. More than just a “container” for the otherwise-standardized operations of the capitalist accumulation process, space and scale were *themselves* seen to be continuously restructured, as arenas of political struggle, and as the means and media for accumulation dynamics themselves. Taking cues from Henri Lefebvre, Smith understood space and scale to be actively (re)produced through the dynamics and contradictions of capitalism.

Smith was writing in the early 1980s, when the perverse logics of capital accumulation, devaluation, and spatial switching were being exposed in especially vivid ways. The “Fordist” model of accumulation, based on the integration of mass production and mass consumption, which had been dominant for three decades after World War II within the “advanced capitalist” countries, had begun to unwind. This threw the gears of industrial growth into reverse, as “capital flight” to low-wage, de-unionized locations in Latin America and Asia, by way of the extension of production chains and the reorganization of multinational capital, left behind deindustrialized regions in new “rustbelts” across the US Midwest and northwestern Europe. Parallel (and inter-related) processes were also at work across the (shifting) scales of metropolitan capitalism, taking the form of suburban economic growth, racialized patterns of inner-city decline, and “frontier” struggles over gentrification as simultaneous moments of displacement and revalorization. These dynamics were taken to represent, at the same time, a manifestation of capital’s never-ending “restructuring of geographical space,” and the historical specificities of a particular moment of crisis, as one pattern was violently displaced by another. “Capitalism is always
transforming space in its own image,” Smith explained, expressing its restlessly dialectical logic in constantly evolving and contradictory forms:

The logic of uneven development derives specifically from the opposed tendencies, inherent in capital, toward the differentiation but simultaneous equalization of the levels and conditions of production. Capital is continually invested in the built environment in order to produce surplus value and expand the basis of capital itself. But equally, capital is continually withdrawn from the built environment so that it can move elsewhere and take advantage of higher profit rates. The spatial immobilization of productive capital in its material form is no more or less a necessity than the perpetual circulation of capital as value. Thus it is possible to see the uneven development of capitalism as the geographical expression of the more fundamental contradiction between use-value and exchange-value. [The resulting pattern] in the landscape is well known: development at one pole and underdevelopment at the other … at a number of spatial scales. (Smith 2008/1984, 208, 6).

In what Smith would disarmingly present as his “seesaw” theory of capitalist dynamics, the movements of profit-seeking capital were seen, simultaneously, to be producing and exploiting the shifting “profit surface,” constantly recalculating, reorganizing, and then flowing in the direction of the highest returns — a phenomenon especially evident at the urban and regional scales. Like a plague of locusts, capital would descend on a place, devour everything of value, and then move on. Meanwhile, “in the process of restoring itself after one plague the region makes itself ripe for another” (Smith 2008/1984, 202).

A parallel concern with the vagaries of profit-led accumulation and abandonment at the regional scale can be found in Doreen Massey’s influential formulation of the spatial division of labor. Here, however, the focus was less on the singular dynamics of capitalism as an integrated system, and more on the variety of restructuring strategies exhibited by different fractions of capital (or sectors, like electronics, finance, and garment manufacturing), along with the diverse array of regional conditions, “problems,” and conjunctures that are both an empirical outcome of, and a causal factor in, these ceaseless geographies. Massey’s conception of the spatial division of labor owed a debt less to Harvey than to a different strain of Marxian scholarship (after Hymer 1972), in which the evolving corporate structure of the multinational (and therefore “multilocalional”) firm found a spatial analogy in the unequal and asymmetrical relations between headquarters regions, back-office sites, and branch-plant locations. More fundamentally, Massey’s approach also spoke to a more intricately “relational” understanding of capitalist spatiality, which took the specificities of contingent variation, in identified localities and regions, as more than empirical particularities, or “noise,” around common structural tendencies. For Massey, spatial divisions of labor were “more than just new patterns, a kind of geographical re-shuffling of the same old pack of cards,” because they entailed much deeper forms of restructuring, along with “whole new sets of relations between activities in different places, new spatial patterns of social organisation, new dimensions of inequality and new relations of dominance and dependence” (Massey 1984, 8).

For Massey, regions occupy unique positions within wider divisions of labor, their political cultures and class and gender profiles reflecting (in “sedimented” form) the cumulative effects of the succession of historical roles that those places have played in different production networks, corporate hierarchies, industries, investment portfolios, and “rounds of accumulation.” Each round of accumulation (or pattern of investment in, say, heavy engineering or business services) is associated with particular, emergent geographies
UNEVEN REGIONAL DEVELOPMENT

of (profitable) production and employment. This framework allows, simultaneously, for the situated analysis of regional economies (in relation to local histories as well as interregional relations) and for a geographically sensitive understanding of sectoral change (in relation to the specificities of technological innovation, employment relations, and managerial strategies in different industries). In one inventive (re)formulation, the spatial division of labor framework is represented not as a pack but as a game of cards (Gregory 1989), where the four suits refer to different rounds of investment, while the hierarchy of (local) functions, from low-skill assembly work through professionalized research and development to managerial control, is indicated by the face value of each card. Each (local) player must work the odds as best they can, with the hands that they are dealt, the succession of hands adding up to what amount to winning or losing runs. On its face, each card is unique, though at the same time its value and role in the game reflect the (complex combination of) relations with the other cards.

Massey positioned her argument against the kind of “two-dimensional” analyses of industrial and employment change found in neoclassical economic geography (where the geography of jobs was correlated with the geography of wages or skills, for example), maintaining that “space is not a passive surface on to which the relations or production are mapped,” and calling instead for the conceptualization and interrogation of what she called the “spatial structures of production,” recognizing the inextricability of the social and the spatial, of production and politics (Massey 1984, 68). She also sought to differentiate the approach in Spatial Divisions of Labour from “mechanistic Marxist’ insensitivity” to particularity, and from styles of analysis that look at the world as if it were merely the pre-determined product of a set of laws and tendencies. Such approaches leave little scope for real conflict and struggle, still less for surprise and setback … [T]he geography of industry is an object of struggle. The world is not simply a product of capital’s requirements. (Massey 1984, 70, 6–7).

Relative to the more abstract treatments of Harvey and Smith, Massey’s involved a closer-focus analysis of shifting class, gender, and employment relations in the British economy, enabling her to draw out the particularities of uneven geographical development associated with (Keynesian) modernization in the 1960s and (neoliberal) monetarism in the 1980s. She was writing, from a position of active political engagement, during a wrenching period of accelerating deindustrialization, resulting in waves of factory closures and massive job losses, especially in the north and west of the country, and culminating in signature political events like the coalminers’ strike of 1984–1985 and the abolition of the municipal-socialist Greater London Council in 1986.

This was also a time, however, when alternate geographies of class relations and new models of economic growth were being forged, which was reflected in the over-layering of new spatial divisions of labor, favoring sectors like business and financial services, and regions like London and the southeast in particular. The “savage harvest” of what David Harvey (2006/1982, 429) had earlier portrayed as capital’s inherent contradictions was there for all to see, but neither the form nor the contradictions of what became known as “restructuring” were being worked out in singular form. This meant that there was not one but a range of localized consequences – for labor unions, for community groups, for economic-development agencies – and not one but a range of potential political openings and opportunities, as well as threats. There were
consequently both political and analytical reasons to take “localities” seriously. Anticipating a theme that Massey (1995, 326) would explore in subsequent work, this attention to the specificities of local and sectoral change was part of an effort to “think the politics of place and uneven development in a different way.”

Problematizing regions

“Region” may be one of the most unstable signifiers in human geography. Around the middle of the twentieth century, the field was practically defined by its preoccupation with regions, and the kind of ideographic descriptions typical of regional geography in which uniquely local characteristics stood for themselves, if they were not being implicitly explained by other (uniquely) local characteristics. The positivist search for “spatial laws” in the 1950s and 1960s represented a reaction against this long-established tradition, in the sway of which peopled places were reduced to spaces of rational economic calculation and cost minimization, as the field was brought closer to neoclassical economics. In human geography, the subsequent turn toward Marxism and then to a wider array of critical social theories, from the 1970s, placed “the region” in question once again, (re)politicizing the regions at the same time (see Dunford and Perrons 1983).

Even in Harvey’s early formulations, regions mostly appeared as epiphenomena of the deeper currents of uneven geographical development under capitalism, being reflected in the relative fixity of the built environment, the territorially of social infrastructures, and so forth. He was not one to deny the play of “human sentiments” in the animation and aggravation of regional (class) conflicts, but his initial concern had been with the “material basis” of these recurrent conflicts, as reflected in the “circulation process of capital itself” (Harvey 2006/1982, 419). As Ray Hudson has argued, however, it is one thing to point out that the production of “problem regions” – like his own home region of the northeast of England, with its history of coalmining, shipbuilding, heavy engineering, and steel production, all in long-term decline – is “inscribed into the inner logic of the capitalist mode of production,” but it is quite another to account for concurrent factors, such as state policy, let alone the array of embedded and acculturated sociopolitical conditions, as expressed and experienced in actual regions.

Although Harvey’s analysis shows that there will inevitably be “problem regions” … because of causal mechanisms that are an integral part of the process of uneven development, it does not and cannot reveal which regions will become “problematic.” This is a contingent matter, as the switch in the position of the North East from “core” to “periphery” in the world economy and the emergence of this aspect of uneven development as a political question exemplifies. (Hudson 1989, ii).

Hudson’s point was not simply that politics can never be reduced to, or “read off from,” the dynamics of uneven capitalist development, no matter how acutely analyzed, but also that the contradictory spatialities of the state exhibited relative autonomy too. The state is not just a manager but also a maker of uneven spatial development, or what has been called “state space” (see Brenner 2004). Even if, as a matter of methodological principle, “chaotic conceptions” like the region should not be objectified, even if the meaning and significance of regions should be emergent from (rather than presupposed by) a theorization of uneven geographical development, they are nevertheless subject to objectification by state policymakers and by other political actors. Clearly, the state was acting in, and on, “problem regions” like Hudson’s
UNEVEN REGIONAL DEVELOPMENT

northeast, the vacillating fortunes of which have been profoundly shaped by a barrage of regional policies and spatially targeted interventions.

These questions around the politics of uneven regional development, state policy, and political responsibility had earlier been posed most emphatically by Doreen Massey in her seminal article, “In What Sense a Regional Problem?” It was here that Massey first introduced the concept of the spatial division of labor, “in order to make a point,” the point being that problems of capital should not be (mis)represented as problems of particular regions, due to workforce deficiencies of some lack of entrepreneurial spirit: historically, since capital accumulation has always involved the “opening up of some areas, and the desertion of others [then] the ‘regional problem’ is not a problem produced by regions, but by the organisation of production itself” (Massey 1979, 234, 242–243). “Solving” the regional problem, then, could not be reduced to a question of spatial distribution or some technical matter of building a better policy mousetrap, in the manner of Keynesian reformism, since regionalized unemployment had deeper roots in aggregate demand deficiency, technical change and the deskilling of labor, the intensification of international competition, and the restructuring of multinational production systems.

In what sense, in other words, was this a regional problem? The commonplace tactic of blaming (problem) regions for their own plight confuses regionalized effects with endogenous causes, evading (rarely innocently) the real answer to Massey’s rhetorical question, “who pays?” Then there are the related questions of who benefits, and where? As subsequent analyses of regressive social and spatial redistribution under Thatcherite neoliberalism and its stealth program of “privatized Keynesianism” would reveal, there were arguably more compelling reasons to characterize the affluent southeast of England as “England’s problem region” (John, Musson and Tickell 2002), in the light of its ill-regulated financialization, its overheating housing, commercial, and labor markets, and its overburdened infrastructures and governance failures (Peck and Tickell 1995; Allen, Massey, and Cochrane 1998). The privileging of regions like the southeast of England was also sapping the developmental potential of the English provinces, and its so-called problem regions.

In few places are these questions of the costs and consequences of regionalized economic growth – not to say the contradictions of uneven regional development – being played out more dramatically than in contemporary China. It was Mao who said that “[n]othing in this world develops absolutely evenly” (quoted in Smith 2006, 182), a truism that few would have questioned during his time as the head of the Chinese Communist Party (1945–1976), but which has been strongly reaffirmed in the dramatic forms of uneven development that have accompanied China’s subsequent embrace of globalizing capitalism. The country’s ongoing transformation from Maoism to marketization has been associated with spiraling inequalities, expressed in both social and spatial terms, and in historically new forms of uneven geographical development – both planned and unplanned. China’s post-1980s growth model has been predicated on uneven regional development, the management, containment, and reform of which has in recent years become a political priority.

Under reformist Premier Deng Xiaoping (1982–1989), China initiated the historical process of substituting one (stage) model of development with another. The declaration that China remained in the “primary stage of socialism” foretold a gradual departure from policies deemed appropriate for “mature” socialist societies, such as the Soviet bloc. The alternative, “socialism with Chinese characteristics,” sought
to accelerate economic development through concentrated capital investment, selective liberalization, and export-led growth in Beijing’s very own favored regions, the Pearl River Delta and the southeastern seaboard, on the coat tails of which the lagging regions of the rural interior and west were supposed to catch up in accordance with the “ladder-step” (tiaodilun) doctrine of market-led modernization. The ladder-step concept is a Chinese variant of orthodox growth-pole theory, which holds that economic development is enabled through the spatial concentration, localized agglomeration, or regional clustering of key industries and activities, the benefits of which are expected to trickle down (or out and back) to less-developed regions, sometimes via secondary growth poles, over time. In the Chinese case, accelerated development along the southeastern coastal areas has been facilitated by geographically targeted, experimental reforms (including in special economic zones like Shenzhen, Shantou, and Zhuhai), which has been the source, in addition to cheaply manufactured goods for global markets, of demonstration and backwash effects for less-developed regions.

China’s (market-friendly) plan has therefore been to achieve the historic goal of “higher” and more egalitarian development by means of an intensification of uneven regional development. These means have certainly been exploited to the full, but the historic goal remains elusive:

By endorsing “socialism with Chinese characteristics” and emphasizing efficiency over equity, Deng became a major force behind the reversal in regional policy. He support[ed] the concept of “stage of development,” which legitimizes uneven regional development as a natural and inevitable outcome of the development process. Once the stigma about uneven regional development is removed, [Chinese policymakers were] then free to advocate comparative advantage, regional specialization, regional division of labor and export-led economic growth. (Fan 1997, 632).

The fact that coastal development in China has been reliant on a vast “floating population” of migrant laborers, impelled by virtue of rural underdevelopment and economic displacement to seek work in the factories of the coastal growth zone – a population mostly stripped of not only workplace rights but residency rights (which attach to home regions under the hukou or household-registration system) – underscores the point that the country’s explosive rates of economic growth since the 1990s have been achieved through uneven regional development. Looming threats not only to economic sustainability but to social and political stability are surely not unrelated to the official embrace, since the late 1990s, of compensatory efforts to bring about a reduction in regional inequities, including massive programs of urbanization and industrialization across the western interior. The often overriding imperatives of capital accumulation, however, continue to drive spatially concentrated patterns of growth in China, often compounding the advantages of the first-mover regions on the top rung of the ladder. In this geographically differentiated context, regional growth models have been proliferating under a mode of regulation that combines centralized political control with devolved institutional experimentation, models that each seek to maximize the profit-making potential of distinctive positions within evolving international divisions of labor (Zhang and Peck 2014).

In contrast to many other “transition” economies, China has never been compelled to accept the policy advice of the multilateral development agencies like the World Bank; it has not been subject to externally imposed “structural adjustment.” China has fashioned its own path toward marketization, in the context of a significant degree of state integrity. Yet ironically,
some will now invoke the country’s experience as proof of the benefits of “free market” agglomeration. Policymakers are now being urged to make the most of the growth-accelerating effects of deregulated urbanization and concentrated investment, uneven regional development being represented as a natural stage on the path to more advanced (and ultimately convergent) forms of economic development. This echoes the long-standing contention, derived from classical economics, that trade-driven specialization and spatial concentration hold the key to long-term dynamic efficiencies. These arguments have acquired newfound legitimacy in the field known as new economic geography – as practiced by the likes of Masahisa Fujita, J. Vernon Henderson, Paul Krugman, and Jeffrey Sachs. By relaxing neoclassical assumptions with respect to increasing returns and perfect information, the new economic geographers account for the persistence of uneven spatial development and entrenched core–periphery patterns by reference to scale economies, comparative advantage, natural endowments, and the cumulative effects of path-dependent growth. Uneven regional development has duly been accommodated anew within mainstream policy orthodoxies.

While somewhat less idealized than the most parsimonious strains of neoclassical theorizing, the new economic geography once again invokes an almost featureless, rational-actor world, largely devoid of social institutions, politics, and power relations. No surprise, then, that this offshoot of orthodox economics has generally been at odds with the temperamentally heterodox field of economic geography “proper” (Peck and Sheppard 2010), where a range of political-economic, cultural, institutional, and socioeconomic theories continue to hold sway, and where uneven regional development is rarely equated with a rationalist path to prosperity, or with stage models, but instead stands as a reminder of the contingent, contradictory, and ultimately always incomplete character of profit-driven accumulation. Consistent with their closer acquaintance with the granulated realities of actually existing economies, uneven regional development remains, for economic geographers, not only a recurring empirical fact but a principled theoretical axiom.

Unfree labor

Siobhán McGrath
University of Durham, UK

As of 2012, the International Labor Organization (ILO) estimated that there were 20.9 million people in some form of forced labor worldwide. Since in the early 2000s, advocacy around so-called “new slavery” has burgeoned alongside private and public anti-trafficking initiatives, contributing to renewed interest in understanding how and why unfree labor plays a role in contemporary economic dynamics. To date, the topic has not been widely studied within labor geography but some geographers are beginning to insist that it is, in fact, central to the questions that labor geography is concerned with (Strauss 2012).

With respect to contemporary labor relations, three of the terms used above—“new slavery,” forced labor, and unfree labor—are used as broad, overarching categories. These terms overlap in many respects, and empirical examples may fit the criteria for more than one category. Yet it is important to distinguish among them and their respective definitions.

Firstly, for Bales (1999), the term new slavery denotes a relationship constituted by three elements: exploitation, violence (or its threat), and loss of free will. New slavery is thus not limited to institutions such as chattel slavery. Rather, it encompasses a range of relations and is, therefore, closely aligned with concepts such as unfree and forced labor. Those in the new slavery school of thought tend to align with the work of Bales and the above definition of new slavery. While the literature on new slavery has arguably helped draw attention to the issue, it has also been faulted for describing a wide range of contemporary practices through the use of a term (slavery) normally associated with a much narrower set of historical practices.

Secondly, forced labor is mainly used as a politico-juridical term, a key reference for which is ILO Convention No. 29 (1930). The convention sets out two elements of forced labor: involuntariness (or a lack of consent) and the menace of a penalty. The ILO has interpreted initial consent as nullified, however, in instances of fraud, deception, or retention of identity documents. In 2012, the ILO published a set of indicators as guidance for interpreting the two elements in practice. (ILO publications on the topic are listed here: http://www.ilo.org/global/topics/forced-labour/lang--en/index.htm.)

Finally, the term unfree labor is generally used by those, including but not limited to Marxist scholars, seeking to understand its role within the wider economy. Unfree labor is understood to involve labor which: (i) is used by someone other than the person providing it, that is, an employer, but (ii) is obtained without allowing workers the type of “free” choice they are believed to exercise in “normal” labor markets. From a Marxist perspective, unfree labor within the context of capitalism is, therefore, doubly dispossessed: workers in unfree labor have neither access to the means of production nor the ability to personally commodify their own labor power.
UNFREE LABOR

Marxist theorization of unfree labor

Marxist scholarship theorizing unfree labor pre-dates the interest in the topic that has emerged over the past decade. Marxists interpret the “freedom” to participate in a labor market as masking the fact that workers are forced to sell their labor in the first place, having been dispossessed or “freed” of the means of (re-)production. Understood in this way, “free” labor has been central to Marxist understandings of capitalism as a class system. The fact that unfree labor, lacking even the opportunity to participate in a labor market, continues to exist under capitalism has thus been contentious. The primacy of “free” labor as the core feature of capitalism has led to numerous debates among Marxists from the 1970s onwards, hinging on the extent to which the existence of unfree labor indicates a noncapitalist mode of production.

One Marxist explanation of unfree labor in the context of capitalism lies in theories of primitive accumulation. These posit unfree labor as part of the process of dispossession that paves the way for capitalism. Another explanation is semi-feudalism, which treats unfree labor as evidence that a transition to capitalism is still underway. Both explanations have been challenged by fellow Marxists, who argue that unfree labor appears to be compatible with or even produced out of the dynamics of capitalism. While it may be possible to understand primitive accumulation as an ongoing process resulting from capitalism’s continued expansion, semi-feudalism appears to have few proponents today.

Miles’ work takes a slightly different approach. He examines how forms of unfree labor – indenture, slavery, convict labor, forced indigenous labor, domestic servitude, and labor in the apartheid system – may be articulated to a capitalist mode of production, or connected to it through economic relations. According to Miles, unfree labor may be reproduced as a means of maintaining the conditions for capitalism to function. Miles points to historical contingency, racism as a relation of production, and the state’s role in mobilizing labor within these articulations (Miles 1987). Finally, Brass’s theory of deproletarianization sees unfree labor as emerging from class struggle – in which those seeking to exploit labor impose unfreedom as a means of curtailing the development of class consciousness and resistance among workers (Brass 1999).

Critical studies of unfree labor

Some recent work on the topic cannot be placed neatly into either the Marxist framework or the “new slavery” school and has, therefore, been referred to as constituting a new school of thought: critical studies of unfree labor (McGrath and Strauss 2015). Many scholars associated with this school have questioned binary approaches to policy and analysis that place concepts such as “new slavery,” forced labor, and unfree labor in opposition to “free” labor. Such binaries are seen as, firstly, depending upon a liberal notion of contract and, secondly, treating unfreedom as an exception. According to this critique, widespread forms of exploitation, precarity, and degrading conditions of work are, therefore, portrayed as less pressing, rationalized through market ideologies in which workers are seen to have “chosen” this work. While the figure of 20.9 million workers in forced labor is shocking, for example, the vast majority of workers are, by virtue of their exclusion from this category, presumed to be “free.”

Marxian analyses of unfree labor are not equally subject to the above critiques, but the free/unfree binary may still be limiting. Social reproductive work involving unpaid labor provided by members of families and communities,
for example, is integral to the capitalist economy but not commodified. It therefore does not fit neatly into either the “free” or “unfree” categories according to the definitions used above. Rather, the extent and nature of unfreedom within these forms of labor would need to be assessed through measures other than the degree of commodification.

While some scholars therefore reject terms such as forced, unfree or “slave” labor altogether, many hold that unfree labor represents one end of a spectrum of exploitation (Lerche 2007). Building on this, a multidimensional view may allow for an assessment of different types of (un)freedom as well as different conditions of work (McGrath 2013a). Moving beyond binary approaches means that all forms of labor relations can potentially be subject to scrutiny in terms of the extent and types of (un)freedom that characterize them and how this, in turn, structures the negotiation over conditions of work. Such an approach would necessitate a challenge to two key ideas which inform much popular understanding as well as a considerable amount of academic analysis: first, the idea that chattel slavery is the ideal-type of unfree labor against which all other forms of labor are measured; and, second, that workers in forced labor, unfree labor, and new slavery are entirely lacking in agency.

“New World” slavery and unfreedom over time

In the Western imagination, chattel slavery is generally seen as not only the most egregious form of unfree labor but also as the “classic” form against which others should be measured. Chattel slavery was of course a critical institution in the development of colonialism and post-colonialism in the Americas. It can be understood as the institutionalized ownership of one person by another, in which this fictitious ownership is violently enforced and thus made real through what Patterson (1982) terms “social death.” (Other forms of slavery have existed which are not structured around property rights.) Historically, of course, chattel slavery in the Americas depended on forced migration of African peoples, and racialization was an explicit and core aspect of this system.

Seeing chattel slavery in the Americas as the ideal-type of unfree labor, though, engenders a somewhat ahistoric view which fails to recognize the variety of forms of unfreedom in labor relations. It is not uncommon for media reports on contemporary manifestations of unfreedom in labor relations to include phrases such as “slavery is back” or has “re-emerged.” Yet varieties of unfreedom can be identified before, during, and after the period of institutionalized chattel slavery in the Americas, in the “New World,” and elsewhere. In the United Kingdom and many former British colonies, for example, master and servant laws still structured labor relations in the nineteenth century, while vagrancy laws were used in many countries as a way to force people to stay in one place and work. “Free” labor as normally understood was, therefore, more the exception than the rule. And, in addition to chattel slavery, colonial regimes also imposed penal transportation, facilitated indentured labor migration, depended upon bonded labor, and imposed forced labor for economic development projects. Nor were all of these practices immediately eradicated with the inauguration of post-colonial regimes. Across the aforementioned labor relations, there were different forms and degrees of choice over who workers would work for and where, how long they would work for them, where they could go, and what relationships they could maintain “outside” of work.

This emphasis on chattel slavery also tends to be accompanied by abolitionist narratives.
UNFREE LABOR

(perpetuated through fictionalized historical portrayals, commemorations, and museum exhibits) that frequently downplay resistance and rebellions by enslaved people, instead emphasizing the actions of enlightened non-enslaved individuals who were involved in either abolitionist movements or in national governments. The abolition of slavery is, therefore, commonly portrayed as part of a march of progress. Yet in many cases when chattel slavery was legally abolished, the expansion of free labor did not immediately follow. In much of the British Empire, legal provisions for “apprenticeships” effectively prolonged enslavement after the legal date of abolition. In the United States, the convict leasing system that emerged in the South meant that former slaves were frequently imprisoned (often on groundless charges) and offered as cheap labor to local employers while dispossession also led to sharecropping arrangements for many former slaves. New or expanded systems of indentured labor emerged in many parts of the world after slavery was legally abolished, and practices of bonded labor continued. Albeit recognizing moment of sudden and dramatic change, some scholars seek to uncover historical continuities and evolutions as well, thereby countering the oversimplified notion that slavery ended and has since re-emerged (Quirk 2011; Kothari 2013).

The question of agency and debates around trafficking

Underlying many of the debates around the terms and concepts described above and about the question of binaries, spectrums, or dimensions is another issue: the question of agency (Rogaly 2008). Much of the writing on forced labor and “new slavery” treats workers as lacking agency altogether – sometimes explicitly so. This lends credence to policy responses that are apolitical and isolated from wider issues of power and regulation. These solutions are often framed in terms of “punishment, protection, and prevention” but fail to account for the rights, needs, and aspirations of workers. As a result, there is a poor record of progress in most of the world relative to the amount of resources dedicated to such efforts. Labor geography may have more to contribute here, as it is squarely focused on workers’ agency. Challenges to the idea that unfreedom equates to an absence of agency have been growing. Workers’ trajectories include various moments in which they exercise agency. Workers may initially seek work and/or migrate in an attempt to improve their social and economic circumstances, experience unfreedom, but then engage in struggles which result in improvements. These improvements may appear minor but nonetheless be significant. For example, workers may be earning incredibly low wages but may exercise agency in demanding some degree of health and safety protections.

Questions of agency and representations of “victims” as in need of rescue are particularly vexed in discussions of “sex trafficking.” Human trafficking has become a key policy concern since the early 2000s, particularly in the Global North, where it is frequently equated with contemporary “slavery” – overtly so by the US government. The ILO estimated in 2005 that (only) 20% of forced labor results from trafficking. As of 2012, they estimate that 68% of those in forced labor are working in the private economy in a range of activities not related to sexual exploitation, including construction, manufacturing, agriculture, and domestic work, with 22% in “forced sexual exploitation,” and 10% in “state-imposed” forced labor. Nonetheless, trafficking garners more attention than other forms of forced or unfree labor, and there is disproportionate attention given
to the sex industry in particular. This is both reflected in and reinforced by the emphasis the media gives to trafficking, particularly sex trafficking.

The United Nations (UN) Palermo Protocol to Prevent, Suppress and Punish Trafficking in Persons, Especially Women and Children defines trafficking as:

the recruitment, transportation, transfer, harbouring or receipt of persons, by means of the threat or use of force or other forms of coercion, of abduction, of fraud, of deception, of the abuse of power or of a position of vulnerability or of the giving or receiving of payments or benefits to achieve the consent of a person having control over another person, for the purpose of exploitation.

According to the Protocol, trafficking may result in forced labor, slavery and “practices similar to slavery.” However, it also includes an ambiguous reference to “exploitation of the prostitution of others” as well as going beyond forced labor to include the practice of organ trafficking. Trafficking is generally understood to involve movement and/or a labor market intermediary and may involve workers crossing (or being transported across) national borders. It is frequently conflated with smuggling and unauthorized labor migration. But even where the definition is used precisely, discussions around trafficking are, in most countries, inextricably linked with debates around immigration. While some see restrictions on labor migration (within the context of contemporary neoliberal capitalism) as the principal reason that migrant workers are made vulnerable to unfreedom, political responses frequently start from the premise that reducing migration will reduce trafficking, and therefore promote even greater legal restrictions on labor migration.

The over-emphasis on trafficking – especially “sex trafficking” – over other forms of forced or unfree labor also creates a perception that trafficking, and by extension forced labor, affects mainly “women and children.” The coherence of placing women and children into a single category has been challenged (Anderson and O’Connell Davidson 2002). The ILO instead disaggregates by sex and estimates that 45% (11.4 million) of those in forced labor are men and boys, and has highlighted the issue in its 2014 report on the economics of forced labor. It has been pointed out that many stereotypes of women as helpless and in need of rescue are reproduced through the trafficking discourse (and to some extent through discourses on forced and unfree labor more widely). The degree to which the image of a stereotypical “victim” can be used to gain attention and resources is reflected in recent revelations that the stories of high-profile “victims” such as Somaly Mam were largely fabricated. Further, and echoing historical concerns over “white slavery,” there have been heated debates over whether all prostitution is “forced” (Doezema 2010). The US government, for example, positions itself as a global leader in the fight against trafficking through its annual trafficking in persons report and through distributing hundreds of millions of dollars in anti-trafficking funds worldwide since 2001. It requires recipients of these funds (and HIV/AIDS prevention funds) to take a stance against prostitution. Thanks to a Supreme Court decision in 2013, the requirement no longer applies to US-based organizations but can be applied abroad.

In addition to laws, policies, and government programs, an anti-trafficking industry has been spawned in which new or existing nongovernmental organizations aim to raise awareness, prevent trafficking, and/or provide services to those who have experienced trafficking. For many scholars, activists, and advocates, the resources and attention that have been mobilized
under the guise of fighting trafficking in recent years have largely failed to prevent labor abuses or to advance migrants’ rights. In fact, many argue that more harm than good has been done. This is based on the contention that anti-immigrant policy is more easily justified where governments are able to claim they have addressed concerns about trafficking. As anti-trafficking policy in particular often prioritizes prosecution over the needs of “victims,” those identified as trafficked often receive little assistance and, in some cases, may even experience harm as a result of anti-trafficking efforts – for example, as a result of police raids on brothels.

Rather than imagining situations in which workers’ agency is entirely absent, then, it has been argued that a more useful starting point is to see unfreedom (and freedom) in labor relations as an exercise of power (McGrath and Strauss 2015). Restricting workers’ options and mobility is, in essence, exercising control over labor (whether this is aimed at increasing the rate of exploitation, ensuring labor is available when needed at a low cost, or other reasons). The mechanisms through which this power is exercised vary across time and space. Further, no one moment is decisive: whether workers are able to participate in a labor market is not the only moment at which the balance between freedom and unfreedom will be determined. The exercise of power in labor relations is not just a matter of how individuals treat each other, for these dynamics are situated within wider political economic contexts.

Mechanisms of unfreedom in contemporary labor relations

The particular forms of unfreedom that are produced and reproduced in labor relations today are constructed out of contemporary socioeconomic dynamics, not least processes of neoliberalization (LeBaron and Ayers 2013) and the fragmented and dispersed processes that characterize contemporary globalized and globalizing capital (McGrath 2013b). Exclusions from or weakening of labor regulations can create an environment in which unfreedom is more easily imposed. Labor migration resulting, in part, from economic change is generally matched with restrictions on workers’ rights to employment if they migrate across national borders. And the power dynamics created through outsourcing and subcontracting in many global production networks can result in pressure on suppliers to reduce costs or improve productivity and flexibility while also partially shielding the most profitable firms from responsibility for the results in cases where workers endure unfreedoms and degrading conditions of work. Thus, the dominant policy approach, which suggests reducing workers’ vulnerability through education and anti-poverty interventions along with government implementation of legal initiatives that target “slavery” and trafficking in isolation from the wider context of labor rights and labor regulations, is clearly inadequate.

While the aspects of neoliberalization and globalizing capital are one key part of producing and reproducing unfreedom in contemporary labor relations, the mechanisms through which this is achieved vary. Trafficking, bonded labor, and other categories seek to define particular systems of unfree labor associated, respectively, with a particular set of mechanisms by which unfreedom is imposed. Debt is a key mechanism, perhaps even the most common mechanism used today, and such debt is often clearly induced. Yet, in South Asia bonded labor is further intertwined with the caste system and caste discrimination. Processes of racialization, which mark certain bodies as suited for more difficult or dangerous conditions of work and able to sustain themselves with lower levels of compensation, play a role
in justifying unfreedom in many contexts. In the case of trafficking, debt (often induced) also tends to play a key role, but so too does migration status (in itself racialized). And it is not just undocumented or unauthorized workers who face unfreedom in labor relations. In many cases, workers’ “legal” status ties them to an individual employer in that they are not allowed to change jobs under the terms of their visas. The kafala system in the Gulf States, Jordan, and Lebanon is the prime example of this but some guest-worker schemes and domestic worker visas in the United Kingdom, the United States, and elsewhere tie workers to their employers. This highlights the role of the state and the threat of state violence in structuring relations of unfreedom. Interpersonal violence and other forms of abuse by employers or labor market intermediaries are mechanisms by which unfreedom is enforced in some cases, but contrary to some analyses they are not the hallmark of unfreedom. Restrictions on physical mobility, sometimes independent of migration status (or residency status in the case of China’s hukou system), also facilitate unfreedom. Isolation, as a feature of some remote workplaces or as an intentional strategy, can contribute to restricted mobility. Threats may be used as well, and/or identity documents may be retained. But restrictions on mobility also include arrangements in which workers are housed in employer-provided accommodation.

A number of other forms of unfree labor exist today. The penal system may be the context for unfree labor. Child soldiers are generally considered to be in unfree labor. Religious beliefs may be manipulated as a mechanism of imposing unfree labor. The restavek system in Haiti and similar systems elsewhere rely on (and manipulate) traditions in which extended family members would take in children of families who were struggling to meet their needs. The sociocultural, economic, legal, and institutional contexts therefore matter in terms of which mechanisms of unfreedom (and freedom) are available and to what extent. For this reason, different categories of unfree labor are constructed in particular moments and places, and systems of unfreedom in labor relations have changed over time. A number of scholars have described forms of “neobondage” in India today, for example, in which relations are less personalized than had previously been the case. There is, then, considerable space to further the study of unfreedom in labor relations from a perspective that is sensitive to temporality, space and place, and the relationships between movement and mobility.

UNFREE LABOR

Unionism, community

Steven Tufts
York University, Canada

The origin of the term “community unionism” dates back to the 1960s when it was used to refer to students organizing in poor city neighborhoods in the United States. It was adopted by geographers in the 1990s as a way of discussing community–union coalitions in the emergent field of labor geography (see Tattersall 2010; Tufts 1998). Amanda Tattersall (2010, 20–21) defines community unionism as: coalitions between unions and nonlabor groups; union strategies that organize workers on the basis of identity rather than place of work; and place-based organizing strategies that mobilize communities around extra-workplace issues. These strategies can range from campaigns to organize racialized domestic workers to struggles against local factory closures to larger conflicts with the state over the regulation of labor (e.g., living/minimum wage campaigns) and the withdrawal of public services (e.g., education and health-care funding).

There are debates over community unionism in terms of the concept itself and its political efficacy. First, there are conceptual issues of how to define community, whether as place, identity, or set of institutions. Such distinctions are important in determining coalition partners and common areas of concern. Second, there is the question of scale and the extent to which common concerns may be too place-specific to build broader geographical coalitions or may fail to focus on the local concerns that often inspire initial action.

Third, there is debate over the limits and power of coalitions as tensions often arise between the needs of communities and workers (e.g., local environmental groups and unions representing workers in resource extraction industries). Here, structures are required to ensure consistent reciprocity among labor and nonlabor groups (Holgate 2009). Building organizational capacities and structures to accommodate such tensions are necessary to allow the community unions to accumulate political power and maintain coalitions after issue-based campaigns have ended.

There are barriers to building effective community unions. Foremost are the unequal resources that different groups can bring to coalitions. Unions most often have greater organizational and financial resources at their immediate disposal given that they have access to revenues from membership dues. At the same time, community groups have fewer resources but may have the necessary expertise and relationships with marginalized communities that unions often lack. The challenge is to establish democratic decision-making bodies that give all members a strong voice. Tattersall (2010) has developed a framework for the categorization of community–union coalitions with “deep coalitions” being the most developed, integrated, and rarest formation.

UNIONISM, COMMUNITY

United Kingdom: Council of British Geography (COBRIG)

Founded: 1988
Location of headquarters: London
Website: www.cobrig.org.uk
Membership: 10 constituent organizations/agencies
Honorary Secretary: Peter Wood
Contact: peter.wood@ucl.ac.uk

Description and purpose

Established in 1988 to coordinate the promotion of geographical education across the United Kingdom, COBRIG links organizations in England, Scotland, Wales, and Northern Ireland where there are separate systems of education, research, and public policy. The Royal Irish Academy Committee for Geographical Sciences has had observer representation since 2012. Members promote geographical knowledge and education in the British Isles through public policy, in school teaching, and in higher education. COBRIG acts in partnership with member organizations on matters concerning the status of the discipline across the British Isles.

Current activities or projects

The council holds twice yearly meetings to review development across the British Isles in schools and university geography teaching and research, and other developments affecting the public contribution of the discipline. It facilitates communication between member organizations and supports meetings of school and higher education representatives to review developments affecting geographical education and research in the British Isles.

Brief history

The Council of British Geography coordinates the promotion of geography in the British Isles and, if necessary, can also act on matters concerning the status of the discipline in education, research, and public policy where geographers’ views need to be made known.

In recent years, COBRIG’s member organizations have developed closer cooperation in various ways. In 1995, the Royal Geographical Society and Institute of British Geographers were merged. The Royal Scottish Geographical Society and Scottish Association of Geography Teachers also work increasingly closely together. Member organizations currently represented are:

- The Royal Geographical Society (with the Institute of British Geographers)
- Royal Scottish Geographical Society
- University of Wales Council on Geography
- The Royal Irish Academy Committee for Geographical Sciences
- Geographical Association (in England and Wales)
- Scottish Association of Geography Teachers
- Welsh Joint Education Committee
- Her Majesty’s School Inspectorate in each country
- Committee of Heads of Geography in Higher Education
- British Science Association Section E (Geography)

COBRIG supports cooperation between these organizations through twice-yearly meetings to
review educational research and other developments affecting the public contribution of the discipline. Issues of regular concern include the status of geography in the school curriculum across the British Isles, the quality of school teacher training, and trends in numbers taking schools examinations and applying for university degree courses in geography.

Description and purpose

The Royal Scottish Geographical Society is an educational charity which promotes an understanding of the natural environment and human societies and how they interact making the connections between people, places, and the planet.

Established in 1884, we have a long and distinguished history of supporting geographical education, research, and exploration. We are the leading organization in Scotland providing geographical understanding on contemporary issues which shape our future.

Journals or major publication series

Scottish Geographical Journal. www.tandfonline.com/loi/rsgj20#.VmXvCfl96VM

Current activities or projects

The Society’s activities focus on the following.

Inspiring people – an annual program of illustrated public talks all around Scotland awarding prestigious medals that celebrate achievement and running a public visitor and education center.

Making Connections – contributing to scientific and policy debate.

Promoting science – encouraging geographical study and research, publishing an academic journal, awarding small grants, and running conferences.

Exciting learning – using our collection, expertise, volunteers, and networks to help support formal and informal education and working at policy and practical levels to promote geographical teaching and learning in schools.

Conserving heritage – maintaining an important historical and contemporary collection of geographical artifacts, images, maps, books, journals, papers, and other publications.

Brief history

The Royal Scottish Geographical Society (RSGS) was founded in 1884 and is based in Perth. The society has a membership of 2500 and aims to advance the understanding of geography worldwide by supporting education, research, expeditions, through its journal (Scottish
UNITED KINGDOM: ROYAL SCOTTISH GEOGRAPHICAL SOCIETY (RSGS)

Geographical Journal) and its newsletter (The Geographer).

Originally based in Edinburgh, the society moved to offices in Glasgow before relocating to Perth in 2009 where the society rejuvenated the city’s oldest building The Fair Maid’s House. This is now a public visitor and education center.

United Kingdom: Royal Geographical Society (with the Institute of British Geographers) (RGS-IBG)

Founded: 1830
Location of headquarters: London
Website: www.rgs.org
Membership: 16,500 (as of 2014)
Director: Rita Gardner
Contact: director@rgs.org

Description and purpose

The Royal Geographical Society (with IBG) (RGS-IBG) has one objective, the advancement of geographical science. In the twenty-first century the society does that through securing and promoting the position of the discipline in education, fieldwork, higher education and research, and raising its profile with the public and government; advancing geographical knowledge and understanding and sharing new scholarship with a wide range of audiences, including global scholars, teachers, students, policymakers, businesses, and the public; supporting the discipline’s practitioners (professional geographers and students) with training, mentoring, networks, and professional accreditation; and serving a vibrant membership.

Journals or major publication series

Current activities or projects

Annual International Conference: three-day event attracting about 2000 scholars worldwide, planned by the society’s 28 specialist research groups.
Grant giving for research and scientific expeditions: about £170,000 annually in small grants mainly to those at earlier career stages.
Professional development and online resources for school teachers: about 1.5 million downloads in 2014.
Influencing policy: at the heart of government reforms of geography school curricula and the revised framework for geography in higher education.
Inspiring next generation: 600 ambassadors talk to 30,000 pupils each year.

Brief history

The RGS-IBG, the UK’s learned society and professional body for geography, is a dynamic institution with a distinguished history and modern reputation. Founded in 1830, the RGS-IBG is the largest geographical society in Europe and one of the most active in the world.
UNITED KINGDOM

The society exists for the “advancement of geographical science.” Today it is involved in a range of activities supporting geographical research, education and outdoor learning, public engagement, and knowledge transfer to policy. The society actively advises on and represents the discipline and is governed by a council of trustees elected from its fellowship.

The society’s collections are an unrivalled repository tracing 500 years of geographical discovery and research. Included are more than one million maps and atlases, 500,000 images (photographs, sketches, art works, and films), and books and manuscripts. Recent initiatives have focused on “unlocking these archives” – enabling public access.

The society was responsible for both the incorporation of the study of geography in schools (at the turn of the twentieth century) and the first university positions in the discipline. Today, the society continues actively to influence educational debates and supports teachers and students in schools and the academic community through grants, journals, conferences, specialist research groups, and the society’s medals and awards.

Broader initiatives to promote the wider understanding of geography include a rich program of public lectures, support for fieldwork and expeditions, debates, walks, exhibitions, and the popular Geographical magazine. Society briefings, proactive media work, and events serve to place geography firmly in policy debates about the future of places, environments, and communities.

United Kingdom:
Geographical Association (GA)

Founded: 1893
Location of headquarters: Sheffield
Website: www.geography.org.uk
Membership: about 5500 (as of 2013)
Chief Executive: Alan Kinder
Contact: akinder@geography.org.uk

Description and purpose

The Geographical Association is a subject association with the charitable objective of furthering geographical knowledge and understanding through education. It is a lively community of practice with over a century of innovation behind it and an unrivalled understanding of geography teaching. The GA was founded in 1893 in Oxford, England to share ideas and learn from each other. Today, the GA’s purpose is the same. The GA’s activities are financed principally by membership subscriptions, but also by the sale of educational resources, conference and CPD event delegate fees, and externally funded curriculum development project work.

Handbooks and other publications

The following are key reference books for teachers of geography, PGCE students, and geography teacher educators.

Geography Through Enquiry (2013) Margaret Roberts.

Current activities or projects

Meeting professional and educational needs: The GA provides support and guidance for geography educators, principally in the UK but with members across 60 countries. This may be grouped under the subheadings: professional development events and networks, publication of resources, provision of geography “quality marks,” and bespoke consultancy services.

Demonstrating the value of geographical education: The GA maintains close relationships with UK central government and directly advises on curriculum matters. It engages with key stakeholders to influence public debate and policy toward geographical education. The association works in partnership with other organizations to ensure that geography’s contribution is maximized and well understood, including through educational research.

Brief history

The GA was founded in 1893 in Christ Church, Oxford, by Sir Halford Mackinder and ten
UNITED KINGDOM: GEOGRAPHICAL ASSOCIATION (GA)

others. Douglas Freshfield was the first president of the association in 1897. In 1901 *The Geographical Teacher* (renamed *Geography* in 1927) became the first GA journal. Membership was opened to non-UK geographers in 1920. In 1930 Professor Sir L. Dudley Stamp led the Land Utilisation Survey of Britain. In 1932 the first edition of *Handbook for Geography Teachers* was published. In 1975 the *Teaching Geography* journal was launched as a practical guide for teachers and in 1987 *A Case for Geography*, edited by Bailey and Binns, helped secure geography as a national curriculum subject. The GA website was launched in 1998 and in 2005 the *GA Magazine* (incorporating *GA News*) was launched. From 2006 to 2011 an Action Plan for Geography, led jointly by the GA and the RGS-IBG, was put in place to boost geography education in England and Wales. From 2013 to date, the GA forms part of the Global Learning Programmes for England and Wales to improve global understanding and development education in schools.

United States of America: American Geographical Society (AGS)

Founded: 1851
Location of headquarters: New York
Website: www.amergeog.org
Membership: 800 (as of 2014)
Executive Director: John Konarski III
Contact: gs@amergeog.org

Description and purpose

The American Geographical Society (AGS) advances and promotes geography in business, government, science, and education. Our goal is to enhance the nation’s geographic literacy so as to engender sound public policy, national security, and human wellbeing worldwide. Since 1851, AGS has been a leading advocate for geography in the United States and around the world. AGS stands for better analysis and decision-making in business and government based on better understanding of how real-world geography affects society, economics, infrastructure, and politics. AGS stands for better science and education based on explicit recognition of the spatial and temporal contexts that shape the real world and influence how it works.

Journals or major publication series

FOCUS on Geography. http://americangeo.org/focus-on-geography

Current activities or projects

A large portion of the work at AGS takes the form of research and special projects. Since its founding in 1851, original research has been a distinguishing hallmark of AGS. Every year AGS participates in research studies either as the primary organization conducting the research or as a supporting organization of research under the direction of an AGS member or an AGS affiliated organization. In addition to original research, AGS has a commitment to supporting special projects such as conferences, lectures, publications, and other projects that help AGS fulfill its mission. Currently, some examples of AGS activities include: the highly regarded worldwide Bowman Expeditions, continued development of the World Standard for Cartographic Representation, updating of the AGS Geographic Knowledge and Values Survey, continued recognition for geographical excellence through the highly prestigious AGS Medal/Awards program and Fliers and Explorers Globe signings, updating the Independent Accuracy Assessment of LandScan Global Populations Data, development of the AGS and MapStory Foundation Ambassador Network, and hosting the AGS Annual Meeting and Geographic Symposium.

*Journal of Geography*. www.ncge.org/journal-of-geography
*The Geography Teacher*. www.ncge.org/the-geography-teacher

Geography for Life: National Geography Standards. www.ncge.org/geography-for-life

Current activities or projects

NCGE facilitates communication and professional development among geography educators. The annual National Conference on Geography Education (www.ncge.org/conference) and live webinar program (www.ncge.org/webinars) strive to enhance the preparation of geography educators with respect to their knowledge of content, techniques, and learning processes. NCGE works to develop, publish, and promote learning materials and curriculum through its journals and publications (www.ncge.org/publications), while also recognizing exceptional supporters and teachers of geography with its annual awards program (www.ncge.org/awards). NCGE supports, gathers, and conducts research (www.ncge.org/research-in-progress) and works in collaboration with organizations that have similar goals.

Brief history

The National Council for Geographic Education (NCGE) was started by George J. Miller of the State Normal School in Mankato, Minnesota, to fill a gap in the field of geographic education. The idea gained support nationally and the first meeting of the organization was held on December 31, 1915.

Originally called the National Council for Geography Teachers (NCGT), the purpose was to increase the effectiveness of geography teaching in America. Miller was concerned with both the quantity and the quality of geography education. His vision was that educators at all levels
be both subject-area experts and trained in the most advanced teaching methods. In 1956, the NCGT changed its name to the National Council for Geographic Education to reflect the idea that not all education occurs in the classroom.

Description and purpose

National Geographic Society is one of the world’s largest nonprofit scientific and educational organizations. With a mission to inspire people to care about the planet, the member-supported society offers a community for members to get closer to explorers, connect with other members, and help make a difference. The society reaches more than 500 million people each month through National Geographic and other magazines, National Geographic Channel, documentaries, films, books, DVDs, radio, maps, exhibitions, live events, interactive media, and merchandize. National Geographic has funded over 10,000 scientific research, conservation and exploration projects, and supports an education program promoting geographic literacy.

Journals or major publication series

Current activities or projects

National Geographic’s grant programs have funded over 10,000 scientific research, exploration, and conservation projects around the world. The society’s Big Cats Initiative focuses on stemming the decline of big cats in the wild and protecting their habitats.

National Geographic’s Genographic Project uses DNA analysis to help answer questions about human origins and migratory history to better understand the connections and differences that make up humankind. The society’s education activities include a classroom magazine, national and international geography competitions, state geographic alliances, and professional development resources for teachers. The society’s public programs include exhibitions, speaker series, films, and special events.

Brief history

The National Geographic Society was founded in Washington, DC, on January 13, 1888, by 33 of the city’s scientific and intellectual leaders who had gathered to consider “the advisability of organizing a society for the increase and diffusion of geographic knowledge.” Lawyer and financier Gardiner Greene Hubbard was elected the society’s first president. He was succeeded in 1897 by his son-in-law, inventor Alexander Graham Bell, who was followed by four generations of the Grosvenor family. The current president is Gary E. Knell, who took office in January 2014.
In October 1888, the first issue of *National Geographic* magazine was published. The first local-language edition of the magazine was published in Japan in 1995. There are now nearly 40 local-language editions, and the magazine is read by 60 million people globally in print and digital editions.

Research, conservation, and exploration have been at the heart of the society’s work since it sponsored its first expedition in 1890 to explore and survey Alaska’s Mount St Elias. The society has funded more than 10,000 scientific projects around the world, including Robert Peary’s expedition to the North Pole in 1909, Hiram Bingham’s expeditions to Machu Picchu from 1912 to 1915, Richard Byrd’s pioneering flight over the South Pole in 1929, primate research by Dian Fossey and Jane Goodall, investigations into human origins by the Leakey family, ocean research by Jacques Cousteau, and dinosaur discoveries by Paul Sereno.

National Geographic television programming debuted with the National Geographic Special “Americans on Everest” on CBS in September 1965. In September 1997, National Geographic entered the cable television market, and National Geographic channels are now available in 440 million households in 171 countries in 48 languages.

As part of an initiative to promote geographic literacy and improve geography education in schools, the society launched a Geography Education Program in 1985. Offshoots of this are the annual National Geographic Bee and the biennial international geography competition, the National Geographic World Championship.

Today, 126 years after its founding, the society is one of the world’s largest nonprofit scientific and educational institutions, reaching more than a half billion people each month. With a mission to inspire people to care about the planet, the multimedia organization reflects the world and explores new frontiers through its magazines, television programs, films, radio, books, DVDs, maps, exhibitions, live events, interactive media, travel and education programs, and merchandise.

United States of America: North American Cartographic Information Society (NACIS)

Founded: 1980
Location of headquarters: Milwaukee, WI
Website: www.nacis.org
Membership: 528 (as of January 1, 2014)
President: Tanya Buckingham
Contact: tanya@nacis.org

Description and purpose

The North American Cartographic Information Society (NACIS) is a collegial collection of map enthusiasts. The aim of the society is to improve the quality of mapmaking and map literacy by creating opportunities for collaboration between everyone who works with cartographic materials and data. The society’s various initiatives bring together specialists from academia, private industry, government agencies, and the media so that we can all be better at what we do and have more fun doing it.

Journals or major publication series

*Cartographic Perspectives*. www.cartographicperspectives.org

Current activities or projects

The society’s annual meeting brings together cartographers, map librarians, researchers, and other map enthusiasts where members trade knowledge and form new collaborations.

To keep the conversation going beyond the conference, NACIS hosts CartoTalk (www.cartotalk.com), a cartography forum with a worldwide membership.

The society’s triannual journal, *Cartographic Perspectives*, is the only free and open-licensed cartography publication, giving contributors the opportunity to reach a broad audience. Our biennial anthology, the *Atlas of Design*, recognizes some of the world’s best recent cartographic works selected from an international competition.

MapGiving organizes cartographers for pro bono work: creating maps for nonprofits, educational materials, and free data sets.

United States of America: Open Geospatial Consortium (OGC)

Founded: 1994
Location of headquarters: Wayland, MA
Website: www.opengeospatial.org
Membership: 472 (as of March 5, 2014)
President: Mark Reichardt
Contact: mreichardt@opengeospatial.org

Description and purpose

The OGC is an international consortium of more than 470 companies, government agencies, research organizations, and universities participating in a consensus process to develop publicly available geospatial standards. OGC standards support interoperable solutions that “geo-enable” the web, wireless and location-based services, and mainstream IT. OGC standards empower technology developers to make geospatial information and services accessible and useful with any application that needs to be geospatially enabled.

Journals or major publication series

The documents published by the OGC are software interface and encoding standards, best practices, public engineering reports, discussion papers, reference models, and white papers. These are all free and available to the public at www.opengeospatial.org/standards.

Current activities or projects

The OGC convenes quarterly Technical Committee and Planning Committee meetings (www.opengeospatial.org/ogc/programs/spec) at locations that alternate between North and South America; Europe, the Middle East and Africa; and Asia Pacific. At these meetings OGC domain working groups and standards working groups discuss interoperability requirements and advances and vote on standards and related best practices.

The OGC Interoperability Program (www.opengeospatial.org/ogc/programs/ip) runs test beds, pilot projects, interoperability experiments, and concept development studies. These fast-paced initiatives enable geospatial technology users and providers to work collaboratively in an agile development environment to develop, evolve, test, demonstrate, and validate candidate geospatial standards under marketplace conditions.

Brief history

The OGC was founded in 1994 to engage geospatial companies and major user agencies in a consensus process to define interface standards that would enable easy and direct sharing of geospatial data. From the first approved OGC implementation standard in 1997 and the first OGC Interoperability Program testbed (Web Mapping Testbed) in 1999, the consortium has expanded to provide a broad array of standards and initiatives. OGC standards have been implemented in hundreds of commercial and open source geoprocessing products deployed in communities and organizations around the world.
UNITED STATES OF AMERICA: OPEN GEOSPATIAL CONSORTIUM (OGC)

the world. OGC standards are key elements in sensor webs, location services, Earth imaging networks, climate models, disaster management programs, and national spatial data infrastructures around the world. To ensure consistency across the Internet and web ecosystem, the OGC maintains alliance partnerships with many other standards development organizations and industry associations who work closely with the OGC on a wide range of topics such as indoor/outdoor location integration, sensor fusion, 3-D urban modeling, emergency communications, smart grid, location based marketing, aviation, meteorology, the Internet of things, points of interest, and the Semantic Web.

Description and purpose

The Society of Woman Geographers is a non-profit association designed to provide a medium of intellectual exchange among traveled women engaged in the study of geography and its allied arts and sciences, to further geographical work in all its branches, to spread knowledge of the world and its people, to encourage geographical research, and to provide fellowship programs that aid outstanding women graduate students in geography and its related fields.

Current activities or projects

SWG supports and recognizes women engaged in the study of geography and its associated arts and sciences through its headquarters’ resources (oral histories, library, and museum), its awards and honors program, and its fellowships for graduate students. Intellectual exchange and interaction occur through SWG’s group meetings and its Triennial conference when members make presentations about their research, work, or explorations. Selected members also carry the society’s flag on expeditions of such unusual character that successful accomplishment adds distinction to the society and makes a permanent contribution to the world’s geographical knowledge.

Brief history

Four exceptional women explorers founded SWG in 1925. Marguerite Harrison, Blair Niles, Gertrude Shelby, and Gertrude Emerson Sen created a group to bring together women who shared ambitions and interests in exploration and achievement. No women’s organization existed at the time to share experiences, exchange knowledge derived from field work, and encourage women pursuing geographical exploration and research. In naming their organization the Society of Woman Geographers, the founders intended the word “geographer” in its broadest sense.

Today some 500 members are connected in ways the founders could not have imagined. SWG has grown from a single group in New York to a total of six nationally, adding Washington DC (the headquarters), South Florida, Chicago, Southern California, and the Bay Area. Each group meets several times (between September and May) to hear from a member or guest reporting on research or unusual travel. In addition, SWG has at-large members living in 36 states and corresponding members, who reside outside of the United States, currently in 32 countries on five continents. Every three years, SWG holds an international conference, the Triennial. At this meeting SWG awards a Gold Medal and an Outstanding Achievement Award to members of particular distinction.

United States of America: The American Association of Geographers (AAG)

Founded: 1904
Location of headquarters: Washington, DC
Website: www.aag.org
Membership: 11 000 (as of December 2015)
Executive Director: Douglas Richardson
Contact: gaia@aag.org

Description and purpose

The American Association of Geographers (AAG) is a professional and scholarly association representing educators, researchers, and practitioners in geography. Founded in 1904 as a nonprofit scientific and educational society, its 11 000 members share interests in the theory, methods, and practice of geography. The AAG is governed by an elected council, which sets overall policy and appoints an executive director who manages the affairs of the association.

AAG hosts approximately 9000 attendees each year at its annual meetings, sponsors international workshops and specialty conferences, and conducts research programs on a wide range of geographical topics. The AAG also publishes some of the world’s most distinguished and influential scholarly journals, newsletters, books, and research reports. Publications include its flagship journals and the monthly AAG Newsletter.

Representing a discipline with a strong international perspective, the AAG also supports and recognizes geographers around the globe through its many professional development programs and prestigious grants and awards programs. Scientific, research and educational programs are conducted internationally and scientific exchange and interaction occurs through the AAG’s annual meetings, its leading scholarly journals, its newsletters, an extensive network of online interactive media and discussion groups, and other collaborative activities. The AAG outreach and research network consists of more than 30 000 colleagues worldwide.

Journals or major publication series

GeoHumanities. www.aag.org/cs/publications/journals/gh
The Professional Geographer. www.aag.org/cs/publications/journals/pg

Current activities or projects

The AAG’s current activities include multiple international educational programs and workshops, the creation and dissemination of professional development and careers resources, and substantial grants and awards programs.

The AAG also sponsors 70 specialty groups which promote geographic research and discussion on specific regional or topical geographic research areas. The AAG’s nine regional divisions organize annual meetings and other activities within their regions. The AAG also developed the capacity to carry out large-scale research programs and now conducts numerous funded cutting-edge research projects which help advance the discipline of geography.
UNITED STATES OF AMERICA

Brief history

In 1904, an emerging need for a society dedicated to the study of geography as a discipline encouraged William Morris Davis and other academic geographers to found the American Association of Geographers. In 1948, the AAG was amalgamated with the American Society of Professional Geographers (ASPG). From a charter membership of 48, the association has grown to more than 11,000 members, now representing geographers and related disciplinary researchers in universities, governments, international agencies, NGOs, and the private sector.

In 2016, the AAG was renamed the American Association of Geographers to reflect the increasingly international composition of its membership.

As the scientific, societal, and university context within which the discipline of geography exists has evolved, the American Association of Geographers has continued to lead, adapt, and evolve in order to sustain and strengthen geography’s intellectual and practical contributions to the needs of today’s rapidly changing world.

United States of America: The GIS Certification Institute (GISCI)

Founded: 2004
Location of headquarters: Des Plaines, IL
Website: www.gisci.org
Membership: 6000 (as of December 2015)
Executive Director: Bill Hodge
Contact: info@gisci.org

Description and purpose

The GIS Certification Institute (GISCI) is a tax-exempt, not-for-profit organization that provides the geographic information systems (GIS) community with a complete geospatial certification program. GISCI offers participants, from the first early years on the job until retirement, a positive method of developing value for professionals and employers in the GIS profession. GISCI offers an industry-wide, internationally recognized, software agnostic GIS certification available to geospatial professionals around the world.

Brief history

From 2002 to 2004, several leading organizations, including the Urban and Regional Information Association (URISA) and the American Association of Geographers (AAG), began exploring the prospect of developing a GIS certification program and both URISA and the AAG had undertaken concrete plans to do so. In 2004, at the invitation of URISA, the AAG decided to join URISA and two other geospatial organizations, the National States Geographic Information Systems Certification Institute (GISCI) and the University Consortium of Geographic Information Science (UCGIS), to form a wholly separate and independently incorporated organization, GISCI, to develop and administer a nationwide GIS certification program. The four founding member organizations of GISCI each appointed two board members to serve as the governing Board of Directors of GISCI and to build the new organization. In 2010, the Geospatial Information and Technology Association (GITA) became the fifth member organization of GISCI, and the latest organization to join is the Geographic and Land Information Society (GLIS) in 2013.

From 2004 through the present, a great deal of work have been undertaken by the GISCI founding member organizations and their board members to develop and build the GISCI as a viable organization, to develop myriad procedures and practices for certification, to collectively develop the GISCI as a credible certification entity for the GIS community, and to recruit new geographic information system professionals. During the past several years, the board members of GISCI have expended a great amount of effort, thought, and funds to develop an examination as a core part of the GISCI GISP application process. This examination-based GISP application process was implemented in 2015.

GISCI’s ongoing purpose is to maintain high standards of professionalism, competency, and integrity within the GIS profession and community and to promote ethical conduct within it.

United States of America: University Consortium for Geographic Information Science (UCGIS)

Founded: 1995  
Location of headquarters: Ithaca, NY  
Website: www.ucgis.org  
Membership: 55 (as of 2014)  
Executive Director: Diana S. Sinton  
Contact: dianasinton@ucgis.org, execdir@ucgis.org

Description and purpose

The University Consortium for Geographic Information Science (UCGIS) is a nonprofit organization that creates and supports communities of practice for geographic information science (GIScience) research, education, and policy endeavors in higher education and with allied institutions. UCGIS advances research in the field of GIScience, expands and strengthens GIScience education, advocates policies for the promotion of the ethical use of and access to geographic information and technologies, and builds scholarly communities and networks to foster multidisciplinary geographic information systems research and education. UCGIS serves as a professional hub for the academic GIScience community.

Current activities or projects

The Geographic Information Science & Technologies, Body of Knowledge project (2006) was the first comprehensive effort to inventory and document the knowledge that comprises this field. In 2014, UCGIS coordinated a community effort to revise the GIS&T BoK.

At its annual symposium, academic thought-leaders share and discuss research activities, educational initiatives, and the policy landscape. Professional networking is a key component of this gathering.

UCGIS hosts workshops on various technical, theoretical, and educational aspects of GIScience.

UCGIS webinars highlight innovative projects and share formative ideas to support the GIScience higher education community.

United States of America: Gamma Theta Upsilon (GTU)

Founded: 1928
Location of headquarters: New Orleans
Website: www.gammathetaupsilon.org
Membership: 60,000 initiated since 1928 (as of 2013)
President: Burrell Montz
Contact: www.gammathetaupsilon.org/contact.html

Description and purpose

Gamma Theta Upsilon (GTU) is the international honor society for geography. Its goals are to (i) strengthen professional interest in geography through student and professional training and academic experiences beyond the classroom and laboratory, (ii) advance the status of geography as a discipline for study and investigation, (iii) encourage high quality student research, (iv) serve as an outlet for research publication, and (v) administer financial support for furthering study and/or research in the field.

Journals or major publication series

Current activities or projects

GTU supports student research and training that advances the discipline of geography. To that end, the organization awards scholarships to undergraduates and graduate students pursuing degrees in geography. In 2013 GTU began a partnership with the American Association of Geographers (AAG) to offer conference travel awards for student members of GTU. GTU also sponsors the Visiting Geographical Scientist Program, which helps institutions bring well-known geographers to speak at colleges and universities. GTU publishes Geographical Bulletin twice annually. The Bulletin is an outlet for students as well as others in the field.

Brief history

Gamma Theta Upsilon traces its origin to the efforts of Dr Robert G. Buzzard. While a graduate student at Clark University in the mid-1920s, Dr Buzzard was influenced by the Clark University Geographical Society (CUGS). CUGS was comprised of students and graduate-level alumni of Clark University. Seeing the value of organizations like CUGS, Dr Buzzard established a geography club at Illinois State Normal University where he served as a professor of geography. On May 15, 1928, Gamma Theta Upsilon was chartered within the state of Illinois as a professional geography fraternity with 33 inaugural members.

For the next three years, GTU thrived as a local organization. At the same time proposals were developed for expanding GTU into a national organization and in the spring of 1931 charters were granted to four additional chapters with Illinois State’s chapter being known as the Alpha Chapter. Since that time, more than 200 GTU chapters have been established, and new chapters are added almost every year. In 1972, as a method to strengthen ties among chapters and among all members of Gamma Theta Upsilon, regional divisions were established that correspond generally to the regional divisions of the American Association of Geographers.

Submitted by Tom Wikle
An unmanned aerial vehicle (UAV) is a flying object without a human pilot onboard. It can be piloted either by a human operator on the ground using, for example, a radio controller (RC) manually, or by an onboard computer-controlled pilot system, the so-called autopilot, autonomously or in a semi-automatic mode. Other terminologies referring to more or less the same thing as UAV are, for example, remotely piloted aircraft (RPA), remotely piloted air system (RPAS), and drones, which were used in the early days and mostly in the military, and nowadays the widely accepted unmanned aerial system (UAS) or unmanned aircraft system (UAS), which emphasize the system components.

Typically, a UAS consists of two main components: a UAV or aerial platform and a ground control station (GCS), which communicate with each other via data links. Onboard a UAV there are, generally, a RC receiver, a data transmitter and receiver pair, different sensors — for, for example, engine temperature, rotation rate, fuel, and power supply — and an autopilot for autonomous missions. The autopilot, the “brain” of a UAV, is mainly composed of a computer, a GNSS (global navigation satellite system) receiver, and an IMU (inertial measurement unit) with some supporting sensors such as barometer and magnetometer. Based on GNSS signals, the IMU, and other sensor data the computer generates pilot commands for the aircraft. Corresponding to the onboard configuration, a GCS may consist of, for example, an RC for a human pilot, a data transmitter and receiver pair for communication, and a computer with ground control software for mission planning, real-time flight state viewing, and/or generating pilot commands.

UAVs can be classified in different ways. Based on the working principle, UAVs can be divided into two categories: fixed-wing and rotary-wing aircraft. Fixed-wing aircraft, commonly known as airplanes, are those which use wings that generate lift caused by the vehicle’s forward airspeed and the shape of the wings. An example of fixed-wing UAV is the Wing Loong.

Rotary-wing aircraft or rotorcrafts, commonly known as helicopters, are those that use lift generated by wings, also called rotor blades, that revolve around a mast. Depending on the type of rotor system, helicopters can be of, for example, main and tail rotor, coaxial rotor, tandem rotor and multirotor design. They fall into the category of vertical take-off and landing (VTOL) aircraft. Some examples of rotary UAVs are shown in Figure 1. A classification based on lighter or heavier than air and powered or unpowered can be found elsewhere (Eisenbeiss 2009).

UAVs can also be classified according to their capabilities and functionalities. For example, based on flight altitude, endurance, data link range, maximum take-off weight (MTOW), payload and size, Bento (2008) presented a comprehensive classification of UAVs. According to Bento, there are four main categories: MAV (microaerial vehicle)/mini
UNMANNED AERIAL VEHICLE (UAV)

UAVs, tactical UAVs, strategic and special task UAVs, and seven subcategories, amongst others, MALE (medium altitude and long endurance) and HALE (high altitude and long endurance). From a geodata acquisition point of view, the payload capacity of a UAV is of special interest, as the sensing system configuration onboard defines the scope of its application. Based on the payload capacity, UAVs can be classified into ultra-light (<2 kg), light (<10 kg), medium (<50 kg), and heavy (>50 kg) categories.

UAVs have a long history of use in the military. The first recorded use of UAVs dates back to as early as the mid-1800s, when Austrians sent off unmanned air balloons filled with bombs to attack Venice. The first pilotless aircraft were built during and shortly after World War I. During the course of World War II, various early types of UAVs were built and used as targets for anti-aircraft gunners training as well as attack missions, for example, drones from the “Radioplane Company” of Reginald Denny, which built nearly fifteen thousand drones for the US army during World War II. While during the Cold War period, the successes of drones as training targets and for attack missions was
extended to data collection and reconnaissance missions. The US military used drones to collect radioactivity data from nuclear tests. During the Vietnam War, the US air force launched 3435 reconnaissance drones over North Vietnam and its surrounding areas, at a cost of about 554 drones lost.

Battlefield UAVs have been developed since the 1980s. As communication technology advanced, real-time reconnaissance, including video and data, became possible. Long endurance UAVs, including solar powered, were also developed. The longest endurance was the QinetiQ Zephyr Solar Electric, which stayed in the air for 336 hours and 22 minutes from July 9–23, 2010.

In surveying and mapping, the early attempts to use UAV as platform employed balloons, kites, pigeons, and rockets around 1900. Whittlesey (1970) used a tethered balloon for archaeological documentation. One of the earliest experiments in photogrammetry using a fixed-wing UAV was carried out by Przybilla and Wester-Ebbinghaus in 1979 (Przybilla and Wester-Ebbinghaus 1979). Wester-Ebbinghaus was also the first to use a rotary-wing UAV for photogrammetric purposes in 1980 (Wester-Ebbinghaus 1980). Vozikis (1983) presented an example of using a balloon-mounted medium-format camera (a Hasselblad 500 EL/M) for photogrammetry. Marks (1989) gave another example of using a balloon for photogrammetry of historical sites. Wanzke (1984) used a hot-air ship for stereo photogrammetric documentation.

As consumer electronics advanced, radio controlled model planes and helicopters were built in such ways that they could be used as platforms to carry cameras to photograph the ground from the air. For example, Tokmakidis et al. proposed a manually controlled model helicopter carrying a Hasselblad camera to photograph the Tholos in Delphi (Tokmakidis et al. 1998) to map an archaeological excavation (Skarlatos, Theodoridou, and Glabenas 2004; Tokmakidis and Scarlatos 2002). In 2000, Zischinsky, Dorfner, and Rottensteiner (2000) used a model helicopter to take images of a historical mill in order to generate a 3-D model. The RMAX rotary-wing UAV system from Yamaha was used for various surveying tasks (Eisenbeiss 2003). The first UAV-borne LiDAR (light detection and ranging) system for 3-D mapping was carried out at Carnegie Mellon University (Thrun, Diel, and Haehnel 2003). Nagai was also among the first to use a UAV integrated with LiDAR scanner, camera, and GPS/IMU for mapping (Nagai et al. 2004).

In 2004, at the ISPRS (International Society for Photogrammetry and Remote Sensing) congress in Istanbul, Turkey, a new intercommission working group – IC WG I/V for autonomous vehicle navigation, including all aspects of navigation of spacecraft, aircraft, UAVs, land vehicles, robots, ships, and underwater vehicles – was initiated. Since then, more work has been conducted using UAVs for surveying and mapping; most of this work was presented at the 2008 Beijing congress of the ISPRS. Everaerts (2008) gave an overview of UAVs used in photogrammetry during the period 2004–2008.

In 2011, the first unmanned aerial vehicle in geomatics conference, UAV-g-2011 (http://www.geometh.ethz.ch/uav_g/index), was held in Zurich; the second unmanned aerial vehicle in geomatics conference, UAV-g-2013 (http://www.uav-g.org/), was held in Rostock, Germany in 2013. The open access journal of Remote Sensing also published a special issue “Unmanned Aerial Vehicles (UAVs) Based Remote Sensing” in 2012 (https://www.mdpi.com/journal/remotesensing/special_issues/uav).

Compared to traditional platforms, such as manned airplanes or satellites, UAVs have the following pro and cons:
UNMANNED AERIAL VEHICLE (UAV)

- safe for humans, especially in high risk situations and inaccessible locations, such as mountainous and volcanic areas, flood plains, earthquake and highly radioactive disaster sites;
- high image resolution (both temporal and spatial) due to low flying altitude;
- hover and low speed;
- easy operations, no need for special launch and recovery facilities (runways);
- low cost, high efficiency;
- small coverage;
- small payloads.

As UAVs were developed for military use from the start, military uses are still the major part of their application; these can fall into three categories: (i) target and decoy – providing ground and aerial gunnery a target that simulates an enemy aircraft or missile; (ii) reconnaissance and surveillance – providing battlefield intelligence; (iii) combat – providing attack capability for high-risk missions.

In civil or commercial applications, UAVs are used as delivery platform or platforms to carry various sensors for data collection. Sensors include, but are not limited to:

- digital cameras, from small consumer products to high-end professional digital cameras;
- video cameras;
- infrared cameras, thermal cameras;
- multispectrum sensors;
- hyperspectral sensors;
- mini synthetic aperture radar (SAR);
- LiDAR;
- vertical cavity surface emitting lasers (VCSELs).

There are many applications of UAVs. It is not the intention here to provide a complete reference list but rather examples. Geoscience is one of the major civilian applications for UAVs, as traditional data acquisition in this area is either satellite or airborne imagery. With the help of UAVs, the range of data acquisition is extended to very low altitude, thus expanding the range of airborne remote sensing from space to near ground. The low flying altitude also provides the possibility to obtain both spatial and temporal high-resolution images, which was not possible before.

UAVs are well suited as image acquisition platforms for 3-D reconstruction, DEM (digital elevation model) or DSM (digital surface model) generation and orthophoto generation. Digital camera technology and onboard GPS and IMU data have made georeferenced full motion video (FMV) in real-time or near real-time, and being viewed within a GIS, possible. This adds another layer of information to the system and is very valuable to many time-critical decision-making situations.

Environmental surveying and monitoring is another good example of UAV application. The ease of operation of UAVs can provide quick and frequent flights allowing land and water monitoring. Dense point clouds can also be used for excavation volume computation and natural resources documentation. Archaeology and cultural heritage site mapping and documentation are typical UAV tasks. 3-D documentation and mapping of sites and structures are easily achieved with a low-altitude image-based UAV survey platform. UAV-borne LiDAR systems can be used for forest inventory, forest fire detection, crop growth monitoring, and precision farming, as well as for the inspection of oil and gas pipelines and power lines.

UAVs specifically designed for cargo and logistics operation, in particular, in time-critical situations or otherwise inaccessible regions, provide extra value to the logistical business. For example, Amazon is testing drones to deliver packages to customers (http://www.foxbusiness.
In scientific research, UAVs also play an important role (Marris 2013). Scientists in various fields nowadays use UAVs as tools to collect data that were difficult or not possible to collect before. Vision-based navigation of UAVs is one of the research areas that interests many researchers. A research group at the University of Oxford, UK, uses fish-cameras mounted on drones to “find” drones themselves using visual information. There is a widespread “TED” talk video by Vijay Kumar from the University of Pennsylvania in Philadelphia that demonstrates multiple quadrotors, that is, MAVs, performing synchronized tasks (Kumar 2012).

Other civil and commercial applications include: search and rescue, traffic surveillance and domestic policing, videography and the filmmaking industry, communication relays – one of the more interesting applications of UAVs. In 2014, Google and Facebook each brought companies that make high altitude drones, Titan Aerospace and Ascenta, respectively (http://techcrunch.com/2014/03/27/facebook-drones/, http://techcrunch.com/2014/04/14/google-acquires-titan-aerospace-the-drone-company-pursued-by-facebook/). It was reported that one of the intended uses of both drones is communication-relay, for example to bring the Internet to the third world via drones.

Regulations concerning UAVs

The practices of UAVs in the civilian sector, especially in low-altitude range (below 500m), are very country specific. Due to safety and security considerations, many countries prohibit UAV flying over populated areas, for example, cities. In other places, for example, in Europe, UAV flights have to be backed up by a qualified pilot with line of sight (LOS), who can take over control of the UAV at any time if it is necessary. In Europe, UAVs with an MTOW over 150 kg have to be certificated by the EASA (European Aviation Safety Agency), while UAVs with an MTOW less than 150 kg are regulated by national authorities. For example, in the United Kingdom, the Civil Aviation Authority (CAA) issued guidance “Unmanned Aerial Vehicle Operations in UK Airspace” in 2004 (CAA 2004). Regulations are one of the biggest barriers that limit the expansion of uses for UAVs in the civilian sector. Safety is the main concern. On the other hand, the rapid development and advances of UAV technologies have made it difficult for the regulatory authorities to “catch up.”

Communities

There are a number of organizations and communities related to UAVs, including governmental, industrial, academic, and open source concerns:

- The European Association of Unmanned Vehicles Systems (EUROUVS)
- The Unmanned Aerial Vehicle Systems Association (UAVS), https://www.uavs.org/
UNMANNED AERIAL VEHICLE (UAV)

- Paparazzi: open-source autopilot hardware and software, http://wiki.paparazziuav.org
- DIY drones community, www.diydrones.com
- APM: open-source autopilot hardware and software, http://plane.ardupilot.com
- Pixhawk: open-source autopilot hardware and software, https://pixhawk.org/
- Dronecode: an open source, collaborative project that brings together existing and future open source drone projects under a nonprofit structure governed by The Linux Foundation: https://www.dronecode.org/about

References

The term unsupervised classification originated from the machine learning field, a branch of artificial intelligence, as a paired concept contrasted to supervised classification. Both techniques have the common objective of categorizing data into a number of classes or clusters. This can be formulated as

\[ F(X) = Y \]

where \( F \) is a classification algorithm (or a classifier, or a classification rule), \( X \) is data, and \( Y \) is categorical class labels that have been or will be assigned to data. A primary difference between unsupervised and supervised classification lies in use of training data in the process of obtaining \( F \). Training data

\[ S_{\text{train}} = \{(x_i, y_i)\} \]

refer to data samples whose class labels \( y_i \) are known for each data point \( x_i \) prior to the analysis. Supervised classification “trains” the classifier \( F \) by analyzing the training data and applies the trained classifier to other data samples that do not have class labels yet.

On the other hand, unsupervised classification classifies data samples without such a priori information on the data–class association. What unsupervised classification relies on instead is data information that is present in the data themselves, namely inherent properties such as similarity between data samples or density. While the forms of unsupervised classification vary in many algorithmic aspects, the underlying ideas of the algorithms are the same – determining the regions where the samples are densely populated (high similarity) by making them disconnected in the sparsely populated regions (low similarity). This explains why the terms clustering analysis and unsupervised classification can be used interchangeably.

Major unsupervised classification algorithms

Hundreds of unsupervised classification algorithms have been proposed in the literature of various scientific and engineering disciplines. Accordingly, it is difficult to categorize and review all the published algorithms. Three major frameworks that embrace unsupervised classification algorithms that are frequently used in the studies are introduced here.

Iterative algorithms

Iterative unsupervised classification algorithms seek for optimal classification of data by repeating certain procedures that are expected to improve classification results. One of the most widely used iterative algorithms is K-means clustering algorithm. The key process of the algorithm is first to assign each sample a class label of the class closest to the sample.
UNSUPERVISED CLASSIFICATION

\[ F(X) = \arg \min_{C_i} |X - X_{C_i}| \]

\[ X_{C_i} : \text{mean value of class } C_i \]

Once this assigning process is complete for every sample, the class means (centers) are then updated using the new assignment status. The class assignment and the mean computation procedures are repeated until a stopping criterion is satisfied. The overall scheme is illustrated in Figure 1.

K-means is relatively scalable (i.e., capable of processing large amounts data) and is easy to understand. However, it is sensitive to noisy data and outliers. Since the class means are required in a numeric form, categorical data cannot be processed by K-means. Classes having unbalanced sizes also cause problems since K-means tends to result in equal-size clusters.

The K-means algorithm might appear to be heuristic, but it has a mathematical foundation connected to the Gaussian mixture model (GMM) and the expectation-maximization (EM) algorithm. The EM algorithm is an iterative method for finding the maximum likelihood estimates of parameters in statistical models. Like the EM algorithm, K-means converges to local optima and has no guarantee of global convergence. To avoid convergence to local minima, a heuristic approach can, for example, be employed by repeatedly applying K-means with difference initializations (i.e., different arrangement of class means in the first iteration).

Different distance measures can be used for computing the distance between samples. While Euclidean distance is by far the most popular distance measure, diverse measures, such as spectral angular mapper (SAM) for high-dimensional data, can be employed depending on the type of applications and data.

Another popular iterative algorithm is ISO-DATA. ISODATA has a similar framework as K-means, but with an advanced feature that allows clusters to merge and split during the iteration. Clusters are split if the standard deviation

Figure 1  Illustration of K-means algorithm for \( k = 3 \).
of samples in a cluster is larger than a user-defined threshold and merge if the distance between cluster centers is less than a user-defined threshold. The advantage of ISODATA is that users do not need to assume the exact number of clusters beforehand. Disadvantages are that ISODATA can be extremely time consuming for unstructured data and may converge to local optima as in the case of K-means.

**Spectral clustering**

Unsupervised classification that is based on graph theory is referred to as spectral clustering. In spectral clustering, a data graph is first constructed by connecting data samples, that is,

\[ G = (V, E) \]

where V is vertices representing data points and E represents edges between data samples. Edges are then weighted by similarity between vertices. Classification takes place by finding an optimal partition of vertices such that the weights of edges between the clusters are minimum (maximum dissimilarity), while the weights inside the clusters are maximum (minimum dissimilarity). The solution is obtained by solving the eigenproblem of a graph Laplacian L. There are many variations in graph Laplacians, but one simple definition is

\[ L = D - W \]

where D is a matrix whose i-th diagonal entries are filled with \( d_i = \sum_j w_{ij} \) and W is the weight matrix given as \( W = \{ w_{ij} \} \).

Spectral clustering has shown good results on relatively complex data sets and has an advantage in that the implementation is easy, requiring only a standard linear algebra without the need to assume any statistical models. The disadvantages are that the computation in solving an eigenproblem may be demanding for a large data set and the classification results are sensitive to the choice of parameters.

**Hierarchical clustering**

Hierarchical clustering is an unsupervised classification algorithm that exploits a hierarchical structure. Two approaches, agglomerative (bottom up) and divisive (top down), are possible. In the agglomerative approach, each data sample forms a single cluster in the beginning and pairs of clusters merge as the level in the hierarchy goes up. The divisive approach starts from one cluster that contains all data samples and proceeds by splitting clusters successively until each data sample forms a cluster. Cluster pairs are selected for merging or splitting based on a distance measure and a linkage criterion between clusters. As in the iterative algorithms, various distance measures can be used for computing the distance between samples; Euclidean, Mahalanobis, Manhattan distances, and cosine similarity. Linkage criteria determine which pair of samples (two samples each of which is selected from each cluster) is to be used for representing the distance between the clusters. Complete linkage criterion defines the distance between clusters as the distance between samples, each of which is from each cluster, that are maximally distant compared to the other sample pairs. Single-linkage criterion uses a minimum distance and average linkage uses the mean distance.

One of the advantages of hierarchical clustering is that the number of classes does not need to be predefined before the analysis. Instead, users can decide the optimal number of classes by analyzing the hierarchy, which is usually visualized in a dendrogram. An example of a dendrogram for human genetic diversity is presented in Figure 2. This advantage comes at the cost of computational load, which stems from its greedy–manner implementation (the distances of newly merged or split clusters to other clusters need to be compared every time the merge/split occurs). Hierarchical clustering is a decisive algorithm and has the disadvantage
Applications of unsupervised classification

Applications of unsupervised classification are countless in various disciplines of social and natural science. Regardless of types of data to be analyzed, the development of typologies is probably the most popular use of unsupervised classification. A clinical study that was performed to analyze the relationship between dietary patterns and body is such an example (Newby et al. 2003). In this study, 459 healthy men and women were classified based on their dietary intake into five clusters – healthy pattern,
white-bread pattern, alcohol pattern, sweets pattern, and meat-and-potatoes pattern – and their characteristic variations in body mass and waist circumference were analyzed for individual clusters.

In the field of geography, unsupervised classification is often combined with geographical location of data to investigate the spatial patterns of the data. Since most unsupervised classification is usually designed without spatial consideration, a separate process is needed for integrating the geographic information into the framework. The easiest solution is to treat the spatial information as one of the data attributes. In that case, a careful normalization of the spatial information is required to balance with other attributes. The second approach is to use unsupervised classification schemes that have a spatial consideration from the beginning (e.g., image segmentation).

There are numerous applications of unsupervised classification to remote sensing. Unsupervised classification has been effectively used for identifying spatially congruent regions in airborne and space-borne images. Examples include land cover (e.g., vegetation, agricultural fields, forest area, mineral fields, snow cover, etc.), oceanic events (e.g., algal blooms, ocean currents, sea ice, cold pool, etc.), and atmospheric features (e.g., cloud cover, aerosol density, sand dust, typhoon trajectory, smoke plumes, etc.). The results of unsupervised classification are used not only as independent final outcomes when it has sufficient interpretability, but also can be used as a prior step of supervised classification when users have no clues on which class categorization will be meaningful for the data to be analyzed.

Urban biogeography

C.Y. Jim
University of Hong Kong, China

Urban biogeography explores the spatiotemporal intricacies of the nature-in-city realm. Half of the world’s human population now lives in cities. The built environment is apparently hostile to nature, yet it offers many overt and latent opportunities for nature to thrive. Urban greenery provides cost-effective means to improve environmental quality and improve the quality of life of 3.6 billion people. It offers a fertile research theme for scholarly and application-oriented inquiries (Jim 2011a).

Humans shifted from the primitive nomadic tenure to settlements to seek relief from nature’s vicissitudes. After acquiring security and solace in the artificial ambience, humans began to miss their natural companions. A selected cohort of plants with practical functions such as edible harvests and ornamental characters was cultivated in domestic spaces. Artificial selection of plants with naturally selected and human-favored traits provided the basis to screen species for a secluded horticultural palette. Plants growing spontaneously in incidental ruderal sites would have fueled the inspiration to drive the innate desire to emulate nature in urban spaces.

The rise of aristocracy initiated large-scale inclusion of nature in human abodes. They engendered the means and taste to create extensive private gardens of stately homes to satisfy horticultural, recreational, hunting, and status-symbol quests. Such human-modified green spaces generated rather novel conditions for selected plants to exist under human care and protection from competitors. Landscape design was developed to regiment nature and present nature on human terms. Nature is allowed to get close to humans in a tamed and filtered form.

The Industrial Revolution pulled people en masse to cities, which trapped multitudes of factory workers in abysmal living conditions. The negativity of extreme severance from nature led to the institution of public parks. They were pioneered by the first purpose-built urban park, the Princess Park in the Liverpool suburb of Toxteth, England, in 1843. Henceforth, the urban park institution has been adopted worldwide as a de rigueur infrastructural component of town planning to embellish cities and encourage salubrious outdoor recreation. Some urban parks were converted from former royal hunting grounds, whereas many were created from scratch.

Before the advent of urban parks, people and nature found ample chances in miscellaneous green sites embedded in the city. Urban parks denote a formal category in the urban green spaces (UGS) typology. They tend to be larger and receive a higher level of design and management inputs. Their creation and maintenance demand massive human inroads into key issues such as floristic membership, means of sustenance, and exclusion of unwanted organisms (weed and pest organisms). They are accompanied by a plethora of informal UGS with less human intervention, permitting nature to flourish of its own accord as habitat islands.

With reference to abiotic and biotic ecosystem components and constituent ecological linkages, processes, and functions, UGS are subsumed under a hemeroby sequence in terms of naturalness vis-à-vis human mediation: (i) remnant or
inherited natural enclaves left by default or design; (ii) incidental ruderal pockets left unallocated or unused in the course of urbanization; (iii) emulated nature which are created green areas that duplicate nature in terms of species composition and biomass structure; and (iv) artificial green sites that follow a human-dominated landscape style characterized by manicured and simplistic design. In urban ecological planning, a wide range of UGS can be preserved or created. Few natural enclaves in cities can sustain their pristine conditions and most sites carry the telltale symptoms of human modifications.

Diverse UGS furnish a broad spectrum of habitats to accommodate a correspondingly varied flora–fauna assortment. A large UGS can embrace a heterogeneous habitat mosaic. Each habitat type supports a species assemblage with some unique members in the core and edge respectively. The interface between habitat types generates transitional or ecotone habitats to attract biota somewhat different from the core. Permutations of core-cum-ecotone species assemblages present significant aggregate urban biodiversity, which can sometimes exceed the pre-urbanization state or surrounding countryside. UGS management should respect inherent ecological makeup and functions and allow nature to run its own course. Overzealous management can degrade habitat conditions for survival of species and ecological processes.

By biogeographical provenance, the urban flora is divided at the high level into native (indigenous) and exotic (alien or introduced). Natives can dwell in natural or anthropogenic sites (apophytes). Exotics can similarly exist in natural or anthropogenic sites. Some may reproduce of their own accord in the new home to become naturalized (adventives). Exotics reaching a recipient site before 1500 are archeophytes, and after, neophytes. Natives or exotics growing in human-modified seminatural sites are ruderals.

Some ruderals originated as cultivated garden plants, and subsequently spread spontaneously as garden escapees. UGS are prone to advertent and inadvertent human disturbances to induce gradual or drastic changes in species composition and ecosystem integrity. At the macroscale, frequent exchanges of people and goods via different transport modes across city boundaries provide opportunities for species introduction. Native and exotic species dwelling in the city’s countryside can move into urban areas. Exotic species can leapfrog directly into cities in jump dispersal, bypassing intermediate migration steps. Such expansion of species’ geographical range involves multiple modes of dispersal through multiple pathways over different time periods.

At the microscale, the built environment and visitor impacts can impose unnatural changes in UGS (Jim 2011b). Seed dispersal within the city could be hampered by unnatural and daunting biogeographical barriers of tall and tightly packed buildings and hostile environmental conditions lying between source and recipient habitats. Without adequate recruitment to replenish the young age bracket, some urban woodlands are suffering from a degenerating age structure dominated by old trees. Such poor regeneration dynamics are unfavorable to long-term sustainability. The heavy recreational use of natural sites may cause trampling, compaction, erosion, and vegetation damage to modify species composition. Visitor can bring seeds unintentionally on their clothing or bags. Sensitive species could be outcompeted whereas aggressive species can take over their niches. Invasion by aggressive exotics into a natural site can trigger fundamental floristic changes. Ecosystem succession could be arrested by deleterious human and natural drivers.

Nature-in-city can maximize holistic ecosystem services to more people. The benefits
are readily enjoyed by residents living in close proximity to UGS. The spatial spillover and penetrative effects of some ecosystem services could favor a larger hinterland. The main ecosystem services include (i) cooling due to latent heat absorption of evapotranspiration; (ii) cooling due to shading of solar radiation; (iii) absorption of some gaseous air pollutants in the process of gas exchanges associated with photosynthesis and respiration; (iv) dry deposition by gravitation settlement or wind impaction of particulate pollutants on leaves followed by rainfall washing into the soil; (v) absorption of carbon dioxide in photosynthesis leading to fixation in tissues and carbon sequestration; (vi) generation of fresh nascent oxygen in photosynthesis to improve air quality; (vii) infiltration of rainwater into the soil to reduce loading on urban stormwater drainage system; (viii) recharge of groundwater aquifer in the urban watershed; (ix) filtration and physicochemical cleansing of water as it passes from soil to groundwater; and (x) habitat islands and corridors as forage and breeding sites for urban wildlife to enhance urban biodiversity.

It is perhaps paradoxical that highly natural enclaves often provide excellent ecosystem services, yet they usually do not require human inputs and management. The manicured UGS that require costly inputs to create and maintain, however, furnish less ecosystem services. It is important for municipal authorities to preserve high-quality natural enclaves in new urban developments. In developing countries, the practice of obliterating nature in new development areas, and then laboriously create new UGS at high cost but with low ecosystem service value, should be replaced by keeping nature’s gifts.

The ecological or naturalistic design can be adopted to emulate nature’s multiplicity, complexity, variability, changeability, and flexibility. The species choice should follow a high degree of fidelity to the relevant local or regional ecosystem. UGS can cater to both people and nature, and contribute to nature conservation and urban and regional biodiversity. It can be exemplified by nurturing the climax of urban woodlands to achieve the most complex and self-sustaining urban ecosystems with reference to native-species content, vegetation cover, biomass structure, leaf area index, and species richness. They demand notably less capital cost and recurrent management inputs than formal UGS, but provide biodiversity hotspots with significant ecosystem services.

In location terms, UGS are found in the urban core, urban fringe, suburb, and countryside envelope. Besides the ground level, greenery is increasingly enlisting the neglected potential of the vertical dimension. The huge total surfaces of buildings are amenable to vegetation cover. With innovative design and materials, green roofs can be installed on rooftops, terraces, and podiums and green walls can decorate low to high floors. The skyrise gardens can adopt different plant growth forms, from turfgrass to herb, shrub, and tree, representing various biomass structure and ecosystem services. Sky woodland can establish on roofs with proper design of soil and drainage and sufficient roof-slab loadbearing capacity. Three-dimensional greening is important for compact cities which lack ground-level UGS space. UGS patronage is notably influenced by accessibility. Most people prefer to walk less than 10 min or less than 400 m to reach a venue. UGS in core areas with high population density can serve more people living in the hinterland. However, core areas usually do not have sufficient land for liberal UGS provision. Green roofs are highly accessible to residents and workers of the building and surroundings.

The geometry (size and shape) of UGS can be optimized based on landscape ecology principles. UGS denote patches occluded in the built-up urban matrix. Individual sites should preferably
be linked by habitat *corridors* or *greenways* to enhance their connectivity. Moreover, they could be linked to natural ecosystems in the city’s surrounding countryside. The equilibrium theory of island biogeography (MacArthur and Wilson 1967) stipulates that well-connected UGS can support more species and are more resistant to species’ decline or extinction. The habitat continuity permits propagules, animals, and their genes to literally flow and exchange among daughter urban and parent extra-urban ecosystems. The spatially connected natural patches and corridors can create a *green network* to permeate the urban matrix, taking ecosystem services to people’s doorsteps. Such a configuration can reduce the distance between residents and UGS, rendering them more accessible and more used. Small gaps between patches could be crossed by wildlife, using a series of sites as *stepping stones* to penetrate the city. Urban development pressure, however, can shrink and dismember UGS to induce undesirable habitat isolation and fragmentation, which can trigger biotic pauperization.

Studies of UGS benefits have extended from environmental-ecological to socioeconomic. UGS should adopt a socially inclusive design to attract users from different strata of society. They can contribute to social interaction, social cohesion, social integration, and social harmony. By encouraging outdoor activities they foster a healthy life style to nurture happy, healthy, successful, and productive citizens. The economic benefits include increasing property value to raise government tax revenues which could be plowed back to develop the community. People are willing to pay more to acquire residential properties to fulfill a hedonic wish of proximity to UGS and pleasant green views. UGS are increasingly factored into green infrastructure development of cities, expected to ameliorate the urban heat island effect, and contribute to climate adaptation and climate resilience of cities.

What is urban climate?

Human settlement, through the development of towns and cities, affects both the properties of the surface and that of the atmosphere above them. Urban regions therefore develop distinct urban climates in which the mean characteristics of the atmosphere within, above, and downwind of cities are modified by the city. These modifications act upon the regional and large-scale climate of a location that is determined by the latitude, elevation, and continental interior or coastal location and further modulated by the specific topographic setting of the city (e.g., valley bottom, lake shore). Urban climates represent an unintentional modification of climate. Understanding these changes is important because they provide a basis for minimizing negative effects of cities on their local climate and maximizing positive aspects that can improve the environmental quality and sustainability of the urban environment.

The urban surface

Much of the urban climate influence arises because of changes to surface characteristics in cities. The surface is important because it is the site at which energy, mass, and momentum are exchanged with the atmosphere. Compared to natural areas, cities alter the structure, cover, and fabric of the surface. Urban surface structure is determined by the arrangement and spacing of structural elements such as buildings and trees (Figure 1; Table 1) and is distinctly three-dimensional. The cover represents the main fractional components of vegetation, built-up, paved, bare soil, and water areas. The climatic properties of the fabric include radiative, thermal, roughness, and moisture properties. The cover and properties vary across the city and can be categorized into local climate zones (Figure 1; Table 2). Cities also incorporate a metabolism associated with city functions. Important metabolism processes include emissions of heat, water vapor, and pollutants that come from energy and water use and industrial processes.

The urban atmosphere

The bottom portion of the troposphere in contact with, and directly influenced by, the Earth’s surface is known as the atmospheric or planetary boundary layer (PBL). The PBL height varies with time and location; it is highest by day (1–3 km) under fair weather when convective turbulence from the surface is strongest. It is lower as winds and cloud cover increase (Figure 1a). At night, as convective mixing from the surface subsides, a shallow stable layer of air develops upwards from the surface that may be several hundreds of meters in height above which is an overlying residual layer that is effectively decoupled from the surface.

Over large cities, the PBL is influenced throughout its depth by the underlying urban surface and is referred to as the urban boundary
layer (UBL). The UBL is typically slightly higher than rural PBL by both day and night and exhibits modified characteristics (temperature, humidity, winds, pollution). The UBL is advected downwind by the regional wind as a plume of modified air (Figure 1a). This extends the influence of urban climate to larger scales.

The bottom 10% of the UBL is known as the surface layer. Here, the urban surface plays an

important role in the climate. From the ground up to a height of about twice the average height of the main surface elements (buildings, trees) is the roughness sublayer (RSL, Figure 1a). In this layer, the wind patterns, receipt of sunlight, temperature, pollutant concentrations, and so on, show microscale variations due to the nearby buildings and trees. The urban canopy layer (UCL), where most of the population lives and where most urban activities takes place, lies within the RSL and is defined by the mean height of the surface elements (Figures 1b, 1c). Above the RSL lies the inertial sublayer (ISL). Here, mixing of the atmosphere is sufficient to blend the microscale variability of the RSL below so that its characteristics are representative of the underlying urban surface. Within the ISL we can make representative neighborhood-scale measurements of the urban climate.

Physical basis of urban climates: energy balance

Energy balance

The physical basis for urban climates is the energy and mass exchanges between the surface and the atmosphere. The energy balance of a surface is a conservation of energy equation. It represents the radiative, convective, and conductive exchanges between the surface, atmosphere, and substrate. For urban surfaces, because of their three-dimensional structure, we consider the energy balance of a volume (Figure 2) written as (neglecting advection):

\[ Q^* + Q_E = Q_H + Q_E + \Delta Q_S \]

\( Q^* \) (units, W m\(^{-2}\)) represents the energy supplied to the urban system from the net absorption of radiation from the sun and atmosphere. It is positive by day (net energy gain) and negative at night (net energy loss). \( Q_E \) is the anthropogenic heat flux from human energy use. Energy transfers between the surface and atmosphere occur as sensible (\( Q_H \)) and latent (\( Q_E \)) heat through turbulent convective mixing of air, and as the change in heat stored via conduction in the urban materials (\( \Delta Q_S \)). Terms are defined as positive when the flux is away from the surface (into the atmosphere for \( Q_H \) and \( Q_E \) and into the substrate for \( \Delta Q_S \)) and negative when toward the surface.

The energy balance is driven largely by the net radiation (\( Q^* \)). The radiation budget of a surface

\[ Q^* = K \downarrow - K \uparrow + L \downarrow - L \uparrow \]

is composed of inputs of shortwave radiative energy received from the sun ($K \downarrow$) with wavelengths of energy < 3 μm and longwave radiation from the atmosphere ($L \downarrow$). The upwelling radiation energy consists of reflected shortwave radiation ($K \uparrow$) and emitted and reflected longwave radiation ($L \uparrow$). The temperature of the surface largely determines $L \uparrow$; surfaces have temperatures that only permit them to emit longwave, not shortwave radiative energy.

All the radiation budget components, $Q_H$, and $Q_E$ terms may be directly measured from instruments mounted on tall towers in the ISL, while $Q_F$ is estimated from inventories, models,
or derived as a residual. The storage heat flux term is most often determined as a residual while \( \Delta Q_A \) is assumed to be zero over a homogeneous urban land-use area. Urban climates can also be studied using numerical models that use equations to represent the surface–atmospheric exchange processes. Such models are important to urban-scale weather forecasting and as a planning tool for helping design more sustainable cities.

**How does urbanization affect the energy balance?**

Figure 3 illustrates the energy balance for three sites along an urban–rural gradient in Basel Switzerland. Relative to most natural surfaces, urbanization leads to an increase in \( Q_H \) and \( \Delta Q_S \), and a decrease in \( Q_E \). The increase of \( Q_H \) is associated with the increase of impervious surfaces in urban areas and the fact they tend to be warmer and drier than the vegetated surfaces they replace. Greater turbulence over cities due to the interaction of winds with the rough urban surface also helps to enhance the sensible heat flux. The ratio of observed \( Q_H/Q_E \) (Figure 4) increases substantially as vegetated cover is reduced (and impervious surface cover increases) for sites of varying intensities of urbanization. Exceptions are cities in very dry climates where significant irrigation and planting may decrease the ratio. The three-dimensional surface structure of cities, which enhances absorption of radiation, and thermal properties of built materials enhance the uptake of heat by conduction and increases \( \Delta Q_S \) by day. This provides a store of heat, which is then released at night acting as source of heat for the urban area.

Changes to \( Q^* \) are often small because changes to the individual incoming and outgoing terms tend to offset (Table 3). Polluted atmospheres reduce \( K \downarrow \) at the surface. Absorption of sunlight along with warming from below increases the temperature in the UBL and increases \( L \uparrow \). Urban surfaces typically absorb more \( K \downarrow \), in part due to the 3-D surface structure that acts to trap the sunlight more effectively and in part due to changes in the reflectivity of urban materials. This reduces \( K \uparrow \). Warmer urban surfaces increase \( L \uparrow \).

The anthropogenic heat flux adds a contribution that is not present for natural surfaces. It comes from the use of energy for space heating and cooling, traffic, and electricity use (Figure 2). Its magnitude varies with the intensity of urban development and is sensitive to the large scale climate and seasonal variations. In the mid-latitudes, \( Q_F \) is larger in winter and smaller in summer (Table 2). \( Q_F \) is also relatively more important in winter because \( Q^* \) is then smaller. On a daily basis, \( Q_F \) is regulated by the cycles of human activity.

**Urban modifications to climate**

Changes to the surface radiation budget and energy balance in urban areas lead to modification of all the atmospheric characteristics that define weather and climate (Table 3).
Temperature

Urban areas are generally warmer than their non-urbanized surroundings. This so-called urban heat island (UHI) effect has been studied for well over a century. The relative warming extends upwards from the surface to the top of the UBL and downwards into the subsurface. The most studied urban heat island is that in the canopy layer air (UHI\textsubscript{UCL}) which is most easily accessed for measurement and represents the air volume in which the bulk of urban activities occur. Satellite-based sensors can provide an urban-scale depiction of the temperatures of the surfaces they view that is referred to as the surface heat island (UHI\textsubscript{SFC}).

The UHI\textsubscript{SFC} forms because the temperatures of most built materials are warmer than those of the natural surfaces they replace. The energy balance of the built infrastructure directs more energy into sensible rather than latent heat and leads to higher temperatures by both day and night.

In the canopy layer, the UHI\textsubscript{UCL} is best expressed under calm and clear weather conditions when differences between urban and rural energy balances that drive the heat island are largest (Figure 5). Under such conditions, rural areas cool quickly in the late afternoon and following sunset as heat conducted from the ground is lost by radiative cooling to the sky. In
urban areas, the rate of cooling in the UCL is slowed because the view of the sky for surfaces is obstructed, buildings provide a sheltering effect and there is a large store of sensible heat released slowly from the built materials (Table 4). This generates a nocturnal UHI\textsubscript{UCL} that grows

Humidity

Spatial patterns of humidity in urban areas are complex owing to the patchiness of urban vegetation, variability in irrigation practices, and large point sources of anthropogenic vapor emissions from industrial or power generation facilities. At night in the UCL, cities are often characterized by an absolute increase in moisture content. Urban relative humidity on the other hand may decrease because the increase in the saturation vapor pressure with temperature exceeds the increase of the actual moisture content. By day, the humidity influence is seasonally dependent in temperate climate cities – urban areas tend to be somewhat less humid than their surroundings in the summer, but more humid in winter. The summer daytime decrease is related to the loss of vegetated surfaces in cities and the reduced evaporation combined with greater mixing; the patchiness of vegetation influences the spatial patterns of humidity along with the extent to which irrigation is used. At night, rural cooling under conditions that favor UHI formation leads to dewfall that depletes the moisture content of the near surface atmosphere. In cities, the warmer urban atmosphere reduces dewfall and
can support some nighttime evaporation. Combustion processes and heat exchangers also add humidity via the latent heat component of the anthropogenic heat flux. In winter, cities are commonly more moist by day as well as at night. In high latitude cold climate cities, the addition of anthropogenic moisture can lead to ice fogs that seriously impact visibility.

The UBL is similar to the UCL in its humidity characteristics. The geographical setting of a city – whether it is near a coast or embedded within a desert – can affect the urban–rural humidity differences. Cities in climate regions outside the temperate zone tend to show similar patterns with the exception of cities in desert climates that may be more moist both day and night as urban sources of moisture contribute to higher humidity.

Wind

Urban areas affect winds at scales that range from the patterns of flow around an individual building up to regional-scale impacts on wind speed, direction, and turbulence within the UBL above and downwind of a city. Urban modified winds are of particular importance to understanding dispersion and transport of pollutants in urban areas. In general, the urban surface is “rougher” compared to its surroundings. This influences the speed, direction, and turbulent energy of the wind at all heights within the urban atmosphere. Air flow in and over cities is also impacted by spatial patterns of temperatures (i.e., the UHI), which induce pressure differences and can create thermally forced winds.

Within the UCL, wind flow is affected by the spacing and dimensions of buildings. Buildings force air flow to divert around and over them and create a downwind “wake” that includes a reverse circulation vortex in the immediate lee of the building (Figure 6a(i)). As the building spacing decreases, the wakes of individual buildings begin to interact and the surface is said to be “rougher” so that it slows the average wind more. As spacing decreases further, wakes merge and eventually the flow becomes almost decoupled from that above the buildings. Very tall buildings can bring higher

Figure 6  Urban flow regimes (a) associated with increasing density of development and the profile of mean wind speed $\bar{u}$ above an urban area (b) showing the extrapolation (dashed line) to the roughness length ($z_0$). The profile is displaced upwards to a height $z_d$ because of the tall roughness elements. Source: modified after Oke (1987).
velocity air downwards to street level with implications for pedestrian safety.

When the buildings are closely spaced and form a relatively narrow canyon a distinct vortex flow forms within the canyon when the wind is at right angles to the street orientation (e.g., Figure 6a(iii)). When the relative orientation of the wind shifts to intermediate angles, a corkscrew-type flow pattern results within the canyon and for winds approximately parallel to the canyon, the flow will be channeled along the street. In particularly narrow street canyons multiple-stacked vortices may be present. The structure and configuration of the vortices can be affected by temperatures of the canyon surfaces as warmer buoyant air tries to rise along heated walls. At night, cold dense air can form on roof tops and drain into canyons leading to mixing that helps to flush air from the canyon. Vehicle traffic within the UCL can also generate turbulence. Flows of denser cooler air out of urban parks and forested areas into surrounding neighborhoods can also occur.

Above the UCL, within the ISL the wind speed shows a characteristic logarithmic profile that is displaced upwards at a distance \( z_d \) by the urban canopy. The roughness length \( z_0 \) is a measure of the overall aerodynamic roughness of the urban surface within a neighborhood. It varies (see Table 2) with the height and spacing of the buildings and the presence of other surface elements such as trees.

Within the UBL, the air flow is more turbulent and slower relative to the rural PBL when regional winds are strong. The slowing air above the rougher city induces convergence of air which leads to uplift and contributes to the doming of the UBL top (Figure 1). The additional friction over a large city produces a turning effect so that winds turn cyclonically within the UBL. This can create additional zones of uplift (sinking) associated with air that convergences (diverges) horizontally. Temperature differences associated with the UHI can drive a thermally induced circulation when regional winds are calm or very light. Air will flow from cooler rural areas into the city, rise, and then return to the rural area aloft and sinks. The strength of this circulation is dependent on the temperature differences and stability; more unstable conditions facilitate the vertical motions associated with the circulation.

**Clouds and precipitation**

Cities have long been suspected of modifying the cloud and precipitation over and downwind of them because they are known to affect upward motion, the presence and properties of aerosols that act as precipitation nuclei, and because individual large sources of water vapor, heat, and pollutant emissions (e.g., power plants and industrial sources) have been associated with cloud formation. However, much of the cloud and precipitation experienced by a city is determined by larger-scale synoptic processes and observing networks are often too sparse for assessing patterns at the urban scale. Thus urban effects on cloud and precipitation are often subtle and difficult to detect.

In the mid-latitudes, there is good evidence that large cities show some increase in cloud cover and precipitation during summer season convective weather events when clouds are more strongly coupled to surface and boundary layer processes. The increase in convective clouds is coupled with an increased incidence in thunderstorms and hail over and downwind of cities, especially when regional winds are light. These weather events, in combination with the modified urban water budget that increases runoff due to impervious surface cover, can be important to the incidence of flooding events in cities. Lightning detection networks, radar, and satellite-
based observations have all contributed to the identification of spatio-temporal patterns of urban precipitation effects (e.g., Shepherd 2013).

The physical basis for the increased frequency of summertime convective precipitation involves multiple factors but a key element is enhanced uplift over and downwind of cities associated with convergence of UBL winds driven by the urban heat island. Surface roughness influences may also play a role; tracking of individual storms cells suggests some cells may divert or split to move around cities and remerge on the downwind side affecting the location and intensity of precipitation patterns. The addition of urban aerosols may also affect the precipitation process. In some circumstances, cloud growth may be invigorated, updrafts are stronger, cloud electrification is enhanced, and precipitation is increased downwind.

In the winter season, cold climate cities can experience a reduction in the frequency of freezing rain and snow events because of urban warming in the boundary layer converting the phase and potentially the amount of precipitation received (through sublimation and evaporation of precipitation in the warmer UBL). Under very cold and humid conditions, individual point sources of water vapor and aerosols can lead to clouds and possibly even snowfall (Koenig 1981) or to enhance naturally existing clouds and their precipitation.

In all climates, the geographical setting of the city influences the spatial patterns of precipitation and must be considered because topography may influence patterns of precipitation. The setting also determines the background aerosol characteristics, the level of which affects the impacts of urban additions of aerosols.

Air pollution

The urban atmosphere is generally more polluted. Urban air pollutants include those directly emitted into the atmosphere (primary pollutants), usually as gases or particulates, and those that form from reactions in the atmosphere (secondary pollutants), such as ground-level ozone that forms in photochemical smog. Air pollution spans a wide range of scales. Indoor air pollutants come from combustion processes, cooking, smoking, and emissions from the ground and building materials. Their concentrations are controlled by the strength of the emission, removal rate, and the ventilation of the interior space. In the UCL, traffic is an important source of emissions, along with emissions from buildings, and strong spatial variations in pollutants are noted, especially with respect to distance from roadways. Leakage from pipes and storage sites also contribute as may accidental or intentional releases of hazardous materials. In the UBL pollutants are mixed upward from below, injected from tall stacks, and can form in situ from secondary reactions. Biogenic emissions of volatile organic carbons come from urban vegetation. Long-lived pollutants and those that form from secondary reactions extend urban climate changes to larger scales because some pollutants are transported or form well beyond the city. Of particular note is the enrichment of urban atmospheres with CO₂. The use of energy in cities drives large emissions of CO₂ from combustion that typically exceeds the uptake by photosynthesis in urban vegetation. The resulting increased concentration of CO₂ in the urban atmosphere is not sufficient to provide significant local warming but the long residence time of this pollutant means that cities are providing important contributions to the global increase in atmospheric CO₂ concentrations.

Air pollution is important to the health of urban residents and also modifies other aspects of urban climate. Air pollutants, especially particulate matter, reduce the incident solar radiation, increase the fraction of scattered
diffuse) radiation, and reduce the ultraviolet wavelengths. The absorption of shortwave and absorption and emission of longwave radiation by pollutants alter the temperature profile of the boundary layer and affects stability of the atmosphere. The addition of particulate matter acts as nuclei for droplet formation and affects visibility, cloud, and precipitation formation and can alter cloud electrification processes.

**Urban climate and global climate change**

Cities both affect and are affected by global climate change. Cities occupy only 2% of the global land surface yet have impacts that extend to the global scale. This is because urban activities are responsible for a large fraction of the greenhouse gas (GHG) emissions that drive global anthropogenic climate change. The warmth of the UHI, however, does not significantly affect global climate. Increased temperatures from global climate change, superimposed with the UHI, will increase the risk of hazardous thermal conditions in summer heat wave situations and may also impact air pollution concentrations. The increased likelihood of intense rainfall events with global climate change will differentially impact cities, since they significantly increase the amount of impervious surfaces that lead to large volumes of runoff, and we must also consider urban enhancements of precipitation from large cities.

Cities will be required to adapt to climate change. Changes to city location, layout, neighborhood design, and individual building technology may all contribute. For example, green and cool roof technologies can both help buildings adapt and to mitigate GHG emissions associated with building energy demand. The design of neighborhoods and cities, including their density and configuration, can use urban climate knowledge to provide solutions that minimize the impacts of climate change on the city and reduce the demand for energy that drives GHG emissions. Understanding urban climates is therefore a growing need as the majority of the world’s population now resides in urban areas.

Urban ecology

Ian Douglas
University of Manchester, UK

The intellectual and social context

Urban ecology is the study of urban areas as a series of habitats for human beings and other organisms; the relationships between all these organisms under changing urban environmental conditions; and the interactions of living things with natural and human-made flows of energy, water, and materials, both deliberate and accidental, in the varied and diverse conditions of the world’s towns and cities. It integrates both theoretical and applied aspects of the natural and social sciences in analyzing, understanding, and managing the diverse ecological conditions encountered in urban areas.

Urban ecology is firmly rooted in ecology, the science studying the processes influencing the distribution and abundance of organisms, the interactions between organisms, and the interactions between organisms and the transformation and flux of energy, matter, and information. It embraces all the sociopolitical, cultural, and economic factors that affect ecological processes in urban areas, paying particular attention to the way those factors continually modify the abundance and diversity of organisms found in particular urban places. Urban ecology also examines specific ecological situations within towns and cities, as well as how urban demands for food, water, energy, and materials and disposal of wastes affect other ecosystems at all scales from entire oceans to individual organisms.

People from many academic and technical backgrounds have written about nature in cities, urban ecosystems, the flora and fauna of towns, the species colonizing newly vacant urban land, and the human benefits from contact with wildlife in built-up areas. Broadly, four general themes emerge from these diverse points of view:

- The ecology of health in urban areas: towns and cities as habitats for humans and disease vectors, including the role of urban nature in human wellbeing.
- Ecology in towns and cities: urban areas as habitats for wildlife, plants, and other organisms, from coyotes in Californian cities to crocodiles in Darwin, Australia, and monkeys in Malaysian towns, and including molds on food and kestrels on skyscrapers.
- The ecology of cities as a whole: the flows of energy, water, materials, and information into, within, and out of urban areas and their internal and external impacts; differentiation within urban areas; rural–urban gradients; and the analysis of complex urban socioecological systems.
- Ecology for cities: enhancing the ecosystem services provided by urban green infrastructure to help build resilience to change, including environmental change, and to increase urban sustainability and improve community cohesion.

The public health theme looks at urban areas as habitats that may improve or threaten human health and wellbeing. Good urban design can reduce the urban heat island effect that leads to...
excess deaths during extreme hot spells. Urban street trees and gardens may alleviate stress and anxiety for some people, and create fear among others. Conversely, poor housing and sanitation can support disease vectors that carry malaria and dengue fever as well as lead to the spread of cholera and viral gastroenteritis. Climate change is allowing disease vectors to extend their range, especially with large urban areas often being warmer than their surrounding countryside. Many zoonoses (diseases transmitted from animals to humans under natural conditions) come into urban areas with pets, farm animals, and imported meat. Thus analysis of ecological conditions reveals urban habitats for disease-bearing organisms, helps establish where risks to health are increasing, and heightens awareness of how social factors, such as poor housing and sanitation, lead to conditions that favor human ill-health.

Urban ecosystems continue to be a major focus for an immense range of biological work on particular urban influences on plants, animals, fungi, and other organisms. Local natural history societies developed in the mid-nineteenth century, many of them concentrating on plants and animals in and immediately around urban areas, for example the London Natural History Society. From such beginnings, ornithologists, for example, have built up great databases on changes in urban bird populations that enable their behavior and ecology in towns and cities to be analyzed in detail. Similarly many invasive plant and insect species are well documented, particularly in cities where large areas of vacant land were created by wartime bombing or industrial dereliction. Such studies often focus on particular species or types of species, but many also examine interactions with the built environment, pollutants, and human behavior. This is the classic urban ecology of Europe: the study of the interactions of various organisms with each other and with their diverse urban surroundings. Similar work is found in many other parts of the world, especially in China (Li et al. 2008) and India (Nagendra and Gopal 2011; Khera, Mehta, and Sabata 2009), and particular attention has also been given to the social aspects of urban biodiversity in developing countries (Cilliers 2010).

The view of urban areas as single systems integrated with their immediate surroundings (the city-region) sees the city-region ecosystem as a life-support system for all the organisms within the urban settlement. It provides ecosystem services such as water supplies, sources of aggregates, areas for landfill, recreation zones, watershed protection, greenhouse gas uptake, biodiversity, and some food supplies. This point of view is often discussed in terms of the ecology of cities or as urban metabolism (a somewhat criticized organic analogy).

The same urban settlement can be seen as creating demands for energy, food, water, and materials that may have widespread, even global, implications. Accessing supplies of coal, natural gas, or oil, of grain, fruits, vegetables, fish, meat, and other foods, and of manufactured goods from distant regions has a global outreach with impacts on other ecosystems, from fine particles of plastic frozen in Arctic ice to residues of agricultural chemicals and mining wastes contributing to the eutrophication of rivers, lakes, and reservoirs in distant countries. This global impact, or ecological footprint, is one expression of the widespread effects that these complex socioecological systems have around the world.

**History of urban ecology**

Urban ecology has diverse roots. One stems from nineteenth-century public health investigations of the relationships between human living conditions, the spread of disease, and the wide variety of disease vectors in urban areas leading to a
vision of cities as socioecological systems that still resonates strongly with twenty-first-century views of urban ecologists about people and nature in urban areas.

A second strand of urban ecology stems from landscape design and urban planning. Changed ideas about housing and sanitation in the nineteenth century included the belief that exercise in the open air improved people's health. Thus, the goals of the first public parks in England, Paxton's Princes Park in Liverpool and his Birkenhead Park across the Mersey Estuary, built in the 1840s, were to provide open space for the benefit of townspeople and local residents in areas being rapidly built up, and to develop attractive designed landscapes as a setting for the suburban residences. Frederick Olmsted took on board some ideas from a visit to Birkenhead in his 1857 plans for Central Park in New York. The many important ecological attributes in such urban landscape formation were incorporated into Olmsted's sophisticated design combining wastewater management and recreational amenity in the Riverway and Back Bay Fens in Boston, Massachusetts, a forerunner of today's sustainable drainage.

Eventually this stimulated ideas of planning new towns as garden cities, beginning with Ebenezer Howard's garden cities at Welwyn and Letchworth in England at the end of the nineteenth century. The subsequent garden city movement influenced the design of suburbs, new towns, and federal capital cities. It had no particular emphasis on planning for wildlife or children's access to urban nature, but it did have a city-region approach emphasizing a green belt of intensive food production around each garden city. The emphasis was on healthier living spaces for people, workplaces close to homes, and easy access to high-quality community services. Even so, garden city designs, with their diversity of urban planting schemes, gardens, and horticulture, created mosaics of habitats for other organisms, producing novel combinations of species in emerging ecosystems. Workers' housing with individual gardens, for example the 1930s council estates in the United Kingdom, arose from the garden city movement. Crises such as World War II saw parks, sports grounds, and golf courses used for growing a wide range of crops in patches of land ranging from domestic vegetable plots to large wheat fields. This intensive agriculture helped to increase urban biodiversity and plant productivity. After 1945, most of the open spaces were returned to their recreational uses, but the urban food-growing tradition remained strong in Europe, with many residents choosing to cultivate family gardens or allotments. The value of urban nature for human physical and mental health remains a central concern of government and civil society organizations involved with urban green spaces and urban wildlife today.

Urban agriculture is even more significant in poorer countries, where urban growers supply as much as one-third of all the food consumed in some cities. Here food growing is necessary for survival, often using public lands and illegally occupied vacant areas, and forming a key component of the urban ecology of most of the world's fastest-growing cities. The value of urban nature for human physical and mental health remains a central concern of government and civil society organizations involved with urban green spaces and urban wildlife today.

By the mid-twentieth century, surveys of introduced and invasive species began to appear in Europe, and specialized work on synanthropic plants and animals in urban areas began to form a third foundation of urban ecology. The rapid ecological changes on bombed sites after 1940 added a further stimulus to modern urban ecology. Derelict bombed sites were invaded by unusual plants and insects, creating new habitats
for birds and leading to novel combinations of flora and fauna. Major studies in many European cities examined the results of this tremendous natural experiment and stimulated notions of novel ecosystems, some of which were considered worth preserving so that city dwellers could see natural vegetation close to their homes. However, the work was essentially on the rubble left after bombing and on derelict industrial land. It concentrated on the newly naturalized plants, the dispersal strategies of particular species, succession under various site conditions, and the formation of new plant communities. It produced the first peak of activity in urban ecology and had a major impact on attitudes to nature in urban areas. Such was the biodiversity on some of these sites that many local groups campaigned to have some remnant areas protected as ecology parks or urban nature reserves. The demands for regeneration and rebuilding after 1945, and the emphasis on creating national parks and protecting the countryside, drew attention away from urban wildlife. However, industrial change, following the replacement of coal by natural gas and the decline of heavy manufacturing industry, left much derelict land that was colonized by unusual combinations of plants. Old factory sites and coal mine waste tips were converted in the public open spaces, and the reclamation of derelict sites created new opportunities for the deliberate planning of new ecosystems. Restoration ecology developed. People began to see the opportunities for allowing natural recolonization to proceed at some sites. By the 1970s urban ecological projects were underway in several European cities and urban ecology parks began to be established. A book on Nature in Cities by Ian Laurie was published in 1979 and the first European symposium on urban ecology was held in Berlin in 1982. The journal Urban Ecology began publication in 1975, and was incorporated into Landscape and Urban Planning in 1986. Now there are at least eight scientific journals concentrating on urban ecology.

Somewhat detached from European developments, studies of urban forests and wetlands in North America developed after the 1969 US Environmental Protection Act stimulated work in urban forestry that has played a major role in establishing methods of evaluating urban ecosystem services and encouraging investment urban greenways and green infrastructure. The 2009 report on Planning the Urban Forest: Ecology, Economy, and Community Development (Schwab 2009) set out the following benefits of the urban forest:

- **environmental**: providing green infrastructure; treating stormwater runoff; shading and cooling the urban heat island; reducing air pollution; providing wildlife habitat;
- **social**: health benefits; environmental justice;
- **economic**: value of trees in business district; influence on property prices; added value from parks.

These benefits interest urban ecologists and indicate how people have come to examine interrelated urban environmental issues from many different disciplines. They also demonstrate how the concept of green infrastructure has become prominent since 2001. So the examination of particular species and special habitats in cities has now grown into a much broader consideration of the place of nature in the city and its benefits to urban inhabitants.

The fourth root of urban ecology extends into the view of the city as a whole ecosystem with inputs and outputs and with its own metabolism. Ideas on cities as dependent ecosystems expanded from William Cobbett’s 1829 description of the impact of London’s food and timber requirements on life in villages 100 km away, to Wolman’s landmark 1965 paper...
on the metabolism of cities. Their ecological significance was first emphasized by the 1972 publication on Sydney as an ecosystem. A new standard was set by Stephen Boydén’s team’s work on Hong Kong in the 1970s. Their book provided an intellectual framework for the research; analyzed empirical data from a wide range of sources to understand the dynamics of the city; explained both ecological and social problems affecting the dynamics of the urban area; and set out the first model for integrating social and ecological process into an urban socioecological system. It became a pilot project of UNESCO’s Man and the Biosphere Programme Project 11 (MAB 11), in which ideas of analyzing urban energy, water and materials budgets, and their ecological impacts eventually expanded into both the industrial ecology and the urban ecology of the early twenty-first century. MAB 11 helped to develop views on the ecological aspects of urban systems, particularly in Rome where the psychological dimensions of urban relationships with nature received much attention. The dependency of urban areas on external ecosystems became well understood, particularly through the readily grasped, but sometimes misinterpreted, concept of the urban ecological footprint. Probably the most significant element of the urban footprint approach is the comparative per capita area of land needed to support an inhabitant of a particular city at its present rate of consumption. Around the year 2000, it ranged from 0.8 ha per person in an informal settlement in Delhi, India, to 11.0 ha per person in Calgary, Canada.

The urban ecological footprint is a modern example of the organic analogy or allegorical use of ecology. An earlier instance arose at the University of Chicago in the first decades of the twentieth century, where pioneering ecologists developed ideas of evolving plant communities and plant succession in the dune systems at the southern end of Lake Michigan. These biological ideas were noted by Chicago sociologists who saw possibly similar changes in human communities and the successions of occupation of various parts of the city by different social groups. This human ecology of urban areas, known as the Chicago School, was termed “urban ecology” by the 1950s. Urban ecologists then studied the spatial organization of the urban community and the changing patterns of segregation and occupation of different districts by various social and cultural groups. With the advent of computers to analyze large quantities of census tract data, urban ecology within sociology developed into social area analyses and factorial ecologies, which engaged many geographers and sociologists in the 1950s and 1960s. While this work continues in public health investigations, others subsequently concentrated on how the socioecological character of their nonwork relationships and interactions influence urban people’s lives.

Since 1990, urban ecology has moved into an era of high-level cross-disciplinary comparative and analytical work, building on MAB 11 and given a major boost by the establishment in 1997 of two US research sites, the Central Arizona–Phoenix Long-Term Ecological Research (CAP LTER) project and the Baltimore Ecosystem Study (BES). The BES aims to understand metropolitan Baltimore as an ecological system, bringing together researchers from the biological, physical, and social sciences to collect new data and to synthesize existing information on how both the ecological and the engineered systems of Baltimore work. CAP LTER is a multidisciplinary, urban ecological investigation of the socioecological systems in central Arizona. The basic questions guiding the research are: How do the services provided by evolving urban ecosystems affect human outcomes and behavior, and how does human
URBAN ECOLOGY

action (responses) alter the patterns of ecosystem structure and function, and ultimately urban sustainability, in a dynamic environment?

Modern urban ecology

Today, a broad cross-disciplinary endeavor is helping to change the appearance of urban areas by improving understanding of urban ecosystem functioning and assisting the design and management of urban areas for human wellbeing, biodiversity, and other ecosystem services. For urban ecology such work is a challenge, requiring the coupling of science with practice to address many of the wider issues faced by humanity.

Although modern urban ecology emphasizes the integrated view of complex socioecological systems, scientific publications tend to deal with parts of systems and it is convenient to examine the contemporary scene in terms of the four themes set out in the introduction: the ecology of health in urban areas, ecology in cities, ecology of cities, and ecology for cities.

Ecology of health in urban areas

The relationships between people and nature in cities are many and varied. Humans have profound effects on species survival, population structure, reproduction, behavior, and evolution; and, at the same time, nature also has profound effects on the health and wellbeing (both positive and negative) of people. As urban areas increase in number and size, so the frequency and intensity of interactions between humans and urban wildlife also increases. These interactions can be with individual animals or plants, or with the habitats in which these species live (such as parks, gardens, and ponds).

The diseases carried by animals (disease vectors) and the diseases occurring in animals that can be passed on to humans are some of the main hazards associated with animals. Attention to zoonoses has greatly increased with the rapid expansion of intercontinental air travel and the movement of animals around the world. Disease can be transmitted rapidly. Climate change is also permitting disease vectors to move into areas that were previously climatically inhospitable. Increasing urban populations, pet ownership, travel, and activities that bring people closer to wildlife are raising the possibility of the rapid transmission of wildlife diseases to, and within, urban environments. Particularly severe in their consequences are exchanges between people and nonhuman primates such as herpes simian B virus and monkey pox (through animal bites) and Ebola (through hunting and butchering). More significant in terms of numbers of people, especially in urban areas, are the diseases carried by nonprimate animals that are close to humans, including dogs and rats. Alligators and large snakes, birds, mosquitoes, and ticks all carry diseases or pose other health risks. Rats (Rattus sp.), for example, cause several possibly fatal diseases including Weil’s disease, salmonella, tuberculosis, cryptosporidiosis, E. coli, and foot and mouth disease (Aphthae epizooticae). Urban birds exploit the built environment extensively. However, they also spread disease by spores from their droppings that are carried on the wind and inhaled as dust. Symptoms of the diseases involved, such as chiamdiosis, a virus similar to influenza, and psittacosis, which is similar to pneumonia, may be minor in healthy adults but are a more serious problem for those with low immunity.

Many insects are disease vectors. The role of mosquitoes in malaria transmission is well known, but they can also carry other diseases, such as dengue fever. Ticks carry many diseases of which Lyme disease and tick-borne encephalitis are among the best known. Some diseases are carried by more than one species of tick, and some ticks transmit more than one disease. Venomous
Spiders are a hazard to many people and insect vectors carry diseases, including malaria, that affect people and other animals, whether those animals are pets, domesticated, or wild species.

Some plants cause more direct harm to people. Plant sap sometimes contains toxic chemicals known as furanocoumarins, which in the presence of sunlight cause phytophotodermatitis: a reddening of the skin, often followed by severe burns and blistering. The burns can last for several months, but even the skin can remain sensitive to light for many years. Toxic plants and fungi may enter the human food chain by being mistaken for edible varieties.

Much emphasis has been placed on the positive aspects and health benefits of urban greenspace. The health effects of nature are usually discussed in terms of stress reduction and attention restoration theories. Even passive viewing of natural environments after psychophysiological stress helps to reduce stress and may later confer health benefits. Contact with nature, or natural views, can confer psychological wellbeing benefits through attention restoration. Thus stress recovery and attention restoration may be central to understanding other psychological wellbeing benefits gained from contact with vegetated urban spaces.

As people have become more aware of the dangers of obesity, heart disease, and high cholesterol levels in urban societies, the lists of the positive health and wellbeing aspect of activity and exercise, of the gentlest kind, in blue- and greenspaces in towns and cities have grown markedly. These benefits are now being expressed in the terms of hypotheses that urban ecology research should be able to test, confirm, or refute.

The way vegetation is arranged and managed in parks and neighborhoods considerably affects how people engage in health-promoting physical activities. Theories relating to visual aesthetics can be linked to visual concepts that are important in landscape design and landscape architecture as they shape the landscapes that are produced. Often the most important issue is that of the perceived safety of the place used for the physical activity. High levels of vegetation do not necessarily equate with more physical activity. The pattern of this vegetation is critical; if vegetation is planted and allowed to grow in ways that limit the ability to visually and physically access one’s immediate surroundings, then fears of being in a potentially unsafe environment may override any motivation to use the space for physical activities.

Urban agriculture provides multiple ecosystems services, helping to improve health by providing better nutrition and by the exercise involved in cultivating the crops. In more developed countries urban household gardens supplement dietary intake and reduce overall household expenditures on food. In poorer cities, urban agriculture provides food that people cannot afford to buy.

Recreational gardening helps people to relax and releases stress. It is widely used in prisons and hospitals to help inmates and patients recover. General public health is improved by involvement in converting run-down, unkempt, garbage-laden urban neighborhoods into vegetable gardens. Such beneficial interactions of ecological and social change are now at the heart of urban ecology. When low-income neighborhoods and market gardeners become involved in transforming their urban landscapes and claiming for themselves a sense of pride and place, urban agriculture becomes a forceful empowerment strategy for community participation and social change.

Poor housing conditions create urban habitats that affect public health. They are associated with a wide range of health conditions, including respiratory infections, asthma, lead poisoning,
injuries, and mental health. Specific relationship- 
ships are well understood; for example, hospital 
admissions for chronic obstructive pulmonary 
disease (COPD) are often higher from crowded 
older buildings in the heart of a city where urban 
heat island intensity, and vehicular traffic and air 
pollution levels, are also higher than elsewhere.

Ecology in cities

Modern urban ecology drew its inspiration 
from detailed studies of urban flora and fauna, 
particularly in Berlin where Herbert Sukopp 
established the Institute of Ecology, which 
concentrated largely on botany and vegetation, 
with a strong emphasis on the phytosociology 
of urban areas (Sukopp 2008); and in Warsaw 
where Maciej Luniak (2004) and colleagues 
concentrated mainly on animal ecology. Com-
prehensive biotope mapping in Berlin provided 
the ecological basis for a land-use plan that 
incorporated nature conservation. No other 
city has been subject to such close ecological 
investigation, which has laid firm foundations 
for studying plant ecology in urban areas. In 
Warsaw, since about 1970, at least 12 new bird 
species and two mammal species have colonized 
densely built-up areas. In Europe as a whole, 
the most well-known species that have been 
more successful in urban areas than in their 
native natural habitats are the blackbird, magpie, 
hooded crow, kestrel, grey squirrel, striped field 
mouse, rabbit, and red fox. This process of synurbanization shows that there are chances for 
some kind of coexistence between nature and 
the expansion of urban civilization. Nevertheless 
most cities show some loss in species diversity 
as many birds and mammals disappear from the 
new suburban areas where they once lived.

In terms of flora, central European urban areas 
are rich in alien plants, which account for a mean 
of 40% of all species, their representation being 
13.7% higher than their representation in the 
total species pool available in the region (Pyšek 
1998). Compared to natural habitats, the differ-
ence is greater, a group of Czech nature reserves 
having an average of 9.8% aliens. The cities are 
thus the habitat that is richest in alien species, 
and serve as an important source of aliens (often 
invasive) for smaller settlements and further 
spread into rural areas.

The changes in urban flora depend on the 
pattern of succession on particular substrates, 
emphasizing the importance of natural and 
artificial soils (often termed “made ground”) 
in the character of naturally colonized urban 
vegetation. For example, in the Czech Republic, 
after 12 years of succession, native woody species 
dominated ruderal (landfill) sites, with Populus 
tremula on nutrient poor sites and Sambucus nigra 
and Salix caprea on moderately rich nutrient 
sites. Similar trends over five years were noted 
in a Berlin experiment, with Betula pendula and 
Populus nigra succeeding on sandy soils, and 
annuals giving way to biennials and perennials 
on topsoils. Work of this type generally leads 
to two hypotheses: the urban environment and 
land transformation create unique environmental 
conditions to which species have to adapt to 
survive and mature, and the loss of native species 
and increase in non-native species, with increas-
ing urbanization, leads to biotic homogenization 
with the same urban-adaptable species being 
found in widely separated cities.

The hypothesis of unique environmental 
conditions needs testing by paying attention to 
urban geomorphology and urban soils, looking 
at the ground on which the city is built and in 
particular paying attention to the deposits and 
surface materials created by past urban land uses. 
In this way urban ecology has links to geological 
concerns for the Anthropocene and geomor-
phological concerns about artificial landforms 
and sediments. Above all, the species occupying 
particular sites reflect the local biogeochemistry.
Gardens are a particular type of Anthropocene environmental change. They reflect cultural aspirations, human needs for food and relaxation, ambitions to acquire the novel and exotic, and desires to express personality and wealth. Sometimes they are made up entirely of materials, including soils and rock, brought onto the site and are planted with exotic non-native species. At others they are but the slightest modification of what would have been there naturally. Detailed work from 1972–1986 in a garden in Leicester, England, noted 2204 species, including 422 species of plants, 1602 insects, 121 other invertebrates, and 59 vertebrates. Further work on the mosaic of habitats and landscape in suburban gardens has found 1166 vascular plant species, of which 30% were natives, together with some 80 lichen species and 68 bryophyte species across 61 gardens in the United Kingdom. Generally along rural–urban gradients, the species richness of some major taxa (particularly plants and birds) commonly exhibits a peak in suburban areas where there is greater habitat heterogeneity, much of it contributed by suburban gardens.

The manipulation of habitats in urban areas provides opportunities to experiment in designing with and for nature. These planned interventions include restoration ecology and creative conservation, and lead to recombinant ecology. Restoration ecology seeks to provide a scientific basis to inform the practitioners working to restore areas affected by overexploitation, farming, industry, or natural catastrophe. The conservation of existing habitat and the restoration of degraded, damaged, or destroyed habitat, through restoration ecology, provide ways to address the trend for habitat loss, species extinction, and the decline of ecosystem services. Practitioners of ecological restoration employ a wide range of techniques including removal of non-native species and weeds, revegetation of disturbed areas, reintroduction of native species using stock with a known local provenance (to ensure, as far as possible, that the genetic diversity of the introduced plants and animals is as close to the naturally occurring population as possible), reforestation, erosion control, daylighting streams, as well as habitat and range improvement for targeted species. Restoration ecology uses ecological theories that guide landscape managers and others to put degraded and disused land into a better ecological condition which will provide habitats for plants and wildlife. Restoration ecology draws on a wide range of ecological concepts, including those of disturbance, succession, fragmentation, ecosystem function, adaptive capacity, and resilience (Pickett, Cadenasso, and McGrath 2013).

Restoration can aim simply to restore and enhance biodiversity, or it can be seen as integral to urban regeneration and environmental improvement, for example in assisting towns and cities to adapt to climate change. Specific examples of the benefits of ecological restoration include the development of wetlands to control water distribution and quality, and of wildflower meadows to enhance the attractiveness of former mown urban grassland, and the establishment of urban forests to provide both wildlife habitat and the potential for wood production by coppicing. Ecological restoration is of great value in areas of changing land use, such as abandoned landfills and mine waste tips, contaminated land, and former industrial sites.

Creative conservation is the introduction of species to new situations and the reintroduction of species to habitats where they have become extinct. In many cases it is simply conserving nature in an adaptive fashion so that ecosystems can respond to changing environmental conditions. In others, it is the reworking of land to introduce either animals that have been bred in captivity for reintroduction to the wild, or plants, particularly wildflowers, that have been
URBAN ECOLOGY

prepared in nurseries or experiment stations to yield seeds or seedlings to be sown in specially prepared areas.

In the United Kingdom creative conservation establishes novel ecosystems that may be totally different from what existed before urbanization or may reintroduce native species onto previously used urban sites (brownfield land). It differs from restoration ecology in not directly attempting to put areas back to some ideal previous condition, but to make an area more attractive to both the local human population and wildlife, such as planting wildflowers meadows around the apartment blocks and row houses of social housing estates. It redesigns the urban landscape for both ecological and social goals.

Ecology in cities thus involves classic botany, zoology, and habitat analysis, but looks in particular at the diversity of ecological situations in urban areas and at ways of improving and managing those habitats for the benefit of wildlife and people. In creating novel ecosystems and deciding what to do about those that have developed naturally, urban managers have to balance people’s landscape tastes and preferences against municipal and private budgets for greenspace care and management. In so doing they are designing future urban geographies under constraints that are often external to their own environment and beyond their control.

Ecology of cities

Studies of the ecology of cities are interdisciplinary and multiscale, incorporating both the ecological and the human dimensions of urban ecosystems. They comprise three broad categories of thinking:

1. ecology of the physical urban system, including the wide range of people-impacted or modified environmental patterns and physical flows, affecting organisms and their habitats, in and through the city, and through urban systems on a regional, national, and global scale;
2. ecology of the social-economic urban system, involving the range of human activities that are in various ways associated with ecosystem and environmental processes, including industrial ecology, ecological design, and ecosystem service markets;
3. ecology throughout the human–environment system, embracing social, economic, cultural, and political patterns and relationships in the human ecology sense of a community of interdependent processes in both human systems and ecosystems.

The CAP LTER studies in central Arizona examine how, in a dynamic environment, the services provided by evolving urban ecosystems affect human outcomes and behavior, and how human actions (responses) alter patterns of ecosystem structure and function, and ultimately urban sustainability.

Ecology for cities

Urban ecosystem services involve scientific, philosophical, political, and practical concerns for urban ecology because, although it is clear that nature provides benefits to humanity and that without those benefits human development cannot continue, organizations promoting nature in cities are being asked to quantify the value of urban greenspaces in terms of the provision of those services. Many of the services are appreciated only by sections of the total population, so valuation is linked to preferences that are difficult to establish equitably. Many of the commonly cited environmental benefits of urban greenspaces remain poorly supported by empirical evidence. Benefits to one group of
people may be ecosystem disservices to another. Some social groups seldom use particular parks, and for many individuals urban woodlands can be “landscapes of fear.” Thus the complexity of urban socioecological systems impinges directly on applying urban ecology.

Local issues of urban design are but one concern. Urban ecology has a central role in the debate about urban futures. Preparing urban settlements for the future involves both creating new eco-towns or eco-cities embodying sustainable lifestyles and smart technologies, and adapting existing settlements to environmental, social, and economic changes by increasing their resilience and sustainability. Green technologies and green spaces are integral to both processes, involving everything from green roofs and green walls to sustainable drainage and urban wildlife reserves.

Globally, urban ecologists are asked to contribute to establishing sustainable and resilient urban areas. Planners, architects, designers, decision-makers, and society expect urban ecologists to be able to offer guidance based on locally relevant ecological information; and, from that, they expect to derive general principles that can be applied more widely, even globally. This is no small challenge. It requires an understanding of the ecological patterns found within urban areas and the processes operating in them, which are very different from the traditional study of urban ecology.

Urban ecology is evolving rapidly with developments in both theory and practice. In working with complex socioecological systems, it is developing new opportunities for sound practice and good urban management. Some of the key elements of an emerging philosophy of adaptive practice for ecological design to help develop existing urban areas into resilient future cities (Pickett, Cadenasso, and McGrath 2013) include:

- using ecological knowledge to improve ecological urban design and to avoid dependence on green, or “eco,” ideology;
- recognizing that urban agglomerations or metacities (complexes of cities, suburbs, peri-urban and ex-urban areas) are spatially extensive, dynamic mosaics, in which flows, distant connections, historic legacies, and the impacts of innovation, redevelopment, and crisis act in localized explicit ways;
- seeing how design affects flows, creating both obvious and inconspicuous or unintentional feedbacks, some of which have the potential to enhance the adaptive capacity of affected areas;
- avoiding the unintended or inconvenient negative effects of designs that produce environmental injustice for sectors of the population;
- using art as a powerful tool for linking design with its ecological implications, to engage the public and decision-makers in the environmental flows and feedbacks that exist in urban systems;
- using socially and politically constructed narratives to help incorporate ecological awareness and knowledge into design processes;
- anticipating changes resulting from feedbacks and from wider-scale factors such as climate, human and biotic migrations, and shifting economic investments in order to include adaptive processes and structures in metacities (urban agglomerations of over 10 million inhabitants) by design as a key tool for resilience;
- using landscape as a shared medium, coupled with the consideration of designs as experiments, to make the learning aspect of design more explicit;
- assessing the ecological effects of proposed projects as part of a process of evaluation–feedback–revision in design and construction.
• constantly appraising impacts of urban growth, change, and adaptation on the hydrological systems to cope with floods and droughts, contamination, treatment, storage, sea level rise and coastal change.

Urban ecology for future cities

Urban ecosystems depend on both natural and anthropogenic substrates, and are highly affected by air, soil, and water pollution. They help to control runoff and reduce the urban heat island effect. They contribute to human health. Although some air and water pollutants may be trapped by trees and aquatic vegetation, in terms of air quality the benefits of urban tree planting programs may be overstated. The great scientific challenges in urban ecology are coupled with the social, cultural, political, and economic challenges of fitting proposed actions into socioecological systems. Studies of urban socioecological systems, for example in Baltimore, United States, and in Cape Town, South Africa, reveal that many urban ecological hypotheses, such as that biodiversity is lower in urban areas than in rural areas, are not valid. They emphasize that the diversity of urban areas has arisen through cultural and social diversity and the different values people place on particular urban greenspaces. Within large urban settlements, biodiversity and biogeochemical characteristics may differ along gradients between the truly rural and the intensely built-up urban core. New frameworks for urban ecology are being proposed to cope with this diversity and complexity, but they are not necessarily transferable from one continent to another in an age where the largest and densest urban populations tend to be found in the high-density but low-rise cities of Asia and Africa. The human impacts of environmental and ecological conditions and changes are most severe in the poorest cities, but the bulk of research on urban ecology is carried out in the more affluent cities. As in many areas of geography, the most salient urban ecological work in Asia, Africa, and South America is on immediate applied issues, aiming to alleviate the worst conditions and to improve health and wellbeing through environmental and changes. Many lessons can be learned from past experiences elsewhere, but all too often political action only happens after a local disaster. Urban ecology can help to avoid some of the disasters, but without relevant local case studies it is difficult to persuade decision-makers that things can be improved. There are real opportunities and challenges in setting new priorities for urban ecology, for action not criticism, for solving problems not political theorizing.

Globally, urban ecologists are asked to contribute to establishing sustainable and resilient urban areas. Practitioners and society generally expect urban ecologists to offer guidance based on locally relevant ecological information, and from that to derive general principles that can be applied more widely, even globally, despite the major differences in natural and social conditions affecting the world’s urban places.

Urban elites

Ferenc Gyuris
Eötvös Loránd University, Hungary

Dominance, division of labor, and differential evaluation exist in all societies. There are always differences between individuals as well as social groups in their ability to command various kinds of resources, even if the appearance and level of these differences vary on a broad scale. Furthermore, most people have a different level of command over various resources. A simple and important concept is Bourdieu’s (1998) notion of the forms of capital and social space, which interprets social position as a function of economic and cultural capitals. In this interpretation, while industrialists may own much economic capital but little cultural, artists may have the opposite combination.

In reality, a much broader set of resources exists than is suggested by this simplistic model. Hence, the number of possible combinations is very high, and most social actors belong to categories with limited command over certain resources. There is always a limited number of actors, however, who are able to mobilize a wide array of resources. This narrow stratum is the (power) elite, which can be identified at various geographical scales. In the urban context, this powerful group of actors is called the urban elite. This is the group whose interests and decisions have a decisive influence on which policies are issued, which economic decisions are made, and which growth image comes to dominate in the city.

Urban elites, of course, are never homogeneous. They are fragmented, and some of their interests can be conflicting. The force that unifies them is the shared interest in sustaining their economic and political position, which is manifest in their support of initiatives and decisions they all expect to benefit from. In contemporary cities of the neoliberal age, this point involves treating the city as a “growth machine,” which means forming “growth coalitions” (Logan and Molotch 1987) with other actors within an urban elite and promoting economic growth as if it were the most important city goal. This argument today is frequently utilized to justify “urban privatism” (Peck 1995), the privatization of the urban commons and communal services such as public spaces, water supply, or education, and deregulation and liberalization in the urban economy, including the management of the urban labor force and the housing sector.

In this context, a multitude of institutional means is put in place to reinforce an urban elite’s special position. These include the legal system or law enforcement organizations, which enable in the postdemocratic city the use of techniques aimed at keeping social tensions under control. Hence, neoliberal urban elites strongly rely on “governing through crime” (Simon 2007), that is, the legal and discursive criminalization and severe punishment of activities and behaviors that elites consider undesirable.

Moreover, urban elites hold key positions in economic institutions as well as in the religious, educational, and civic realms, which play a key role in indoctrinating people to accept prevailing conditions. Crucial elements in this are advertising economic growth as the central imperative for the survival of cities, as well as creating a common identity for urban inhabitants through fabricating collective memories about
Urban elites are usually demographically distinctive in the city. Besides being disproportionately affluent, owning property, and having easy access to the levers of local power, they are also highly educated and predominantly male, and embody the dominant racial category of that city and society. Hence, urban elites are highly genderized and racialized, and their residences are segregated in urban space.

Although urban elites occupy a leading position in urban society, they are also embedded in a complex power hierarchy of various actors at different geographical scales, who also have the ability to shape urban realities. Even political leaders and influential economic actors in the city have to consider and adapt to events at the national and global scales. Metropolitan governments, for example, cannot ignore the actions and expectations of the national government or multinational institutions such as the United Nations, the World Bank, or, in Europe, the European Union, even if these conflict with their own desires. Furthermore, though urban elites are much more powerful than other urban actors, they are also strongly reliant on, and to some extent even constrained by, the latter, for without other actors the city could not function, either in economic or in political terms. Therefore, urban elites never have exclusive mastery over urban realities.

Power relations among urban elites are also dynamic and ever evolving, which often muddies the sense of who constitutes the most powerful political institution in the city. Powerful institutions can, under certain circumstances, quickly lose power. New institutions can step in to fill the void, creating an ever-changing political reality of who rules the city. Such institutions, it follows, must read political trends and processes in the city meticulously to stay relevant and in power. Without identifying emerging political and social trends, currently powerful political institutions place themselves at risk of losing touch.

In the current neoliberal world, with a historically unprecedented intensification of transnational flows of information, capital, and labor, urban elites are much less tied to a single city in geographical space. They are increasingly becoming part of a transnational elite, which is reliant on a number of places, mainly urban ones, where, for example, their children can be educated and their economic partners and political allies reside, and where they organize their leisure activities. The globalization of urban elites also makes them increasingly open to adopting globalized urban policies with the potential of political success. This results in extreme geographical mobility of neoliberal policies, such as those of the creative city.

The exclusive position of urban elites and the resulting urban inequality raise important normative questions. On the one hand, divisions of labor attributing more power to certain individuals are necessary prerequisites for the functioning of society and are thus present in urban social systems. It would be misleading to suppose that the interests of urban elites necessarily conflict with those of other urban actors, and that urban elites themselves unavoidably change the situation of other social strata in the city for the worse. For these reasons, the emergence of urban elites seems unavoidable and, in some ways and under certain circumstances, desirable. On the other hand, however, the mechanisms that determine who can join urban elites, who can remain in the group, and who is dropped should be subject to continual critical investigation.

Similar important questions are what activities urban elites should engage in (in moral terms),
are allowed to do (in a legal sense), can do (in technical terms), and actually do in a given situation, and to what extent these are in accordance with the expectations of disparate social groups. These questions are clearly open and debatable, both in neoliberal and non-neoliberal cities. To define related legal and institutional structures and practices and to continually fit them to the constantly changing views and interests of society are necessary and difficult tasks that should be addressed by urban elites.

Urban geography

Matthew B. Anderson  
*Eastern Washington University, USA*

The principal focus of urban geography has been and continues to be the city, and how political, economic, and social forces and human–environmental relations flow and reverberate through urban landscapes. Urban geography is among the largest and most diverse subfields of human geography, as urban geographers have been influenced by numerous (and often competing) philosophical and epistemological approaches to the study of the city. There are just as many ways to define and understand the city as there are to discuss the ways in which it has been examined by urban geographers.

The city is widely identified as a location marked by a concentration of people, economic producers, services, and physical infrastructural elements. At the same time, it is widely seen as a political and administrative entity, a space of flows (i.e., money, goods, and people), a setting through which social relationships are established, sustained, and evolve, and where everyday lives unfold. The discipline is best summarized as concerned with untangling this complexity, with understanding the myriad urban environments that the majority of people in the world call home, and with explaining the varying “socio–spatial similarities and differences that exist between and within urban places” (Pacione 2005, 17–18).

Urban geography also has a dynamic, interdisciplinary character. The discipline has historically reached beyond the confines of geography, frequently engaging with and incorporating insights and perspectives from urban planning, sociology, or economics. Urban geography can be conceptualized as an organic entity, coevolving in dialectic relation with other disciplines, both within and beyond geography. It might seem that urban geography therefore lacks a center, or core set of identifiable or coherent characteristics. This is not so, as what distinguishes urban geographers from urban scholars in other disciplines is the centrality of what is often referred to as the spatial perspective, perhaps the key defining feature of geography as a whole. This concept ties urban geographers together as the common thread that harnesses the discipline’s integrative power.

But what is this spatial perspective? There is no simple answer, as the significance and even meaning of space varies, from the Cartesian conception of space in, for example, Walter Christaller’s central place theory to Henri Lefebvre’s conception of space as a social product. In general, however, and in the context of urban geography specifically, it is a perspective that identifies and treats space as an important analytic concept for understanding and explaining the development of urban landscapes, from sprawling suburban subdivisions to disinvested urban cores and glossy downtowns, and how these landscapes are experienced by users and inhabitants. The process of urbanization is also a material force, the manifestation, or spatial expression, of the broader social system within
URBAN GEOGRAPHY

which it is embedded, that both shapes it and is shaped by it.

Positivism, spatial analysis, and modernist urban planning

During the early twentieth century, urban geography was a much smaller discipline. This began to change around 1950, when a rapidly increasing proportion of the world's population shifted to urban locations. As a result, greater scholarly interest in the city and the process of urbanization emerged. In many ways, this early history of urban geography is reflected through the history of human geography in general, as most subfields evolved through a succession of dominant epistemological paradigms that marked the discipline as a whole, such as environmental determinism, possibilism, and the region (Cresswell 2013).

Positivism and spatial analysis

During this time, urban geography was still a minor research area, which began to change during the so-called quantitative revolution in human geography. To be considered a legitimate spatial “science,” an elusive goal for decades, urban geographers adopted the philosophy of positivism and the development of quantitative methods, models, and testable theories of human spatial behavior. Here a central tenet is that only things that can be experienced as observable and countable facts can and should count as the empirical foundation of true and objective knowledge, the substance of a science where hypotheses are to be formulated mathematically (Cresswell 2013).

Much of this research, led by Brian Berry, William Bunge, Edward Ullman, Peter Haggett, and David Harvey, happened to be situated within the urban context, invigorating urban geography as a result. Supported by new computer-based technologies, the possibility of identifying general patterns through statistical data and replicable (and falsifiable) hypotheses led geography down the path of a “hard” and empirically grounded science guided by the “principles and practices of scientific method” (Hubbard 2006, 28). In the process, urban geography became a more prominent subfield geared toward the search for general laws in the spatial structure and organization of the city.

Spatial analysis was also influenced by the principles of neoclassical economics, introduced to geographers by European scholars such as Walter Christaller, Alfred Weber, and August Losch. The primary origins of this influence resided in the location theory of the nineteenth-century economist Johann Heinrich von Thunen, who sought to understand the location and spatial distribution of economic activity. Building on this background was Christaller’s *Central Places in Southern Germany* (1966/1933), which posits that clusters of economic activity function as “central places” that service surrounding areas. A key assertion was the notion that people typically travel the least distance to acquire the goods and services they need, and that certain types of economic clusters typically locate in close proximity to important resource base or critical mass of consumers. For example, Pittsburgh is located where it is because of its proximity to the coal deposits and mining operations in Pennsylvania and West Virginia. This location, according to the theory, is what underpinned this city’s early manufacturing of steel.

In short, the locational patterns of human behavior, from local-scale interaction and movement to the spatial ordering of entire urban landscapes, was understood as a function of the friction of distance, people minimizing the costs of transportation and communication, otherwise known as the principle of least net effort.
This principle was treated as a central explanatory variable, and underpinned the assumptions, models, and theoretical formulations (i.e., spatial interaction theory) of many scholars working in this tradition, from William Alonso’s oft-cited bid rent theory to the methodological expositions outlined in David Harvey’s landmark text Explanation in Geography (1969).

The Chicago School of urbanism

This approach to urban geography was also influenced by early twentieth-century urban sociology, particularly the Chicago School of urbanism. The Chicago School was composed of a number of scholars working in or affiliated with the sociology department at the University of Chicago during the 1920s and 1930s, and included Robert Park, Ernest Burgess, and Louis Wirth. Inspired by nineteenth-century European scholars, notably August Comte and Émile Durkheim, this school of thought pioneered the positivist approach to understanding social and morphological change in the industrialized city. Much of their work was based on quantitative analyses of dense descriptive statistics derived from participant and visual observation. It also highlighted Chicago as the paradigmatic modern city (see Park, Burgess, and McKenzie 1925).

The Chicago School presented a model of urban growth and change, perhaps best reflected in Ernest Burgess’s concentric-ring diagram of 1920s Chicago. Depicting the sociospatial differentiation of Chicago, the diagram visualizes a theory of how cities were understood to grow and evolve over time, marking different zones dominated by particular land uses and functions, such as working-class housing, industrial factories, commerce in the central business district, affluent housing at the periphery, and the oft-cited zone in transition of newly arrived immigrants. This model, often referred to as a scientific urban ecology, conceptualized the city as a living organism, with the different zones of the diagram reflecting the different organs that functioned within (and in the service of) the broader, living entity of the city.

This approach also adopted Darwinian explanations for the social behavior and patterns that were being observed. Replete with biological metaphors, people were seen to be enmeshed in competitive struggles to survive. The city’s spatial ordering (represented by concentric rings) can be understood as the outcome of this supposedly natural competition. This process was made explicit by Park: “Reduce all social relations to relations of space and it would be possible to apply to human relations the fundamental logic of the physical sciences” (Park 1936, 7).

For Chicago School scholars, this assumption explained why particular social-class groups tended to live in the same neighborhoods, as the manifestation of intergroup competition where particular groups found it more advantageous to congregate together as a competitive strategy. This schematic also formed the basis for the theory of invasion and secession, the phenomenon where one group is observed to move into, or “invade,” another group’s neighborhood, resulting in their relocation, or succession, to another area, thereby pushing the city further outward into the periphery and reproducing this checkered, hyperdifferentiated urban landscape. This process was interpreted as a natural process of neighborhood change.

This model also competed with others, such as Homer Hoyt’s sector model. Both models, however, are now considered overly simplistic and limited in explanatory strength. The Chicago School was nonetheless an important reference point in the subsequent development of urban geography as a positivist spatial science during the 1950s and 1960s, as it represented among the first attempts to draw conclusions
about the ever-changing spatial structure and social patterning of the modern urban landscape (Hubbard 2006).

The behavioral critique

The quantitative revolution proved important for catapulting human geography in general, and urban geography in particular, to the status of a legitimate science. The positivist approach became an object of critique, however, particularly in response to the rather poor predictability of the models this research generated (Pacione 2005). While these were designed to account for all aspects of human spatial behavior, much seemed to fall through the cracks. Despite the general patterns explained by the principles of distance decay, minimization of transportation costs, and so on, there still existed a notable degree of variability that could not be accounted for by these models.

This concern led to a shift toward what became known as behavioralism, an attempt to highlight the role of human agency, particularly people’s cognitive or decision-making processes, as a contingent variable that mediates general patterns. As an outgrowth of positivist spatial analysis, this shift was perhaps most influenced by Kevin Lynch’s *The Image of the City* (1960), where the mental map concept was first introduced. Deployed here was a method of cognitive mapping designed to visually construct people’s spatialized imaginings of the city using questionnaires and interviews. This method inspired a range of scholars, such as Julian Wolpert and Larry Brown, who sought to understand people’s less than utility-maximizing behavior by illuminating the rather messy, subjective, and often inaccurate imaginings people held of urban environments.

Through the use of more qualitative methods, it was asserted that the previously too simplistic models of the city could be strengthened to better account for variability, from people’s migratory and spatial mobility patterns to their residential preferences and perceptions of city spaces. This critique, although still situated within the positivist frame, ultimately provided the foundation for the subsequent development of humanistic urban geography (to be discussed in the next section), an epistemological approach that departed from positivism altogether.

Modernist urban planning

With the emergence of the modern industrial city, the necessity of managing and accommodating the spatial demands of a rapidly growing and urbanizing industrial capitalism became the purview of an emergent professional practice: urban planning. This would become another source of influence and inspiration in the development of urban geography, as both disciplines have historically placed a shared emphasis on the spatial dimension and constitution of social life in the modern city; however, during the early to mid-twentieth century, urban planning remained somewhat disconnected from urban geography. While some research in urban geography was meant for planning audiences (i.e., Christaller’s central place theory and Kevin Lynch’s cognitive mapping), only recently have these two communities of scholars and practitioners entered into more substantive dialogues.

Haussmann’s restructuring of Paris during Second Empire France (1852–1870) is typically noted as the first significant example of modern planning – sanitized water, plumbing, and sewage systems, street lighting, monumental civic squares, and the city’s famous network of wide boulevards – and deeply influenced the ways in which the supposedly rational internal ordering of cities was to be imagined and materialized. In North America, this influence
was first manifest through the City Beautiful Movement of the early twentieth century (Hall 2002). Perhaps the most prominent figure of this movement was the planner Daniel Burnham, who designed the reconfiguring of many cities (i.e., Chicago, Cleveland, Washington, DC, and San Francisco, among others) using Haussmann’s Second Empire Paris as the template.

This mode of planning, while it was rational to civic elites and industrial capitalists, ultimately resulted in numerous problems, most notably felt by the urban poor. In short, the living conditions of the working class were neglected, and they suffered immensely as investment was concentrated in the construction of grand avenues, central city monuments and civic spaces, and the servicing of more affluent residential areas. Famously chronicled by Frederick Engels in *The Condition of the Working Class in England* (1844), this worsening state of affairs – starvation, poverty, disease – ignited the garden cities counterplanning movement led by Ebenezer Howard. Based on a polycentric network of garden cities linked via mass transit, Howard envisioned more equitable social processes engineered through spatial planning, with each garden city linked with mass transit through radial concentric rings of avenues, small-scale enterprises (including agriculture), and central civic spaces.

Although this vision never really came to fruition, its influence has been felt through the twentieth century across Europe, North America, and beyond. For instance, it is here that the neighborhood unit in urban planning first emerged, and later influenced the regional planning of Clarence Perry, Lewis Mumford, and others. This vision, however, was subordinated to the emergence of what is often referred to as modernist urban planning, a paradigm and vision of the city that dominated much of the twentieth century. Modernist urban planning, sharing much in common with spatial scientists, was also based on the understanding of humans as rational economic beings, and held that similarly rational planning designs could help improve lives and contribute to “progress.” Reflected most famously in the Swiss planner Le Corbusier’s grandiose designs of high-rise living marked by right angles and standardized monolithic facades amid plentiful parkland and high-volume expressways, and implemented by neo-Haussmann technocrats, such as New York’s Robert Moses, the influence of this planning paradigm on the urban landscape has been profound.

From the sprawling cookie-cutter suburban landscapes that dot the periphery of most North American metropolitan regions to the public housing high-rises that marked many now deeply stigmatized inner-city spaces, the characteristics and consequences of the modernist urban landscape – municipal fragmentation, inner-city decay, automobile dependency, and deepening sociospatial polarization – have also become the context and substance for what much critical scholarship in urban geography and planning has since been about. The critique of this trend, initiated perhaps most notably by Jane Jacobs in her classic text *The Death and Life of Great American Cities* (1961), sought to recover the importance of the neighborhood unit as the basis for the flourishing of urban life. Planning should be a bottom-up, rather than a top-down, affair, with emphasis placed on, for example, close proximity between work and home, higher-density living, and a vibrant and walkable street life. The influence of Jacobs and Mumford, in particular, has since gained considerable momentum and has deeply informed much of urban design reform over the past few decades, most notably the principles of New Urbanism.

The year 1970 was a watershed in human geography. Spatial analysis was now under assault from numerous critical commentators, whose critiques took one of two different forms, each shaped by different philosophical influences. Both were stimulated, in part, by a sweeping rejection of positivism and the notably less than scientific assumptions and problematic interpretations that marked the spatial analysis tradition. Yet they were also markedly at odds with one another.

Humanistic urban geography

Extending the behavioral critique of spatial analysis, humanistic urban geography emerged in the 1970s and flourished into the 1980s. This tradition’s influence in urban geography and beyond is considerable and remains strong today. Spurned was the supposedly delusional rationalism that had previously pervaded the work of urban geographers, sociologists, and planners. To humanists, positivism sharply limited the kinds of questions that could be asked and, ultimately, the types of knowledge that could be produced. And, rather than merely studying the urban world, it was also having very real and destructive impacts, echoing the critics of modernist planning. For instance, urban landscapes were observed as being steamrolled by a globalizing homogeneity that reflected an increasingly technocratic understanding of the city shared by planners and spatial scientists and envisioned from the same towering elitist throne.

For humanists, what were inherently subjective interpretations and assumptions about the world masqueraded in the form of statistics and models, the positivist veneer of objectivity. For spatial analysts, knowledge was not being produced by subjective humans, but via a science (including supposedly impartial scientists) that could overcome such subjectivity. But, for humanists, such thinking led to an impoverished conception of human beings, whereby people were reduced to mere predictable things that circulate through the city according to some rational logic – what many now refer to pejoratively as homo economicus. To these critics it was no surprise that the models predicted human behavior so poorly.

Building on this critique, the humanistic approach adopted a different and alternative epistemology for the study of the city. Concerned less with hypothesis testing of only observable and quantifiable facts, humanism was (and remains) especially influenced by phenomenology, a philosophy about the “essence” of things which drew its inspiration from a variety of philosophers, particularly Edmund Husserl. According to phenomenology, everything has an essence, a core of what makes things what they are, which can be ascertained only through deep immersion in and experience of these things (Cresswell 2013).

For urban geographers, this new direction focused on the concept of place, and on how places, defined as spaces inscribed with human meaning, are experienced (i.e., home, workplace, civic square, or public park). As notably presented by Yi-Fu Tuan in his landmark text *Space and Place: The Perspective of Experience* (1977), the myriad ways in which people experience the spaces they encounter (and the meanings they attach to them) are important in understanding the nuanced contours of urban life.

Urban political economy

The humanistic tradition was critiqued by another parallel movement that emerged during the 1970s, urban political economy, which
was informed especially by Marxist analysis. Humanists purportedly allocated too much agency to individuals in their experiences and shaping of urban landscapes. Humanist research was also considered too apolitical, silencing uneven power relations between, for instance, elite capitalist actors and working-class minority populations. Where was the power of structural forces and influences? Where was the recognition of profound constraints imposed on actors and institutions in the everyday realities of capitalism? The humanistic perspective, according to these scholars, had very little in the way of answers to these questions and, as such, was deemed too simplistic an approach.

During the 1970s a revival of critical social theory and Marxism swept across universities in the English-speaking world. In geography, this “radical turn” was particularly influenced by an emphasis on the structural forces at work in shaping the world around us (including our perception of it). In continental Europe, the Marxist tradition had remained comparatively strong through the twentieth century, propelled by a number of philosophers, notably Manuel Castells and Henri Lefebvre. In this setting, urban political economy emerged as a major intellectual force in urban geography. The figure who spearheaded this movement in geography was, ironically, one of the key promoters of spatial analysis a few short years earlier, David Harvey.

Amid the world’s volatile social climate in the 1960s, including the Civil Rights Movement in the United States, the numerous urban uprisings and violent protests against the Vietnam War across North America and Europe, and the economic evisceration of many inner cities (particularly in North America), Harvey (1973) argued that geography risked falling into irrelevance. In short, both spatial scientists and humanists were deemed incapable of asking the kinds of questions that could shed light on the state of affairs.

Urban political economy conceptualizes cities as economic engines that are internally shaped by political and economic processes, though always mediated by local actors and institutions. They are thus sites where both local and multinational businesses and civic elites make and remake landscapes to produce and sell goods and services. In the process, governing actors (i.e., mayors, developers, and financial institutions) are understood as keenly responsive to changing economic realities and sociopolitical conditions, and continuously impact and revolutionize the spatial structure of the city in order to maximize profitability.

Spatial patterns of cities, in this perspective, are not merely the outcome of a natural competitive process. Rather, they are a manifestation of a central feature of capitalism, what Neil Smith (1984) termed “uneven development.” Poor neighborhoods, for instance, are poor precisely because wealthy neighborhoods are wealthy; these two phenomena are not unrelated. Why? Because poverty is not only an outcome of, but also a necessary input to, the inner workings of an economy driven by the capitalist mode of production. It is an outcome that represents the materialization of the exploitative relationship between capital and labor. But it is also a vital precondition for the source of profit, the surplus value maximized and appropriated from workers by capitalists through the labor process. A perpetually underemployed population, thus, maintains favorable conditions for profitability.

In short, uneven urban development is understood as the spatial expression of a deep structural force. Deindustrialization, for instance, is the flight of capital investment from high-rent urban districts in the Global North to much cheaper labor supplies overseas, for example in China. This flight is a means to restore and enhance profit margins, a process that comes at the expense of the very places where
URBAN GEOGRAPHY

investment had previously been fixed. In this way, capitalism requires some places to be less developed than others, the consequences of which – homelessness, despair, deepening inequality – were critically examined through the 1980s by a plethora of urban geographers and sociologists, such as Michael Dear, Jennifer Wolch, Loïc Wacquant, and William Julius Wilson, among others.

Richard Walker similarly chronicled uneven movement at the metropolitan scale in the context of mass suburbanization in North America. Here, the flight of middle-class whites, jobs, and resources during the 1950s and 1960s to the suburban periphery contributed to the decimation of inner-city districts (also see Beauregard 2006). This spatial fix later became regional, as Southern and Western cities (i.e., Houston, Atlanta, Phoenix) grew rapidly at the continued expense of the declining cities of the Northeast and Midwest, the so-called Rust Belt. In short, capital, in its search to restore profit margins, became attracted to the cheaper land, fewer regulations, and nonunionized labor that marked much of the Sun Belt. This process was not confined to North America; Doreen Massey (1984) chronicled a similar multiscalar uneven development in the United Kingdom, as the manifestation of shifting spatial divisions of labor.

In these ways, poverty and inequality are not some accident or natural phenomenon, but actively made and remade conditions endemic to the economic system within which we live. For the spatial scientist, these conditions may have appeared to be natural, but for the Marxist this is only the surface appearance. The Marxist tradition was also not just content to produce knowledge. Like the humanist critique, the Marxist approach considered objectivity an illusion and that the spatial scientist was ultimately (wittingly or not) advancing elite agendas under the cover of objectivity. But, for Marxists, academics should also actively embrace the politics of their work by intervening in the world, changing it for the better. For these scholars, to do otherwise would be to support bourgeois practices.

In a series of articles by Harvey (1989a), urban political economy was significantly developed through a critical re-evaluation of urbanization in North America. By adopting Marx’s methodological approach of historical materialism, Harvey cast his analytic gaze on the dialectical relationship between urbanization and capitalist development. The role of technological innovations in transportation and communication was seen as transforming the urban landscape periodically – repeatedly demolishing and recreating it on a new and expanded scale. Urbanization unfolded by navigating a tension between fixity and mobility: as soon as one phase of capitalist investment materializes in the urban landscape, in the form of transportation infrastructure, housing stock, hospitals, office towers, shopping malls, and so on, this landscape becomes a prison that inhibits further growth precisely because it is (relatively) immobile. To accommodate the always enhancing flow and mobility of capital, capitalist elites, to paraphrase one of Harvey’s oft-cited passages, must walk a knife’s edge between, on the one hand, preserving the flow of value through the existing urban landscape and, on the other, having to tear down this very landscape to meet the dictates of an inherently expansionary capitalist economy.

In contrast to the humanist and the spatial science approaches, social conflict, has been a central concern in urban political economy, and is widely interpreted as a function of resistance to the effects of capitalist-induced inequality. People do not necessarily desire to live in a city that is functionalized as an incubator for capitalist profits. Rather, and usually in contrast, people desire decent housing, jobs, communities, and quality of life. And, as urban economies ebb
and flow according to the broader economy’s crisis-prone rhythms, the ability of workers, capitalists, and city governments alike to achieve their myriad and competing goals is subject to these changing conditions, with the effect of further intensifying conflict.

The humanistic critique and urban geography diversified

The influence of urban political economy has been nothing short of profound, and it remains a dominant perspective in urban geography today. It has also become quite diverse, incorporating other theoretical frames and insights in addition to Marxism. The radical turn was felt across human geography and influenced the rise of environmental studies, political ecology, feminist geography, and beyond. Urban geography was also, in turn, influenced by each of these other subfields, with scholarly inquiry in urban political economy gradually informed by insights from feminist scholars, political ecologists, and political geographers, as well as those working in emergent interdisciplinary fields, such as cultural studies.

The Marxist approach did face criticism, particularly from humanists, in the 1980s. Articulated perhaps most forcefully by David Ley and James Duncan, everything seemed to be explained by or reduced to the logic of capital. The supposed inner logic and large-scale structures are portrayed in a mystified way, with research findings ultimately resting more on belief than on empirical data. In this context, Marxism was also proclaimed as depriving people of agency: mysterious structural forces, rather than human nature, were now dictating human motivations and behavior.

This critique was levied perhaps most notably in the context of gentrification, the process of urban redevelopment whereby a low-income population is displaced by a more affluent one moving into the area. This phenomenon, although widespread and generalized today, had just begun to be noticed by urban scholars in the 1980s. Neil Smith, a student of Harvey, famously explained gentrification as the closing of what he called the “rent gap” (Smith 1996), the gap between existing land values (i.e., from low-income apartment units) in a given neighborhood and the potential values of that same land under different uses (i.e., high-income condominiums). The more depressed the land values, particularly in favorably located neighborhoods, the more likely gentrification is to unfold.

According to this thesis, gentrification should be expected in the most disinvested neighborhoods, but this has generally not been the case. Ley (1996) responded by asserting that Smith’s explanation is focused entirely on the supply side and, as a consequence, is severely limited. He argued for the importance of demand-side considerations, that gentrification is more a function of a mass of consumers seeking specific “cultural” amenities in particular neighborhoods. As such, developers must necessarily respond more to the specificities of this consumer demand than the size of the rent gap. This debate raged through the 1980s and 1990s, with gentrification now widely understood as a product of both supply and demand forces. In much Marxist thought, the rent gap is a reality, but it is mediated and complicated by particular consumption tastes, local business climates, the (re)packaging of ethnic histories and historic housing stocks, and stigmatized racialized spaces (i.e., public housing).

This debate was situated within the broader “cultural turn” that unfolded across the social sciences in the 1980s as a response to a prevailing Marxism considered too dominated by the influence of structuralism. Urban political
URBAN GEOGRAPHY

economy responded by incorporating these insights and adopting a wider methodological and analytical toolkit, which has resulted in a considerably more nuanced and diversified perspective. The outcome is an urban geography that is now quite eclectic, characterized not by the dominance of one or two paradigmatic epistemologies, but by different groups of scholars working within particular topical areas and informed by myriad cross-cutting theoretical approaches.

Contemporary urban geography (1990 to the present)

Contemporary urban geography is a discipline marked by its pluralism and multidimensionality. Spatial analysis, propelled by advances in technology, such as geographic information systems (GIS), has rebounded from the critical onslaught experienced through the 1970s and 1980s, and evolved into a more diverse and nuanced mode of inquiry. The more recent emergence of critical GIS in urban studies is a notable example of this (see the work of Sarah Elwood, Rina Ghose, Sara McLafferty, and Matthew Wilson), from research that uses GIS to examine shifting patterns of socioeconomic segregation to the differential access to resources (e.g., healthy food and health care) experienced among minority populations. Both humanistic and Marxist approaches have also been increasingly nuanced by the insights of the other as well as by a variety of new influences, such as postmodernism, post-structuralism, actor-network theory, critical race theory, and feminism. This section introduces some of the most significant thematic areas of contemporary urban geography and concludes with some brief remarks on the present moment.

The Los Angeles School of urbanism

During the 1980s it had become increasingly clear that metropolitan regions, particularly across North America, were developing in a notably polycentric fashion. No longer were cities structured around high-density cores and low-density, primarily residential, suburban peripheries. The urban/suburban dichotomy no longer made sense as the suburbs were urbanizing in the form of edge cities, and central city areas were increasingly targeted for gentrification and an entertainment-oriented “revitalization” in the form of elaborate consumption zones not unlike those of suburban shopping complexes. Urban landscapes were also increasingly marked by gated communities, hyperpoliced spaces, and a more pronounced socioeconomic polarization.

According to scholars of the emergent Los Angeles School of urbanism, cities had ceased to reflect the now outmoded concentric-ring model of the modern industrial city offered by the Chicago School. Urbanization was seen to be unfolding through a new historical layer of development, which, for these scholars, required a new set of theoretical and analytic tools to understand.

Led by Michael Dear, Edward Soja, Mike Davis, and a host of other predominately Marxist urban scholars working in Los Angeles, a new paradigm for understanding the so-called postmodern city was formed to understand the ways cities were developing (Soja 1989; Dear 2000). Los Angeles, in contrast to the classic modern industrial city of Chicago, was the empirical setting for this new mode of empirical and theoretical analysis, and was portrayed as the new prototype of the emergent postmodern city. Even in Chicago, this hyperdifferentiated layer of notably decentralized and disorderly development was superimposed on the relics of the older industrial landscape.
The Los Angeles school was based on a wide range of influences. Perhaps the most significant of these was postmodernism, which entailed a further rejection of modernist science by asserting that no objective truth could ever be obtained because all knowledge claims reflect as much the subjectivities of the researcher as the supposed truths being revealed, whether about the essence of places, powerful economic forces, or laws of spatial mobility. Michael Dear was a central proponent of this new urban geography, which incorporated insights from (and critiques of) social theorists as diverse as Henri Lefebvre, Michel Foucault, and Fredric Jameson into a new urban theory built on a taxonomy of postmodern urbanisms based on Los Angeles (Dear 2000).

Not all who were linked to the Los Angeles School were as eager to embrace the postmodern turn, however, which was impacting the social sciences in general through the 1980s. Mike Davis, for instance, rejected it, while Allen Scott and Michael Storper both tended to situate their work on emergent patterns of regionalization within the broad transition from Fordist to post-Fordist modes of production, which were marking the developed world during the 1970s and 1980s. Others criticized the claim of Los Angeles as paradigmatic and the notion that this emergent urban form represented some radical break from the past. To Harvey (1989b), the seeming disorder and chaos of Los Angeles was mere surface appearance, confusion arising from the ensuing spatial reworking of urban landscapes in accordance with the evolving dictates of an inherently expansionary capitalist economy.

This debate unfolded through the 1990s and early 2000s and is now extensive, with many of the insights stimulated by the Los Angeles School, such as the increasing polycentric and kaleidoscopic topology of metropolitan regions, now generally accepted. It also forced scholars to reflect on the part played by their own biases and subjectivities in the very knowledge they were producing. The incorporation of postmodernism into urban geography was also accompanied (indeed even influenced) by a host of other emergent epistemological approaches to the study of the city, from posthumanist studies of animal geographies (see Wolch 2002), to feminist approaches to the study of social reproduction in the household, and the experiences of women and children (see the work of Melissa Gilbert, Sallie Marston, Susan Hanson, Meghan Cope, Dolores Hayden, and Cindi Katz, among others).

**The production of space**

A number of texts by the French urban theorist Henri Lefebvre were translated into English for the first time during the early 1990s, most notably *The Production of Space* (1991/1974), which propelled another new kind of urban geography. For Lefebvre, space is a social product, an active ingredient in the constitution of the dominant mode of production driving a given society, whether feudalism, capitalism, or state socialism. Space, from this perspective, is both a constitutive variable and a mirror of the broader social system that produces it, including entire urban landscapes. In this capacity, produced social spaces also function as signifiers of symbolic meaning, or the spatial manifestation of ideological content, from, for example, themed residential housing districts (e.g., Thames Town in Shanghai) to public housing towers, urban parks, or monuments like the Empire State Building or the 9/11 memorial site in New York City.

The impact of Lefebvre, across human geography in general, and urban geography in particular, has been nothing short of profound, stimulating entire new areas of inquiry into the
URBAN GEOGRAPHY

relationships between space, the city, and capitalism. This “spatial turn” in urban geography has ranged from those engaged in the Right to the City movement and the politics of public space to those examining the myriad processes whereby social meaning is inscribed within particular spaces (see Cresswell 1996; Mitchell 2003; Merrifield 2013). In this way, Lefebvre explicitly rejected the structuralism that characterized much previous Marxist-inspired research.

Urban governance

Urban political economy was now a much more diverse perspective in the 1990s, as established Marxist insights melded with new conceptual approaches, particularly the poststructuralist emphasis on discourse. Incorporating insights from a variety of philosophers, such as Michel Foucault, Pierre Bourdieu, and Antonio Gramsci, a hybrid urban political economy perspective was developed to examine what was observed as a broad transition unfolding in the city, from urban managerialism to entrepreneurialism (Harvey 1989c). City governments were now partnering more with private actors – developers, business elites, and financial institutions – to develop policies aimed at resuscitating the city from industrial decline by stimulating private capitalist investment in the urban built environment. Now on their own to balance their budgets, city governments were spurning established social welfare provisions in favor of renewing central city areas as sites for capital accumulation (Merrifield 2014).

Scholars examining this “new urban politics” (Cox 1993), such as Jamie Peck, Roger Keil, Gordon MacLeod, and David Wilson, emphasized the discursive means of producing consent to legitimate this agenda. With mayors and developers cast as salvationists and the racialized poor demonized, the global trope was identified as a fear-based discursive formation that justified gentrification and central city refurbishment, a necessary endeavor in the face of the new harsh realities of globalization. A variety of conceptual frames – regime theory, regulation theory, and growth machine theory – were developed to study this emergent form of governance, the broader regimes of accumulation and regulation within which it is situated, and the sociospatial effects of these strategic discursive tactics (Jonas and Wilson 1999).

This research thrust also consisted of a broader critique of globalization. Identified more as a discursively constructed reality than anything else, globalization was understood less as the mysterious, actor-less force commonly portrayed by governing elites than as a process mobilized by and through the profit-seeking acts of these very governing elites. This reality was characterized by Erick Swyngedouw as “glocalization,” a term that overcomes the long-standing local/global binary that ultimately works to the advantage of the mainstream conception of globalization and the seemingly innocent localities subjected to its blistering impacts and dictates.

During the 2000s, this mode of inquiry inspired further critical theorizations of what was increasingly understood as the discursive division between culture and economy. The result was another conceptual frame – cultural economy – notably developed by Ash Amin and Nigel Thrift, Bob Jessop, and Allen Scott. These scholars have examined both the cultural dimensions of urban economies and the economic constitution of urban cultures. Parallel to this work is the influence of actor-network theory, derived from the French theorist Bruno Latour, which conceptualizes the city as a space of flows constituted by relations, networks, ideas, and material objects as signs and signifiers of a multiplicity of functions and meanings. Here, assemblages of sociomaterial relations are both
constituted within and extend well beyond the scale of the city (Amin and Thrift 2002).

Neoliberalism and the city

In the early 2000s a growing emphasis on the concept of neoliberalism emerged as an outgrowth of the burgeoning literature on urban governance. Neil Brenner and Nik Theodore’s edited volume, *Spaces of Neoliberalism: Urban Restructuring in North America and Western Europe* (2002), inaugurated what has now become a voluminous literature on the neoliberalization of the city, a process of political-economic restructuring that has been unfolding since the 1980s. Neoliberalism is a political ideology and ensemble of human sensibilities that privileges small government, deregulation, defunding of social programs, individual culpability, and the unleashing of the “free market.” Strongly promoted as the solution to the recession of the 1970s, it was first institutionalized by the Reagan and Thatcher administrations in the United States and the United Kingdom, respectively, and has since spread across the world.

The previously observed shift from government to governance was situated within the broader process of restructuring. The effect has been the drastic sociospatial transformation of urban landscapes, beginning with the rolling back of existing welfare state sociospatial structures (i.e., public housing, labor unions), followed by the rolling out of new institutional forms, policies, and practices guided by neoliberal principles, such as central city revitalization, mixed-income redevelopment, historical preservation, participatory governance, and tax-increment financing. These practices are not inherently negative, but evidence suggests that when they are mobilized within neoliberal agendas the outcome has generally been the gentrification of, and the eviction of low-income populations from, central city districts.

Research on urban neoliberalism has emphasized both its top-down dissemination from power centers (conservative think tanks, politicians, ideologues) and its contingent, uneven manifestation across urban contexts (see the work of Neil Brenner, Jamie Peck, Nik Theodore, Jason Hackworth, Roger Keil, and David Wilson, among many others). More than a simple monolithic ideology, neoliberalism is a complex, variegated institutional formation that is always mediated by local actors in a multiplicity of ways, perpetually mutating in relation to broader social, political, and economic conditions. It has also become deeply embedded in the social and physical form of the contemporary city, disciplining local populations and providing civic elites with the discursive resources and guiding rationality – from Richard Florida’s creative class to Andrés Duany’s New Urbanism – for justifying policies and practices geared toward facilitating upscale redevelopment.

Much of this research has been situated within urban political economy. Yet, within this frame, neoliberalism has been conceptualized in a number of different ways, from a set of policy prescriptions to a hegemonic ideology and mode of governmentality, with each understanding informed by a particular melding of neo-Marxian and poststructuralist insights. The literature on neoliberalism and its multifaceted impacts on the city now constitutes a significant proportion of critical research in urban geography and cognate disciplines.

World city theory

Another area of research that emerged in the 1990s is world city analysis. The sociologist Saskia Sassen first coined the concept of the global city in her now classic text *Global City: New York, London, Tokyo* (1991). Sassen provided a framework to analyze the function and
importance of cities within the global capitalist economy, and presented a conceptualization of globalization as constituted by a complex hierarchy and global network of metropolitan regions, linked together as interconnecting nodal points within this broader globalizing economy. For Sassen, New York, London, and Tokyo were the three alpha global cities in the world, the primary command and control centers propelling the global capitalist economy.

Loosely influenced by the world-systems theory of Immanuel Wallerstein, a number of urban geographers, notably Peter Taylor and his colleagues at Loughborough University, have further developed this mode of analysis since the turn of the twenty-first century. Of primary importance have been the methodological questions surrounding which variables are most important in measuring global city status and how cities are best categorized and ranked. One of the key insights is that population size does not necessarily equate with global city status. Some of the most populated metropolitan regions in the world, such as Mexico City, Lagos, and São Paulo, are not particularly high-ranking cities. Although the variables included and their degree of importance are debated, global cities are calculated by their political experience (innovations in political, economic, and business practices); their cultural experience (the ethnic diversity of the population); their information exchange (the existence of mass media and communications infrastructure for global networks); their human capital, particularly the existence of high-quality educational institutions and skilled workers in key sectors (finance, legal, and information); and the degree of business activity that takes place in them (the volume of transactions, commodities, and money that flows through sea- and airports and container facilities, and the number of multinational corporations and stock exchanges).

As the global economy expands and evolves, so does the global urban system, as some cities, such as Shanghai, Hong Kong, Beijing, and Moscow, have risen in the ranks while others have declined in importance. The shift in global hegemony from North America to East Asia is reflected in the rise of East Asian cities in the rankings. However, by some accounts, Tokyo has fallen, while other analysts have not only retained Tokyo but added Paris as a fourth alpha global city. This area of inquiry continues to attract urban scholars interested in charting the macroscale geography and evolution of the global urban system.

Urban political ecology

Urban political ecology also emerged in the early 2000s as a prominent research area within urban political economy. Its focus is ecological and environmental social issues informed predominately by Marxist insights. As such, urban political ecology can be understood as a point of intersection between physical, environmental, and political-economic domains. The city, and urbanization in particular, is a point of emphasis and is conceptualized as an always unfolding process propelling what many have termed the “metabolic” relationship between nature and the capitalist mode of production.

Developed by Erick Swyngedouw, Maria Kaika, and Nik Heynen, this approach draws inspiration from Neil Smith’s (1984) conception of nature not as a pregiven terrain on which humans exist but as a human construct itself. Based in Enlightenment notions of progress, the very concept of nature is anthropocentric, and stems from the ideological removal of humans from the so-called natural world of raw materials and nonhuman forms of life. In short, since the Industrial Revolution, nature has been conceived as an input of production, the source of
all raw materials, resources, commodities, and thus wealth. The capitalist system, essentially, is underpinned by this appropriation and transformation of nature by human labor and propelled by innovations in what is an always evolving, metabolic relationship.

Urbanization, it follows, can be understood as the process of perpetual shaping and reshaping of elaborate urban environments, or humanly constructed natures. Cities are not just social landscapes, the realm of human civilization divorced from some pristine nonhuman world, but rather are socio-natural landscapes, assemblages of people, raw materials, and resources. They are underpinned by myriad human–environment relations, from the oil that fuels human mobility to the coal that supplies electricity, the materials used to construct buildings, transportation systems, and the communication infrastructure, and the food and water (often transported over significant distance) that provide the very basis for human life and further development. Moreover, carbon dioxide is pumped into the atmosphere, fueling global warming, within or in support of the capitalist urbanization process. These various urban–nature relations are now well documented within this frame, with notable texts by William Cronon (1991) and Matthew Gandy (2002) frequently cited.

In short, the dominant Western conception of nature is based on a problematic premise, the division between the human and the nonhuman worlds. In this way, urban political ecology is also a critique of environmental conservation movements, whose object of conservation is typically some romanticized or pristine version of the same nonhuman nature. Thus, rather than promoting the conservation of nature, urban political ecologists tend to ask what kind of relationship with nature humans should construct, and in what kind of urban environments we want to live. At the core of urban political ecology are social justice, and the envisioning of a more progressive human–nature relationship and a socio-natural urban environment that privileges the majority of its human (and nonhuman) inhabitants rather than the contemporary city, which is fashioned by and for elite capitalist interests.

**Racial economy**

Only recently has the issue of race become important in urban political economy. While it was an important topic of study in urban sociology and critical race studies for decades, following David Wilson, Ruth Gilmore, Laura Pulido, and others, the specific connections between race and political economy have been only minimally examined. Racial economy, to Wilson (2009), is a perspective that explicitly analyzes race as a constitutive force within the unfolding of urban economies. Here, race is understood as a social construct rather than as an objectively existing thing, and functions as a semiotic resource drawn on by governing actors in their rhetoric justifying and shaping urban redevelopment agendas.

Research in racial economy is now diverse, from studies examining the role of race in narratives of industrial decline to the disproportionate targeting of the racialized poor by the rapidly growing prison industrial complex and the deepening marginalization of low-income racialized populations in the neoliberal period. Much of this work tends to be marked by qualitative methods such as ethnography, deconstruction of texts, and historical analysis. In general, race is conceived as a human construction and an expedient opportunity structure through which governing actors pursue their profit-seeking interests. In the process, such actors are seen to navigate people’s passions and predilections concerning race, as a racialized cast of characters (i.e., the demonized drug dealer or, more
recently, the civically responsible entrepreneur and corresponding imaginative spaces (public housing towners, ghettos, and gentrified townhomes) are discursively choreographed to the tune of central city revitalization.

Another area of inquiry within this perspective stems from the work of Elvin Wyly, Daniel Hammel, Phil Ashton, and Daniel Immergluck, among others. Here, for example, spatial analyses of quantitative datasets are mobilized to reveal the perpetuation of discriminatory lending patterns by financial institutions through the dissemination of subprime mortgages to previously untapped populations, such as Latinos and African Americans. Reflecting a kind of critical positivism (Barnes 2009), the analytic tools of spatial science are here melded with critical social theory to illuminate the uneven power relations operating behind a financial industry mobilized less by extending opportunities for homeownership to historically excluded populations, as was frequently pronounced, than by channeling accumulated financial capital (in the form of subprime mortgages) to new outlets for capitalist investment.

Current trends: the post-2008 crisis and planetary urbanization

The current moment tends to be marked by the influence of the global financial crisis of 2007–2009 and the myriad uneven impacts these events have had on cities around the world. Particularly noteworthy has been a plethora of commentary concerning the fate of neoliberalism amid what many have interpreted as a crisis of its own making. Despite initial pronouncements of the demise of neoliberalism, a consensus has emerged that not only have we not entered a post-neoliberal world, but that this mode of rationality has only been enlivened as a means of justifying business as usual (i.e., fiscal austerity, further cuts to social programs).

Others, such as Eric Sheppard, Andy Merrifield, and Neil Brenner, have proposed that significant reform is needed to the existing arsenal of theoretical tools urban scholars have at their disposal for understanding the city. For some, such models are disproportionately based on the cities of the Global North, particularly in the United States and the United Kingdom, which should be clear from this entry. In short, urban theory is in need of revision through analysis of the Global South, particularly the most rapidly urbanizing cities in East and South Asia, cities that do not necessarily reflect the various paths of development taken in the Global North. Indeed, much urban research now emphasizes the experience of cities in, for example, China, India, and postsocialist Central and Eastern Europe.

Moreover, the process of urbanization is now planetary, with more than half the world’s population living in areas classified as metropolitan. Words like “city” and “urban” have lost their former meanings as some of the largest metropolitan regions – Tokyo, Shanghai, Moscow, and Los Angeles – now extend hundreds of miles in any direction. Even rural communities are now shaped by and plugged into the global urban network. The world is becoming increasingly urbanized and linked through social and mass media. As such, resistance movements have also become global in that, everywhere from the global Occupy movement to the Indignados in Spain, from the revolts in Tahrir Square in Cairo to Syntagma Square in Athens, Iran, Tunisia, and beyond, social media and a greater global awareness among people in distant places can swiftly mobilize a critical mass of people in any public square. These emergent dynamics of urban resistance are now increasingly the focus of scholarly inquiry and debate.
Others have argued for more scholarly attention devoted to what Jennifer Robinson (2005) has referred to as “ordinary” cities. Here, understanding the city and urban processes is too reliant on overly studied large global cities like New York, Chicago, or London. The experiences of these cities do not necessarily reflect those of smaller, medium-sized cities, and may, in fact, be more exceptional than paradigmatic. The critique of this assertion, however, has been that all cities exhibit some broader structural patterns combined with local contingencies, and that a focus on ordinary cities, while not unimportant, may not reveal anything particularly novel or thought-provoking in how we understand the contemporary city.

This entry has provided an expansive account of both the historical development of urban geography and the major areas of inquiry that currently constitute the contemporary discipline. It does not, of course, capture everything, as urban geography is now far too diverse to comprehensively review in a single entry of this length without omissions; however, it is hoped that this entry can be used as a point of departure to further investigate the conceptual approaches and historical periods that have been discussed, as well as the key texts cited and recommended.

Haggett, Peter. 1965. Location Analysis in Human Geography. London: Edward Arnold.

Urban managerialism developed as a framework for applied urban-scale policy research in the 1970s. As originally conceptualized, proponents of what became known as urban managerialism advocated for a focus on a class of professionals who, by virtue of their positions in state or parastate organizations, had “control” over the allocation of scarce resources in cities. These professionals were given various labels: gatekeepers, controllers, or simply managers. Conceived specifically in analyses of the operations of the British welfare state by sociologists, urban managerialism became embedded in methodological and theoretical debates and practices at the intersection of urban sociology, human geography, and urban studies for about 20 years.

It is important to note, for the sake of clarity, that the phrase managerialism was also used to denote a phase of urban governance. Here, the function of the local state was seen to be as manager of the provision of services (known as collective consumption) as well as a variety of place-based economic development functions at the urban scale. In this account, as the epoch of global neoliberalism and late capitalism unfolded, urban managerialism gave way to new forms of governance with state actors engaged in an array of public–private partnerships. This new phase of governance was captured with the concept of urban entrepreneurialism (Harvey 1989).

Here we will focus on scholars who worked with the original and subsequent conceptualizations of urban managerialism. They used this methodological lens and framework for analysis to examine the interplay between individual autonomy and organizational constraint in urban-scale governance which also, coincidentally, came to include the types of governance changes seen in the transition to urban entrepreneurialism.

The phrase urban managerialism originally coalesced in the writings of British urban sociologist Ray Pahl – particularly in the classic book Whose City? (Pahl 1970). This widely read book catalyzed debates over the interplay between a focus on collective consumption and work-place or production-based class struggles. Through analyses of access to, and distribution of, scarce urban resources and facilities, Pahl isolated the role of “controllers” in both the public and the private sector. In this earliest formulation, the scarce resources and facilities were often in the housing sector, with urban managers – or gatekeepers, as they were sometimes called – directly involved with the provision of housing units themselves. But it also included actors linked to sales and marketing, finance, and management. The housing sector studied included both owned and rental units. Many facets of the character of “controllers” were also examined, including their individual value systems and political and class ideologies. In Pahl’s formulation, which has endured in other scholars’ work, inequality through the uneven allocation of resources at the urban scale influenced the life chances
of individuals and groups who were already subjected to inequality in the world of work (the production sector) and therefore deserved an explicit and sustained research effort.

Early debates about this approach to the analysis of urban space and resources revolved around the tension between proponents of a progressive welfare state, which included Pahl, and others, including David Harvey, who saw these urban-scale allocations of resources as a sideshow to the “main event” of the inequalities systematically produced by capitalism. Critics questioned both the authority of local-scale actors and their autonomy to act. Pahl himself had struggled with this contradiction as well as with more focused critiques which questioned which specific managers were worthy of study and for what reasons. In fact, in a revised version of the original book and in other writings, he reformulated his original thesis to move away from a direct causal role for managers. It’s fair to say that for his critics, Pahl’s adaptations further undermined the relevance of the urban managerialist framework itself. This was especially the case in the United Kingdom as the welfare state was dismantled or hollowed out through privatization or through the imposition of market-based rules and structures which privileged narrow quantitative measures of “success.” This retrenchment of the state occurred under the leadership of both the Conservative Party and the Labour Party.

Several scholars, however, continued to focus on the interplay between the broader power relations of capitalism and the actions of gatekeepers or managers. Peter Williams was a key contributor to the collation and evaluation of empirical work in the late 1970s and early 1980s, and to a brief resuscitation of urban managerialism in the United Kingdom. In the United States, meanwhile, urban geographer David Wilson was also actively applying aspects of the approach to studying urban change (Wilson 1987). Wilson’s empirical investigations included both urban revitalization and the implementation of the United States Federal Community Development Block Grant program, which focused on housing, infrastructure, and other urban-scale redevelopment. He argued for the continued potential of an examination of the complexities of the blending of the individual life paths of gatekeepers with the institutional and organizational development of urban resources. The resulting accounts and analyses of the decision-making processes of managers, and their impact, recognized that while specific historic and material circumstances constrain the behavior of “managers,” they do not determine them. While considering broader political and economic changes and the structural design and rules of individual programs and local conditions, there was still room for explorations of the intentional actions of managers who had direct access and control of “scarce resources.” This brought Wilson and others full circle to the analytical power of some of sociologist Pahl’s original formulations and to rich, place-based accounts of urban change.

It is important to note that the focus of this later work was not restricted to distributional aspects of housing and other so-called scarce resources but was also applied to aspects of commercial redevelopment, urban revitalization, and neighborhood change. Here we see the analysis of the constrained behaviors of actors by Wilson and others finessing the either/or dichotomy of structure and agency which was the focus of intense theoretical debates at the time. This middle-level analysis was a contribution to debates and discussions of the hollowing out of the state, the development of new forms of local growth machines and place-based urban redevelopment, and the critical examination of state and parastate organizations. The lens
of urban managerialism and other facets of organizational analysis were deployed to examine the structure–agency contradiction through a synthesis with tenets of urban political economy.

The earlier tensions between studies focused on collective consumption and “sites of production” ameliorated somewhat as an ultra-commodified urban real estate sector, in all of its complexity, became the site for windfall profits, speculative investment, and place-based displays of wealth and power. It also provided cheek-by-jowl evidence of economic and social inequality as a context for interrogations of place-based economic and political processes.

The attentions of scholars in urban geography moved much more toward the analyses of urban entrepreneurialism and public–private partnerships for economic growth and away from a distinct focus on managers or gatekeepers per se. As a result, the explicit lens and conceptual label of urban managerialism has diminished in visibility in more recent times. However, insights from urban managerialism were deployed in analyses of the housing and service economies of the socialist and transitional economies of Eastern Europe and China.

Most recently, though less explicitly, examinations of urban governance driven by critical network theory, new institutionalism, and critical policy studies, reveal a deep and continuing concern with the complex interplay between organizational structure and regulatory and programmatic design, and with the autonomy and authority of “controllers” at various spatial scales. These studies include examinations of the provision of housing and other services but also broader topics related to urban redevelopment and local-scale sustainability. They are typically embedded in the discourses of stakeholder processes, and the interplay or even interchangeability between state actors as place-based entrepreneurs and capitalists as place-based managers in local applications to urban-scale social and economic change.

The establishment of multiple racial and ethnic groups in cities often results in a patchwork of neighborhoods that can aptly be described as an urban mosaic. The urban processes that lead to an urban mosaic were described as far back as the Chicago School, by the sociologists Park, Burgess, and McKenzie (1925). The Chicago School sociologists were a group of human ecologists who used Chicago as their laboratory to learn how immigrants locate in the city. At the time of their writing, Chicago was a major port of entry for European immigrants (i.e., Italians, Germans, Polish, and Irish) who settled in distinct and separate neighborhoods. The human ecology principle of competition served as the primary organizing agent where, under the pressure of competition, ethnic groups carved out residential and functional niches within the city. The effect was to segregate people of similar origin into relatively homogeneous residential and functional subareas of the city.

Following this tradition in urban studies, the phrase “urban mosaic” was adopted as a title of a book in the mid-1970s (Timms 1975) to illuminate residential patterns in US cities. Yet, 20 years earlier, the quantification of city patterns using the techniques of social area analysis had begun to reveal neighborhood patchworks. Social area analysis attempted to describe and explain ethnic clusters within cities. Shevky and Bell (1955) first initiated social area analysis in the study of Los Angeles and San Francisco, using three groupings of variables they labeled social rank, family status, and ethnic status. The social area analysis method became widely used in the 1960s and was enhanced by computers that could handle large census datasets. The technique became known as factorial ecology (Berry and Kasarda 1977). Factorial ecology lasted as a leading methodology to investigate the city through the 1970s and 1980s, with the following common findings of the variable groupings:

- social rank or economic status exhibited sectoral characteristics;
- family status exhibited a concentric ring pattern; and
- ethnic status variables formed clusters.

Timms (1975) overlaid these findings of social space onto the physical space of the city to demonstrate a pattern he referred to as the urban mosaic. Today, the urban mosaic pattern persists in cities, but much of the contemporary discussion is embedded within the segregation literature, with debates ranging from those who see a rise of diverse multi-ethnic neighborhoods to those who suggest that the segregation of racial and ethnic groups persists.

URBAN MOSAIC

Urban planning: human dynamics

Bruce Appleyard
San Diego State University, USA

Historically, one of the main forces driving the creation of physically proximal collective human settlements (villages, towns, cities, and metropolises) is the utility gained from interpersonal and inter-collective exchanges of goods, services, knowledge, sociocultural support for reasons of prosperity, security, love, learning, enlightenment, satisfaction, hope, and so forth.

As interpersonal communication is a central requirement of these exchanges (gestures, spoken and written language), early advances in personal telecommunications (telephone, fax, and computer) and mobility (automobiles) loosened spatial requirements for people to live and work in close proximity to one another to conduct such exchanges face-to-face. However, recent rapid increases in the availability and power of mobile hand-held devices enabling dynamic, on-demand exchanges in urban environments, improving people’s ability to navigate and execute the exchange and management of goods and services to meet their wants and needs (also known as “urban access”), is central to the sharing economy phenomenon emerging in the early twenty-first century and may significantly transform human settlement and behavior patterns (Appleyard 2013; Figure 1).

Origins of urban planning

Modern urban planning originated in response to the poor and overcrowded living conditions of the mid-nineteenth century cities, rapidly transformed by the Industrial Revolution. Public response was galvanized by writers such as Friedrich Engels in the United Kingdom and newspaper reporters (also known as “muck-rakers”) such as Jacob Riis in the United States who exposed abuses in tenement housing in his 1890 book How the Other Half Lives.

Modern urban planning grew as a profession to improve the health, safety, and welfare of overcrowded industrializing cities by focusing on technical and political processes guiding such things as the orderly use of land and the provision of infrastructure (streets, water, and sewer). In the mid- to late twentieth century, sustainable development, livability, and social equity came to represent ideal outcomes of all urban planning goals.

Early on, several key movements formed around the redesign of cities. One of the most notable city redesign efforts was Georges Eugene Haussmann’s redevelopment of Paris, between 1853 and 1870, undertaken during the rule of Napoleon III. Drawing on Baroque, axial planning ideas with terminating vistas, Haussmann carved new wide boulevards through the city linking important public places (parks, civic buildings, and rail stations). The boulevards were lined with trees and mandated six stories of housing over groundfloor retail
The ubiquitous use of GPS-enabled mobile hand-held devices that can facilitate dynamic, on-demand exchanges, and knowledge acquisition, such as how much time it will take until a bus arrives, are improving people’s ability to navigate urban environments and improve the quality of a transit rider’s experience. Photo by Bruce Appleyard.

An innovatively new municipal sewer system was also built beneath the boulevards. At the time, Haussmann’s work was admired worldwide as the model of city modernization. However, following the excesses and failures of modern urban renewal projects in the 1950s, Haussmann’s work has been criticized as an expression of positivism and political subjugation for how it cleared out old working-class neighborhoods that were areas of unrest, displacing many, mostly poor, people. Nevertheless, the boulevards of Paris are viewed as an important invention in urban planning as they not only opened up vast areas of the inner city to the public, providing sunlight, space, and “breathing room,” but they also forced the middle and upper classes to confront the reality of urban, working-class poverty as people from the dense surrounding urban areas spilled out onto the boulevards. The boulevards also introduced modern traffic to the inner city by providing wide, unencumbered roadways allowing private carriages to move at much faster speeds than previously possible (Larice and Macdonald 2012).

In addition to Haussmann’s modern redevelopment of Paris, other urban planning movements grew in response to overcrowding and poor living conditions of the Industrial Revolution, as follows:

- the parks movement,
- the city beautiful movement,
- the city efficient movement,
- the garden city movement,
- the modernist movement,
- New Urbanism and a place agenda.

The parks movement

During the time of Haussmann’s reconstruction of Paris, the works and writings of Frederick Law Olmsted Sr (1822–1903) bore the beginnings of the US parks movement. In 1858, Olmsted, with his partner Calvert Vaux, won the competition to design New York City’s Central Park, an 843 acre open space carved out of the city’s street grid pattern (designed in 1813). Viewed as the founder of modern landscape architecture, Olmsted believed that naturalistically designed parks with gentle landscapes offering views of pastures, meadows, and calm waters could play a central role in counteracting what he saw as the debilitating physical and mental stresses of living in crowded and congested urban settings.

The city beautiful movement

The 1893 Columbia Exposition in Chicago, led by Daniel Burnham, melded both the parks and city beautiful movements. Sponsored by local civic groups, and led by activists (mostly women), the implementation of these
movements advocated for improving the public realm through such elements as street lighting, fountains, ornamental plantings, shade trees, public art, and classically designed civic buildings and centers. While short-lived (mostly between 1900 and 1910) and derided for being concerned only with shallow design tastes of urban elites, the city beautiful movement is credited with historic preservation movements of the 1970s and maintaining focus throughout the city efficient and modernity movements on valuing urban aesthetics.

The city efficient movement

City beautiful began to give way to the city efficient or city practical movements in 1909, where many speakers at a 1909 Washington, DC, national conference on city planning prioritized efficiency and economy over beauty. Critics of “city beautiful” had varying complaints, such as largely ignoring solutions for the problem of overcrowded urban housing. But the prevailing beliefs were that city planning should foremost make cities more efficient, particularly in transportation and land use. Although city planners often ridiculed the city beautiful movement after 1909, elements of the city beautiful existed in dozens of city plans drawn up during the 1910s, such as park systems and civic centers. But the emphasis of city plans increasingly shifted to traffic and transportation.

Eventually, city planners would seek two types of authority. The first involved increasing cities’ powers to finance improvements, such as by raising debt limits and issuing special assessments for projects. The second involved greater public control over private property. The most notable result was the development of zoning laws. Zoning, initially known as districting, placed limits on the type of development that could take place in a particular area. Starting in California in 1908, at least 20 cities had adopted zoning proponents of the city efficient movement and had attempted to distance themselves from the city beautiful movement, but the movements were in many ways two steps on the road toward modern urban planning. For the first time in the history of the United States, a profession developed around the goal of shaping the development of the urban environment. Although efforts had been made in the nineteenth century to guide city building, the city beautiful and city efficient movements were the first attempts to deal with the issue on a citywide scale rather than on a piecemeal basis by 1917.

While different, both the city efficient and the city beautiful movements are viewed as major steps toward modern urban planning. Both represented initial attempts to deal with the issue on a citywide scale rather than on a piecemeal basis.

The garden city movement

The garden city movement was one of the most influential planning and design ideas of the late nineteenth century for providing a remedy to the perceived ills of the crowded and congested conditions of the nineteenth century city. The garden city concept was most influentially articulated by Ebenezer Howard in his 1898 book, To-morrow: A Peaceful Path to Real Reform, which was then reissued in 1902 as Garden Cities of To-morrow. In sum, Howard’s garden city concept provided a new vision of urban life that responded to the poor conditions of an industrial city in the following ways.

1. It envisioned new settlements that brought production and workers out of the tenements of the cities.
2. It also balanced agrarian ideals without ignoring the rise and utility of the capitalist, manufacturing economy, as shown
in Howard’s the “three magnets” diagram, shown in Figure 2.

Howard’s “three magnets” represent elements of both town and country, but showing a clear preference toward creating human settlements balancing town/country characteristics. More than just a physical plan for design, Howard’s vision included details on a garden city’s government/organizational structure and financing. For example, Howard provided guidelines that a limited dividend company should borrow money and buy land in the relatively cheap countryside and that the increased value brought on by development should help fund the enterprise. He also believed that each garden city should be limited in size – no larger than 1000 acres, or 32,000 in population – and surrounded by a large greenbelt with farms as well as some institutions. Once a garden city would reach its limits, new garden cities should then be created as part of a regional network connected to other garden cities and to the central city by rail transit lines.

Unlike other utopian visionaries, Howard saw his ideas put into practice, although in somewhat compromised form. In England, Letchworth (1900) and Welwyn (after World War I) garden cities were built. In the United States, new deal greenbelt towns, Sunnyside (Queens, New York) and Radburn (New Jersey), are the closest examples.

In the United States, concerns with the rise of the automobile and how “raging streams of traffic” were impacting neighborhoods led Clarence Perry to build on the garden city concept proposing the formation of “neighborhood units” within which schools, local streets, and parks would be located and protected from through traffic in such a way that “children should never be required to cross a main traffic street on the way to school” (see Figure 3).

As only parts of the physical concepts of both the garden city and neighborhood unit were mostly adopted in practice, they served as a foundation for suburban development the world over. In an overwhelming number of cases, these new neighborhoods lacked key benefits of both Howard’s and Perry’s visions for such elements as a balance between jobs, housing, and retail; organized around transit; walkability; and equitable access to all.

City planning’s modernist movement

The Swiss/French architect Le Corbusier (1887–1965) envisioned bold, rational, efficient, and technology based approaches to urban development. Le Corbusier provided powerful images of high-rise residential “towers in the park” and elevated highways serving segregated...
flows of traffic swooping through and out of cities. In the United States and elsewhere, these ideas spurred countless central city urban renewal projects, displacing thousands of people, mostly of low-income and minority groups. Le Corbusier was also a founding member of the Congrès Internationaux d’Architecture Moderne (CIAM), or International Congresses of Modern Architecture (created in 1928 and disbanded in 1959). CIAM espoused its modernist philosophy in its 1933 manifesto, the Charter of Athens.

After World War II, the decentralizing forces of suburban development exploded driven by aspects of both the modernist approach (building grade-separated freeways) and garden city ideals and fueled by technological advances (personal automobiles, telephones). In the United States, urban planning practice specifically facilitated suburbanization through zoning with exclusionary provisions (minimum lot sizes, lack of multifamily housing); the building of the interstate highway system and designing local streets solely around automobile travel (in many cases lacking sidewalks entirely); and US government policy favoring home ownership by insuring home mortgages (Figure 4).

New Urbanism and the rise of a “place” agenda

A number of urban theorists, dissatisfied with the increasing homogeneity and soullessness of mid-twentieth-century urban spaces, in both garden city-inspired suburbs and modernist inner-city urban renewal projects, began questioning current approaches. Early on, Jane Jacobs soundly refuted Le Corbusier’s ideas and those of the modernist movement in her 1961 seminal book, *The Death and Life of Great American Cities* (Jacobs 1961).

In the 1960s, with the rise of a hyper-networked society in view, some thought that the importance of city centers and quality urban places may fall by the wayside. Webber’s 1964 paper “Urban Place and the Non-Place Urban Realm” introduced the idea of “community without propinquity” (which is nearness in space, time, or relationship). He suggested that technological advances in communication and mobility would directly undermine some of the main historic forces pulling people to agglomerate in urban settlement, mainly the utility people gain from exchanges over knowledge, goods, services,
the arts, and so forth. Webber argued strong city-center metropolises would disperse toward suburban clusters, determined primarily by social links and economic networks in a “non-place urban realm.”

While there are findings of dispersion and centralization on both sides, people’s preferences for quality urban places and city centers remain, at least to a certain extent (Florida 2002, 2014). Given this, it is therefore important to study the influence technology, such as GPS-enabled mobile devices (smartphones) and their ability to facilitate people’s “civic operation” and exchanges in and around urban environments, so we can better understand and plan for future human settlement and behavior patterns.

In 1982, Donald Appleyard and Allan B. Jacobs authored *Toward an Urban Design Manifesto* (Appleyard and Jacobs 1982), which took on the Charter of Athens and the garden city concept for their overly strong and unrealizable utopian programs in response to the physical decay and social inequities of the industrial city. Instead they called for an urbanism based upon social objectives and upon how people live and experience cities and space, espousing more human-scaled development. Inspired by this and other writings, urban designers sought ways to
recreate what were felt to be the best physical qualities of traditional neighborhoods and small towns – mixed uses, local shopping, connected street grids, community parks, rear alleys, and front porches.

Initially referred to as “traditional neighborhood development” (TND), New Urbanism, and, later, as “smart growth,” one of the catalytic events in this movement occurred in 1991 when some of the nation’s most influential urban designers and architects gathered in Judy and Michael Corbett’s home in Davis, California, to conceive the Ahwahnee principles which, in 1993, would provide the foundations for the professionally based Congress of New Urbanism (CNU). In 1996, CNU published its charter of New Urbanism which espoused 27 guiding principles organized according to three interrelated spatial scales: metropolis, city, and town; neighborhood, district, and corridor; and block, street, and building. The New Urbanist theorist Peter Calthorpe re-conceptualized the garden city idea in the form of transit oriented developments (TODs), placing prominence on linking urban settlements by public transit networks.

Broader goals for urban planning: social equity, sustainable development, and livability

While social reformers, such as Jane Addams, pioneered social programs to help the poor immigrant populations around the turn of the twentieth century, the urban planning profession focused more on the technical, aesthetic, and political processes to guide things like the orderly use of land and the provision of infrastructure such as streets, water, and sewer. During the latter half of the twentieth century, however, social equity, sustainable development, and livability emerged to represent ideal outcomes of the sum of all planning goals.

Social equity emerged anew in response to discriminatory and unfair housing practices and the displacement of poor, minority communities for urban renewal projects, interstate highways, and other major projects. One of the first to conceptualize “advocacy planning,” Paul Davidoff (1930–1984), argued that a planner could speak for the interests of a group or individuals’ affected plans, but such a planner may have limited influence and not be included in the planning process (Davidoff 1965).

In 1961, the federal government took action in response to problems of the urban poor by passing the 1961 Housing Act which had provisions for housing, public transit, and open space acquisition. In 1964, President Johnson led the passage of four major pieces of legislation for urban populations, including the Civil Rights Act, the Economic Opportunity Act, the Housing Act (which provided $750 million for urban renewal, but also included funds for renovation of existing homes), and the Urban Mass Transportation Act (UMTA) which provided $375 million mass transit.

In response to the urban riots of the mid-1960s, President Johnson convened an advisory commission on civil disorders (Kerner Commission 1968) to study the causes of the riots in order to guide federal policies. The report released on February 29, 1968, made clear and concise findings on how the riots were the result of systematic discriminatory practices against African Americans, denying them critical opportunities and fostering their racial isolation in inner city ghettos.

In light of the riots and Kerner Commission findings, Congress in the Spring of 1968 considered new fair housing legislation, but was unable to make significant progress until April 4, 1968, the day Dr Martin Luther King Jr was assassinated. Since the summer of 1966, Dr King had been strongly in the fight for fair housing.
On April 10, 1968, Title VIII of the Civil Rights Act of 1968 (Fair Housing Act) passed, prohibiting discrimination concerning the sale, rental, and financing of housing based on race, religion, national origin, and sex.

By the mid-twentieth century, air, water, and chemical pollution emerged as major national issues in sustainability and the rise of the environmental movement. One of the most influential books to jumpstart the environmental movement was Rachel Carson’s 1962 *Silent Spring*, which documented the damaging effects of DDT and other pesticides on birds (particularly songbirds) and other species. Up until then, such chemicals were regarded as epitomizing progress through technology. By 1965 DDT was outlawed in the United States. Meanwhile air and water pollution had emerged as serious problems. In 1969, Cleveland’s Cuyahoga River caught fire and Los Angeles appeared to be continually overtaken by air pollution. Following Rachel Carson’s lead, there were increasing studies of the damaging health effects of air and water pollution.

The rapid rise of the environmental movement during this time was an unprecedented political and social paradigm shift in US history marked by the millions who celebrated the first Earth Day on April 22, 1970. By the mid-1970s, most Americans identified themselves as environmentalists. The following are some of the major policy milestones. On January 1, 1970, the National Environmental Policy Act passed, requiring full disclosure and scientific analysis of the environmental impacts of general policies and projects. In his 1970 State of the Union address, Richard Nixon declared clean air and water legislation to be at the center of his domestic agenda, leading to the bipartisan passage of the Clean Air Act (CAA) in 1970 and the Clean Water Act (CWA) in 1972. Nixon also argued for creation of a one-stop environmental policy agency, leading to the establishment of the Environmental Protection Agency on December 2, 1970.

In 1972, the environmental movement entered worldwide prominence at the UN Conference on Human Development in Stockholm where the international community first met to consider global environment and development needs, leading to the creation of UNEP, the UN Environmental Programme. In 1987, the UN created the World Commission on Environment and Development (also known as the Brundtland Commission), which produced the 1989 report, *Our Common Future*. This report presented the UN’s definition of sustainable development with the central theme being that growth “meets the needs of the present without compromising the ability of future generations to meet their own needs.”

In the first decade of the twenty-first century, in order to combat climate change, California passed several climate action initiatives requiring the public agency to lower greenhouse gas (GHG) emissions.

In the 1960s and 1970s, *livability* emerged as an objective to go beyond minimum standards of environmental quality and social equality to include a broader range of characteristics allowing people to achieve higher levels of quality of life. One of the first works to clarify and popularize the concept of livability was the 1981 book *Livable Streets* by Donald Appleyard, which revealed the detrimental impacts automobile traffic had on the quality of life on streets for other users. This work laid the foundation for later work by his son, Bruce Appleyard, who proposed a set of livability ethics which argued that one’s pursuit of livability (such as a driver speeding down the street in a car) should not be allowed to unduly impact the livability of those trying to more humanly experience the street environment, such as walking, talking.
with neighbors, or resting (Appleyard, Ferrell, Carroll, and Taecker 2014).

On June 16, 2009, livability was formalized as federal policy when the secretaries of HUD (US Department of Housing and Urban Development), USDOT (US Department of Transportation), and EPA (US Environmental Protection Agency) introduced the six livability principles of the sustainable communities partnership, which sought to promote transportation choices (walking, bicycling, transit); housing affordability; access to employment, education, and service opportunities; target federal policies and funding within existing urban areas served by transit – also referred to as “smart growth” or transit oriented development (TOD) – and, finally, to coordinate federal policies and funding with all levels of government to plan more effectively for future growth. Many efforts have been made to capture and cross-reference associated metrics and indicators of livability, sustainability, and social equity. One of the most promising initiatives has been the livability calculator which provides a comprehensive understanding of a community’s performance in relation to the six livability principles of the EPA/HUD/USDOT sustainable communities partnership (Figure 5).

**Origins of human dynamics**

The term “human dynamics” finds some of its origins in the study of personality dynamics and statistical physics and refers to a body of work begun in 1979 by Dr Sandra Seagal and her associates on the distinct inner processes in the way people inherently learn, assimilate information, relate, communicate, approach tasks, problem solve, contribute to others, respond to stress and trauma, and maintain health and wellness. The early research into these fundamental distinctions in people emerged as a result of a discovery related to the human voice; namely three frequencies that corresponded to a high, middle, and low frequency. These three frequencies, or capacities of a person, were organized into the following principles – mental (objective), emotional (relational), and physical (practical).

The current concept of “human dynamics” emerges from the convergence of new developments in spatial science, mobile technology, big data, and social behavior research. According to Dr Ming-Hsiang Tsou, professor and founder of the HDMA center at San Diego State University, “Human Dynamics is a transdisciplinary research field focusing on understanding the dynamic patterns, relationships, narratives, changes, and transitions of human activities, behaviors, and communications” (Tsou 2015).

**Disruptive innovation and the sharing economy improving our urban access**

The advances in hand-held devices and their ability to improve people’s ability to navigate...
Figure 6  Geo-locating Twitter feeds related to transit corridors in the Washington DC metro area, based on transit corridor livability typology work by Appleyard, Ferrell, and Taecker (2016). Integrated corridors are green; transitioning corridors are yellow; emerging corridors are red.

Urban environments as well as to engage interpersonal exchanges central to the emerging “sharing economy” – in short, improving our “urban access” – are becoming major forces influencing human settlement and behavior patterns. Such innovations can be viewed as part of the “spatial turn” or the humanities-based quantitative study of “place” as facilitated by the emerging technological advances such as GIS and access to data on mobility patterns and preferences from dynamic mobile devices (see also Figure 6). These new capabilities can also be viewed as a “disruptive innovation,” a term first coined by Bower and Christensen in 1995 and later, in 1997, by Christensen. A disruptive innovation is an innovation that helps create a new market and value network that eventually disrupts an existing market and value network (over a few years or decades). Such innovations improve a product or service in ways that the market does not expect, typically, first, by designing for a different set of consumers in a new market and later by lowering prices in the existing market. And since these new technologies create and/or serve emerging market segments that are not being served by existing stewardship systems, the field of urban planning and human dynamics (UPHD) seeks to also help
decision-makers and institutions understand how to appropriately integrate these new capabilities into current practices.

Theoretical foundations of urban political ecology

Urban political ecology (UPE) has a distinctly Marxist origin. The analysis of urban form and social process within UPE is an effort to better incorporate the ways capitalism not only produces cities but also produces nature in cities at the same time. The Marxist geographic logic that led to the development of UPE can be clearly connected to the work of David Harvey, Neil Smith, Henri Lefebvre, and Manuel Castells, as well as other key scholars. While the explicit attention to urban form is what is most recognized in discussions of UPE, wrestling through the centuries-old struggles to reunite the ideas of nature and society is just as central to UPE and especially important for recognizing the early Marxist influence. This rings clear when Smith (2006, xii) said:

Enlightenment thinkers from Newton to Kant, Adam Smith to Montesquieu – and many others – answered the demand to understand the externality of nature. This is neither to diminish their contributions necessarily, nor to cast aspersions on their accomplishments, but it is to contextualize the ideological power that their contributions came to have. In many ways, the stunning question today – still almost unaskable – is not how to reconcile nature and society, how to understand the “interaction” of nature and society – the agenda of most in the environmental movement – but how western ideologies could have got to the point of flattering themselves so successfully that they were somehow separate from nature.

As the rapidly growing literature demonstrates, a central contribution of UPE asks this very question: How do we pull back the Western mindset regarding the separation from nature in its urban form? UPE scholars have sought to do this from its earliest efforts through urbanizing discussions about “metabolism.” These scholars have also pushed toward a deeper understanding of how the metaphorical rendering of metabolism offers a way to cut through the dualisms that have historically been problematic for the discussions of nature and society. However, UPE scholars have also taken seriously the egalitarian potential that is embedded within a robust conceptualization of urban metabolism. This is another distinguishing characteristic of this literature. In seeking to roll back the historically imposed separation of urban nature and urban society, many working within UPE have sought to replace it with an ideology of urban nature’s revolutionary potential.

The idea of metabolism goes back to Marx within socio-natural theory. This idea of creativity continues to be expressed through interrelated and interconnected socio-natural urban processes. Their resulting uneven configurations are a main contribution of UPE. UPE scholars have been working to articulate urban metabolism as a dynamic process. Central to this is showing how new sociospatial formations, entwinings of materials, and collaborative enmeshing of socio-nature emerge through human labor and nonhuman processes simultaneously.
Too narrow a focus on “ecological” processes within urban ecology opened up a critique that helped facilitate the development of UPE. Much of the urban ecological approach excludes the role of uneven social power relations. These critiques opened pathways for thinking about the urban interactions between political economy and nature using a more holistic and dynamic approach. To this end, David Harvey notably suggested:

It is inconsistent to hold that everything in the world relates to everything else, as ecologists tend to, and then decide that the built environment and the urban structures that go into it are somehow outside of both theoretical and practical consideration. The effect has been to evade integrating understandings of the urbanizing process into environmental-ecological analysis. (1996, 427)

However, a study originating in urban ecology necessitates that primacy be given to urban space, form, and process. Alternatively, ecological processes, while implicit in much of urban cultural research, often tend to simply play the role of backdrop for other spatial and social processes.

**Becoming urban political ecology**

While in the past there have been ideas, logics, and empirical research that sounded like what we call UPE today, it was not until 1996 that Erik Swyngedouw named “urban political ecology” as such. Swyngedouw explicitly articulated the significance of urban studies traditions up to that point, while simultaneously highlighting their intersection in the theoretical strands of political economy, political ecology, and science and technology studies (STS). This is an important moment in thinking about the city, as Swyngedouw discussed uneven development in a synthetic language bringing together “representational,” “discursive,” “ideological,” “material,” and “biochemical” constellations of power relations through the notion of urban metabolism. If there is a founding passage for what we call UPE it was when Swyngedouw suggested:

In the city, society and nature, representation and being are inseparable, integral to each other, infinitely bound-up, yet simultaneously this hybrid socio-natural “thing” called the city is full of contradictions, tensions and conflicts … Only over the past few years, a rapprochement has begun to assert itself between ecological thinking, political-economy, urban studies and critical social and cultural theory. This may provide the ferment from which a new and richer urban ecology or urban political-ecology may germinate. (1996, 65–66)

As engaging urban nature seemed a logical continuation of Marxist approaches to the city, it made sense to many urban theorists interested in the environment when Keil (2003) suggested that urban political ecology is the appropriate response to Lefebvre’s call for creating an “urban science for an urban world” (2003, 23). Here, there started to be a more deliberate focus on the historical lack of attention to how social power relations contributed to uneven development by focusing on how political and cultural economy shape and are shaped by urban environments (see Swyngedouw and Heynen 2003). Access to water, food, nonpolluted air, and green space within uneven matrices of class, race, gender, age, and physical ability would all pose the sort of examples urban political ecological investigations started to engage.

Not seeing political ecology in the city was a gap not just for those working in urban ecology but also for those who have worked in the much more historically rooted tradition of political ecology. Indeed, many engaged in political ecology have not acknowledged the impact of cities
within their framing of political ecology despite the now common tropes of the twenty-first century connecting “the urban century” with “the Anthropocene.” Like the blind spots within urban ecology, the blind spots within political ecology, according to Braun (2005), are simultaneously related to both the long tradition of social scientists not being comfortable with thinking about cities as part of nature and to the heavy attention within political ecology, at least historically, on rural “third world” forms of nature.

During the 2000s, urbanists took up this challenge and produced a series of important books and articles that collectively constitute some of the most influential foundations of UPE. In these texts can be seen the articulation of important thoughts about urban nature that go beyond much of the urban ecological discussion that came before it. These texts started to create more theoretical space and coherence toward an expanded way of thinking about nature in cities. These ideas helped form what today are the taken-for-granted (if not always agreed-to) principles of UPE.

Cronon’s (1991) *Nature’s Metropolis: Chicago and the Great West* paved the way for the development of UPE in important ways. Cronon did this by illustrating early on how the production of socioenvironmental changes between the city and its hinterland always results in the continuous production of new forms, dynamics, and interconnections within urban nature. He illustrates, in rich and nuanced historical context, how the interlocking spatial relations of unfolding urban social and physical environmental conditions develop and are always part of ongoing urban–rural systems. Cronon also helped to situate the role of political power within these socio–natural dynamics within Chicago. By bringing class, ethnicity, race, and gender into the articulation of Chicago’s environmental history, Cronon helped to integrate different ways of seeing the power struggles through which varied individuals and groups of individuals shape their local environments.

Another important book that prefigures the development of UPE is Matthew Gandy’s (2002) *Concrete and Clay: Reworking Nature in New York City*. Just as Cronon focused on Chicago’s socio–natural history, Gandy thinks through the ways in which New York City offers examples for seeing social struggles over urban nature transform both those involved and the city itself. More precisely, he argues that “Nature has a social and cultural history that has enriched countless dimensions of the urban experience. The design, use, and meaning of urban space involve the transformation of nature into a new synthesis” (Gandy 2002, 2). As Gandy helps to illustrate, attention to the processes that give way to uneven development, and thus uneven nature, is necessary to the work of compressively thinking through urban nature. These struggles, through this sort of textured analysis, led UPE away from apolitical understandings of urban ecology.

Kaika’s (2005) *City of Flows* offers some important departures from both Cronon and Gandy as another exemplar book often thought of as foundational to the development of UPE. Cronon and Gandy approached their respective North American cities from diverse processes of socio–natural interaction, ranging between processes as diverse as agriculture, lumber, and transportation in the case of Cronon, and water, landscape, poverty and pollution for Gandy. Kaika, however, focuses her analysis on the relationship between modernity and water as a way of understanding the urbanization of nature and UPE. Struggles over water access and infrastructure quickly became one of the most concentrated areas of inquiry as UPE continued to evolve. Much of Kaika’s empirical effort focused on “decipher[ing] the historical geographical process through which modernity
discursively constructed the modern city and the modern home as autonomous ‘space envelopes’ independent from natural and social processes” (2005, 4). For Kaika, as well as many others working in this tradition, much attention has gone beyond simply trying to articulate that the nature/society dualism is intellectually problematic, but rather they demonstrate the political implications of the Enlightenment era ways of seeing the world and the city.

Robbins’s (2007) Lawn People: How Grasses, Weeds, and Chemicals Make Us Who We Are offers up yet another innovation for the early formation of UPE through his theoretical and empirical attention to the role of ideas in shaping urban nature. For Robbins, “apolitical ecology” has too long dominated understandings of the decisions and behaviors central to shaping urban nature. Instead, through a grounded study of the prominence of the lawn in US cities, Robbins works against the traditional apolitical approach within urban ecology. His “apolitical approach” includes:

(1) a focus on free individual choices, (2) a propensity to assign culture a driving role in understanding group behavior, (3) a predisposition to think of economic activities and the behavior of firms as meeting consumer demand, and (4) an inclination to think about human actions, whether those of individuals or companies, as sovereign relative to the influence of nonhuman actors, objects, and animals. (Robbins 2007, 4).

As such, his book helps demonstrate “the mutual tyrannies of urban political ecology” (2007, 13) by showing how in urban nature, “each of the separate pieces is not independent, but instead made to be the way it is by virtue of its relationships to all the other parts” (2007, 14).

If these books, and others, served as the empirical and theoretical foundations of what has become UPE, there were also key articles that have helped name UPE. Early on, Roger Keil (2003) started to do the work of sorting and situating the internal differences of what was clearly becoming a subdisciplinary domain of geography’s much larger tradition of nature–society research. In an important review essay in the journal Urban Geography, Keil was one of the first to say:

There is now a rich body of literature with much diversity of origin and some diversification across various academic and philosophical traditions. In contrast to the more policy-oriented and problem-solving work on urban sustainability … the UPE literature is characterized by its intensely critical predisposition; critical is defined here as the linking of specific analysis of urban environmental problems to larger socioecological solutions. This necessitates, at a minimum, some modicum of indebtedness to radical and critical social theory. It is no coincidence then, that the emerging field of UPE has many of its multiple roots in the intellectual traditions of fundamental social critique: eco-Marxism, eco-feminism, eco-anarchism, etc. It is also, however, indebted to a neo-pluralist and radical democratic politics that includes the liberation of the societal relationships with nature in the general project of the liberation of humanity. (2003, 724).

Similarly to Keil’s authoritative first progress report, Swyngedouw and Heynen’s (2003) introductory essay in a special issue of the journal Antipode on UPE also worked to knit together the research and insight that was by that time increasingly being referred to as UPE, even as some authors were not actively using that language. In this essay, they suggest:

Urban political ecology provides an integrated and relational approach that helps untangle the interconnected economic, political, social and ecological processes that together go to form highly uneven urban landscapes. Because the power-laden socioecological relations that
go into the formation of urban environments constantly shift between groups of actors and scales, historical-geographical insights into these ever-changing urban configurations are necessary for the sake of considering the future evolution of urban environments. (Swyngedouw and Heynen 2003, 914).

In this language we see another defining feature of much UPE, which like Robbins, insists on a logic that seeks to “untangle the interconnected.” Untangling the interconnected also related to the discussion in another early and important essay related to UPE published in Progress in Human Geography by Braun. In it Braun suggests:

This concern with contextualization, as well as its focus on the processes and practices that produce uneven and spatially differentiated environments also differentiates UPE from the large environmental justice (EJ) literature, which has been dominated by a liberal discourse of “distributional justice” rather than a radical analysis of capitalist urbanization. (2005, 644).

Situating the difference between UPE and EJ, in the earliest phases of UPE development was important in terms of showing the trajectories of different kinds of intellectual and political projects. It is worth saying, however, that while there are some differences between UPE and EJ there are also productive similarities. In part this is because, as UPE continues to be defined through empirically grounded studies, its coherence continues to open up toward productive partnerships with other like-minded scholarship. Braun foreshadowed this to some degree in his article when he said:

The rapid growth of UPE is likely to continue, with its definition and scope expanding accordingly. This is true in part because political ecology does not name a single, coherent field, or seek its own distinctive theory. This renders it open-ended, perhaps for the good. To the extent that urban political ecology interrogates the complex and interrelated socioecological processes that shape cities and their uneven urban environments, there is no reason to exclude Mike Davis’s … splendid writings on Los Angeles, or David Harvey’s … reflections on nature, justice and difference, even if neither uses the term. (Braun 2005, 644).

One of the most referenced collections within UPE is an edited book by Heynen, Kaika and Swyngedouw (2006) entitled In the Nature of Cities: Urban Political Ecology and the Politics of Urban Metabolism. One reason for the attention to this collection has both to do with the timing of its publication at a moment when UPE was maturing. Another reason the collection has attracted attention relates to the rich melding of theoretical and empirical research conducted by many of the scholars who supported the need to think about the politics of urban nature in more comprehensive and interconnected ways. The timing meant that particular statements in the book, backed up by robust collaboration across empirical terrains, both helped foster the ongoing development of UPE and also gave a name to something that could be critiqued and expanded on. A particular passage from the introduction of the book, like other defining passages in other early works, concisely sums up what UPE is about:

An urban political ecological perspective permits new insights in the urban problematic and opens new avenues for re-centring the urban as the pivotal terrain for eco-political action. To the extent that emancipatory urban politics reside in acquiring the power to produce urban environments in line with the aspirations, needs, and desires of those inhabiting these spaces, the capacity to produce the physical and social environment in which one dwells, the question of whose nature is or becomes urbanized must
be at the forefront of any radical political action. (Heynen, Kaika, and Swyngedouw 2006, 15).

While there has now been considerable effort to develop UPE, Loftus’s (2012) Everyday Environmentalism: Creating an Urban Political Ecology is one of the first monographs that explicitly engages UPE. Loftus develops both the history and the scope of UPE by grounding his empirical project in South African hydro-struggles. The book pushes the evolution of UPE in useful and provocative ways. The range of urban environmental processes used to organize the project is important for showing the possibilities for producing a more democratic urbanized planet. Loftus utilizes qualitative research on South African water politics in an effort to show how grassroots struggles within informal settlements of Durban help to embody UPE. His empirical insights invigorate the politics of possibility within UPE as deliberately framed. The “everyday” desires, possibilities, emancipatory potentials, and dangers that swirl within this narrative push an explicit understanding about the articulation of “urban” and “political” and “ecology.” Loftus’s research expands the reach of UPE by showing, through a blend of theory and grounded politics, who benefits and who suffers through the particularities of the production of urban nature.

As the confluence of nature, political economy, and the city continue to evolve we can see more distinction and diffusion of the research done within UPE. The earliest and most significant research within UPE related to urban hydroscapes and how uneven socio-natural power relations configured these landscapes differently. The foundations provided in this work help open up other ways of articulating nature in the city through a wide spectrum of more diverse dynamics (e.g., air pollution, urban forests, wildlife corridors, gentrification, insects and pesticides, gardens and food, hunger, health). Much of this work responds to something that Smith said:

A dialectic is at work here. As part of a broader political movement, an urban political ecology can help integrate a politics of nature into a more established “social” politics; at the same time an ecologically enhanced politics focusing on the productive metabolism of nature can further exoticize the absurd separation of nature and society while denying any anti-social universalism of nature. (2006, xv).

Provoked by both critique and support, efforts continue to better connect UPE with political ecology more generally, as well as literature on environmental and food justice and other important threads of nature-society scholarship. In an article expanding on the UPE of food justice Agyeman and McEntee (2014, 211) suggest:

Our central proposition is that urban political ecology (UPE) offers up a broader theoretical frame for advancing and retaining the potency of the field of Food Justice while also allowing the movement to progress in alleviating the problems of hunger and inadequate food access.

This move toward great expansion and inclusion of more and more urban dynamics helps to illustrate that UPE is likely to continue to develop into the future. Agyeman and McEntee go on to say:

UPE’s emphasis on hybridity, scale, and commodity relations has the potential to ensure that FJ [food justice] remains true to focusing on outcomes and processes as well as symptoms (e.g., immediate needs such as inadequate access to food) and causes (e.g., structural inequalities) of food injustice within the current neoliberal system. (2014, 211).
Again, seeing the application and expansion of the dialectical logics that led to the formation of UPE in the first place is another productive signal regarding the growth of this way of thinking about urban nature.

**Ten key ideas in urban political ecology**

Despite the theoretical differences that are increasingly defining new work in UPE, and given the encyclopedic purposes of this current entry, it would be useful to recount 10 core principles that increasingly characterize much of UPE scholarship which Swyngedouw developed after his 1996 *Capitalism Nature Socialism* essay.

1. **Environmental and social changes codetermine each other.** Processes of socioenvironmental metabolic circulation transform both social and physical environments and produce social and physical milieus (such as cities) with new and distinct qualities. In other words, environments are combined sociophysical constructions that are actively and historically produced, in terms of both social content and physical-environmental qualities. Whether we consider the making of urban parks, urban natural reserves, or skyscrapers, each of these contains and expresses fused sociophysical processes that contain and embody particular metabolic and social relations.

2. **There is, therefore, nothing a priori unnatural about produced environments like cities, genetically modified organisms, dammed rivers, or irrigated fields.** Produced environments are specific historical results of socioenvironmental processes. The urban world is a cyborg world, part natural, part social, part technical, part cultural, but with no clear boundaries, centers, or margins.

3. **The type and character of physical and environmental change, and the resulting environmental conditions are not independent of the specific historical social, cultural, political, or economic conditions and institutions that accompany them.** It is concrete historical-geographical analysis of the production of urban natures that provides insights into the uneven power relations through which urban “natures” become produced, and that provides pointers for the transformation of these power relations.

4. **All sociospatial processes are invariably also predicated on the circulation and metabolism of physical, chemical, or biological components.** Nonhuman “actants” play an active role in the mobilizing of socio-natural circulatory and metabolic processes. It is these circulatory conduits that link often distant places and ecosystems together and permit relating local processes with wider sociometabolic flows, networks, configurations, and dynamics.

5. **These metabolisms produce a series of both enabling and disabling social and environmental conditions.** Indeed, these produced milieus often embody contradictory tendencies. While environmental (both social and physical) qualities may be enhanced in some places and for some people, they often lead to a deterioration of social and physical conditions and qualities elsewhere.

6. **Processes of metabolic change are, therefore, never socially or ecologically neutral.** This results in conditions under which particular trajectories of socioenvironmental change undermine the stability or coherence of some social groups or places, while the sustainability of social groups and places elsewhere might be enhanced. In sum, the political-ecological examination of the urbanization process reveals
the inherently contradictory nature of the process of metabolic circulatory change and teases out the inevitable conflicts (or the displacements thereof) that infuse socioenvironmental change.

7 Particular attention, therefore, is paid to social power relations (whether material or discursive, economic, political, and/or cultural) through which metabolic circulatory processes take place. It is these power geometries and the social actors carrying them (out?) that ultimately decide who will have access to or control over resources or other components of the environment, and who or what will be positively or negatively enrolled in such metabolic imbroglios. These power geometries, in turn, shape the particular social and political configurations and the environments in which we live. Lefebvre’s “right to the city” also invariably implies a “right to metabolism.”

8 Questions of socioenvironmental sustainability hereby become fundamentally political questions. Political ecology attempts to tease out who gains from and who pays for, who benefits from and who suffers (and in what ways), from particular processes of metabolic circulatory change. It also seeks answers to questions about what or who needs to be sustained and how this can be maintained or achieved.

9 Political-ecological perspectives seek to unravel the nature of the social relationships that unfold between individuals and social groups and how these, in turn, are mediated by and structured through processes of ecological change. In other words, environmental transformation is not independent of class, gender, ethnic, or other power struggles.

10 It also seeks to question the actual processes of metabolic reconstruction and recasting, and advocates a position on sustainability that is achieved by means of a democratically controlled and organized process of socioenvironmental (re)construction. The political program, then, of political ecology is to enhance the democratic content of socioenvironmental construction by means of identifying the strategies through which a more equitable distribution of social power and a more inclusive mode of the production of nature can be achieved.

The ideas contained within these principles continue to inform efforts to better connect and better embody the ways in which urban nature is struggled over and reproduced in the image of those struggles. While there are many important ways that the false dualism between nature and society has been addressed, UPE offers a way of addressing this issue with specific attention to urban socio-natural form and spatial processes.

Urban politics are complicated. Urban politics is often treated as a distinctive form of politics and “the urban” itself is often taken as a self-evident concept. Neither is quite so straightforward.

The contemporary notion of urban politics has its roots in Manuel Castells’s work on “the urban question” in the early 1970s. In Castells’s structuralist formulation, capitalist society is expressed through the spatial forms of its economic, political, and ideological systems. These systems take material, spatial form in association with the production activities of factories, mines, offices, and so on; the consumption activities of housing, stores, recreation, and so on; and the circulation and exchange activities of banks, roads, telecommunications, and so on. The spatial structuring of production, reproduction, and circulation and exchange has “return effects” on society, giving rise to localized urban problems, urban planning conflicts, and ultimately urban politics, including urban social movements, which address collective consumption issues. Urban politics, in other words, has its roots in the spatial expression of a capitalist society’s structural contradictions. Urban politics are not merely epiphenomenal, however, as they influence the actions of the state, which intervenes in cities and attempts to ameliorate conflicts around collective consumption.

With the publication of his classic book, The City and the Grassroots (1983), Castells signaled a major theoretical shift in his approach to urban politics. While he continued to highlight conflicts around collective consumption as the defining concern of urban politics, Castells dropped the structural focus, instead emphasizing the concerns and conflicts of everyday life. For Castells, the city was the basis of the territorial organization of urban politics (and especially urban social movements), focusing on three dynamics: (i) conflicts over the city as a space of use-values versus a space of exchange-values; (ii) conflicts over neighborhood cultural identity, neighborhood cultural autonomy, and communication; and (iii) conflicts over territorial or neighborhood self-management. Based in everyday experience at the city or neighborhood scale, these collective-consumption-based conflicts were largely defensive in nature. Urban politics were about the defense of localized lifeworlds from commodification and state control, and were to be viewed as a very specific type of territorially based politics, both reactive and inward-looking.

In the same era that Castells and other urbanists were analyzing the urban politics of collective consumption, global changes in state regulation and economic and class structure were underway. The Fordist regime of accumulation gave way to post-Fordism or, even more chaotically, after-Fordism. Post-World War II processes of economic restructuring had accelerated in the 1960s, and became widely felt by the 1970s when declining profits, rising unemployment, and declining state revenue led to what James O’Connor (1973) called “the fiscal crisis of the state” and Jürgen Habermas (1975) labeled a “legitimation crisis.” Cities were forced to cut funding for services, maintenance, and infrastructure investment, bringing many of
them to the brink of bankruptcy and under-mining support for the welfare state. The urban politics of collective consumption gave way to a very different outward-looking type of politics oriented to the attraction of new capital investment and tax base enhancement. An early influential analysis of this shift was Harvey Molotch’s classic 1976 article, “The City as a Growth Machine.” To Molotch, research based on the traditional definitions of what an urban place is has had very little relevance to the actual, day-to-day activities of those at the top of local power structure[s] whose priorities set the limits within which decisions affecting land use, the public budget, and urban social life come to be made. (1976, 309)

Molotch argued that those at the top of local power structures were increasingly promoting growth rather than satisfying collective consumption demands, and that growth was being pursued at the expense of competing localities. Beggar-thy-neighbor strategies were driven, first and foremost, by landed elites who stood to gain substantially from increasing property values and rents. Landed elites frequently led growth coalitions that included other business interests, which also benefited from local economic expansion, such as local newspapers. While Molotch acknowledged the contested nature of growth politics and pointed to countercoalitions challenging the ideology of growth, growth coalitions became the norm while retrenchment of the welfare state and its collective consumption functions deepened. These transformations were part and parcel of the slow creep of neoliberal urban policy which entailed rolling back state functions, responsibilizing the individual, and demanding lower taxation to facilitate continued private consumption in the face of declining incomes. A critical milestone in this trend was the passage of the populist “People’s Initiative to Limit Property Taxation” referendum, commonly known as Proposition 13, in California in 1978. Proposition 13 signaled the turn away from an urban politics of collective consumption to an urban politics of low taxation and economic growth.

By the early 1980s, right-wing national governments pursuing neoliberal policy agendas had been elected in many countries in both the Global North and the Global South. Deregulation, the “freeing” of markets, downloading central state functions to local states, and the pursuit of economic growth became hegemonic. Economist Paul Peterson’s book, City Limits (1981), argued that cities were now shaped by external structural forces and faced the necessity of adopting policies to attract capital investment and highly skilled labor. Urban governments had little scope to address issues of collective consumption and redistribution. In this economic-deterministic view, politics had essentially become irrelevant since all elected city officials, regardless of political allegiance, faced the same powerful structures. Harvey’s (1989) analysis addressed the sweeping social consequences of this transformation: accelerated gentrification, increased investment in facilities that enhance interurban competition, the rise of place marketing, the shift to consumerist spectacles for the wealthy, increasing income inequality, and the rise of public–private partnerships.

Yet, while much analysis focused on economic development strategies and politics of cities, it was clear that urban politics and policy now needed to be understood in a broader context. Cities did not adopt policies in a vacuum and the road to urban entrepreneurialism was riddled with contradictions and conflict. Drawing from French regulation theory, many urbanists came to a broader understanding of the post-Fordist crisis as both ideological and inherently geographical. Drawing from Gramsci, regulation theory posits hegemonic ideologies underpinning regimes of
accumulation and modes of regulation, allowing accumulation to proceed on the basis of provisional “grand compromises.” The Keynesian welfare state, relatively secure employment, and rising wages underpinned the Fordist grand compromise. Post-Fordism has yet to arrive at a grand compromise and it remains unclear whether the ideology of “free markets” and individual responsibilization will be sufficient to hold the post-Fordist regime of accumulation together. What is clear, however, is that the shift from Fordism to post-Fordism has entailed a massive geographical restructuring of regulatory arrangements. Under Fordism national forms of regulation were dominant, with the national state promoting the general welfare. Under the regulatory logic of post-Fordism the nation-state has been hollowed out – programs and funding cut – and many of its functions rescaled. In some cases regulatory functions have been shifted to supranational institutions, but in many other cases functions and regulatory responsibilities have been downloaded to local states, which were often lacking the fiscal capacity to carry out these new responsibilities (Peck and Tickell 1994). It is in this context that the shift to urban entrepreneurialism and growth machine politics must be understood.

It should be emphasized that the new scalar set of regulations was a necessary precondition to creating a relatively autonomous urban growth politics. Urban entrepreneurialism did not arise in the same way everywhere, and in many parts of the world it was relatively muted, raising the question of whether the turn to urban entrepreneurialism had its roots in anything that could be called “urban.” Whether there is such a thing as a specifically urban process and, in turn, specifically urban politics, was the topic of a lively debate in the 1980s between David Harvey and Peter Saunders. Recounting this debate, Kevin Cox (2001, 760) argues that, while politics is necessarily spatial, “there does not have to be ‘a relatively autonomous urban politics.’” Instead, Cox stresses that the scalar structure of the state sets the preconditions for the politics of urban development. In highly decentralized federal states like the United States, city is pitted against city in the quest to attract capital investment, making possible an urban politics of interurban competition; however, strong central states that directly fund municipal functions may mute or even preclude interurban competition and its associated politics.

While the work of Cox, Harvey, and others demonstrates the importance of the state’s scalar structure in shaping urban politics, the question remains of how and why certain actors become politically active. Harvey’s work on the mobility of capital and labor is an important starting point for understanding how and why particular actors are likely to become involved in urban development politics. Building from Harvey’s work, Cox (1993) develops a particularly powerful and nuanced analysis of what he calls the “new urban politics” (NUP). Cox proceeds by questioning sweeping claims for the hypermobility of capital and the immobility of labor, and points out that different fractions of capital and labor differ in their mobility. Some fractions of capital (and labor) may be highly mobile, allowing them to address conditions not to their liking by relocating to more favorable locations. Other fractions of capital and labor, however, may be locally dependent, and therefore their ability to relocate is limited, which leads them to engage in struggles in the local political arena. This formulation calls into question Molotch’s original thesis that growth politics is led by landed elites. In Cox’s analysis, growth politics tends to involve actors whose interests are highly locally dependent – not only landed elites – and to give rise to a variety of cross-class coalitions rooted in local dependence. Political actors
are constantly “negotiating the contradiction between fixity and mobility” (Cox 2001, 761), and this negotiation can take place at a variety of scales, not only the urban.

The epistemological question of what “the urban” is and how it is constituted has been raised by numerous scholars. As early as 1970, Henri Lefebvre asserted that the issues that cities face can no longer be analyzed through the lens of the bounded, independent city. Instead, the commodification and bureaucratization of urban life – what Lefebvre termed the conflict between abstract space and social space – has become a global problem and, indeed, urbanization processes have themselves become global. These processes, Lefebvre (2003/1970) argued, need to be understood relationally. More recently, scholars such as Neil Brenner and Christian Schmid have advanced similar arguments. Brenner and Schmid assert that three macro-trends undermine the capacity of areally delimited models to adequately capture the processes that shape “the urban”: (i) “new geographies of uneven spatial development mutually produce one another at all spatial scales, from the neighborhood to the planetary” (2015, 151–152); (ii) the “basic nature of urban realities … has become more differentiated, polymorphic, variegated and multi-scalar than in previous cycles of capitalist urbanization” (152); and (iii) “the regulatory geographies of capitalist urbanization have likewise been undergoing profound, rapid mutations” (153).

Combined, these three trends call into question any analysis based on a single areal unit such as a city. Brenner and Schmid’s point, much like Lefebvre’s, is that we have to look beyond the city to understand the processes, including political processes, that shape cities. Indeed, many urban political activists understand this point. As Cox (1998) has argued, there is a scale division of politics and the problems of cities are not always best addressed at the scale of the city. In some cases, urban issues may be addressed at the scale of the neighborhood, and in other cases at the regional or even the national scale. In other words, the scales at which urban political issues might be engaged are not necessarily the scales of the social relationships of the city.

Nonetheless, while the spaces of urban political engagement may extend well beyond the city, the conditions that give rise to collective political mobilization are most commonly found in cities. As spaces of diversity, density, and frequent encounter, cities are “spaces of politicization” (Miller and Nicholls 2013). Experiences of oppression, the formations of social bonds and social capital, and the working out of shared identities, common understandings, and political strategies most commonly occur in cities (Martin 2003). Patterns of interaction and encounter that foster politicization are structured by the characteristics of urban places. As John Agnew (1987, 28) explains, three dimensions of place shape the nature of politics: through locale, the settings in which social relations are constituted; through location, the area encompassing the settings of social interaction as they are shaped by social and economic processes operating at wider scales; and through sense of place, the local “structure of feeling.” Urban places structure and facilitate (and, in some cases, hinder) social contact, social bonding, alliance building, and resource mobilization. It is from these places that political initiatives to address the processes shaping urban life are launched, whether the specific issue at hand is highly localized, such as a neighborhood conflict over a development proposal; city-wide, such as protests against city-wide policing practices; or global in scope, such as protests against growing income inequality and austerity policies, as exemplified by the Occupy movement.

An understanding of urban politics must start from an understanding of urban social life and its complex geographical constitution (Nicholls,
Miller, and Beaumont 2013). The processes of politicization are not necessarily geographically congruent with the processes that structure cities and the problems urban residents face. Urban politics grows out of the social relationships, social bonds, and experiences of urban residents; they decide which grievances to politicize and where to direct those grievances. While the imperative of growth in a capitalist economy and the geographical structure of the state always figure prominently in the politics of capitalist societies, they do not define the totality of urban social life. Urban politics is ultimately grounded in the diversity of the city but cannot be reduced to a particular issue or areal unit such as the city.

Urban redevelopment

*University of Toronto, Canada*

Urban redevelopment is the process of re-establishing the profitability of devalorized and declining urban districts, using a mix of residential, commercial, office, or entertainment-related land uses. Often called “urban regeneration” or “urban renewal,” and encompassing infill, brownfield, and intensification projects, urban redevelopment is carried out by public or private actors (or through public–private partnerships). The process typically involves the remaking of urban space for more affluent users, both physically (through demolition and reconstruction) and symbolically (with the discursive renaming and reimaging of place). Urban redevelopment is often promoted as a way to reverse economic decline, attract new investment, and stimulate middle-class vibrancy. It is also likely to promote unjust social outcomes – through displacement – that are disproportionately experienced by low-income and racially marginalized communities.

Theoretically, urban redevelopment can be understood as one aspect of physical and social change in the broader play of capitalist processes of urbanization. Typically targeting central urban areas, redevelopment is driven by the same set of forces that produce deindustrialization, inner suburban decline, and peripheral suburban expansion. According to Gotham (2001a, 2), these processes are “part and parcel of the continuous reshaping of the built environment to create a more efficient arena for profit making.” Harvey (1982) describes such reshaping as “uneven geographical development” resulting from the contradictory dynamics guiding the production of space under capitalism. These dynamics can be understood as a “see-saw of uneven development” (Smith 1984), in which capitalists invest where profit margins are high, only to experience diminishing returns as competitive pressures erode the local advantages of place. At this point, capital seesaws away from disinvested sites to new areas with hot property, only to seesaw back again at some future time when the first location has once again become profitable. In this theory, disinvestment and decline are directly related to redevelopment, playing a crucial role in creating areas that are ripe for reinvestment. As areas decline, according to Smith (1984), a “rent gap” emerges between the profits that can be reaped from a currently devalorized land use and the potential profits that could be gained from a “higher and better” redeveloped land use. Once the rent gap widens to a certain point, redevelopment and gentrification become possible.

Urban redevelopment can also be understood as a part of the capitalist process of creative destruction. Harvey (1978) explains how capitalism creates a built environment “in its own image” to facilitate accumulation. As technology improves and the needs of capital change, however, this landscape of roads, buildings, and infrastructures begins to present a barrier to continued accumulation. In order to create a
built environment suited to present conditions, it must destroy the physical assets that exist. As Harvey (1978, 83) put it:

under capitalism there is, then, a perpetual struggle in which capital builds a physical landscape appropriate to its own condition at a particular moment in time, only to have to destroy it, usually in the course of a crisis, at a subsequent point in time.

Urban redevelopment targeting “outmoded” housing, factories, port facilities, shopping outlets, transportation networks, and the like destroys these relics from capitalism’s past to create new built environments for future accumulation. While the “creative” aspect of urban redevelopment is often celebrated, critical scholars focus on its destructive impacts and the social dislocations experienced by low-income and marginalized groups (including racialized communities, women, seniors, people with disabilities, and LGBTQ communities) who are displaced by processes of capitalist reinvestment. Indeed, in a number of developed nations, urban redevelopment is fundamentally ordered by racial inequalities, which it reinscribes in urban landscapes (Gotham 2001b). Rather than meaningfully addressing the impacts of segregation, inequality, poor housing quality, and disinvested infrastructure in poor communities, urban redevelopment often works instead to shift residents of these communities elsewhere. However, it is also possible for socially just forms of urban redevelopment to occur.

Urban redevelopment discourses

Urban redevelopment often leads to gentrification, although the latter term is rarely openly used by public or private actors promoting urban redevelopment. Instead, a range of other linguistic terms work to justify and promote projects that might otherwise provoke political resistance. Terms such as “revitalization,” “rejuvenation,” “upgrading,” “renovation,” or “renewal” carry more positive connotations among the lay public, implying that urban neighborhoods with aging infrastructure and housing, which are often occupied by poor and racially marginalized people, are not “vital” and are in need of improvement. This rhetoric often masks the violent and unjust processes of residential displacement and dispossession that redevelopment entails. When discussing urban redevelopment, critical scholars argue that language is important, and insist that we hold on to the word “gentrification” when appropriate in order to politicize the process and foreground the realities of associated class- and race-based inequalities.

Early urban redevelopment: Engels and Haussmann

Patterns mirroring contemporary urban redevelopment were already being described and critiqued in the nineteenth-century city, notably in Friedrich Engels’s pamphlet The Housing Question (1988/1872). Industrial cities, Engels noted, tended to house their working classes in substandard, cramped, and overpriced tenements near centrally located employment. With time and neglect, these buildings would deteriorate, depress land values, and be demolished to make way for new structures. According to Engels, “They are pulled down, and in their stead shops, warehouses, and public buildings are erected,” in the process enriching landlords and displacing poor tenants. In London, Manchester, Liverpool, Berlin, and Vienna—everywhere—the effect was the same: “the result is that workers are forced out of the centre of towns towards the outskirts; that workers’ dwellings … become rare and expensive and often altogether unattainable.”
(1988/1872, 319). “Slum clearance” in this era offered landlords the opportunity to capitalize on the rent gap, and created attractive and sanitized districts for middle-class homeowners and consumers. Dispersal of the urban poor also soothed the worries of the bourgeoisie, who feared the spread of communicable diseases and the threat of social unrest. This early approach to urban redevelopment was not a real or just solution, according to Engels. He argued that the bourgeoisie settled the “housing question” by merely shifting the problem elsewhere, “in such a way that the solution continually poses the question anew” (1988/1872, 365).

A famous early model for large-scale, planned urban redevelopment was the renovation of Paris carried out by Baron Georges von Haussmann, Louis-Napoléon Bonaparte’s appointed Prefect of the Seine. Between 1853 and 1870, “Haussmannization” cut straight wide boulevards through Paris’s medieval alleyways, and introduced modernized sewage, water, and gas systems; new parks; train stations; public markets; and squares – all in line with an imposing and uniform architectural style. Urban redevelopment in this case was motivated by public health concerns – overcrowding and poor sanitation had led to multiple cholera outbreaks – but was also a way to enhance social control over the “dangerous classes,” which were concentrated in these areas and often rose up in revolt. Wide streets were intended to prevent the construction of barricades and to provide easy access for the marching military to swiftly put down future attempts at revolution. Urban redevelopment under Louis-Napoléon had another aim, with parallels in the contemporary era. The broad streets, regularized facades, and imposing terminal vistas were meant to create a spectacle, and to convey an image of the French capital as grandiose, elegant, and modern. Despite its visual appeal, redevelopment was socially destructive, displacing poor Parisians to outlying districts with overcrowded housing and poor sanitation, hence shifting the problem elsewhere and creating it anew.

Postwar urban redevelopment: urban renewal, slum clearance, and public housing

In the postwar period, urban redevelopment took the form of “urban renewal,” an approach that eviscerated inner urban areas with vast swaths of demolition, highway building, commercial and office development, and public housing construction. After World War II, the suburbanization of housing and decentralized industry dominated patterns of urban growth, often aided by government policies subsidizing both highway construction and middle-class homeownership. The inner city suffered tax loss and state-led disinvestment over this period, and in many US cities was abandoned to low-income and racially marginalized residents who were systematically excluded from good jobs and suburban homeownership. Inner-city disinvestment was paired at this time with sporadic urban redevelopment under the auspices of federal urban renewal programs (in the United States, launched as Title I of the 1949 Housing Act), which enabled government expropriation of “blighted” private land. This land was then sold at a reduced price to private actors willing to develop it for a “higher and better” use. Business elites and real estate interests profited massively from this program, building high-rise office towers, convention centers, shopping malls, and luxury apartments in the space of cleared “slums.” Renewal often introduced a modernist architectural and design landscape to inner cities, with wide highways, segregated land uses, and unornamented concrete towers.
Urban renewal and highway development resulted in the demolition of far more homes than were replaced, and displaced tens of thousands of residents and businesses (Gotham 2002). Postwar urban redevelopment also intensified and reproduced patterns of residential racial segregation, and disproportionately targeted racialized communities for dislocation and upheaval. In the United States, nearly 70% of the homes demolished for renewal were black-occupied, leading opponents to dub the program “Negro Removal” (Gotham 2002, 88; Greer 1965). Displaced families did not typically receive any assistance, and were shuffled into increasingly scarce and overcrowded housing markets. For black home-seekers in the United States, the reality of redlining, racially restrictive covenants, real estate steering, and white homeowner activism limited options to within the “color line” of segregated cities (see Figure 1). Echoing Engels, Greer (1965, 55) argued that urban renewal amounted to “slum shifting” and “pushing people around,” without properly addressing their housing needs. While it was perhaps most egregious in the United States, similar patterns are evident in cities across the developed world.

Postwar urban redevelopment programs also included the creation of public housing, to address housing shortages resulting from years of depression and war, and to improve the safety and sanitation in inner-city “slum” housing. In North America, fierce resistance from real estate interests ensured that public housing construction was limited, and built to minimum standards, so as not to compete with the private housing market. In the United States, public housing siting policies have been criticized for concentrating projects in low-income and African American inner-city districts, intensifying racial segregation. In Canada, federal urban renewal targeted racially marginalized inner-city populations for displacement, produced far fewer affordable units than were demolished, created stigmatized public housing in low-rent areas, and was massively profitable to real estate and business interests. The modernist design of postwar public housing has also come under fire, for its lack of relation to surrounding communities and building styles, and its distinctively austere functionalist style – now commonly associated with poverty, disadvantage, and stigmatization.

Postwar urban redevelopment programs, ostensibly intended to address slum housing and revitalize inner cities, were in reality programs that provided “federal subsidies to the private sector to encourage urban reinvestment” (Gotham 2002, 87). Urban renewal programs ended in 1969 in Canada and in 1974 in the United States, amid mounting criticism. Conservative writers railed against its bureaucratic nature, while neighborhood activists fought against expropriation, demolition, and displacement, and decried the destruction of historic cityscapes, modernist architecture, and authoritarian top-down planning. The rising tide of “new left” activism...
associated with civil rights, antiwar movements, and environmentalism ushered in a new political moment supportive of more citizen-oriented, participatory efforts toward urban redevelopment. While urban renewal was halted, the era of “postmodern” urbanism would present new opportunities for capitalist urban redevelopment and new rounds of dispossession and displacement.

**Contemporary urban redevelopment: postmodern revitalization and gentrification**

The contemporary context for urban redevelopment emerged after the global economic crisis of the mid-1970s and the period of global economic restructuring that followed. In Western advanced capitalist nations, this crisis ushered in a shift from the Fordist–Keynesian “regime of accumulation” that sustained decades of postwar economic growth to a new period of “flexible accumulation” and neoliberal ideological hegemony. This new era is marked by a range of trends, including a weakening of the collective power of labor, the introduction of flexible production systems, a rise in both precarious low-paying jobs and high-paying service employment (in finance, real estate, and insurance), deindustrialization in the Global North associated with increasing corporate mobility, and increasing financialization of the economy (Harvey 1989). Politically, these shifts have been guided and accompanied by the economic theory of neoliberalism and its emphasis on individualism, limited government, unencumbered markets, private property rights, and free trade. Neoliberal policies have underpinned the rollback of Keynesian social policies and institutions through budget cuts, privatization, deregulation, and enforced programs of austerity; and the rollout of neoliberal statecraft and regulations, including market-friendly policies and the aggressive disciplining and regulation of marginalized groups (Peck and Tickell 2002). A final shift associated with this era has been the “glocalization” of regulation, in which national state powers have shifted both upward to global institutions (such as the IMF and the World Bank), and downward to municipalities. Such a process often results in a rescaling of responsibility, in which the downloading of social services is not accompanied by sufficient resources, limiting municipal capacities and encouraging them to pursue entrepreneurial strategies coupled with antilabor policies and budgetary austerity.

For cities, this era has marked a shift in urban governance practices, from the managerial approaches of the 1950s and 1960s, which focused on providing public services, to an entrepreneurial model focused on facilitating private sector development and attracting economic development in a context of global intercity competition (Harvey 1989). Neoliberal urban governance involves creating favorable policies for investment (using tax breaks, subsidies, “empowerment zones,” etc.) in order to attract production functions (especially key command and control functions of the new global economy) and consumption dollars from tourists and middle-class urbanites. Cities are now active in public-private partnerships (absorbing considerable risk) and aggressive self-promotion, through “place marketing” and city branding exercises.

**Postmodern urban redevelopment: consumption landscapes and place-making**

In this context, a new style of urban redevelopment emerged in the 1980s and 1990s, targeting
the disinvested inner-urban landscapes of the “postindustrial” city for revitalization. With the loss of traditional manufacturing and production functions, cities began to support the construction of consumption-oriented attractions related to tourism, culture, professional sports, and entertainment. Aging downtowns, warehouse districts, and old port facilities have made way for themed shopping malls, convention centers, aquariums, luxury hotels, ballparks and stadiums, theaters, and festival marketplaces (Hannigan 1998). More recently, urban redevelopment has been boosted by a discourse promoting “creative cities” under the assumption that economic development follows middle-class consumers who work in “creative” jobs in white-collar management and information fields. Luring office- and knowledge-related production facilities, and creating consumption-oriented landscapes for leisure and entertainment to attract tourists and “creatives,” are a new preoccupation for revitalization-minded urban boosters and officials.

This style of postmodern urban redevelopment was promoted to stimulate investment in aging downtowns, and to catalyze spin-off economic impacts and “trickle-down” benefits. Since the 1980s, projects such as these have proliferated, becoming ubiquitous in North American central cities and beyond. Places like Winnipeg, St. Louis, and Birmingham have tried to capture the success of early adopters – duplicating Boston’s “festival marketplace” at Faneuil Hall (Figure 2), the “waterfront redevelopment” at Baltimore’s Inner Harbor, London’s Canary Wharf, or Bilbao’s successful “cultural revitalization” with its branch of the Guggenheim Museum. According to Harvey (1989, 10), this “repetition and serial adoption” of redevelopment strategies is a feature of the neoliberal era that results from interurban competitiveness to attract increasingly mobile capital investment. Competition between cities acts as an external coercive force, compelling municipal decision-makers to latch on to redevelopment trends or risk missing out. Ironically, the result is repetitive sameness rather than distinctive urban attractions. Rather tragically, Harvey argues, any gains that come from redevelopment are likely to be ephemeral, as imitation and innovation in other cities swiftly erode the competitive advantages of place. Competition for private investment also leads to a very narrow range of policy options for city governments, who are focused on tax cuts for business while engaging in a neoliberal race to the bottom in the areas of social policy and welfare provision.

Contemporary urban redevelopment has been criticized for favoring urban elites and private partners who profit directly from the development projects that are subsidized and facilitated by the public sector. In cases where redevelopment enhances the urban tax base, city administrators and landowners also win out. When revitalization doesn’t have the economic impacts that are expected, however, it is city taxpayers who end up subsidizing the loss. This outcome is typical, for example, of stadium-based revitalization: while countless...
cities have subsidized sports facilities to rejuvenate their downtowns and to keep or lure in sports teams, studies show again and again that economic impacts are illusory. Some argue that the democratic process is another casualty of entrepreneurial urban development because it elevates the profit-oriented goals of private developers over the general interests of diverse urban constituencies. Finally, despite hopes that economic benefits might trickle down to marginal and low-income urban residents, studies find that redevelopment tends to enrich development partners while displacing the urban poor. In the case of Baltimore’s famous (and serially replicated) Inner Harbor, for example, redevelopment did nothing to address the high rates of poverty, underemployment, and housing distress facing African American neighborhoods near the site (Levine 1987). Unfortunately, unequal outcomes appear to be as serially replicated as the museums, aquariums, and revamped waterfronts that are the hallmarks of postmodern urban redevelopment.

Place marketing, spectacular cities, and securitization

An important dimension of contemporary urban redevelopment in the neoliberal era is its tendency to focus on qualities of place, by creating urban districts that are themed, spectacular, and aesthetically appealing (Hannigan 1998). This focus on place is understood as a result of intense interurban competition, in which elite tourists, footloose high-tech industry, and its creative employees can pick and choose which place offers the best package of urban amenities. A focus on creating “livable,” safe, and beautiful urban environments, with parks, coffee shops, cool bars, upscale boutiques, and art galleries is seen as paramount for cities seeking to edge out the competition. Urban redevelopment is accompanied by place marketing, image-making, and efforts to sell a city (or the city’s crafted brand) as a commodity. As central areas are symbolically remade and rebranded into “fantasy cities” (Hannigan 1998) and theme parks for the affluent, the reality of resistance, diversity, and poverty in urban spaces must be both symbolically and physically removed. Urban redevelopment since the mid-1970s has been accompanied by “revanchist” (Smith 1996) policies and policing to control public spaces, criminalize homelessness, and keep “undesirable” or “deviant” users from compromising the image, which disproportionately targets the poor and people of color. “Quality of life” bylaws in many urban areas limit panhandling, loitering, sitting or sleeping on the ground, skateboarding, squeegeeing, and so on in an effort to sanitize urban space for the maximum comfort of affluent consumers and residents.

Gentrification and public housing redevelopment

The move toward central-city redevelopment is increasingly linked to the broader process of gentrification. Gentrification is defined as “the transformation of a working-class or vacant area of the central city into a middle class residential and/or commercial use” (Lees, Slater, and Wyly 2008, xv). While initially viewed as a marginal and strictly residential process, gentrification scholars now view it as the “leading edge” of global neoliberal restructuring, an all-encompassing process consisting of “the class remake of the central urban landscape” (Smith 1996, 39), or the “production of space for progressively more affluent users” (Hackworth 2002, 815). Beginning in the global cities of advanced capitalist nations in the 1970s and 1980s, and
stretching worldwide after the 1990s, gentrification has altered patterns of urban development, shifting the “land value valley” of devalorization, as well as traditional immigrant-reception functions, outward from inner cities into postwar suburbs, which are becoming the new urban districts of racialized urban poverty, territorial stigmatization, and disinvestment.

Early cases of gentrification began to occur when urban renewal was still the dominant type of urban redevelopment, and when discourses of inner-city decline were hegemonic. In London, England, and in US cities such as Boston, New York, and Philadelphia, “pioneer” gentrifiers (artists, bohemians, and risk-taking middle-class homeowners) began to upgrade housing and to displace working-class residents in disinvested central neighborhoods in the 1950s and 1960s. By the 1970s and 1980s the phenomenon had become more widespread, but was still seen as an anomaly in the context of trends toward suburbanization and inner-city decline. Even so, the process was becoming increasingly corporate and state-driven, as developers followed (and even preceded) “pioneers,” and as banks “green-lined” areas for reinvestment and municipalities worked to facilitate the process. Resistance and opposition movements emerged to fight back against gentrification and the social and cultural displacement it entailed. This resistance was at times militant (Smith 1996), and in some cases effective in slowing the process and forcing municipalities to preserve affordable housing and stop gentrification-related evictions.

Gentrification re-emerged after the recession of the mid-1990s with a new set of characteristics, and has diffused outward from global city cores into distant neighborhoods and downward along the urban hierarchy into cities previously untouched (Hackworth 2002). Early areas to gentrify have since been re-gentrified via processes of “financification” and “super-gentrification” (Lees, Slater, and Wyly 2008). Since the 1990s, big corporate developers have replaced individual owner-occupiers as initiators of the process, often forcing urban redevelopment into areas requiring larger capital investment to overcome barriers to property value appreciation. The role of the state as an active player in facilitating and encouraging redevelopment via gentrification has expanded since the 1990s. In the United Kingdom and the United States, national state programs (such as the United Kingdom’s “urban renaissance” programs and the United States’ HOPE VI program) have encouraged gentrification, and entrepreneurial city governments enthusiastically promote it. Indeed, with gentrification now generalized in the urban landscape, it has been globally adopted as urban policy by decision-makers and urban elites. Critics of gentrification point to its negative social impacts on the less affluent, working poor, and racially marginalized groups, who tend to experience displacement and exclusion as property values rise.

Since the early 1990s a new trend in urban redevelopment has involved the demolition of postwar public housing, the dispersal of public housing residents, and the construction of mixed-income communities in their stead (Crump 2002). This incarnation of urban redevelopment involves the extensive reach into areas previously thought “un-gentrifiable” (Hackworth 2002), including “ghetto” neighborhoods, single-room occupancy (SROs), and public housing. In the United States, public housing redevelopment was popularized by the federal HOPE VI program (1992–2010), which provided funding to local authorities (much like urban renewal) to demolish public housing and “deconcentrate” poor (predominantly African American and Hispanic) residents. HOPE VI redevelopment targeted many projects in gentrifying areas and resulted in a net loss
of social housing units and considerable displacement. Public housing redevelopment is not only an American phenomenon; it has been adopted around the globe, in the United Kingdom, Australia, Europe, Hong Kong, Singapore, and Canada as a “best practice” for eliminating postwar projects and facilitating gentrification by “social mix” (see Figure 3). In these places too, redevelopment can be violent and distressing, marked by unscrupulous and threatening behavior, and “revanchist” politics targeting low-income tenants (August 2014; Slater 2013). Community resistance has emerged to counter the destructive impacts of this new approach to urban renewal. In the United States, a grassroots coalition called the Right to the City Alliance published *We Call These Projects Home* (RTTC Alliance 2010), a community-driven research report arguing for the protection and expansion of public housing and the extension of housing rights. These demands envision a socially just approach to urban redevelopment, which prioritizes the needs of low-income communities (including women, LBGTQ communities, and people of color) over the needs of capital.

**Socially just urban redevelopment**

While geographers have shown that urban redevelopment has typically been associated with gentrification, displacement, and intensified...
spatial inequality, this does not have to be so. It is possible to envision a socially just urban redevelopment, in which the urban poor have the right to remain in their homes and neighborhoods, to send their children to high-quality schools, and to secure livelihoods within their communities. This vision would require interventions into capitalist market processes. Social housing can be built in wealthy and gentrifying areas to tip the balance away from concentrated wealth, targeting “redevelopment” toward rich areas, with the benefits also flowing to the poor. Inclusionary zoning can force developers to include a certain proportion of affordable units in their market-rate projects. A socially just form of urban redevelopment would set minimum requirements for such units at 50%, ensuring that wealthy households cannot dominate community governance. Redevelopment should incorporate a mix of housing styles and sizes, so that households of differing needs, life stages, incomes, and sizes can age in place. Similarly, urban redevelopment needs to include employment lands, for industry as well as community services, daycare, and health services—providing jobs and amenities within walking distance. Low-income, racialized residents and underrepresented groups should be guaranteed a voice on local councils making decisions on such matters, ensuring that urban redevelopment will be of benefit to the full range of people in a community. Such a democratization of urban redevelopment would necessarily mean limiting the reach of private sector investors and elites in determining city building processes. Otherwise, urban redevelopment cannot address contemporary urban problems, but will instead necessarily revert to the same basic pattern that Engels noted back in 1872, which is a hallmark of capitalist urban redevelopment—displacing the poor to make room for the rich.

Urban regimes

David Wilson

University of Illinois at Urbana–Champaign, USA

Urban regimes and its conceptual partner, urban regime theory, has been a dominant perspective in urban geography, political geography, and the social sciences for more than three decades. From its origins as a framework to explain city development and its relations of power in US cities, the concept has been applied across a diversity of settings: at the neighborhood level, city level, and metropolitan level. The perspective has been used to examine a multiplicity of questions, including how machine-style political formations stay in power, whether or how various interests (e.g., poor African Americans, poor Latinos, alternative sexualities, working-class communities) are incorporated into governing coalitions, how programs like urban renewal and public housing are established and implemented, and how uneven development in cities is deepened through government programs.

This work identifies urban regimes as amalgams of city-based institutions that construct, manage, and regulate the social, political, and spatial domains of cities. Such regimes — city governments, builders, developers, realtors, businesses, corporations, chambers of commerce — are seen to operate as semi-monolithic political entities in order to advance goals and plans. Their actions — plans, programs, initiatives — reflect the simultaneous drive to make cities ideal sites for capital accumulation and to successfully reproduce regime formation and maintenance. Successful regimes are formed when their dominant narratives successfully suggest that such amalgams and their actions are fruitfully and progressively advancing the best interests of the city and its populations.

The notion of urban regimes is inseparable from its underpinning theoretical base, urban regime theory. Regime theory views power as fragmented and regimes as the collaborative arrangements through which local governments and private actors assemble the capacity to govern. The original focus of urban regime theory, rooted in 1970s work, was the connections between locally based urban amalgams of institutions and the structure of the world economic system. Here such regimes were theorized as mediators and interpreters of transcontinental economic and political structural features. This focus soon shifted to the connections between US city regimes and the American capitalist economy. Fainstein and Fainstein’s (1983) work was extremely influential. To them, the character of urban regimes is derived from two structural features of the political economy: local government dependency on property taxes for fiscal solvency, and production of commodities being primarily privatized. These structural features, to Fainstein and Fainstein, explain the dominance of business, privatization, and property value interests in local politics.

More recently, regime theory has deepened to incorporate the realities of how city regimes must be responsive to political struggles, changing political and cultural conditions, and contradictions in local, regional, and national economic formations. As poststructuralist and postmodern sensibilities have suffused urban studies since the turn of the twenty-first century,
regime theory has seamlessly incorporated these concerns. Yet, still, the regime perspective continues to embrace a political economy orientation that rejects both pluralist assumptions that governmental authority is adequate to make and carry out policies, as well as structuralist assumptions that economic forces determine policy. Regime analysis, observed Clarence Stone (1989), should always be anchored in a foundation that examines the interconnections between the inheritance of structural forces, how these are interpreted, responded to, and modified, and the human decision to act. Urban regimes, to Stone and to current practitioners of this perspective, are structured but actively building and structuring constellations of power.

Urban renewal

David L. Prytherch
Miami University (of Ohio), USA

Urban renewal is a set of policies and planning practices addressing urban problems through government-led redevelopment. Urban renewal specifically connotes slum clearance policies in mid-twentieth-century North America, but is inseparable from wider urban redevelopment and gentrification processes.

Urban renewal, like biological metaphors often justifying it, dates back centuries. But urban changes accompanying industrialization prompted more systematic public interventions, particularly to relieve congestion. The Haussmann Plan for renovating Paris is one nineteenth-century example, but advocates of progressive tenement reform and modern(ist) social housing justified “slum clearance for its own sake” (Zipp 2012) in the twentieth century.

New public health and social sciences offered emergent welfare states techniques for analyzing urban problems, and planning provided the tools to address them.

Urban renewal took specific policy shape in the United States with the Housing Act of 1949, which promoted community development and “elimination of substandard and inadequate housing through the clearance of slums and blighted areas.” Grants encouraged local authorities to draft plans identifying slums and “deteriorating areas,” purchase or condemn them for redevelopment, and construct public housing. A revised Housing Act of 1954 shifted emphasis from public housing to “urban renewal” and commercial redevelopment. Urban Renewal Authorities across American cities targeted high-density, mixed-use, and typically minority neighborhoods for replacement by modernist commercial development and high-rise housing projects. But housing construction lagged, and millions – mostly African Americans – were displaced before what some called the “federal bulldozer.”

As impacts of these policies grew, so did critiques. Urbanist Jane Jacobs framed her book The Death and Life of Great American Cities (1961) as “an attack on current city planning and rebuilding” (p. 3), likening renewal to the “pseudoscience of blood-letting” (p. 13). Sociologist Herbert Gans highlighted the inequitable emphasis on developer over resident needs, and historian Robert Caro argued renewal created new slums as quickly as it cleared the old. By the 1970s, these critiques and public protest helped shift federal policy away from modernist planning and toward redeveloping existing neighborhoods through block grants.

But urban renewal continues today, if under different names, and remains subject to debate by policy actors and urban scholars. Cities today partner with private capital in strategic investment, planning, and use of eminent domain to encourage gentrification and mixed-use development. This “new urban renewal” (Hyra 2012) may emphasize historic preservation over clearance, but “serial forced displacement” continues apace (Fullilove and Wallace 2011). And the high modernist ideals and practices of urban renewal still enjoy a prominent planning role in industrializing and urbanizing countries like China, where historic neighborhoods – like Beijing’s hutong – are razed for high-rise development.
URBAN RENEWAL

Urban renewal may have specific connotations, but can be found wherever public planners encourage redevelopment and displacement in the name of blight removal and modernization.

Urban resilience

Richard Friend

Urban Climate Resilience in Southeast Asia Partnership (UCRSEA)

Urban resilience has become a ubiquitous motif but one that has emerged from disparate conceptual and historical roots, and is being applied with a diverse range of definitions, interpretations, and objectives. The rise of urban resilience brings together two agendas; the growing interest in and concern for an urbanizing world, along with a sense of a future that is increasingly uncertain and fraught with risk, in relation to global ecological change and to economic and political uncertainty. In order to understand urban resilience, it is necessary to unpack these two separate strands and to scrutinize the ways in which they have become entwined.

That the world is increasingly urban is widely accepted, even if the extent and significance of such urbanization is very much a matter of critical debate. With statistics in 2008 pointing to the majority of the world’s population being urban, a critical turning point in the ecological and social history of the world has been reached. This is interpreted in different ways – from an evolutionary perspective, in which the transition from rural to urban is an inevitable, necessary, and positive progression, to a debate framed around the growing importance of the globalized economy and the ways that cities are linked across territories and geographies, to representing an era beyond the nation-state. Cities and urbanization are powerful metaphors.

At the same time, resilience has emerged as a way of framing responses to the vicissitudes, uncertainties, and risks of life, whether on a personal, psychological level or at the ecological level, in the face of climate change and disasters and of emerging economic and security concerns. As a consequence of the prevalence of large-scale natural disasters, the economic crisis of 2008, and the spread of global terror and security fears, resilience has become a metaphor (Olsson et al. 2015) that appears to have crept into all facets of contemporary life at a time when life itself is portrayed as inherently uncertain.

The 2000s have also witnessed a series of major “natural” disasters that have struck urban centers in both the Global North and the Global South – Hurricanes Sandy and Katrina, Typhoon Haiyan, and the floods of 2011 in Thailand. Each of these events portrayed the implications of shocks and crises on large urban centers vividly. Intergovernmental organizations, international financial institutions, national and local governments, and large charitable foundations have all embarked on a range of initiatives targeting urban resilience to climate change and disasters, creating funding mechanisms to leverage investment finance to pay for building urban resilience. Urban considerations, and the language of urban resilience are also being taken up in critical global policy commitments such as the Sendai Framework for Disaster Risk Reduction, Sustainable Development Goals (SDGs), the United Nations Conference on Housing and Sustainable Urban Development (Habitat III), and the Paris Agreement of the United Nations Framework Convention on Climate Change. In the parlance of international development commitments and policy, achieving resilience is both an end in itself and a means to an end.
With so much of the world now framed as being urban, it is not surprising that the interest in resilience should be coupled with the urban world. Yet, in considering resilience and its application to the urban context, it is important to distinguish between resilience as a theory and concept with its own intellectual (if diverse) roots, and resilience as discourse that generates a whole set of connotations and meanings in its own right. Drawing this distinction between the theory and discourse of resilience becomes all the more critical when the two terms are used in combination. Much of the confusion and more heated debate around urban resilience has been caught between these two very distinct threads.

The theoretical concept of resilience has a long tradition of complex systems thinking, largely based around the ecological sciences but also found in the disciplines of psychology and engineering. Each of these intellectual fields influences its application in the urban context. Across these disciplines the significance of systems and functions is center-stage. Resilience thinking from the ecological perspective argues that complex systems are shaped by universal fundamental, natural laws that allow them to adapt to changing circumstances and, if necessary, transform themselves. Ecological systems possess qualities of dynamic equilibrium, thresholds, and self-organization (Olsson et al. 2015; Gunderson and Holling 2001). This interest in complex systems that have their own boundaries, structures, and functions and that can change and adapt, yet still maintain their core function, fits neatly with approaches to cities as organic systems, with their own structure and metabolism, yet with a whole set of fragilities, vulnerabilities, and risks. The psychological sciences tend to adopt resilience as an innate human characteristic, partly shaped by social and environmental factors, that in some circumstances requires intervention and nurturing to allow it to come to the fore. Building resilience allows individuals to function as full human beings, overcoming adversity, tragedy, and trauma; disturbances that are themselves seen as part of the human condition. From both disciplinary perspectives, resilience is thus an innate, natural feature of social-ecological systems and a universal characteristic of life. In many ways the engineering perspective on resilience is less problematic; the boundaries of the system, and the social purpose, function, and structure of an engineering initiative, are clearly defined as part of its design, which itself is a product of social and economic processes. Thus, identifying the boundaries of the system, and maintaining structure and function in the face of shocks and crises, are less problematic.

Images of both ecological and engineered systems are often alluded to in how resilience theory is defined and applied in the urban sphere. A common thread running through the theory of urban resilience lies in the application of at least some aspect of systems-based approaches to the contemporary urban sphere (Elmqvist 2014). The city is presented in some way as a system itself. This has been framed in different ways. The city as a system has been an enduring metaphor in urban studies. Ecological approaches have also been applied to the urban system. The link with the natural world also led to the city being presented as an urban metabolism, an ecological system with quantifiable flows of energy materials and information. This general approach has been developed into a view of cities bringing the natural and social world together, in line with concepts of the social ecological, in which the city is a combination of biophysical and social factors.

The urban systems approach has other traditions. It is argued that contemporary urbanization is distinct from other periods in human history because of its dependence on complex systems of infrastructure and technology that
allow for the scale and intensity of urbanization, and create linkages and networks of cities across specific territories and geographies. The engineering perspective has a clear link to approaches to urbanization that prioritize the built environment and the dependence on infrastructure and technology that characterize contemporary urbanization (Graham and Marvin 2001).

There are clear parallels with earlier approaches on networks of cities and global perspectives that highlight the ways in which cities are globally networked and interlinked, whether through infrastructure and technology (e.g., fiber-optic cables) or through flows of natural, financial, or labor resources.

Work focused specifically on urban climate resilience, an influential field in urban resilience, presents urban systems as composed of the interactions between (i) ecosystems, infrastructure, and technology; (ii) institutions (the rules, norms, regulations, and daily practice); and (iii) actors, that is, organizations, communities, households, and individuals (Tyler and Moench 2012; da Silva, Kernaghan and Luque 2012). Grounded in the theory of social ecological systems, this approach presents urban climate resilience as a contested process that brings together different interests and stakeholders, and that requires dialogue and different types of knowledge (Tyler and Moench 2012). For some authors it is an essentially political process. From this perspective, building resilience cuts across these three dimensions of urban systems, each with its own set of characteristics.

Such systems-based approaches to the urban phenomenon also points to emerging points of vulnerability not only as lying in shocks and crises that are place-based but also as being related to fragilities and potential failures that reside within multiscale systems themselves. Again, this kind of perspective appears in different forms and with different interests. It is argued that many cities are facing critical natural resource constraints: drawing core resources from increasingly distant hinterlands, they are yet unable to meet the needs of many citizens, and increasingly under strain as they expand and intensify. The infrastructure systems on which cities depend, and the ecological systems that make these viable, are increasingly vulnerable. While a shock or crisis may originate in one specific location, the way in which such systems are interlinked and interlocked creates impacts that cascade from one location to another, in some cases cascading across the globe through the systems that link different geographies.

These concerns also appear in a theory of urban conflict and resilience more overtly focused on military security. From this perspective, emerging urban systems create a whole new series of security threats that are argued to be irregular, hybrid, and nested (Kilcullen 2012). Such security threats are directly related to the connectedness of urban systems and to the trend for urbanization to occur in hazardous coastal locations. This again reminds us that, while climate change and disasters have been fairly persistent concerns running through urban resilience literature and debate, thinking around resilience has long been prominent in security theory.

Urban resilience theory, and the systems perspectives that underpin it, also draw on particular concepts of governance. Resilience has been closely associated with approaches to ecological governance that highlight issues of scale, arguing the need for multiscale, polycentric, participatory, and learning-oriented approaches. Similar basic approaches have been taken on in the urban resilience literature. Some emphasize issues of process and public learning (Reed et al. 2013) and others the need for institutional planning processes that are better able to deal with uncertainty and risk. Such systems-based approaches to urban resilience operate alongside...
a more individualistic dimension, where the adaptations that are argued to be most plausible, rather than most needed, are said to be realized at the individual, household, and community levels rather than through formal mechanisms of the state.

Much effort in the urban resilience literature has also been directed at identifying and measuring resilience. With so much debate as to what urban resilience means, there is also an effort to define the conditions of urban resilience, and especially to find globally applicable indicators and metrics. In this way, characteristics of resilience are outlined, for example redundancy, safe failure, diversity, flexibility, which can be measured quantitatively according to universally applicable indicators, and which allow for both self-assessment and comparison across different urban areas.

While urban resilience has certainly been in the ascendant in recent years, a number of critiques have also emerged, of both the theory and the concept of urban resilience, but perhaps more often of the discourse and policy narratives with which it is associated. These critiques have emphasized the importance of political economy perspectives of urbanization, pointing to the constraints of systems approaches and their application to the urban context, and to the limitations of resilience more broadly.

Resilience theory has been widely critiqued for its inadequate consideration of politics and power (Béné et al. 2012; Tanner et al. 2015). When applied to an urban context, this criticism relates to the ways in which cities create social and political relations, to cities as contested arenas, and to cities as performing symbolic functions in creating physical embodiments of meaning and value. For some authors, the urban (climate) resilience agenda has been poorly informed by theories of urbanism or of urbanization and the city, with inadequate attention to historical and political economy perspectives. From this perspective, urban resilience needs to take on board how urbanization is both a product and a necessary condition of capitalism that allow for the agglomeration of assets of production in specific locations and the transformations of social and economic relations of production and exchange.

Both urbanization, and by extension resilience-building efforts, inevitably support certain interests and groups at the expense of others. Depending on how the city is defined, and by whom, the resilience of the city does not necessarily mean a just and equitable outcome. Critics argue that, without a theoretical approach that is grounded in history and political economy, it is not possible to contextualize or to analyze the urban.

Despite this rich intellectual history, much of what appears as urban resilience is not always so clearly grounded in theory and concepts. Across the development and humanitarian sectors, resilience has emerged as a loose discourse, in which there are competing efforts to define what it means and what it implies rather than attempts at conceptual clarity. With the plethora of competing definitions, and public campaigns to say what resilience means, it is a term that means all things to all people, and eventually risks meaning nothing at all. It is in the discourse of urban resilience that the murkiness is greatest. Yet the discourse also takes on some of the core principles from resilience theory, but as metaphor with connotations rather than as precise theoretical application.

The influence of the discourse of urban resilience is thus not so much in terms of what it defines but what it symbolizes and the connotations that surround its use – and how such discourse can help shape policies, legitimizing certain kinds of solutions, knowledges, and actors while delegitimizing others. As Raymond Williams (1976) wrote of keywords in policy
discourse, their pervasiveness and endurance relate to the combination of the everyday with the technical, and their essentially positive associations. Being resilient is clearly a good thing, and so it is difficult to be against resilience.

The discourse of resilience draws as much on its everyday meaning as its more technical meaning. Connotations of coping with adversity and of stoicism in the face of repeated shocks and crises lend themselves to a whole set of urban policy framings, with a range of political implications. When the discourse of systems is introduced, this becomes additionally problematic, with urban resilience easily lending itself to policy narratives that privilege the protection of existing systems without considering how these systems are constructed and reinvented or whose interests they serve. Given resilience’s connotations of withstanding and bouncing back from shocks and crisis, and the need for tradeoffs in order to maintain system structure and function, there is less consideration of the systemic causes of such shocks and crises. As such, when resilience enters policy discourse, it tends to be more readily associated with a conservative or a more reactionary political agenda (Peyroux 2015; Tierney 2015).

The communitarian and individualistic arguments that emerge from urban resilience can similarly be problematic. These arguments have two quite distinct sets of interests. For some commentators, community is held up as the driver of radical, grassroots change: the mechanism to counter the extremes and injustices of both the market and the state. Yet individualistic framings are also in line with arguments around “autonomous adaptation” with the responsibility for action at individual, household, and community level. As such, urban resilience can be very much in line with neoliberal arguments, about the failings of the state, and the inadequacy of formal government systems to deal with complex, multiscale challenges. Such arguments tend to privilege markets and individual responses.

Emphasized as a human quality to be nurtured in individuals, households, and communities, the concept of resilience takes responsibility for shocks and crises out of the public sphere, thus lending itself to a narrative of coping and bouncing back – even when the system might be broken (Harrison 2012). For others, that the discourse of urban resilience has emerged during a period of global austerity is no coincidence (Slater 2014). Resilience narratives can easily legitimize the state pulling back from its responsibilities (Harrison 2012; Peyroux 2015; Tierney 2015).

Along with the discourse of resilience, a more persistent urban policy discourse has emerged that is shaped by interpretations of what cities mean as they become metaphors for a whole range of political, economic, and social values as centers of business and economic activity and thus of innovation; the need for infrastructure; and the business case for building smart cities. These shifts lend themselves to large programs of investment-led resilience building, of bringing in the finance to build a resilient future.

This discourse has also been challenged around issues of power and knowledge, with a critical counternarrative of urban resilience emerging (Slater 2014). Resilient cities are not necessarily cities that are socially just or equitable – and indeed critics would argue that arguments around resilience operate by diverting attention away from these more overtly social and political considerations. In many ways, the grounding of resilience theory in systems theory, and the connotations of innate universal natural conditions reinforce a discourse and range of policy narratives of a resilient city that ignore such issues. Yet other interpretations again highlight the political dimension of urban resilience, and
framing the problem as fundamentally one of governance (Friend and Moench 2015).

In other disciplines, resilience has been presented as part of a continuum (Elmqvist 2014). For example, in the literature and practice of disaster risk reduction, resilience is a necessary but not a final condition. Ultimately, the reduction of the risk of disasters requires transformative solutions that address the root causes of vulnerability; where systems are broken they need reconfiguring. Increasingly both the urban resilience, or perhaps more accurately the urban futures debate, and the climate change debate have begun to scrutinize the trajectory of economic development, in which urbanization plays a central role. A more critical body of theory has emerged arguing that both urbanization and climate change are features of capitalism and that, in order to avert global ecological catastrophe, we need a transformative urban agenda that is climate compatible and also socially just, equitable, and inclusive.

A common notion across these debates is that we are entering a critical and uncharted period in human history, and are thus caught up in a struggle about reconfiguring social life that is very much about an urban future, in relation not just to the city space itself but also to what the increasingly globalized world should look like and for whose benefit. Perhaps these struggles of the urban future are as significant as similar, more familiar, struggles over citizenship, nationhood, and nationality; social justice, equity, wellbeing, and rights; and human–nature interactions.

Urban transit covers the realm of nonpersonalized transportation in cities. Known by many terms including “mass transit” and “public transportation,” it refers to the task of moving people throughout urban environments in shared vehicles where origins and destinations are accessed by vehicle stops that can be either at predetermined stops or stations, or at ad hoc locations, both types of which can feature varying levels of infrastructure. The challenge of the mass transit of people is a formidable one in transportation, and immense amounts of money and time have been spent on utilizing urban transit to alleviate congestion, move individuals in a timely and efficient manner, and advance the interaction of transit with land use and economic development. This entry reviews the evolution of this process and the different modes of urban transit that have been utilized. It ends with a discussion of how urban transit varies by region, and of the future outlook of urban transit technologies, use, and deployment.

Evolution of urban transit

In the United States, urban transit has been described by Peter Muller (2004) as developing in four overlapping eras of the spatial evolution of cities: the walking/horsecar era (1800–1890), the streetcar era (1890–1920), the recreational automobile era (1920–1945), and the freeway era (1945 to present). Though this timetable is obviously US-centric, urban transit across the world can be seen developing through these stages at different times and places.

Urban development has occurred as a function of the speed and carrying capacity of its transportation system. Therefore, urban transit has evolved as a function of the relationship between the technologies available for transportation with the type of urban development supported by the characteristics of that travel technology. The level of economic development of a city and its host country; its cultures of mobility, development, and personal space; and the structure, legitimacy, and efficacy of its political institutions also influence the evolution of a city’s urban transit system.

The walking/horsecar era

Before the middle of the nineteenth century, most American and European cities were small, highly clustered settlements where citizens were able to walk from the center of the city to the edge in 30 minutes or less. After the early 1830s, the Industrial Revolution placed pressure on the boundaries of the city by increasing population and population densities, innovating building construction to allow for taller structures, and creating intense pollution in areas of the city near factories. It also provided the railroad, whose steam- and coal-powered locomotives provided a means to power larger-capacity vehicles at speeds faster than walking along dedicated rail tracks. Along with the horsecar (where horses pulled passenger trolleys along existing roads), the railroad provided the speed and carrying
URBAN TRANSIT

capacity to expand daily travel in and out of the inner city to new “suburban” residential development built around stops that featured more single-family homes and settlement at lower population densities. The railroad also helped introduce and then make commonplace the act of “commuting” from home to place of work, whereas before people usually lived near or in the same buildings as where they worked. These introductions provided an opportunity for middle-income citizens to move away from the congested city center, and helped start the gradual dispersion of the urban center (Muller 2004). Some cities in the developing world experienced this stage of urban development and transit deployment, especially those that were parts of colonial powers, at similar times or in the ensuing decades after the Industrial Revolution spread through the developed world.

The electric streetcar era

By the early 1890s, the electric trolley or streetcar was the most common mode of intraurban transit in the United States. Systems progressed with similar speed in European cities, and their impact on the development of urban areas was profound. This new ease of movement further encouraged rapid outward expansion of the city, with new land utilized for home development and city subcenters along trolley lines and trolley stops, and saw the emergence of specialty districts for commerce, industry, and transportation. Running on electricity, streetcars lacked the point-source pollution of the locomotive railroad’s smokestack and the horsecar’s equine waste, and served to help clean up urban areas dramatically. Trolley lines stretched out to the edge of the city, allowing for the rapid expansion of urban development while improving access to all the essential activity nodes of the city. These lines would later go on to pave the path for major boulevards (and later freeways), which aided the proliferation of the automobile (Muller 2004). Colonial cities in the developing world saw parallel developments, while such established, fixed guideway transit systems were largely bypassed in urban areas, which were growing rapidly under modern globalization, in favor of bus and informal, small-scale means of urban transit.

The recreational automobile era

It was the early 1920s before automobile ownership began to spread beyond early adopters to the general population. The roaring twenties and the economic expansion that preceded the Great Depression, as well as assembly-line innovation and Henry Ford’s Model T helped to democratize automobile ownership and establish it as an economic and cultural aspiration. During this period up to the end of World War II, the trolley lines and subways of urban areas were at their maximum use. Every urban settlement of any size had an established streetcar network, and the combination of relatively limited spatial expansion of the suburbs (compared to what was to come), extensive transit infrastructure, accessible mixed-use development near widespread transit stops, and limited automobile ownership and highway infrastructure (but still enough to alleviate some transit congestion) has led to this being called the point where “intrametropolitan transportation achieved its greatest level of efficiency” (Muller 2004, 69). Modern European cities more closely resemble this now, though the proliferation of the automobile within them is still much greater than what cities in this era saw. Many rapidly growing cities of the developing world (in particular, those in China) are currently going through a version of this stage, though their population densities are so great and their automobile growth so rapid that they
are experiencing choking congestion and urban air pollution, and much more of their urban transit is by bus than rail.

The freeway era

Production efforts for World War II and the preceding 15 years of economic depression hindered the expansion of the automobile industry. However, in conjunction with the petroleum industry, the automobile industry boomed once the postwar economy transitioned from military production to the production of consumer goods. Additionally, in 1956, the Interstate Highway Act was implemented, which would provide high-speed infrastructure to maximize the speeds with which the automobile could travel. A rising standard of living, along with numerous other cultural factors and institutionalized policies (such as incentives for homeownership and mortgage loans) helped prioritize individual automobile travel as a social status symbol and transportation necessity. As urban areas grew, they rapidly decentralized, and single-family housing proliferated. Cities encouraged radial expressways around their central business districts in the 1950s and 1960s, believing that it would increase accessibility to downtown by speeding up travel. The proliferation of these freeway systems sped up residential and commercial decentralization (Muller 2004).

This changing physical and social environment of transportation had a profound and lasting impact on urban transit. As transit use declined with increasing automobile use, petroleum and automobile companies purchased private transit operators, removed their extensive track systems, and replaced them with buses (or motor carriages), which were more flexible in routing and had smaller carrying capacities. The service quality and extent failed to match those of their rail-based predecessors, and, with rapidly dropping population and housing densities, transit use declined to near zero in many areas and private transit operations almost ceased to exist. Urban transit was reinstated as a publicly managed social service to provide transportation to those who couldn’t afford or were unable to own an automobile in American cities in the 1960s and 1970s. At this point, urban automobile congestion began to reach critical levels, and in the 1970s and 1980s urban transit first began to be reintroduced to urban areas as a way to combat this congestion and to help redevelopment in declining central city areas. This continued into the 1990s as heavy rail, and then later light rail and dedicated busways, began to proliferate in US cities, and bus services grew to help feed some of these lines. Rising gasoline prices also placed pressure on automobile use, and by the early 2010s urban transit use was at its highest level in the United States since the early postwar period.

Many European cities had a different experience, with the evolution of urban transit after World War II in large part due to the extensive damage as a result of the conflict. In the reconstruction of these cities, historical city centers were preserved and urban transit prioritized to a greater extent than in postwar US urban growth. Proliferation of the automobile has long been an issue in European urban areas, but greater constraints on automobile use, funding for transit and taxation of automobiles, and tighter coordination of land uses with transit investment meant that urban transit has always enjoyed a much larger role and presence compared to its American counterpart.

Cities in the developing world often find themselves in a hybrid version of the recreational automobile era and the freeway era. Rising standards of living, rapid economic and population growth, and automobile ownership as a sign of social status encourage its use, but extraordinary wealth
disparity and poorly functioning state institutions hinder management of this growth and of urban transit as a means of alleviating the problem. As such, many cities in the developing world are characterized by extreme urban congestion.

Urban transit vehicular modes

Urban transit is deployed through an array of technologies. These technologies vary by cost and powertrain, as well as by carrying capacity, speed at which the vehicle can travel, and the means of piloting the vehicle. They also vary by infrastructure needed for the transit vehicle to operate and the nature and frequency of stops used to access the transit vehicle. Lastly, transit operations vary by the degree of structure and formality of the entity operating the transit service. Some modes, particularly in developing countries, play an instrumental role in the transportation of people around busy urban areas despite not being formalized by the state or by public transportation agencies.

Bus transit

Perhaps the most recognizable and ubiquitous form of urban transit is the bus. Buses come in many shapes and sizes, but are characterized by having a single driver and a mix of seats and standing room for passengers. Buses have often run on diesel fuel, though in the developed world there has been a transition to cleaner burning fuels such as liquefied natural gas (LNG) or hybrid electric motors. Buses usually run fixed routes and pick up passengers at predetermined stops, though ad hoc and on demand services are also deployed. They usually run in traffic with other cars and share roadway infrastructure with private transportation. Many buses have signal priority and dedicated spaces to pull into stops to improve their ability to maintain a schedule and ease their impact on urban congestion.

Light rail transit (LRT)

Light rail transit most closely resembles the vehicles of the electric streetcar era. These systems usually operate single cars or short trains along exclusive rights of way at ground level, though sometimes they also operate in mixed traffic. Additionally, they can operate on dedicated aerial or subterranean structures. The flexibility of LRT is what distinguishes it from other forms of fixed guideway modes of transportation (Transportation Research Board 2000). Light rail can take on many forms and names (modern streetcars, trolleys, and trams often feature LRT characteristics). Some systems are very short, serve almost exclusively tourist or recreational trips at low speeds, and operate with other traffic; others resemble heavy rail systems more closely, operating in long multicar trains at high frequency along dedicated tracks, with extensive infrastructure around stops. Light rail has been a popular choice to help alleviate urban congestion and instigate urban development around stops and central cities in the developed world, particularly in North America, and to a lesser degree in European cities.

Heavy rail transit (HRT)

Heavy rail transit systems have separate rights of way from all other vehicular and foot traffic, with sophisticated signaling and high platform loading. They operate with heavier loads of traffic at higher speeds in larger cars and with less frequent stops than light rail. Heavy rail transit can also be defined by its power source, which is usually supplied electrically by a third rail. Heavy rail commonly runs underground in the form of subways so as not to interfere with already
dense street surface congestion, though it sometimes appears on the surface and may also run on elevated structures within a system. Sometimes referred to as a metro, heavy rail is usually limited to densely congested corridors of the largest cities in a country, and is an essential part of a city’s transportation system in these places. New York, London, Paris, Mexico City, Tokyo, and Moscow are all examples of places with extensive, heavily used metro systems.

**Commuter rail transit (CRT)**

Commuter rail systems are electric or diesel-powered railways for distance travel between a central urban city and its surrounding suburbs. Services on commuter rails are operated on a regular basis under contract for the sole purpose of transporting passengers within or between urbanized areas and their outlying areas. They are not usually meant to influence urban development; instead, they are meant to serve it and to alleviate congestion in highly traveled corridors. A specific characteristic of commuter rail systems is their offer of multitrip tickets from station to station, usually with only one or two main stations within the urban core of a city.

**Bus rapid transit (BRT)**

Bus rapid transit can be described as having all the characteristics of a rail-based system without running on actual rails. BRT is a high-capacity rapid transit system that operates on a dedicated, fixed guideway lane. As with a train, passengers are picked up and dropped off at stations, and the grade-separated lane gives the BRT the ability to avoid automobile traffic. Many BRT systems also include an intelligent transportation system (ITS), which tracks BRT vehicle locations, controls traffic signals, and predicts arrival times in order to streamline the process. BRT is increasingly popular among urban policymakers because its infrastructure costs are cheaper than those of light rail and other fixed guideway modes.

**Cable car**

A cable car is a railway-based individually controlled transit vehicle similar to a trolley or a streetcar, which uses a moving cable system located below the street surface and is powered by a central offboard motor. An iconic example of cable cars is the much loved system in San Francisco, California. Cable cars are also capable of traveling on steeper gradients than light or heavy rail, because they are pulled by cable rather than trying to push their way up gradients, which also explains their use in places, like San Francisco, which have many sharp elevation changes. Most cable car systems are used primarily for tourism, because the small cars cannot handle a heavy load of traffic such as those of light or heavy rail systems.

**Aerial tramway**

An aerial tramway consists of an electrically powered system of cables that carry suspended, powerless vehicles. While the most common use of aerial tramways can be seen at ski resorts as gondolas or in a mountainous area that draws a lot of tourism, some cities use aerial tramways as a quick way to move people up and down highly mountainous urban areas. One successful example of aerial trams as urban transport can be seen in Portland, Oregon, which introduced the Portland Aerial Tram in 2007 in order to ease traffic congestion for patients and employees of the Oregon Health and Science University, the largest employer in Oregon (Greenhalgh 2013). Medellín in Colombia has also used aerial
URBAN TRANSIT

tramways as a form of urban transit across its mountainous cityscape.

Ferry boat
Ferry boats are most commonly used in coastal areas to transport people (and sometimes vehicles) across large bodies of water that divide urban areas. Most ferry boats are powered by diesel or steam, and have the ability to carry a large amount of weight, which is useful when commuters driving across bays or harbors need the use of their vehicle once they reach the ferry’s destination. New York City and Seattle are examples of areas that feature ferry boats as essential parts of their transportation systems.

Taxi
Taxis are individual cars that are usually part of a larger fleet working for a private company, as opposed to a state-funded and organized agency. The distinguishing characteristics of taxis include their ad hoc, point-to-point pickup, metering charge by distance, and usually small carrying capacity. They are extremely common in urban areas, and are often used when people prefer the convenience and privacy of individual transport that picks them up and drops them off exactly at their desired points of origin and destination. Many traditional taxis operate by the driver traveling through high traffic areas and picking up passengers who signal to them. Increasingly, taxis also operate in response to demand, where a trip is arranged ahead of time. Recent developments have included the rise of car-sharing services such as Uber, which have challenged the traditional structure of the taxi cab company. Other types of taxis which are more common in cities in developing countries include the jitney, which is a shared taxi between the size of a passenger vehicle and a bus, and a rickshaw, which is a cart pulled by one or more people on foot or tricycle.

Regional differentiation

Urban transit deployment varies considerably across different regions of the world. Many factors drive these differences. Economic development and standard of living are important influences. Cultural factors, policies, and institutional structure also influence distinctiveness, as does physical geography. These are discussed in greater detail by region in the rest of this section.

North America
North America has already been largely covered in this entry. Urban transit in the United States and Canada has been closely tied to the development of the automobile and (in particular in the United States) national-level policies designed to facilitate automobile mobility and single-unit homeownership. With industrialization in the late nineteenth and early twentieth centuries, urban population densities grew to extraordinary levels. Since the automobile boom of the mid-twentieth century, private transportation has become an ever-growing necessity in North American culture. The Interstate Highway Act is one of the most important public works projects in American history because of its influence on the modern structure of cities, through facilitating the suburbanization of housing and single-use development by the rapid expansion of roadway infrastructure after World War II. Urban transit has had a revival in use and prioritization in quite a few North American cities in the late twentieth and early twenty-first centuries, but it still constitutes a small proportion of overall travel in these places.
Europe

Urban transit in Europe, as in North America and East Asia, has a long history embedded within the evolution of transportation technology and the spatial characteristics of the city. Major differences from North America include the influence of the age of cities and the rebuilding of many European cities after World War II. As in the United States, the history of urban transit began as a response to industrialization in the eighteenth and nineteenth centuries, and its effect in creating very large urban densities of population. Partly as a result of the natural density of the old European cities, the negative effects of heavy automobile transportation like air and noise pollution became more acute than in their North American counterparts after World War II. Many policies have been enacted that regulate vehicles in congestion-free zones during certain periods of the day, and that make gasoline consumption and automobile purchase considerably more expensive, which explains to some extent the smaller number of vehicles on the road compared to in the United States (European Commission 2015). Nearly 60% of Europeans use public transportation in some form, compared to a mere 5% of Americans (Benfield 2011).

Australia

Australia has urban transit very similar to its developed world counterparts, though it more closely resembles American than European cities. Sydney and Melbourne have large, advanced fixed guideway systems complementing bus systems. Since the end of World War II, most of the urban cities in Australia changed drastically from small, close-knit cities, to relatively sprawling and auto-dependent. In the 50 years between 1955 and 2005, the number of registered cars increased from 2.5 million to over 11 million, while the number of citizens who depend on trains or buses has steadily decreased (Australian Bureau of Statistics 2005). As in the United States, there has been uptake in the use of urban transit and an acknowledgment of the role it can play in transportation and urban sustainability since the early 1980s.

China

Urban transit in China, through much of its history, consisted largely of informal, small-capacity modes like the rickshaw. Increasing urbanization and industrialization saw the arrival of some bus and streetcar systems in a few cities. In the latter half of the twentieth century, with China’s economic boom, came a rush of urban development that put rapidly growing pressure on its nascent urban transportation systems. Rapid, sustained urban growth and modernization have contributed to urban China experiencing American-style traffic conditions, featuring expansion in automobile travel and, with it, traffic and urban air pollution at scales and speeds far greater than what was seen in the developed world. For example, by 2004 the average speed of traffic on major highways around Shanghai had slowed to 10 km per hour, and this kind of congestion is now commonly seen in Chinese cities that were small towns only a decade ago. Many Chinese cities have begun to address these issues by developing and implementing innovative plans for expanding road infrastructure, subway and light rail systems, rapid bus transit vehicles that bypass automotive congestion, and magnetic levitation systems (Peng 2011). Today many citizens living and working within the urban core of a large city also depend on walking and a metro system to get around, though car use grows with an increasing standard of living.
**East Asia**

Japan and South Korea offer distinct urban transit environments characterized by their post–World War II redevelopment, limited urban land availability, and high population densities. Though they have extensive urban roadway networks and automobile congestion, they are also characterized by dense urban development and extensive railway and busway networks designed to serve these extraordinary densities. Their municipalities are also characterized by high economic standards of living, and there is no stigma attached to the use of mass transit as there is in some other developed countries. Rather it is seen as an essential part of the fabric of urban life. Other municipalities in Southeast Asia, such as Singapore, Hong Kong, and Kuala Lumpur also fit this description, featuring heavily used metros, high density, and relatively high standards of living.

**Central, South, and Southeast Asia**

Much of the rest of urban Asia doesn’t have the same level of economic development as China, Japan, or South Korea, and as such have a wide array of urban transit modes, which are influenced by the culture and policy within each country. Urban transit within bustling Southeast Asian cities is highly informal and more dependent on the private sector to provide it. Aside from rail systems, which are one of the consistently formalized transportation systems across Southeast Asia, modes of transportation range from rickshaws and three-wheeled covered bicycles, to buses and overnight trains. In addition to the cities of Southeast Asia mentioned earlier, the densely populated major cities of India also feature extensively used heavy rail systems, which have helped alleviate massive roadway congestion and feature a wide mix of public and private transportation modes. In places such as Vietnam, one of the most common short-distance modes of urban transit is by scooter, or “moto.” Shared taxis are also commonplace across southeast Asian countries (Dean 2011).

**South and Central America**

Though they lack the level of economic development and standard of living of their North American counterparts, many cities in Central and South America have extensive and well-organized urban transit systems, some of which offer better accessibility than similar North American cities. Governments in Central and South America are fraught with issues of institutional legitimacy, which hinder development in many of these places. Urban transit was once exclusively based on buses, private taxi systems, and private vehicles, but since the 1970s many cities have implemented BRT systems, trams, and aerial tramways, and have pioneered innovative solutions such as outdoor escalators to enable pedestrians to climb the steep hills of those cities embedded in undulating terrain more easily. Mexico City and Sao Paulo are examples of cities that feature extensive heavy rail systems, though much of Mexico City’s system actually runs on rubber-tired vehicles. Curitiba, Brazil, pioneered the BRT style of transportation in the 1970s when the city opted to build infrastructure for “long buses” instead of a subway or light rail system. This saved the city hundreds of millions of dollars and, alongside concomitant land-use policies, had a positive impact on urban congestion and development that many other cities have tried to emulate (Khana and Khana 2011). Outdoor escalators were installed in the slums of Medellín, Colombia, to enable citizens to walk to the city center easily (Henley 2013). Many cities across South America, like Bogotá in Colombia and Rio de Janeiro in Brazil, have begun to implement new and innovative urban...

*URBAN TRANSIT*

Japan and South Korea offer distinct urban transit environments characterized by their post–World War II redevelopment, limited urban land availability, and high population densities. Though they have extensive urban roadway networks and automobile congestion, they are also characterized by dense urban development and extensive railway and busway networks designed to serve these extraordinary densities. Their municipalities are also characterized by high economic standards of living, and there is no stigma attached to the use of mass transit as there is in some other developed countries. Rather it is seen as an essential part of the fabric of urban life. Other municipalities in Southeast Asia, such as Singapore, Hong Kong, and Kuala Lumpur also fit this description, featuring heavily used metros, high density, and relatively high standards of living.

Central, South, and Southeast Asia

Much of the rest of urban Asia doesn’t have the same level of economic development as China, Japan, or South Korea, and as such have a wide array of urban transit modes, which are influenced by the culture and policy within each country. Urban transit within bustling Southeast Asian cities is highly informal and more dependent on the private sector to provide it. Aside from rail systems, which are one of the consistently formalized transportation systems across Southeast Asia, modes of transportation range from rickshaws and three-wheeled covered bicycles, to buses and overnight trains. In addition to the cities of Southeast Asia mentioned earlier, the densely populated major cities of India also feature extensively used heavy rail systems, which have helped alleviate massive roadway congestion and feature a wide mix of public and private transportation modes. In places such as Vietnam, one of the most common short-distance modes of urban transit is by scooter, or “moto.” Shared taxis are also commonplace across southeast Asian countries (Dean 2011).

South and Central America

Though they lack the level of economic development and standard of living of their North American counterparts, many cities in Central and South America have extensive and well-organized urban transit systems, some of which offer better accessibility than similar North American cities. Governments in Central and South America are fraught with issues of institutional legitimacy, which hinder development in many of these places. Urban transit was once exclusively based on buses, private taxi systems, and private vehicles, but since the 1970s many cities have implemented BRT systems, trams, and aerial tramways, and have pioneered innovative solutions such as outdoor escalators to enable pedestrians to climb the steep hills of those cities embedded in undulating terrain more easily. Mexico City and Sao Paulo are examples of cities that feature extensive heavy rail systems, though much of Mexico City’s system actually runs on rubber-tired vehicles. Curitiba, Brazil, pioneered the BRT style of transportation in the 1970s when the city opted to build infrastructure for “long buses” instead of a subway or light rail system. This saved the city hundreds of millions of dollars and, alongside concomitant land-use policies, had a positive impact on urban congestion and development that many other cities have tried to emulate (Khana and Khana 2011). Outdoor escalators were installed in the slums of Medellín, Colombia, to enable citizens to walk to the city center easily (Henley 2013). Many cities across South America, like Bogotá in Colombia and Rio de Janeiro in Brazil, have begun to implement new and innovative urban...
transit infrastructure to alleviate congestion and provide accessibility for their rapidly growing populations and economies.

Africa

Africa’s urban transport systems, while well developed in countries like South Africa, are the least-developed transportation systems in the world. Many African cities have encountered a surge in growth with urbanization, which has led to the need for stronger infrastructure to handle rapidly growing need for mobility in their population. Most cities have not been able to keep up with this rapid growth and motorization, which leaves many roads unpaved, overwhelmed with car congestion, and lacking in traffic control. Rampant corruption and issues of institutional legitimacy also plague African urban transport management. Because of the infrastructure shortfalls in many countries, the use of large buses or rail transit is not feasible, so the use of minibuses, shared taxis, and motorcycles is promoted by cities (Kumar and Barrett 2008). Bus systems account for up to 44% of all transport in many cities, while personal vehicles account for only 7% of daily transportation. While bus transport is by far the most popular mode of motorized transportation, walking in urban areas accounts for 47% of daily travel within a city. There is also a great amount of walking in addition to many bus trips (Howe and Bryceson 2000).

The future of urban transit

Urban transit serves many different purposes across the world. In many American cities, it is little more than a social service for those who cannot afford to own an automobile. In the large dense cities of the developed world, it is a vital and frequently used component of a thriving metropolis. In much of Europe, it is a standard way of travel within a modern transport system that is coordinated with land-use management. In the burgeoning urban environments of the developing world, it operates through a diverse array of formal and informal forms that struggle to keep pace with a rapidly growing population.

Technological development has always influenced transit. Future developments of alternative fuels, and remote power and control of transit vehicles, should continue to permeate urban transit operations. The replacement of fossil fuels in transit operations with electrification, natural gas, and even hydrogen fuel cells continues, and in many aspects urban transit is far ahead of private automobile transport in advancements in the sustainability of its energy sources.

Perhaps the primary set of questions for transit in the near future involves operation and management. In the United States, political and economic trends have put increasing pressure on the ability of governments to fund essential operations such as transit. Urban transit also has to contend with a negative image and associations for much of its car-driving populace; continued investment in capital projects, technological advancement, and operation and management are therefore always an uphill battle. Many local governments have had success in attracting investment for fixed guideway transit projects to help revitalize urban development around its stops, but these serve a fairly limited subset of the population. Elsewhere in the developed world, urban transit is far more established and extensive, and land use is more suited to access by transit. Despite this, car ownership and use in Europe is rising, as preference for the convenience, luxury, and status of the private automobile grows despite considerably higher costs through taxation and the regulation of automobile use.
Lastly, the developing world provides what is likely the best opportunity for transit to serve a population and influence land use. Most cities in the developing world are growing at exponential rates. This growth into previously rural land and the redevelopment of underutilized land, coupled with an existing low standard of living and long-standing use of urban transit and other nonmotorized modes of transport, could provide a blank slate for a transit-oriented development that discourages automobile use. However, organized public transit faces an uphill battle in many urban areas in the developing world. Institutions in these places are often poorly organized and function extremely inefficiently. Car ownership is also widely seen as an essential status symbol and component of economic development and personal achievement. The population density in many of these places includes undesirable living conditions reminiscent of extreme versions of urban development during the Industrial Revolution, whereas suburban-style development is viewed as a positive and desired goal. The momentum of Western-style suburban, auto-oriented development in the developing world may already be so great that the outcome is inevitable and the latter no longer has the option of developing a transit-oriented urban model.

Urban uneven development

Christopher Mele
University at Buffalo, USA

The concept of urban uneven development refers to the particular spatial expression at the city or metropolitan scale of a larger process of uneven development under capitalism. Uneven development is defined as asymmetrical capitalist social relations of production across geographic space at varying scales (hemisphere, nation, region, urban area, etc.). Central to the theory of uneven development is the principal connection between the investment of capital in one or more places over time: the concentration of capitalist growth and investment in one area (e.g., the rise of Sun Belt cities in the United States) requires a correlate underdevelopment in another (e.g., deindustrialization and the decline of Rust Belt cities in the United States).

Uneven development provides two essential interrelated functions to modern capitalism: as a sociospatial process of accumulation, tied to a broader theory of capitalism related to the production of space for purposes of surplus extraction, and for accumulation, through the production of space as a commodity itself within the second circuit of capital (investment in production). The uneven production of space for accumulation in the second circuit of capital is an important subarea of research in critical urban studies in the disciplines of geography, sociology, politics, and cultural studies. Research on urban uneven development focuses primarily on the production of urban space as a commodity for capitalist accumulation. This entry summarizes the two aspects of uneven development tied to accumulation that are the basis of the concept of urban uneven development, and discusses the driving roles of the state and real estate sectors.

Uneven development is a necessary precondition for the continued accumulation of capital and, therefore, the historical development of capitalism itself. The spatial form of development acts directly on the reproduction of relations of production: the spatial expression of land values, labor costs, technology, and transportation necessary for surplus value extraction and capital accumulation. Periodic crises in accumulation therefore entail both a social reorganization of production and the (re)development of new spaces for restructured surplus extraction. The unevenness in the social relations of production between spaces triggers investment capital to move in order to seek higher rates of return, resulting in urban uneven development. Recent technological innovations, the expansion in multinational corporations, and the restructuring of economic boundaries between nation-states have facilitated the acceleration in the global circulation of capital, information, commodities, and labor. The acceleration of flows enhances the prospects of accumulation crises and the restructuring of space. Global capitalism not only links different places across the globe to surplus extraction more efficiently but also subjects them to recurrent bouts of uneven development due to the ease of movements of capital.

The second, linked, component of uneven development emphasizes the production of space itself as a commodity for accumulation, subject to crisis. It developed out of a social justice perspective that took hold within critical geography in the wake of the global proliferation of
urban social movements in the late 1960s and
the spatial polarization and social inequalities in
Western cities in the 1970s. Since the 1970s,
uneven development has formed the theoretical
basis for critical research on suburbanization,
urban decline, and gentrification, thus connect-
ing urban development to the larger process
of uneven development. At the center of this
research agenda is the conception of urban space
itself as a core component of capitalist accumula-
tion in addition to acting as a space for the social
relations of production (as summarized earlier).
The critical geographer David Harvey’s core
contribution to urban uneven development is
his analytical linking of the social production of
space to the circulation of capital. To Harvey, the
key to the functioning of the capitalist accumu-
lation process is the ability of capitalists to shift
investments between three interrelated circuits
of capital. The primary circuit consists of finance
capital invested in commodity production, such
as manufacturing and services. The second
circuit is fixed capital, consisting of land and
the built environment. In the third or tertiary
circuit, capital is embedded in scientific research
and knowledge and in social expenditures for
the reproduction of labor power. Because of its
enhanced liquidity, investment in the first circuit
is optimal for the return of profit. But continued
investment in finance capital lowers productivity
rates and creates a crisis for profitability, prompt-
ing capitalists to seek a higher return of profit
elsewhere. Investment in the fixed capital circuit
provides an alternative – what Harvey refers to as
a “spatial fix”: the flow of investment capital into
the production of space. The reverse process is as
tenable; during periods of spatial disinvestment
capital “fixed” in the land and the built envi-
ronment can flow into the first or third circuits.
Alternatively, capital can remain in the second
circuit but shift to another space (geographic
switching). The free movement of capital in
search of higher investment returns produces
recurrent patterns of spatial unevenness; as one
place is subject to disinvestment and declines, the
other benefits from (re)investment and thrives,
and so forth. The operation of the second circuit
of capital provides the material basis for uneven
development, as capital is deployed in the spec-
culation, development, or disinvestment of the
built environment.

Building on the work of Harvey, the geogra-
pher Neil Smith’s research has added significantly
to the understanding of uneven development at
the metropolitan–urban scale. Smith’s theoretical
contributions are best conveyed through a
synopsis of his empirical analyses of the aban-
donment and gentrification of the urban built
environment. Urban uneven development in the
late twentieth century involved the systematic
incremental flow of investment capital out of
and back into the built environment. Given that
the built environment is a fixed commodity and
not prone to easy liquidity, capital flows tend
to occur “below the surface” (such as the spec-
culation in empty lots or deteriorated buildings
for later development) and sequentially (such
as reinvestment block by block over time). The
value of urban space to capitalists, according to
Smith, consists of its actual (at a given moment)
land rent and potential (at some point in time
in the future) land rent; in terms of investment
flows, the potential rent is the more important
of the two values. Smith refers to this difference
between actual and potential land rent as the rent
gap. Gentrification is a mostly invisible process
(from abandonment to speculation to actual
redevelopment) of closing the rent gap. Smith
showed how disinvestment and reinvestment in
urban space are intrinsically part of the same
process: the uneven development of urban space.
In addition to a political economic analysis,
Smith pointed to the importance of social and
cultural factors that mediate or accelerate urban
uneven development, including state policies
relating to the urban poor and homeless and grassroots social struggles and resistance to displacement pressures, showing that urban uneven development is neither a mechanistic nor an inevitable force of capitalism.

Urban uneven development is a process contingent on the sometimes volatile interplay between structural forces (e.g., government policy, land values) and various agents and stakeholders with different interests (e.g., existing residents, gentrifiers, and neighborhood groups). The process of “switching” in the second circuit of capital involves a number of institutions and actors, including developers, speculators, investors, realtors, government officials, and financial institutions. These actors can form growth coalitions to advance their collective interests in development. Cohorts of residents (e.g., working-class renters, early gentrifiers, artists, students, middle-class homebuyers, etc.) participate in uneven development as stakeholders in favor of change or in resistance to it. State intervention in urban uneven development facilitates investment capital flows through various direct and indirect actions, including financial subsidies (e.g., tax abatements, eminent domain, issuing bonds, etc.), governance (e.g., police patrols, clean streets, etc.), administrative support (e.g., zoning variances, building permits, etc.) and infrastructure projects (e.g., construction of roads, sidewalks, etc.).

Recent work in critical geography on neoliberal urbanism places urban uneven development at the center of its analysis of urban political economy. Neoliberalism is an ideology and a mode of governance based on the primacy of free-market principles, including privatization, entrepreneurialism, and enhanced competition between places, to further capitalist accumulation. Neoliberal urbanism refers to governance practices that privilege market mechanisms, including limiting state oversight and regulation of the private sector, reducing expenditures on social welfare, and forming public–private growth partnerships, to create conditions favorable to capital reinvestment. The increased dependence on market forces in urban governance and the expanded control of the private sector in the planning, financing, and implementation of local economic growth has enhanced urban uneven development. Greater competition between localities to attract investment capital (e.g., development incentives and subsidies) enhances urban uneven development and the potential negative social and economic outcomes for communities.

User-centered design is a design methodology and philosophy in which the needs, goals, and success of the end user are considered. User-centered design can be applied to any type of system, object or product intended for human use, but the term is used most frequently in connection with computer information system design.

In user-centered design, the ease with which a system can be understood by its intended users, how easily they can complete tasks with it, and how satisfied they are with their use of it, become the key measures of the success of the design. User-centered designs typically require less documentation and training to be successfully used because they have been designed specifically to match the expectations and abilities of the users. Although user-centered design is closely associated with the discipline of user interface design, it can cover almost every aspect of a system, not only its user interface. Elements of a system such as its documentation, how data are entered and structured within the system and made available for use, how it is deployed and presented within an organization, and how the system use fits into the business goals of an organization, can all have user-centered design applied to them.

The term “user-centered” design was made popular by Donald Norman, a cognitive scientist working in the field of system and product usability. He first referred to “user-centered system design” in 1986. His bestselling book, The Design of Everyday Things (Norman 1988) (originally published as the Psychology of Everyday Things), introduced the concept to a wide audience.

Successful user interfaces meet users’ expectations. The application of human factors and ergonomic design principles result in displays and controls that are clearly visible and easy to interact with. User-centered design ensures that displays and controls make sense to the user. A key tenet of user-centered design is that to be intuitive the user interface should match the user’s mental model of the task they are performing.

Norman gives the compelling and memorable example of the cooktop found in most kitchens. Cooktops typically have four cooking rings: two at the front nearest the user, and two at the back closer to the kitchen wall. However, the knobs with which the user controls the rings are often arranged in a straight line. This is a bad user interface for this system because there is no immediately obvious relationship (also called “mapping”) between the location of the knob and the location of the ring it controls. The spatial arrangement of the knobs does not match that of the rings they control. This basic user interface design flaw makes it hard to use the system and causes the user to frequently turn the wrong ring on.

User-centered design recognizes that the user’s ability to understand how to use controls for the cooktop’s rings is an important design problem that must be solved before the cooktop is put into production for users to struggle with. When the
Figure 1  A cooktop with a user interface that is not user-centered. There is not an obvious spatial relationship between the rings and the knobs that control them. Icons are usually added next to each knob to try and make this clearer to the user. (Diagram by Rupert Essinger after Norman.)

four controls are presented in a linear arrangement, there is no obvious relationship of which one controls which ring (Figure 1).

In a kitchen cooktop in which user-centered design has been applied, the controls are arranged as a group in the same pattern as the rings: two in the front and two at the back. This natural mapping of the position of the controls to the position of the rings is immediately understandable by the user because it matches the task as they see it (Figure 2).

When a user interface is not user-centered, documentation is required. In the cooktop with the linear controls, the documentation is usually provided in the form of little icons under each knob designed to show the user which ring each knob controls. These icons are not needed when the knobs are arranged in the same way as the rings: two in the front and two in the back. This illustrates another key tenet of user-centered design: when user interfaces match the user’s model successfully, less documentation is required. The goal of user-centered design is to create systems that are successful because they are intuitive and self-explanatory, and that therefore reduces the need for end-user documentation and training.

It may seem obvious that any system aimed at users should be designed with the user in mind. And especially now that the term “user-centered design” is well known, it is unlikely that a system engineer or designer would admit that their system has not had some amount of user-centered design or at least user-centric thinking applied to it. But modern system development processes vary in the extent to which they involve user-centered design techniques. These techniques include persona-based or role-based design where the needs and workflows of typical users are considered, usability testing of prototypes and development versions of systems with sample users, the involvement of designers with specific usability and human interaction expertise and qualifications, and successive refinement based on feedback from early adopters and beta testers.

User-centered design techniques

Applications and systems may not have one idealized user. User-centered designers realize that they are often not designing for one user, but for a number of different types of users. An application’s users will often be segmented by designers into smaller role-based groups, with specific needs based on the information they require and the tasks they want to perform.
Sometimes those needs may pull the user interface design in different directions (Garrett 2003). For example, novices learning new work tasks may find it easier to learn a new application if it presents its workflow as a sequence of simple steps. Experts who have mastered getting the work done, however, may view the sequence of steps enforced by a linear user interface as tedious. These expert users may need a user interface that provides rapid access to a breadth of functions the application provides.

User-centered design recognizes that it may not always be possible to meet both sets of user needs with a single interface solution. One option is to provide different ways for the different user groups to accomplish the same task. Another option is to focus on one group of users and exclude support for the other. This kind of decision has consequences on many of the other choices the designer will need to make as they craft the user interface.

Once an application’s users have been identified, the central focus of user-centered design is to provide a solution that solves the users’ real problems. The first step involves researching and understanding the activities and tasks that the application’s users want to accomplish. This is followed by identifying software features that support those activities. If a feature does not address a real user activity, it does not make it into the user interface design specification. Features that support key user activities get the highest priority in the design specification, and are expected to be both easy to find and easy to accomplish in the user interface.

User-centered design recognizes that users are much better at providing critical feedback in response to a prototype user interface, that is, something they can see, than they are in providing up-front detailed descriptions of what they need or seek. To address this designers often jump-start the process by beginning with nonfunctional mock-ups or storyboards illustrating what the screens could look like, and then change them in response to the users’ feedback. The benefits of starting with mock-ups or storyboards include:

- rapid, iterative prototyping to support key user tasks and “use cases”;
- prioritization of features and workflows before actual software coding starts;
- users and subject matter experts may feel more comfortable giving feedback on mocked-up prototypes rather than systems that are already in development.

After the mock-ups are implemented, the application will often go through additional usability testing and acceptance testing before it is released, with successive iterations used to refine the user interface and functionality.

Once the application is completed and deployed, user-centered design can still continue. The ability of users to perform their tasks and activities with the system can be reviewed and assessed. Plus, as users gain more experience with the application, they can provide practical feedback and requests for improvements reflecting their actual usage. This is extremely beneficial as it:

- helps focus the priorities and attention of the development team, and is a key input in the planning and design of future iterations of the application;
- supports the refinement and development of any complementary documentation and training both for users and technical support specialists working with them;
- enables managers and user representatives to discuss enhancements to the application in terms of user tasks and roles rather than technical software features;
USER-CENTERED DESIGN

- allows, once the application is completed and deployed, user-centered design to still continue.

There is a large body of literature about user-centered design, its methodologies, and user interface design. There is also an International Organization for Standardization (ISO) standard dealing with the ergonomics of human-system interaction (ISO 2008).

User-centered design in geographic information systems (GIS)

User-centered design can be applied to geographic information systems (GIS), GIS applications, online mapping systems, and websites designed to provide access to maps, geographic information, and data. A successful GIS implementation involves not only the use of GIS software, but database design, data acquisition, the development of workflows, best practices and management, data publication, project-based analysis, cartographic design, and application development. User-centered design can be applied to each of these key areas with the goal of ensuring that a system fits with the needs of the people who will use it, rather than the other way round. For example, when an organization plans how data will be acquired, collected, and maintained in its GIS, it will want to ensure that these workflows and policies are easily understandable by the people who will be performing them, and the tools and training provided to different personnel based on their roles, from data collection in the field to database administrator, are successful.

Validity and verification

Ashton M. Shortridge
Michigan State University, USA

The late statistician George Box famously noted that, “all models are wrong, but some are useful.” This perspective is a critical one for understanding validity and verification (V&V). V&V engage the general problem of determining how closely data and models reflect reality. This problem is a central scientific concern: it encompasses philosophical issues, representation challenges, sampling and measurement concerns, and forms the basis of inferential statistics. This entry considers V&V within the spatial domain, a context that introduces particular opportunities and challenges. While it is convenient to separately discuss the validation of data and models, the distinction is somewhat artificial: the consensus in geographic information science is that data are the consequence of a considerable modeling process.

Data

The terms “validity” and “verification” are used in the context of spatial data production, and are closely tied to data quality standards. Validity is the degree to which the produced dataset meets agreed-upon data quality standards. Validation is the process by which this is done. Verification is typically reserved for efforts to assess whether data were produced following an agreed-upon protocol, and is concerned with the sources and methodologies used in the data production process. Taken together, V&V are used to evaluate the positional and attribute accuracy of spatial datasets as well their completeness and consistency, all key elements of spatial data quality.

Data validation

In the spatial data quality standards domain, accuracy assessment is a validation issue (Veregin 1999). The US National Standard for Spatial Data Accuracy (NSSDA) specifies a generally applicable validation approach to assess horizontal and vertical positional error from a large feature dataset.

1 Select a representative subset of test locations from the data.
2 Obtain an independent dataset of higher accuracy (“reference”) for those locations.
3 Calculate an accuracy metric based on the differences between the data and the reference positions.

As an illustration of the NSSDA standard validation procedure for horizontal positional accuracy, consider a dataset of point locations representing the centers of 346 vernal pools, as interpreted from digital aerial imagery. Vernal pools are ephemeral wetlands that provide important springtime habitat for many kinds of plants and animals. In the first step, 20 of these pools are randomly selected, for a sample size just larger than 5%. In the second step, the selected locations are visited, and the geographic coordinates of each pool’s center are carefully surveyed. This set of observations is the reference. The coordinates from the dataset and from
VALIDITY AND VERIFICATION

the ground survey for these pools (showing just five to save space) are presented in Table 1.

Accuracy metrics summarizing the horizontal positional error distribution include the sample mean error, the mean squared error, and the root mean square error (RMSE) of the sample. RMSE (Equation (1)) is a widely reported metric. This is the square root of the mean squared error, in the horizontal units of the coordinates, for the N sample points. The larger the RMSE, the greater the discrepancy between the data-reported and reference positions. If the error is unbiased, RMSE corresponds to the standard deviation of error for the sample (note that by custom the denominator is $N$ rather than $N-1$).

$$
\text{RMSE} = \left( \frac{\sum (x_{data} - x_{reference})^2 + (y_{data} - y_{reference})^2}{N} \right)^{0.5}
$$ (1)

If one assumes positional errors are normally distributed in $x$ and $y$, then the 95% horizontal error can be calculated (Equation (2)). This value represents the radius of a circle that, when centered on each coordinate in the dataset, can be expected to contain the actual location for 95% of the points, providing the underlying assumptions are met. This accuracy measure is called the NSSDA in the United States spatial data quality standards community and is commonly reported in metadata; it has been criticized for relying on assumptions which may frequently go unmet (e.g., normality and independence of errors, random sampling) (Zandbergen 2008).

$$
\text{NSSDA 95\%} = 1.708 \times \text{RMSE}
$$ (2)

For nominal data such as land cover/land use, a similar approach is used: reference information from another source, such as ground survey or higher-accuracy classified imagery, is obtained for a representative sample, and summary metrics based on class error or confusion are calculated (see Modeling uncertainty in categorical fields).

Table 1  Vernal pool test point coordinates, reference coordinates, and positional errors. All measures are in meters. Squared differences in $x$ and $y$ are reported for each test point, as well as the sum of squared differences. Summary statistics in the bottom right report the mean square horizontal error, the root mean square error (RMSE), and the NSSDA 95% statistic.

Mean 586.19

RMSE 24.21

NSSDA 41.90

All measures are in meters. Squared differences in $x$ and $y$ are reported for each test point, as well as the sum of squared differences. Summary statistics in the bottom right report the mean square horizontal error, the root mean square error (RMSE), and the NSSDA 95% statistic.
Measures such as RMSE, 95% error, percent correctly classified, and related metrics are global indicators of validity. Local properties, including spatial or other patterns in the degree of positional accuracy, are not captured by these metrics, nor are other metrics that could assess local validity used or reported by mandate through metadata standards.

Data verification

While accuracy assessment is a validation issue, other aspects of data quality fall under the purview of verification. Verification is an integrated component of the data production process for large geospatial data producers, and is concerned with ensuring that the data are developed to align with established protocols. Core data characteristics that can be verified include the following:

**Resolution:** data may have spatial, temporal, and spectral (in the case of imagery) resolutions. Each of these dimensions plays a key role in determining the scale at which features or processes may be characterized, and it is clearly important for data to offer resolution commensurate with the desired process scale. Spatial resolution is straightforward to report for raster data structures given its relationship to pixel or cell size, though the effective resolution may be coarser than the cell size. For vector data, scale or resolution of the source of the digital data (e.g., paper map, imagery) may determine the resolution, or digital resolution may be dictated by the effects of subsequent processing.

**Consistency:** this term is concerned with the degree to which key data characteristics match their intended properties. If a vector data product is expected to obey certain topological rules (e.g., planar topology, in which every line crossing must have a node, polygons cannot overlap, and so on), then the data must follow those rules. Logical consistency of attributes implies that stored thematic properties of features should not conflict with one another.

**Completeness:** data are intended to represent some real-world features. Completeness considers the degree to which all real-world features, as specified in the data model ontology, are represented by the dataset. This feature specification is typically quite constrained. Consider a “building footprint” polygon dataset in a municipal GIS database. Buildings eligible for inclusion would be constrained: only those within the city limits, only those present in imagery from a particular year, and only those above some minimum area might be included.

Like validation output, verification results generated by large public data producers are intended both for internal quality assessment/quality control (to determine, for example, if data products generated by an external contractor meet specific standards) and for external communication to data users via metadata, to satisfy the “fitness for use” criterion. Metadata standards for reporting V&V findings are generally mandated by government and therefore can vary from country to country and also across regional and local jurisdictions; however, there is substantial consistency among many of them. These mandates can indirectly influence V&V-based data quality reports for nongovernmental producers as well.

Models

Few words have as many distinctive meanings as *model*, but here the term is defined as a computer-based simulation of one or more social
or environmental processes. A model attempts to capture either the key mechanisms of the process or the characteristic patterns manifested by the process. Models ingest data and parameter inputs and produce an output intended to reflect the actual process. Models may be dynamic: such models reflect behavior over multiple periods of time, and may therefore seek to characterize changing relationships and patterns over that time. Regardless of the type of model, its output may be regarded as data – often spatial data – and can serve as inputs to other models. Figure 1 presents a generalized computational model. It might be a hydrologic model characterizing both surface and groundwater flow within a stream basin over time. In that case, input data include precipitation time-series data, a digital elevation model (DEM), and soil data. Model 1 characterizes the flow and infiltration properties of the basin, while Model 2 characterizes surface and groundwater response to specific precipitation inputs, producing output maps of properties of interest (e.g., saturation, flow rate) at particular intervals.

In many computational modeling contexts, validation and verification may refer to distinct aspects of model performance assessment. However, these terms are not used consistently across all scientific domains: in weather forecasting, verification can refer to the comparison of model output to what actually occurred, while in statistical modeling, validation is reserved for this context. In algorithm assessment, verification is an evaluation process that determines if the algorithm has been implemented correctly, while validation is reserved for determining if the algorithm is appropriate for the application task. Similarly, the hydrologic modeling community uses validation to refer to the comparison of model output with reference data, and verification to refer to the assessment of the correctness of the model’s implementation. The latter definitions will be used in this entry, as they parallel use of the terms in the data section. Figure 2 characterizes the modeling process and the role of validation and verification in it. The simuland is the environmental or human process that is to be modeled. A conceptual model is derived for this process. The conceptual model is implemented as a computational model. This model is used, with input data and parameters, to generate results. Validation is the comparison of the results with the simuland, typically through reference data sampled from the simuland. Verification is the
Figure 2  Verification and validation in the modeling process. Adapted from Figure 10.2 in Petty 2010, with permission of John Wiley & Sons, Ltd.

comparison of the computational model with the conceptual model.

Model validation

Validation of spatial models can be done by pointwise comparison of modeled output to reference data, in a similar fashion to data accuracy assessment. This procedure is straightforward for any modeling context where reference data is available, such as high-resolution weather forecasts. In addition to RMSE, the coefficient of determination, or R², is often used as a model validation metric (Arnold et al. 2012). Let \( \{y_1, y_2, \ldots, y_n\} \) be reference measures at \( n \) locations, and \( \{m_1, m_2, \ldots, m_n\} \) be the model predictions at the same \( n \) locations. Then \( R^2 \) measures the ratio of the sum of squares of the residuals to the total sum of squares of the data (Equation (3)).

\[
R^2 = 1 - \frac{SS_{res}}{SS_{tot}} 
\]  

(3)

where:

\[
SS_{tot} = \sum (y_i - \bar{y})^2
\]

\[
SS_{res} = \sum (y_i - m_i)^2
\]

\( R^2 \) varies from 0 to 1 and indicates the goodness of fit of the model predictions to the reference observations.

However, pointwise approaches ignore spatial components of accuracy that have important consequences for verification. Considerations such as the spatial autocorrelation of model errors may undermine classic assumptions of independence of model residuals. Further, the match of scale-dependent spatial structure of predictions to reality, as well as the geographic displacement of a modeled spatial feature from its actual occurrence, is not well-handled by pointwise measures (Gilleland, Ahijevych, and Brown 2009). As an illustration, consider a forecast for a storm event. Suppose that the storm does in fact occur at the indicated time with the predicted magnitude, but its position is just to the north of the predicted location. A pointwise accuracy measure such as RMSE or \( R^2 \) will indicate that the model has performed quite poorly, while other important but unassessed aspects of the forecast capture reality with good fidelity. To account for this, spatial filtering has been used with comparison metrics to validate model performance for field-based output. Alternative, object-based approaches determine the degree of spatial deformation needed to most closely match model-generated feature positions to reference, or use fuzzy, rather than crisp-set comparison methods. Figure 3 illustrates a representative spatial validation typology of field- and object-based validation methods.

Many models use empirically derived parameters that capture key environmental properties (e.g., a hydrologic model may use soil particle size, vegetation cover type, and surface slope to drive flow speed, infiltration rate, and other characteristics). Realistic values for these parameters may vary over space and time, and may in fact be unique to a particular context. For example, output of the Schelling Model,
an agent-based model that characterizes urban segregation, is affected by many environmental and household parameters (Crooks, 2010). *Model calibration* is the process of identifying reasonable parameter values, while validation of those parameters generally requires reserving a subset of observations from the calibration process for independent assessment.

**Model verification**

Verification refers to the implementation of the conceptual model, typically in a computational
setting. Representative verification questions include the following.

- **Does the algorithm reflect the process described in the conceptual model?** In hydrologic models, for example, equations reflecting the physics of water flow across surfaces (“overland flow”) and within streams (“channelized flow”) are commonly implemented. The computational model must correctly implement and solve the equation. This may be difficult to assess when a heuristic is used: an approximation of the conceptual model in situations where solving the model might be computationally complex, time-consuming, or impossible.

- **Was the algorithm coded correctly?** This is a central concern in software engineering, and a range of procedures and approaches have been developed to address it. Logical errors, especially in contexts outside of the typical range of inputs and conditions, are particularly difficult to identify and correct.

Verification is an essential element of model development. Typically it is evaluated by implementing the model on synthetic data with known solutions. The boundary between verification and validation is particularly thin for activities such as parameter assessment.

Models are typically complex, with multiple input datasets and starting parameters. The model may be well validated and verified but still perform poorly if the input data are not also carefully assessed via V&V approaches. Input data fitness for use must be carefully assessed: if critical factors such as accuracy or spatial resolution do not match model specifications, it is unreasonable to expect quality model results. As the old saying goes: garbage in, garbage out.

VALIDITY AND VERIFICATION

Value added

C. Michael Wernerheim
Memorial University of Newfoundland, Canada

Value added is a measure of the production that occurs within an industry. It bears a close relationship to the gross domestic product (GDP), as GDP can be estimated as the sum of values added for all producing entities in the economy. GDP is the most widely used indicator in national accounts, as it summarizes in a single estimate the value of the output (goods and services) produced by all firms, nonprofit institutions, government bodies and agencies, and households in a given country or region during a given time period. The concept of value added makes a profound contribution to the computation of GDP in that by design it eliminates the double-counting that would otherwise occur in the aggregation of production from the micro (firm) level to the macro (national) level. GDP is above all else an instrument for measuring the magnitude, growth, or decline of the economy as a whole, and for determining the economic process that accounts for the composition of the national product. In value added, national accountants thus have a measure of GDP that is at once theoretically meaningful and empirically measurable.

Measuring the output of a single firm is comparatively simple. Measuring the output of an entire country is a complex matter that requires innovative concepts and the use of a vast array of data. Consider first the value added concept at the firm level. If all firms in a given industry produced all the inputs they used in production, the ratio of value added to sales would be one. This is generally not the case. Instead, they rely in varying degrees on firms in other industries for inputs (raw materials, intermediate and/or semi-fabricated goods and services), implying a ratio of value added to sales that is less than one. The value added (or production) of each firm in each industry may thus be aggregated across the entire economy. However, if purchased inputs were not subtracted from the firm’s sales prior to aggregation, double-counting of inputs would occur. To see the importance of this, consider next the estimation of output at the macro-level.

To begin, there are three equivalent approaches to GDP: the output (production) approach; the final demand (expenditure) approach; and the income (supply) approach. The important point here is that all three measures give the same total for GDP. (For a more detailed discussion of GDP, the reader is referred to the reference sources shown.) The output approach is best suited to explicating value added, as it defines gross domestic product as:

\[
\text{GDP} = \sum \text{value added}
\]

As value added in turn equals production minus intermediate inputs, then:

\[
\text{GDP} = \sum \text{production} - \sum \text{intermediate inputs}
\]

That is, rather than crediting each firm with the value of its sales (or output), national accountants count only the value that the firm adds to that of businesses supplying its intermediate inputs. By deducting the portion of intermediate input usage from that of sales ensures that the input portion is not counted more than once when the output produced by one industry is re-sold as intermediate input.
to another industry. The result is a measure of the value that is “added” to each product or service by firms at each stage of domestic production.

To illustrate, take the example of a smartphone manufacturer. Value added is the revenue from sales of smartphones less the amount the manufacturer pays for plastics, metals, electronics, circuit boards and other hardware, producer services such as software and engineering services, and other inputs. The way in which sales of the intermediate inputs “wash out” in the computation of GDP according to the production or value-added method is described by Hall and Taylor (1986, 35) as follows: “If a firm sells a final product, the sale appears in that firm’s value added but nowhere else. By contrast, if the firm sells its output as an input for another firm, that sale appears negatively in the other firm’s value added. Thus, when the two firms are added together in computing GDP, sales of intermediate products effectively cancel out.”

Furthermore, it follows that by eliminating double-counting, the resulting measure of aggregate value-added-based production is also independent of how firms are organized, that is, independent of the number, size, and type of economic units that account for national output. This matters because corporate structure and industrial organization are subject to change over time.

It must be emphasized that precise measurement of economic activity on a large scale is virtually impossible; hence, partial data, estimates, and statistical methods are necessary to approximate economic activity. As suggested earlier, the method for estimating GDP thus involves considerable reliance on large numbers of surveys, and administrative (secondary) data initially collected and compiled by central governments for other purposes. Sources include private industry associations, public statistics agencies, income tax returns, value added tax (VAT) declarations, regulatory reports, imputed rents, business and government transfer payments, corporate profits, depreciation, records of employee compensation, dividend income, income statements by firms, and the value added by the services of general government. The uneven quality of this data gives rise to inevitable measurement errors and, hence, a statistical discrepancy across the three independent measures of GDP. Technically, the statistical discrepancy is the “product side” minus the “income side” of national accounts.

As for the theoretical equivalence of the product side and the income side of the accounts, it should be noted that the income side includes only those transactions (i.e., events where money changes hands) involving the generation of value added. National income excludes, for example, procurement of raw materials, loans, gifts, and government transfers. The reason in this case is that these activities do not generate net output in the domestic economy, even though these and similar activities do, at some point, involve the exchange of money.

Similarly, domestic product does not include sales and purchases of existing assets (real or financial), as it is defined on a value-added basis. Domestic product is thus an index of the total volume of newly produced goods and services in the domestic economy. The present definition of GDP is internationally agreed upon, which explains its extensive use by policymakers, researchers, and the media at large. Finally, GDP is estimated annually or quarterly, but it can also be obtained monthly.

**Value added tax**

An important use of value added is in the calculation of a widely implemented tax often referred to as a value added tax. A VAT is a so-called
“multistage” tax calculated as a percentage of the value of a firm’s sales minus the tax the firm has paid on its purchases of inputs produced by other firms. In effect, the firm thus pays tax on the value it has itself added to these inputs, and not on the value created at earlier stages in production (on which the tax has already been paid). VAT is an important source of tax revenue for governments in many countries worldwide. In European countries, for example, they are typically levied at rates exceeding 20%. Although such rates can appear high, most tax experts argue that consumption taxes (VATs) are preferable to income taxes in that the former discourage saving and investment less. This is because the latter tax income twice; first on the original income, and then again on any earnings from savings and investment of that income. This matters greatly as private savings and investment underpin economic growth.

Value-added services and location

It has been argued that lower value-added corporate functions, such as processing activities, logistics, and supply functions, are more likely to relocate abroad, typically to emerging economies, whereas high value-added service functions, such as R&D, are more likely to locate in advanced economies (Daniels 2007). This centralization of high value-added services in global cities, and the decentralization of low value-added services into the global low-wage periphery, is evidenced by analysis of global commodity chains, various types of studies of agglomeration economies, and also by sectoral studies of back offices, call centers, and offshore banking. The common denominator is the processing of standardized information and the use of relatively unskilled labor. These empirical observations and findings have also been predicted by various theoretical approaches, such as actor-network theory, which purports to explain the global division of labor and the simultaneous centralization and decentralization of different kinds of value-added services. A central conclusion of actor-network theory is that, notwithstanding the geographical segregation of value-added services on the basis of their value-added content and the types of skills and knowledge utilized, both high and low value-added services are embodied in people and embedded in a complex mix of local and international contexts. The result is a restructuring of the service economy globally, resulting from, in part, novel means of production and delivery via telecommunications networks (Warf 2007).

Parenthetically, it should be noted that R&D has historically been treated in national accounts as current expenditure on intermediate inputs and has, therefore, not entered GDP. However, starting with the current version of the system of national accounts (2008 SNA) (EC et al. 2009), R&D is treated as capital formation, except where the activity does not benefit the owner, in which case it continues to be treated as intermediate consumption. This development promotes the role of services in the modern economy. Services are now increasingly seen as a key component of global value chains, as they facilitate value-added activities in different markets. However, this enhanced role played by producer services gives rise to new conceptual problems in measuring the value added of such services. This is because they increasingly form part of entire complex platforms of highly integrated manufacturing and service functions. The value added by the services components can thus be difficult to disentangle and measure in such applications. The value added by producer services is difficult to measure also in situations where these services are not used as one-off inputs in the production process but may be
VALUE ADDED

re-used, perhaps in an entirely different context. Examples include various consultancy services and market research.

Value added and industrial structure

The greater the reliance of a firm in a given industry on firms in other industries, the lower will be the ratio of value added to sales, and vice versa. In the industrial organization literature, higher ratios of value added to sales are, therefore, sometimes seen to reflect greater vertical integration – a measure of the vertical linkages in the supply chain, achieved either by forward or backward merger or investment in a given industry.

Value added and income distribution

In light of the preceding discussion, it should be understood that value added per unit of labor and wages, though correlated, are not the same. All else being equal, the higher the value added per worker, the higher the wage rate, and vice versa. More to the point, the value added typically exceeds the wage. This follows from the way these measures are computed. Since labor and other inputs (such as capital) cooperate to produce value added at each stage of the production process, the computation of value added per worker must include the payment to labor (the wage bill), as well as the return to owners of capital. Introducing a small amount of notation serves to clarify this point. Under perfect competition, profits in excess of a normal return to entrepreneurship (an opportunity cost) are zero by definition, and total revenue equals total cost.

Write this as:

\[ p \cdot Q - (w \cdot L + r \cdot K + v \cdot M) = 0 \]

where price \( p \) times output \( Q \) represents total revenue, the wage rate \( w \) times the labor input \( L \) denotes the wage bill, the rate of return to capital \( r \) times the capital usage \( K \) denotes the payment to capital, and the per unit cost of intermediate inputs \( v \) times input usage \( M \) represents the corresponding factor payment. By definition, value added is total revenue less the cost of intermediate inputs, as shown in equation 1.

\[
VA = \sum production - \sum intermediate inputs = pQ - vM = wL + rK
\]

Value added per worker is thus:

\[
\frac{(w \cdot L + r \cdot K)}{L} = w + r \cdot K/L > w
\]

That is, value added per worker exceeds the wage. Moreover, the more capital intensive the production, the greater is this effect all else being equal.

Value added: further applications

It should be clear from the discussion that value added plays a major role in the system of national accounts and, consequently, in a host of related applications, such as the national and regional input–output tables (Isard 1960; Leontief 1986). The concept of value added has important uses in other areas as well. For example, in regional analysis it is sometimes used as a base to compute the so-called location quotient – a measure indicating the location (or a region’s share) of an industry relative to the geographic distribution of its labor productivity in the aggregate (Isard 1960).

Venture capital

Jun Zhang
University of Toronto, Canada

Venture capital (VC) is a special form of financial institution designed to provide financial support and business assistance to emerging firms with high growth potential, particularly in technology sectors (Gompers and Lerner 1999; Cumming 2010). Venture capital firms are professionally managed equity investors: they provide money and value-added services to emerging firms in exchange for an equity stake in the business, expecting the market value of the shares to grow exceptionally quickly in the time frame of a few (typically three to seven) years. Returns to VC are expected to be obtained through a “liquidity event,” ideally in the form of an initial public offering (IPO) of the business in a stock market or a trade sale: a merger or acquisition.

Venture capitalists are highly selective, usually on the lookout for some extremely rare combination of innovative technology, a well-developed business model, and an impressive management team, providing an emerging firm with the potential for rapid growth. Such opportunities are most likely in technology sectors, and VC thus has become almost synonymous with technology finance in sectors such as computers, the Internet, semiconductors, telecommunications, electronics, biotechnology, clean technology, and health care. Given the high level of risk, and that investments are illiquid and require an extended time frame for realization, venture capitalists usually carry out detailed “due diligence” analysis prior to investing. They also nurture investee firms in many ways to help them move faster in developing products and bringing them to market.

Economic geographers have become increasingly interested in VC, because it is believed to be a key engine driving technological innovation and entrepreneurship. It is also an area of increasingly active public policy aimed at creating or stimulating VC funds to boost technological innovation and economic development, especially in laggard regions. Venture capital is characteristically a highly localized practice, whose investments have been highly concentrated in a few hotspots such as Silicon Valley. At the same time, VC is highly mobile and has become increasingly globalized. This intricate interaction between spatial centralization and decentralization has posed new challenges for geographers.

Fundamentals of venture capital

Venture capital can be defined as dedicated pools of capital managed by independent, professional institutions that focus on equity or equity-linked investments in young firms with expected high growth potential. This definition distinguishes VC from three other forms of investment: (i) nonventure private equity investment, in the form of buyouts, restructure, and mezzanine funds targeting relatively mature firms with stable cash flows and limited growth potential; (ii) public equity investment in mature firms with high liquidity and low risk; and (iii) individual angel capital, commonly understood as wealthy private individuals who use their own money to provide the first round of external
VENTURE CAPITAL

finance and hands-on business support to get a company established. Institutionalized VC firms can also play the role of angels by offering seed money and entrepreneurial support to budding firms. In Europe the terms “private equity” and “venture capital” are often used interchangeably, but it is important to differentiate them. Venture capital funds are managed by investors with entrepreneurial experience and industrial knowledge (frequently with a related technological background). They invest in early-stage ventures, actively participating in their investee companies to provide value-added services. By contrast, private equity funds are managed by individuals with a background in investment banking or other financial organizations, and with short-term investment horizons. Whereas VC funds are heavily involved with the start-up companies in their portfolio, in both a monitoring and an advisory capacity, private equity firms, working with more mature firms, do not have such imperatives. Private equity investors are more susceptible to speculation, and face much fewer spatial constraints than venture capitalists. Thus they imply entirely different geographies.

Most VC firms are structured as limited partnerships, with general partners (GPs) who manage the firm and serve as investment advisers for the VC funds raised. These GPs and related investment professionals are often referred to as venture capitalists. Investors contributing money to VC funds are known as limited partners (LPs), and consist of wealthy individuals and financial institutions with large amounts of available capital, such as state and private pension funds, university financial endowments, foundations, insurance companies, and pooled investment vehicles (termed “funds of funds”). Venture capital funds typically have a prespecified investment focus: for example, location, sector, or stage of business development. A fund is closed once the expected amount of money is raised from LPs, initiating its life cycle. For most funds the investment cycle is generally three to five years, after which the focus shifts to managing and making follow-on investments in an existing portfolio. Most VC funds have a fixed life of 10 years, with the possibility of limited extensions to accommodate private companies still seeking liquidity. Venture capitalists are compensated through a combination of management fees and carried interest. Typically, the GPs receive an annual management fee equal to around 2% of the committed capital made by the LPs. Carried interest is a share of the profits of the fund (20–30%), paid to the VC fund’s GPs and professionals as a performance incentive. The remaining profits are paid to the LPs.

There are two other types of VC fund: captive and government. Captive VC funds are partly or wholly owned by a parent company, which may be a bank, a financial institution, or a large transnational corporation. A few large nonfinancial companies, particularly technology companies such as Intel and Microsoft, have their own corporate VC subsidiaries which invest strategically, to complement their internal research and development activities, to gain access to new technologies and/or products, or to limit competitive threats. Government VC funds are policy tools aimed at filling local gaps in private VC, accelerating economic growth and employment, or commercializing technology. One US example is Small Business Investment Companies. Publicly owned or funded VC firms often face restrictions in where their investments can be located.

Venture capital investment is constituted through an inherently interrelated cycle of fundraising, investing, divesting, and new fundraising: a staged process of screening, investment, monitoring, management assistance, and liquidation or exit. Venture capitalists generate
their deal flow mostly by tapping their networks. Entrepreneurs will get warm referrals to venture capitalists through a respected and trusted member of the latter’s network: Unsolicited proposals rarely capture the venture capitalist’s attention. When competition becomes fierce, however, venture capitalists also actively seek deals in a number of ways, including forums, university events, and even cold-calling interesting prospects. Through screening, venture capitalists quickly decide whether a potential venture merits further evaluation. Most businesses seeking VC do not meet investors’ investment criteria and are declined. Those passing the initial screening stage are scrutinized in detail. In this due diligence phase venture capitalists examine the various dimensions of the venture, including quality of the management team, the business model, the product and its market segment, and the firm’s financial standing. Particularly critical is evaluation of the firm’s founders. Due diligence takes a considerable amount of the venture capitalist’s time, and may last a few months in each case.

If due diligence is completed to the venture capitalist’s satisfaction, he or she and the entrepreneur enter into negotiations on the specific terms of the investment. Several issues are pertinent in this stage, including valuation, contract provisions providing protection against agency risks, staging of future investment rounds, and board representation and oversight. Given the inherent uncertainties associated with any venture investment, venture capitalists often contract to protect themselves from agreeing to an inflated valuation. Rather than providing the entire sum of money at the outset, it will be staged over time as various milestones are met. This provides the investor with the option to revalue or abandon the investment in light of unfavorable new information, or to increase the capital committed in case of positive progress by the investee company. Venture capitalists typically take at least one seat on the board of directors of the firm to gain control over key decisions.

Venture capitalists spend around half of their time monitoring and supporting the companies in their portfolio, focusing particularly on early-stage companies. They use their expertise and networks to provide value-added services to investee companies, including monitoring financial performance and general business operations, serving as a sounding board, assisting in the acquisition of additional funding, helping with recruitment for, or replacement of, the management team, advising on strategic planning and key decision-making, coaching inexperienced entrepreneurs, and assisting with IPOs. There is a positive correlation between the level of the venture capitalist investor’s sectoral expertise and value added. It is fairly common for VC investments to be syndicated between several VC funds, especially in second and subsequent funding rounds. Syndication allows venture capitalists to pool expertise, diversify their portfolios, and share information and risk. However, any syndicated investment requires a lead investor – usually the initial investor – to perform the key monitoring and support tasks.

The VC industry is plagued by various conflicts as a result of informational asymmetry. Differences in opinion and conflicts of interest arise between venture capitalists and entrepreneurs as well as other parties (angels, coinvesting venture capitalists, creditors, exit counterparties). Coordination failure can even lead to litigation, although this is uncommon. While conflicts can be addressed in complex contracts, such contracts remain incomplete and are often insufficient to curb opportunistic behavior. Indeed, many of the terms in venture capitalist–entrepreneur agreements designed to protect the venture capitalist may invite opportunistic behavior by them at the expense of the entrepreneur and
other equity investors. As a result, reputational concerns play a major role in preventing venture capitalist opportunism.

The final stage in the investment process is to secure profitable exits for their investments. As a rule of thumb, if venture capitalists can realize spectacular successes in just one or two of every 10 investments, this suffices to guarantee expected returns and compensate for losses from failed investments. An IPO, in which the shares of the venture capitalist and potentially other shareholders are sold on the stock market, usually produces the highest return, but this may be feasible only for the best companies in a portfolio. Alternatively, a trade sale is pursued, especially for poorly performing investments, setting a lower valuation that can be immediately paid in cash or shares of the acquiring company.

Geographies of venture capital

The first independent VC organization, American Research and Development Corporation (ARD), was incorporated in Boston in 1946. Venture capital was regarded more or less as an American phenomenon until the late 1980s, when a significant VC industry emerged in Western Europe and Israel. The Internet boom at the end of the 1990s triggered rapid worldwide growth in the VC industry; the bursting of this dot.com bubble at the end of the decade resulted in a dramatic decline in the number of VC firms and the amount of VC. The market has gradually recovered to the pre-dot.com level in the core countries such as the United States and the United Kingdom, but has yet to return to its peak of 2000.

Research into the geography of VC commonly finds that the geographical concentration of VC funds closely overlaps with the location of high-technology industry. Numerous studies have documented this co-location. Martin et al. (2005) thus define spatial proximity effects in the VC industry as the tendency of, or necessity for, VC firms to focus a significant proportion of their investment in enterprises in their own immediate region. This reliance on proximity is considered to result from the very nature of VC operations. Apart from searching for new deals and assessing business proposals through a densely knit community with frequent face-to-face interactions, the bulk of a venture capitalist's time is normally spent serving on the board of directors and offering frequent managerial counsel to portfolio companies. Venture capitalists must also devote a large amount of time to fundraising under very high time pressure, and to monitoring, advising, and managing work more effectively when portfolio firms are located nearby. This implies that there are strong incentives for VC firms to locate in places that offer them the highest concentration of profitable investments.

But decentralized VC distribution also exists. Historically, many VC organizations were formed through spin-offs from, or at least linked to, existing financial institutions, and consequently tend to be based in or near major financial centers. Indeed, VC funds in high-tech clusters used to be outposts, established by investment institutions located in major financial centers. While the clustering of VC funds in high-tech centers evolved through feedback effects, VC funds continue to exist in non-high-tech financial centers such as New York, exporting their capital to established high-technology regions elsewhere. In short, venture capitalists are both mobile and local, developing many ways to overcome the liabilities of distance, particularly through investment syndication (Sorenson and Stuart 2001).

Meanwhile, lucrative investment opportunities in core countries have been decreasing; the
global decentralization of VC is underway. Such key target sectors as the Internet and telecoms have matured in the core, passing their innovative peak, with new breakthrough technologies yet to emerge (Mason 2009). The 2007 economic crisis in the core economies further cut into VC business, driving mainstream venture capitalists to search for investment opportunities in emerging markets. While the mature VC markets in the United States and the United Kingdom continue to evolve, traditional regional or national geographical boundaries are diminishing as more venture capitalists look to new regions, especially China and India, for new ideas, markets, and entrepreneurs.

In addition to investment syndication, VC companies are globalizing by establishing special funds dedicated to foreign markets and opening satellite offices in foreign hotspots. New VC clusters in emerging economies, such as Beijing and Shanghai, have been rising out of their pre-existing industrial bases, generating sizable investment targets for venture capitalists and successful track records of VC investments (Zhang 2011). The lack of strong regulatory and normative institutions in many emerging markets means that venture capitalists have to place more emphasis on employing personal networks for their operations. Combined with underdeveloped formal information infrastructures, and shortage of entrepreneurial experience and technological competency, VC investments there are generally constrained by even stronger proximity effects than in the advanced economies.

Spatially uneven VC development is also a product of variegation in institutional and policy contexts. The VC cycle from fundraising to investing and divesting is a highly regulated process. Thus VC operation is strongly shaped by the characteristics of the national and regional financial markets and institutional arrangements. The rise of VC in the United States was critically enabled by regulatory changes that removed restrictions on pension funds from investing in VC, reductions in capital gains tax rates, and the creation of NASDAQ in 1971 as a stock market for young firms with minimal listing criteria (Lazonick and Mazzucato 2013). Stock market-oriented markets in the United States and the United Kingdom are clearly more favorable to the development of VC than bank-centered markets such as in Germany and Japan (Sunley et al. 2005). The recent ascendance of VC in China is also associated with regulatory liberalization and institutional emulation of the United States (Bruton and Ahlstrom 2003; Zhang 2011).

It is not clear, however, to what extent VC is necessary and conducive to spurring innovation. Lazonick and Mazzucato (2013) argue that the socially devised, politically charged institutional arrangements that support VC have questionable implications for innovation and income distribution; the profits of innovation have been privatized but its risks socialized. In the United States, venture capitalists’ most favored investment targets in electronics and biotechnology were largely based on technologies generated through massive risk-taking state investments via National Institutes of Health, the National Science Foundation, the Department of Defense, and so on. The rewards gained by venture capitalists may thus be disproportionately high relative to the actual risks taken at the cost of taxpayers, especially for those late entrants in the development of a sector, after most of the real uncertainty and risk has already been absorbed by the public sector. Moreover, VC investments have propelled the spread of executive compensation through stock options, and have resulted in speculative or fraudulent management behavior, and massive corporate spending on stock buybacks aimed at boosting stock prices at the expense of research and development.
Simply supplying VC does not automatically create its own, high-tech-based demand. Very few businesses are capable of meeting the demanding investment criteria of VC, and the structure of venture investments is inappropriate for many young firms. Pisano (2006), for example, argues that, given the 10–20-year time frame for developing biotechnology products and the lack of profitability of the industry as a whole, biotechnology is not a suitable sector for VC. Also, the minimum amount of VC investment is simply too large for most small firms. For other parts of the world, it thus might be naive to copy the poorly understood Silicon Valley VC model without also funding and nurturing the underlying state-funded knowledge base on which VC in the United States has always depended. It is implausible to expect VC to lift innovation in the vast majority of less developed and economically lagging regions; it can never supplant other wellsprings of innovation – vibrant universities, corporate research laboratories, and policies supporting ordinary businesses, basic education, and labor training.

“Vertical integration” refers to the merging together of two or more businesses that are at different stages of production – for example, a meatpacking company and a chain of supermarkets. One most famous case of vertical integration is the expansion of Andrew Carnegie’s steelmaking empire in the nineteenth century. His company, Carnegie Steel, controlled not only the mills where the steel was made but also the iron ore mines and the coal mines, the ships that transported the iron ore, the railroads that transported the coal to the mills, and the coke ovens where the coal was cooked. Another good example is the restructuring of the oil industry in the second half of the twentieth century, where a handful of multinational oil companies, including Exxon, Shell, and BP, began to actively establish control along the entire supply chain from locating deposits, drilling and extracting crude oil, transporting the oil around the globe, refining it into petroleum products, to distributing the fuel to company-owned gas stations. It is believed that the benefits of vertical integration come from the greater capacity it gives organizations to control access to inputs. In other words, by establishing ownership along the supply chain, firms are able to control the cost of production, the quality of their product, and the delivery times of the inputs.

Two associated concepts that often come with the term “vertical integration” are forward integration and backward integration. Forward integration refers to the merging in the direction of further on into the production process (and thus closer to the point of sale). Merging with something further back in the process (if a food manufacturer were to merge with a farm, for example) is known as backward integration.

Vertical integration can be contrasted to “horizontal integration,” which refers to the merging together of businesses that are at the same stage of production, such as two supermarkets or two meatpacking companies. The integration of two organizations that are in completely different lines of business is referred to as “conglomerate integration.” One good example is Korean conglomerate Samsung, whose businesses range from electronics, heavy machineries, food processing, insurance, and shipbuilding to advertising.

The issue of vertical integration was at the center of the flexible specialization debate within Marxist geography during the 1980s. Regulation school scholars, such as Piore and Sabel (1984), Aglietta (1979), Scott (1988), and Lipietz (1987), argued that the transformation of capitalism during the 1970s can be understood as a transition from “Fordism” to “post-Fordism.” According to their view, from the interwar period to the mid-1970s the advanced capitalist countries were dominated by Fordism – by mass production of standardized goods in huge factories owned by large, vertically integrated global firms. Towards the end of that period, however, the system had begun to run into crisis: mass markets had begun to break up as consumers tired of standardized products; labor resistance
VERTICAL INTEGRATION

had built up; industries met inherent technical barriers, such as line balancing problems; and the system was too rigid to cope with the uncertainty of economic recession. Meanwhile, a new model of flexible specialization, or post-Fordism, emerged: small batch production in interlinked, specialized small firms, flexible in organization, work process, and output, and tending to concentrate spatially into industrial districts. As production processes become increasingly vertically disintegrated, firms are now becoming more responsive to changing tastes, and to the tendency for consumer products to support the construction of personal identities.

One of the primary examples that regulation school scholars use to make the case for post-Fordism is the Third Italy. The term refers to clusters of small firms and workshops developed in the 1970s and 1980s in the central and northeast regions of Italy, including Tuscany, Umbria, Marche, Emilia-Romagna, Veneto, Friuli, and Trentino–Alto Adige/Südtirol. Each region specialized in a range of loosely related products and each workshop usually had 5–50 workers (often less than 10). The wide range of products in each cluster suggested a shift from economies of scale to economies of scope. Additionally, these small firms and workshops were known for producing high-quality products and employing highly skilled and well-paid workers. The workshops were also very design oriented and multidisciplinary, involving collaboration between entrepreneurs, designers, engineers, and workers. This unique industrial structure was in sharp contrast to the large-scale mass production systems seen in Turin, Milan, and Genoa (the First Italy) and the underdeveloped South (the Second Italy).

Sayer and Walker, in The New Social Economy (1992), criticized the thesis of flexible specialization for being “long on speculation and short on coherence.” They pointed out that the binary histories implied in the flexible specialization thesis led scholars to only select cases and data that would fit into the story. The result of this dualistic rhetoric is the reduction of the richness of the history. For example, it is problematic to characterize the pre-1970 capitalism as “Fordism,” as vertically integrated firms constituted only a small part of the economy even in advanced countries. Moreover, the examples that the regulation school scholars used were too selective to build up the case for post-Fordism. While fascinated with the batch production of Third Italy or Los Angeles, regulation school scholars have ignored the mass production system in Japan, which was a real threat to the manufacturing powers of the United States and Europe. Last but not least, the need to respond to the diversified consumer demands alone cannot explain vertical disintegration. The Japanese postwar economy, for example, is highly vertically disintegrated: its manufacturing is carried through multiple layers of subcontracting, which are governed by industrial groups. The products that this system is good at producing, such as automobiles, however, are for the mass market. There is, therefore, no clear causal relationship between the market and industrial organization.

Sayer and Walker argued that the shift towards vertical disintegration is more likely the result of innovation in organization. Here, “organization” refers to the coordination of different production stages. A firm that looks vertically-integrated may actually be very weakly organized. By the same token, production systems that are formally vertically disintegrated may have strong interfirm organization. Thus, while there is evidence of an increase in vertical disintegration, an increase in “vertical organization” in both vertically integrated and vertically disintegrated cases is of more significance. The term “innovation,” on the other hand, emphasizes the need of
an evolutionary perspective on the change of industrial structure. They argued that industrial structure is not the product of some timeless logic of rational choice, but the consequence of organizational evolution and learning that characterize capitalism. Such an evolutionary perspective recognizes the role of place and local happenstance in the development of new forms of industrial organization. The extreme physical restrictions on space and the population density of Japan, for example, have been more congenial to agglomerated, highly organized, and disintegrated production than has the American context, in which giant, decentralized, multidivisional companies prospered.

Description and purpose

The institute is one of the research organizations of the Vietnam Academy of Science and Technology. The institute focuses on the various research tasks in the field of applied geography, such as the integrated study of the natural environment and resources including socioeconomic problems for the establishment of the scientific foundation for socioeconomic planning in Vietnam; participation in appraisal of projects on natural resource exploitation, spatial distribution of population, and territorial organization; and research, assessment, and forecast of environmental changes under human activities including natural processes to support sustainable development and disaster mitigation. Postgraduate education is also one of the functions of the institute.

Journals or major publication series

Journal of Sciences of the Earth

Current activities or projects

Activities include:
- the development of sustainable socioecological models for Tay Nguyen Highland;
- development of the scientific foundation to resolve conflicts in water exploitation in Tay Nguyen Highland;
- integrated study of soil degradation and desertification in the southern part of central Vietnam;
- integrated study and assessment of natural resources and the demography situation in the border area between Vietnam and Laos in Kontum and Attapeu provinces for sustainable development and spatial planning of the population; and
- acting as the principal organizer of the 31st Asian Conference on Remote Sensing, held in Hanoi in 2010.

Brief history

The institute has a long history which dates back to 1957 when the idea for the current format of the institute was formulated under the Ministry of Education. This first body was named the Research Committee on Literature, History, and Geography. In 1961, a team was formed to research biology and geography under the State Committee of Science. Two important research projects were conducted: physical geography zoning in the north of Vietnam and spatial distribution mapping of population and ethnic groups in the north of Vietnam. In 1967, the Department of Geography under the Institute of Natural Science, State Committee of Science and Technology, was founded. In 1975, the Vietnam National Center of Science was established and geography research was moved...
to the Institute of Earth Sciences. In 1987, the Center of Geography and Natural resources was founded. This center brought together geographers from several research units to enhance capacity in research implementation. Finally, in 1993, the center became the Institute of Geography and a national authority in geography and environment research. The institute plays an important role in the development of a scientific foundation for various socioeconomic planning tasks in Vietnam. Environmental assessment of important infrastructure and hydropower station development have also been conducted by the institute.

Violence

Michael J. Watts
University of California, Berkeley, USA

Problems of violence still remain very obscure. (Sorel 1961/1906, 60)
What Sorel remarked sixty years ago … is as true today as it was then. (Arendt 1969, 3)

During World War II, a German officer apparently visited Pablo Picasso in his Paris studio, where he was confronted with what he saw as the modernist chaos of Guernica, perhaps the defining artistic representation of contemporary war and violence. “Did you do this?” he asked, whereon Picasso was said to have calmly replied, “No. You did this.” Picasso’s accusation – your politics is responsible for this violence – speaks directly and powerfully, of course, to several defining aspects of the twentieth and twenty-first centuries: interstate and civil wars, state violence and terror, and endemic political conflict. It has been calculated that war-related killings in the twentieth century exceeded 105 million, including 62 million victims. For Isaiah Berlin, the twentieth century was “the worst century there had ever been” (quoted in Mazower 2002, 1158). For every person killed, many more were subject to a multiplicity of physical forms of violence: torture, injury, brutality, persecution, imprisonment, starvation, and so on. This was the century of secret police, concentration camps, gas chambers, labor camps, and the calculated liquidation of specified populations. In the five years after the end of the Cold War — when it was plausibly expected that the fall of the Berlin Wall would bring to an end the raft of Cold War proxy and imperialist wars in the four decades that had followed the Allied victory in 1945 – there were 177 violent conflicts in 79 countries (Cramer 2006, 1). Even though data seem to suggest that deaths from interstate and civil wars have declined since the mid-1980s, there is a proportionate increase in so-called new forms of conflict (militias, terrorist groups, transnational gangs, piracy, organized crime) and a recognition of the conflict–security–development nexus associated with fragile and conflicted (and often highly populated) states such as Nigeria, Pakistan, Indonesia (World Bank 2011). The UN High Commissioner for Refugees’ (UNHCR) annual report on Global Trends for 2014 documents that the number of worldwide refugees and displaced peoples – precisely the “collateral damage” of these conflicted states – had been at the highest level ever recorded: the number of people forcibly displaced at the end of 2014 had risen to a staggering 59.5 million compared to 51.2 million a year earlier and 37.5 million a decade ago (UNHCR 2015). The increase represents the biggest leap ever seen in a single year, and the situation is likely to worsen. Globally, one in every 122 humans is now either a refugee, internally displaced, or seeking asylum (if all refugees constituted a country, it would be the world’s twenty-fourth biggest).

It is no surprise, given the proliferation of political violence – indeed of all manner of forms of violence, some of which do not sit easily within the circumference of “the political” – that violence has come to be seen as central to an understanding of modern politics (think of Thomas Hobbes, John Locke, Max Weber, Hannah Arendt) and to stand at the heart
of much social science theorizing, including geography. It is now commonplace to acknowledge that the great arc of modernization – or, for that matter, the Enlightenment – bears all the marks of coercion, social conflict, and struggle (Tilly 1992); that organic nationalism gave birth to genocidal forms of nationalism and ethnic cleansing; and that state violence and terror figure centrally in what might be called modern mass or totalitarian violence, whether perpetrated in the name of fascism, communism, or state building (Arendt 1973).

It needs to be said immediately that such views do not go uncontested. Psychologist Steven Pinker’s recent book, *The Better Angels of Our Nature* (2012), argues that violence has declined, that the premodern societies were “shockingly violent,” that brutality was woven into the fabric of premodern social life, and that the frontier of violence has receded because of our deepening empathy, self-control, and morality; the spread of government, literacy, trade, and cosmopolitan worldviews; and our deepening powers of reason. Whatever the empirical scope and trajectory of such brutality over the past couple of centuries, the term “violence” itself is capacious. It can refer to specific sorts of events (e.g., interstate, civil, ethnic, religious, electoral, political, communist, revolutionary, guerilla, insurgent, imperialist, terroristic), as well as to a variety of forms and analytical categories (e.g., racial, queer, psychological, structural, silent, symbolic, repressive, normalized). All of this makes any entry purporting to capture geographical and social scientific scholarship on the subject fraught and exceedingly difficult.

Two related but rather different ways of thinking about violence can be deduced from the word’s etymology (Bufacchi 2005). Violence is derived from the Latin *violentia* (vehemence), meaning a passionate and uncontrolled force. Force is typically seen to be constitutive of violent acts: the *Oxford English Dictionary* defines the word as the exercise of physical force so as to inflict injury or harm and to cause damage to persons or property. Violence, said John Dewey, the American pragmatist, is force gone wrong. Not all acts of violence deploy force, of course – persons might be killed by the using of chlorine gas, say, as in contemporary Syria. But violence is necessarily destructive and is often defined by intentionality. A simple relation between force and violence has, of course, been questioned. Hannah Arendt (1969, 1973) rejected the purported synonymy of force and violence, and suggested that we should instead focus on the relations between violence and power. Force is a potentiality or a capability – for Arendt it is a sort of energy – while violence is an act, something that is perpetrated and enacted. In the same way, force carries none of the moral and pejorative opprobrium of the concept of violence.

There is a second and more capacious meaning of violence, however, which turns on the word’s relation to violation from the Latin *volare* (infringement). There is here an association between violence and words such as “dishonor,” “violation,” and “emotional or psychological injury.” Violence as violation is a more capacious subsuming force but also one acknowledging and emphasizing the transgression of norms and rights. Bufacchi (2005) identifies three sorts of violations: first, violations of personal rights and of the dignity of the person; second, violations of rights to ourselves; and, third, violations of human rights in the fashion articulated by peace theorist Johan Galtung in his notion of structural violence and in the way that much of the humanitarian international and human rights communities see their mission.

The differing circumferences of both notions of violence – one aimed at excessive and destructive force, the other pointing toward...
what Randall Collins (2009) would call violent “situations” capable of embracing conditions of threat, fear, and intimidation which imply psychological harms – call attention to quite differing theoretical traditions, including those deployed by geographers. Violence in these differing senses also stands in quite different relation to conceptions of power (repressive vs biopolitical, for example). Much social scientific scholarship turns on the character and consequences of the putative state monopoly of the means of violence – Weber's classic definition of the state and the state’s ability to declare states of exception in moments of crisis. Virtually any state increasingly obsessed with security – not least in a post-9/11 paranoid world in which the American empire is seen to be under direct threat – is inclined to terror by the provocation of terror. The relation between state power and the desire to identify new or old enemies (internal and external), and the state power’s complicated connection to authority, law, and the military, stand at the heart of much modern political violence and naturally of much social scientific (and geographical) analysis.

These points of theoretical contrast – and the degree to which they invoke contrasting theories of the role and capabilities of the modern state in the perpetration of violent acts, whether war, genocide, counterinsurgency, or repression – can be glossed over briefly in reviewing a quartet of foundational theorists of violence: Hannah Arendt, Frantz Fanon, Walter Benjamin, and Michel Foucault. Arendt argues that, while they are related, power and violence are distinct concepts: the former arises from the consent of groups, “the human ability not just to act but to act in concert” (Arendt 1973, 143), whereas violence requires neither numbers nor consent but relies on implements that are capable of multiplying their strength. Two less important but related concepts in Arendt are strength and force. Strength Arendt defines as belonging to the individual and as distinct from power, which is a property of groups. Force is used to designate the energy released by physical or social movements. Violence, according to Arendt, has the role of ensuring the stability of international relations, which means national independence and the claim to unchecked and unlimited power in foreign affairs as identified by nations (Arendt 1973, 107). Arendt concludes that, as the power of violence in international relations diminishes, it is enhanced and intensified in domestic relations. A government that relies entirely on violence has no power. Tyranny is both the least powerful and the most violent form of government (Arendt 1973). Power stands as a counterpoint to violence, and where violence interacts with power it inevitably destroys it. In the same way, violence can never create power (Arendt 1973, 152).

Conversely, Fanon (1969) draws on both conceptions of violence in his account of the postcolonial condition and of the relations between violence and human emancipation. His notion includes force, physical injury, coercion, militancy, and, importantly, psychological injury. Settler colonialism was itself a violent imposition, and decolonization, faced with the alienated condition of the “native,” required both the physical freeing of a territory from a colonizer but also the psychological freeing of an alienated and subjugated consciousness. Decolonization was always a violent phenomenon for moral and practical reasons (settler colonialism was ruled through violence; only through violence could humanity be restored), and only through violent decolonization could the native (and colonial society) be purified. Fanon takes on the question of race and racism seen as central to totalitarianism but inverts Arendt’s logic to see the emancipatory potential of violence.
Benjamin (1978) emphasizes the complicity between the order of violence and the law. He counterposes natural law (law as a pure means to an end, that is to say, an act is violent to the extent that its ends or objectives are unjust) against positive law (in which the means of a certain action comes under scrutiny regardless of justness). Benjamin focuses on the question “Under what conditions is it possible to distinguish between legitimate and illegitimate violence?” He distinguishes between law-making and law-preserving violence, both of which are irreducibly connected by power. At the heart of his analysis is the state (rather than nonstate actors) and the notion that violence reaffirms the law and the law reaffirms violence. There is always violence at the heart of every form of political and legal authority.

Foucault’s (2010) genealogy of power also allows us to see how society settles each of its violations within a system of rules. Power (as for Benjamin) is not an instrument or a capacity (repression); it must be freed from the law and sovereignty. Power is seen through the lens of violence. War was woven into the fabric of society and, says Foucault, it operates as an ontological schema for interpreting the world, a grid of intelligibility. In the modern period, violence and war find form in a specific set of operations of power, namely biopolitics: violence is now inscribed in modern societies through the administration of life, through forms of regulation and calculation, in which wars are fought by states on behalf of the populations they administer. Biopower is organized around the principle of security and the preservation of life.

Running across these four figures is an interrogation of the relations between the state, power, law, authority, and violence. Each tradition has been drawn on, in different ways, by geographers to grasp violence in particular places and times, to locate violence in a specific space–time nexus (Gregory 2011). Geographic work on what one might call “economies of violence” (Watts 2013) has been especially shaped by three formative events and processes. The first is the close relation between the discipline of geography and the twin forces of state formation and empire (Smith 2003). Exploration, cartography, the deployment of geographical knowledges in forms of militarism, and imperial conquest have been central themes in geographical scholarship, whether through geopolitical theory, the biographies of key geographers and geographic institutions (Smith 2003), or analyses of colonial and postcolonial state building (Bryan and Wood 2015). A second is of course the “war on terror,” post–Cold War militarism, and the deepening invasiveness of the national security state particularly after 9/11 (Gregory and Pred 2007; Paglen 2009; Kosek 2010. The third has been a body of work inspired by Edward Said’s observation that:

Just as none of us is outside or beyond geography, none of us is completely free from the struggle over geography. That struggle is complex and interesting because it is not only about soldiers and cannons but also about ideas, about forms, about images and imaginings. (1993, 7)

These struggles have focused on multiple spatial and territorial arenas, from the city to indigenous territories, to liberated insurgent zones, to prisons, to the domestic sphere, to the violence of neoliberalism and the wageless class, to more recently the violence associated with police brutality and the Black Lives Matter movement. This considerable body of work draws on both conceptions of violence and varied notions of power (repressive, disciplinary, biopolitical, and patriarchal) in addressing a raft of geographical problems.

Some of the richest geographical work on violence has emerged from two theaters of conflict: the first surrounds resources and the
environment, where political ecology figures centrally as a frame for exploring violent and conflicted struggles over access to resources (Peluso and Watts 2001), and the second addresses the so-called new forms of post-Cold War conflict (militias, transnational gangs, ethnic gangs, organized crime), particularly in the “failed states” of the Global South. The World Development Report 2011: Conflict, Security, and Development (WDR 2011) argues that violence may not just be a cause of poverty but perhaps the central cause for the “bottom billion of the population” (World Bank 2011). One and a half billion people currently reside in areas affected by what WDR 2011 calls fragility, conflict, or large-scale organized criminal violence. Central to the condition of the poor is, in short, a violence trap. Peace confers conditions in which economies can grow; conversely, poverty is concentrated in states riven by civil war, ethnic conflicts, and organized crime. WDR 2011 asks what spurs the risks of violence, why conflict prevention and recovery have proven so chimerical, and what can be done by national leaderships and international development organizations alike to restore stable development in conflict-torn and fragile states, or what the Clinton administration in the 1990s famously called “failed states.” The central message of the report is that “strengthening legitimate institutions and governance to provide citizen security, justice and jobs is crucial to prevent cycles of violence,” a key point being that violence is recursive and high rates of recidivism plague war-torn countries.

There is a dialectics of violence: conflict can cause poverty (death, injury, and displacement reduce life chances) as much as poverty can cause violence: if you are poor, it pays to rebel. As a result, not a single low-income conflict-affected or fragile state has achieved a single Millennium Development Goal. And, finally, the cyclical and repetitive nature of conflicts, identified by Paul Collier (2007) and his colleagues in their earlier work, produces a geographical and politico-economic condensation of violence and its destructive consequences. In other words, the territorialization, or spatialization, of organized violence falls disproportionately in some parts of the Global South, with devastating effect. For every three years that a country is affected by violence, poverty reduction lags by 2.7 percentage points. The figures are mind-numbing: globally, 42 million people are displaced by violence, and two-thirds of those who are undernourished, without potable water, and without primary education reside in conflict-affected states. The indirect costs of conflict – in which children and women bear a disproportionately high burden – are mind-boggling: the indirect medical costs of violence in Brazil are 40 times higher than the direct costs (World Bank 2011). While these putatively new forms of violence are not exclusively the preserve of resource-dependent (or resource-“cursed”) political economies, the intersection of postcolonial state building and resource-rich states (see the so-called resource curse literature: Collier 2007), some of which are confronting the challenges of global climate change, has provided an exceptionally rich setting for geographic study (Dalby 2009).

As Philippe Le Billon’s important book on resource conflicts (2012, 1) points out, the 1990s were crucial because, even if the trend line of the number of armed conflicts began to fall, those that remained seemed increasingly “tied to resource sectors” while the armed groups themselves came to resemble “militarized commerce” rather than “ideological sponsorship.” All of this was framed, says Le Billon, by the rapid restructuring of the global economy, the “third wave” of democratization, the liberalization of the resource sector, the volatility of commodity prices, and the arrival of new
resources companies from “emerging countries, chiefly China.” These observations were (and remain) part of a more expansive body of scholarship and policy work addressing the changing face of conflicts in general, variously framed in terms of new and old wars, of the rise of asymmetrical warfare, of the disappearance of 1960s-style guerilla movements and their attendant political commitments and ideological orientations, or the various species of “new conflicts.” Le Billon focuses exclusively on resource sectors (although his analysis has implications for how we think about armed nonstate actors and patterns of violent or contentious politics more broadly) and how resources influence the likelihood and course of armed conflicts. He provocatively claims that all resource sectors influence conflicts in the same way – through location, mode of production, revenue accessibility – and that resources themselves do not cause conflicts. Rather, he argues, resources are hybrids (products of joint social and economic processes) that contribute to shaping social relations and are in turn expressive of social relations. Le Billon offers “three dimensions” of his analysis – vulnerability (economic dependence on a resource), risk (social relations of production that overdetermine conflict over access, control, and extraction of resources), and opportunity (how resource properties provide differing opportunities for insurgents and armed conflict) – which “engender various types of violence.” He addresses three of these: unrealized potential (failure to harness and spread wealth), environmental violence, and multiple forms of violence associated with armed conflict (Le Billon 2012).

Geographers of resource conflicts share the field with armies of economists and political scientists, many of whom have been drawn to study civil wars of various sorts through large-N studies. Le Billon and other geographers (e.g., Richards 1998) are critical of the econometric approaches and three broad sets of conventional political economic mechanisms linking resources and armed conflicts: the institutional weakening effect (the orthodox resource curse analysis), the motivational effect (grievance and greed theory), and the opportunity effect (rebel finance). The strength of a geographical analysis is that it links political economy, the material qualities, and differences of resources (location, abundance, material form, forms of extraction, and so on) while simultaneously being attentive to their properties as commodities (their social life, the ways in which resources cannot be represented or discussed just in terms of the meanings attached to them but also in terms of how they might be fetishized). Resources are social processes demanding what Le Billon calls “thick historical and geographical contextualization” (2012, 13). History matters through memory and identity, through the timing of resource discovery and insertion into institutional and political economic arrangements, and geography itself is a historical product (Watts 2013). By emphasizing vulnerability, risk, and opportunity, geographers have generated a typology of resource conflicts that turn on whether the resource in question is proximate or distant from sources of economic and state power, and whether the resource is at a point or diffuse. Le Billon’s (2012) matrix yields four conflict outcomes: coup d’état (proximate point), secession (distant point), mass rebellion (diffuse–proximate), and warlordism (diffuse–distant). The originality of this sort of analysis is that it takes the materiality of the resource – for example, how the “oilyness” of oil makes a difference – very seriously, and Le Billon attempts to draw out these implications for the onset, duration, and severity of the conflicts. He concludes that resources can motivate and finance both before and during the onset of violence, and can also shape the internal
coherence and cohesion of the movements themselves.

Geographic work has delved deeply into the material worlds of specific resources understood as commodities within global capitalism: oil, timber, and diamonds have figured centrally. Vulnerability, risk, and opportunity all play a role in the case of oil, as did the location of oilfields and the “institutional setting.” In the case of diamonds, diamonds are not a rebel’s best friend because they can also set out constraints and barriers (tactical, logistical, financial) for belligerents. In relation to timber, there is no statistical evidence that forests make any difference to the onset of risk or to the duration of conflict. Insurgent groups may opportunistically use forests as advantageous terrain, and there may also be links between forests and rebellions through particular histories, institutions, and capabilities of forest-dwelling peoples.

Political ecologists, and geographers generally, have resisted the urge to offer “a theory of violence,” or Olympian claims about the powers of particular resources, or indeed easy solutions and prescriptions. Political ecology properly encourages a sensitivity to history, space (at various scales), and the institutional and political economic settings into which resource exploitation and resource revenues are inserted, while being attentive to the properties and qualities of the resources. It is this complex overlapping and nesting – in effect, a recognition of the simultaneous coexistence of various forms of conflict in and around the very same resources that collectively comprise a vastly complex social field of violence – that geographers are exploring. There is interesting new work of this sort on resources, state-making, and frontier violence, on transnational gangs, and on the geographies of counterinsurgency. These sorts of complexities – that is, the historically and spatially granular contextualizations they invoke – sit uneasily with much of the social science research running large-N regressions. As Gadda (2007, 5–6) put it in describing not violence but crime:

the apparent motive, the principal motive was, of course, single. But the crime was the effect of a whole list of motives, which had blown on it in a whirlwind … and had ended by pressing into the vortex of the crime the enfeebled “reason of the world.”

Virtual geographic environments

After Michael Batty first used the term “virtual geography” in 1997 (Batty 1997), the term “virtual geographic environments” (VGEs) was formally proposed by Lin and Gong as a concrete object of study in the discipline of virtual geography (Lin and Gong 2001). The term “virtual geographic environment” stems from two other well-known terms, “geographic environment” and “virtual environment.” A geographic environment refers to the portion of Earth’s surface on which creatures (especially human beings) live. It consists of natural (e.g., water, air, and soil) and social (e.g., human behavior) factors related to this geographic space, and it is continuously changing as a dynamic system. The virtual environment, which is also called a virtual world, digital world, or electronic environment, is widely used to describe virtual spaces that are built based on visualization and virtual reality (VR) technologies; recently, many of these spaces have been developed through the Internet. Users can participate or become immersed in these virtual environments by “feeling” and “exploring” spaces that do not exist in real life or that cannot be reached at the local time and location. Although many types of virtual environments are rooted in game playing, they have potential usefulness for scientific research (Bainbridge 2007). Many applications have been appeared in various fields, such as house design, urban planning, and social network analysis. With the two terms, a VGE can be regarded as a typical virtual-based geographic environment that allows users to “feel the geographic scenarios in person” and to “know the geographic laws beyond reality” (Lin et al. 2013b).

In this context, since the mid-2000s, more researchers have begun to study this new branch of geographic information science (GIScience) from a theoretical or a technical perspective (Lin et al. 2013a, 2013b). Although the main concept remains the same, the development process indicates that VGEs have experienced a gradual evolution in terms of their content and functions. Overall, three primary stages are apparent.

The period from 1998 to 2002 can be regarded as the embryonic period of VGEs. The term “virtual geographic environments” was coined at a conference and later published in the conference proceedings (e.g., Gong and Lin 1998). However, no clear definition of it was given at the time. After three years, the term was formally proposed in Lin and Gong’s article “Exploring Virtual Geographic Environments” (2001), which described VGEs as “environments pertaining to the relationship between post-humans and 3-D virtual worlds.” Five types of space (i.e., Internet space, data space, 3-D geographic space, personal perceptual and cognitive space, and social space) were defined to characterize VGEs. Lin and Gong also mentioned the “georeferenced virtual environment” to “allow
VIRTUAL GEOGRAPHIC ENVIRONMENTS

distributed users to congregate virtually on the Web and interact with 3-D graphical worlds to explore the Earth’s geographic phenomena and processes in an immersive or semi-immersive way.” In their opinion at that time, a “georeferenced virtual environment” was a component of VGEs. Although their idea of VGEs was slightly clearer than the former concept, it appears that the meaning was so broad that it was difficult to understand the main purpose of providing such a VGE. A gap still existed between VGEs and geography. In contrast, the definition of “georeferenced virtual environment” suggests that it has a use for the exploration of geographic phenomena and processes on Earth. It is easy to understand and appears to focus on solving geographic problems.

The following six years (up to 2008) are regarded as a continuous exploration stage. During those years, in order to study the relationship between VGEs and geography, scholars interpreted VGEs from the perspective of geographic language as a basic tool to represent geospatial information that is related to both the physical and social aspects of an environment. By considering multidimensional expression and multichannel interaction as typical characteristics, they regarded VGEs as the result of the evolution from verbal language through text, maps, and geographic information systems (GIS). This evolution is a reflection of the continual improvement of spatial information communication (Lin and Zhu 2006). Accordingly, studies on VGEs then focused on how to provide a virtual environment that corresponds to the real world to allow users to better understand it through a visual or immersive experience. At this stage of its evolution, a VGE is similar to the previous “georeferenced virtual environment.” Although the objective of VGEs was narrowed down, its contribution to geographic problem-solving emerged. This concept is more practical for today’s development of VGEs.

The years 2009–2015 are regarded as the explosive stage of VGEs, as an increasing number of scholars have conducted research on VGEs. For example, Goodchild (2009) proposed that volunteered geographic information (VGI) could be an important data collection mode for the development of a VGE; Mekni (2010) discussed the use of agents to simulate human behavior in VGEs; Priestnall et al. (2012) highlighted that VGEs can be employed in education and geographic learning; and Konecny (2011) summarized the challenges in the study areas of VGEs. Although the different perceptions were linked to various research approaches and achievements, this period saw the clarification and clearer conception of VGEs. To provide a summary of the previous research over nearly one decade, Lin, Chen, and their colleagues (Lin et al. 2013a, 2013b, 2015; Chen et al. 2015) redescribed their proposed VGEs as a new generation of geographic analysis and computer-aided geographic experiment tools. VGEs are “a type of typical web- and computer-based geographic environment” built “by merging geographic knowledge, computer technology, virtual reality technology, network technology, and geographic information technology,” “with the objective of providing open, digital windows into geographic environments in the physical world, to allow users to ‘feel it in person’ by a means for augmenting the senses and to ‘know it beyond reality’ through geographic phenomena simulation and collaborative geographic experiments.” Thus, a VGE can “contribute to human understanding of the geographic world and assist in solving geographic problems at a deeper level” (Lin et al. 2013b). Compared with the ideas in the former two stages, the latest definition of a VGE has a closer relationship to geography. The construction of a
VGE is currently targeted at geographic understanding and problem-solving through not only geovisualization and human immersion but also geosimulation and geocollaboration. To some extent, this definition has provided an answer to one of the “big questions” proposed by Cutter, Golledge, and Graf (2002), namely, “what role will virtual systems play in learning about the world?” The definition also coincides with three of Goodchild’s five future points about GIScience: multidimensional visualization, dynamic phenomenon simulation, and public participation (Goodchild 2010; Lin et al. 2013b).

Structure and components of VGEs

To achieve a better understanding of real geographic environments through VGEs, the features of real geographic environments should be addressed. Three keys characteristics are noteworthy: (i) a geographic environment is a comprehensive system consisting of natural factors (e.g., soil and water), social factors (e.g., human), and their interactions; (ii) it is a dynamic system because geographic processes change over time; and (iii) in this environment there are generally two types of geographic objects, discrete objects with boundaries (e.g., a tree or building) and continuous fields without boundaries (e.g., the air). These characteristics require substantial detailed functions of VGEs. Thus, to date, a VGE must support (i) geovisualization and human immersion to assist in acquiring a visual image and to foster participation; (ii) geosimulation for reproducing and predicting dynamic geographic processes; and (iii) geocollaboration of experts from various fields to conduct comprehensive geographic analyses and experiments through the Internet.

The current structure of a complete VGE is shown in Figure 1. The foundational technologies are computer technology, VR technology, network technology, and geographic information technology. However, the most important basis is the thorough consideration of geographic knowledge during the building and implementation processes. For example, in some game-like virtual environments, a man can fly everywhere at any instant, which is not possible according to common geographic knowledge in the real world. A VGE is built to solve geographic problems so that these common laws should be integrated into the VGE as restraints. Based on these foundational technologies and factors, four components (i.e., the data, modeling and simulation, interactive, and collaborative components) and two cores (i.e., a geodatabase and a geographic process model base) should be equipped within a complete VGE. Finally, the virtual geographic scenarios are built for the public to immerse themselves in and to provide their spatial knowledge, and for the researchers conducting collaborative geographic experiments.

The functions of the four components have been discussed in detail by Lu (2011) and Lin et al. (2013a). A short summary is provided here. Geographic data (geodata) are the basic resource for geographical scene expression and geographic problem analysis. The collection, management, and usage strategies of geodata are always key components of geographic analysis tools. In a VGE, the data component is designed to take responsibility for geodata management and organization. Today, with the rapid development of photogrammetry and remote sensing technologies, mass geodata from the sky to underground can be acquired by different professional methods with various tools. At present, more timely social data (e.g., behavior choice) can be provided by the public as a result of the wide distribution of sensors and the wider availability of natural data (e.g., the temperature and air quality of a location). Although the
accuracy and precision of this type of data are sometimes still worthy of discussion, there is no doubt that the data will contribute to the construction of VGEs (Goodchild 2009). In the context of mass multisource and heterogeneous (e.g., differences in data structure, semantic, scale, or coordinate system) geodata originating from the real geographic environment directly or indirectly, putting these data back into the computer via data integration to form a virtual environment for representation, simulation, and prediction is a significant challenge. Many types of geodata models in traditional GISs were designed for visualization (2-D/3-D) and spatial analysis; thus, a gap still exists between traditional geodata models and efficient geosimulation (Lu 2011). If these issues are solved, then the functional geodatabase, which is a core base of the VGEs, can be developed and fully utilized as a foundational support to other functions.

The current research priorities of GIScience are changing from static snapshots to dynamic complex processes (Goodchild 2010). A static scenario is easily described, but it is powerless for trend predictions. Geographic modeling and simulation are important for gaining a better understanding of these geographic processes. Studies in this field have produced various geographic process models, many of which have been used for hazard analysis, weather forecasting, and flood warnings. However, except for the developer and owner, other researchers typically

Figure 1 Current structure of a complete VGE. Modified from Lin et al. 2013b.
have difficulties in understanding and reusing these models, which causes a problem of “model islands.” Thus, a type of model reuse mode should be promoted. In practice, one needs to buy the model resources or related software and deploy them on a server, even for small experiments. This process is costly and inefficient. If these models can be packaged and shared in a network and provided by a unified architecture, then the fee can simply depend on the times that the model users request. Under the precondition that the safety of both the data and model are strictly protected, this approach will not only benefit model users but also allow model owners to promote and test their models. The modeling and simulation component in a VGE aims to help researchers share and reuse the existing model resources in a VGE conveniently without focusing on the configuration of the network and hardware. Thus, it can be regarded as a bridge between the geographic process model and distributed model users. Technological problems related to this component are under consideration (e.g., Wen et al. 2013), and the geographic process model base, which forms the second core of VGEs, will be construed based on this component. Thus, in a VGE one may rent and implement a single model through the Internet after it is packaged and integrated into the geographic process model base, regardless of the user’s budget or technological knowledge of the computer’s configuration environments. Combined with the functions that are provided by the data component and the interactive component, a VGE can provide the simulation result and corresponding visual or sensible “real” geographic processes that are calculated by the process models. Moreover, because of the complexity and comprehensiveness of the geographic environment, scientific geosimulation urgently needs the collaborative efforts of multidisciplinary models (e.g., rainfall, soil erosion, and evaporation and diffusion models). These models must be coupled in a systematic workspace. According to Lin et al. (2013a), the modeling and simulation component will also provide multidisciplinary researchers with the opportunity to create a conception model based on the complex geographic processes in a VGE. Then different unit models can be linked to conduct a comprehensive simulation to explore a cross-cutting geographic problem. The results can be examined in terms of intuitive feeling and common understanding.

The modeling and simulation component of a VGE reflects the design of the tools that support multichannel geointeraction. This component is the bridge between the users and virtual scenarios. For the users, interaction can be divided into perception (through vision, hearing, touch, smell, and taste) and manipulation (through a mouse, gesture, or voice). Related research on human–machine interaction (HMI) is increasing in various areas, such as VR and artificial intelligence. Those achievements have been fully referenced in the development process of a VGE. However, specific challenges remain to realizing geointeractions in a VGE in order to achieve a “natural” feel and comfortable manipulation. For example, a lake may release different smells when it is polluted by different sources or under different levels. When such a lake is rebuilt in a virtual environment, for an immersed avatar, the various smells may need to be provided to warn a user of the pollution conditions. In another example, a mouse can be used to rotate or zoom in or out in traditional GISs. In the VGE, beyond this mode, if the user wants to control his or her immersed avatar by voice, it is necessary to translate the verbal commands (e.g., turn left, toward the south) into manipulative commands. Moreover, the costs of the related interaction tools must be reduced if more participants are expected to be involved in the geographic exploration tasks using VGEs.
VIRTUAL GEOGRAPHIC ENVIRONMENTS

Collaborative work is common in today’s scientific research. Geocollaboration aims to bring different users together to contribute their knowledge and to work cooperatively. This popular approach may be explained by several factors. First, the geographic environment is a complex system that covers various natural and social factors. Thus, the research of the geographic environment requires a closer collaboration of multidiscipline experts. Second, during a task, one person may have basic data only; the suitable process model may be held by another person, whereas another person may know the empirical parameters of a certain experimental area. Collaborative work is also important in such situations. In a VGE, the collaborative component is designed to provide related tools to support such collaboration. When performing collaborative work, the actors of different participants should be defined first, and the total workflow should be designed. Then, every task and subtask must be clearly divided and assigned to different actors. The necessary tools are requested for each task (e.g., provide the metadata of the original data resource, set the model parameters). Conflict detection and communication strategies are also critical during this process. These issues are the main research topics in the development of a collaborative component of a VGE.

Contributions of VGEs

Geographic experiments and analysis

As mentioned, the main goal of developing a VGE is to provide a tool, or a workspace, for geographic experiments and analysis. This geo-oriented conception may distinguish VGEs from other digital worlds, such as digital Earth and virtual games. Geographic experiments aim to simulate the natural and social worlds under one explanatory umbrella (Matthews and Herbert 2008). Conducting geographic experiments in VGEs will provide the following advantages.

First, although traditional geographic experiments have played an important role in geographic research, they are limited with regard to specific times, environments, and scales. A traditional geographic experiment often employs a fieldwork method or conducts process analysis based on a physical model. In the fieldwork method, it is difficult to control the surrounding environment (e.g., unexpected rain), and experiments that aim to make predictions are difficult to conduct. In the model-based method, the shortage of field data may affect the accuracy of a simulation. Moreover, a large region study area in a traditional geographic experiment also requires a significant amount of money and human resources. A VGE can fill in these gaps to some extent. With a VGE, geographic scenarios may be developed at multiple scales, from global to local. Thus, researchers can zoom in or out to visit the study areas and perform experiments at various scales. They can add different factors to the study area to view the outcomes under certain assumptions (e.g., set a virtual rain or flood over a virtual farmland or village). A visual image can be obtained through this low-cost experimental mode through the use of geographic process models at the appropriate scales. Using the tools designed in VGEs, researchers can then adjust the parameters to obtain different experimental results and choose a suitable one to explain the real-world scenario.

In addition, human behavior has proven to be an important influence on the changing geographic environment. Although data on human behavior may be collected and sorted through questionnaires, surveys, or statistical materials, there is an alternative method to fill this gap. Today, psychologists often test human feelings and behaviors by placing volunteers in small virtual spaces
This mode can be referenced by geographic experiment as a strategy to involve human factors. Generally, two types of users are involved with VGEs: professional users (including scientific researchers and decision-makers) and public users. Even without professional knowledge, public users are encouraged to enter into virtual scenarios through multichannel interactive tools to gain their own perceptions and experience. Through this means, they can also indicate their geographic knowledge and living choices. For example, to conduct a human–environment interactive experiment, a virtual polluted small town may be created in a VGE, and 1000 virtual people placed in it. Among these people, 900 may be simulated by ruled agents and the remaining 100 by invited volunteers as avatars, through multichannel interactive tools. These volunteers can perceive the surrounding environment and attempt to make personal suggestions through their judgments. They may control their avatars to change the conditions in the virtual environment by, for instance, planting virtual trees or reducing the number of virtual cars. Avatars and agents can interact with each other as well as with these virtual geographic factors. After recalculation by the corresponding process models, a comprehensive result is identified that considers the natural and social impacts, which will facilitate further comprehensive experiments by researchers (Chen et al. 2013).

Finally, decision-makers generally need to have a plan before starting large projects in the real world (e.g., demolishing a dam or building a large petrochemical plant). Traditional decisions may be made based on documents, reports, and figures, but a recent trend has been for decision-makers to use virtual worlds to obtain a more realistic projection (Bainbridge 2007). Researchers with professional knowledge often conduct some experiments and build various virtual scenarios as proposed solutions (e.g., in city planning) beforehand. Then the decision-makers may choose one scenario as the final solution from the several proposed solutions. However, limitations still exist because it is difficult for decision-makers to comprehend the overall concept proposed by a solution. Thus, the potential problems during the entire process have not been fully identified. With a VGE, decision-makers can more easily identify a solution in collaboration with researchers because, apart from the professional formulas and parameters, they are confronted with the same virtual environment. Decision-makers can join in the experiments directly and ask the researchers to perform potential actions in the virtual environment (e.g., remove 60 chimneys from the southeast sector of a city or reduce the traffic flow in the northwest sector of a town) to determine the outcome. The results are represented after each step is conducted and recomputed, and the solution can be adjusted in a timely manner. Using this mode, less time is required, and the efficiency of the decision-making process can be greatly enhanced.

Geographic knowledge sharing

Geographical thinking and reasoning are important ways of exploring the world and its inhabitants. They produce geographic knowledge of the world’s natural and social phenomena. Golledge (2002) noted that the nature of geographic knowledge over the past 50 years has evolved from phenomenal to intellectual, such as understanding why and how in addition to what and where. Hence a change is required from geographic form representation to geographic process analysis.

A main feature of VGEs is that they own a geographic process model base. A geographic process model is an important foundation for geographic simulation. In some ways, it can
also be regarded as a type of representation of geographic knowledge because the inner mechanism and related formulas in geographic process models are generally produced from a summary and induction of former geographic knowledge (Wen et al. 2013). As discussed earlier, the modeling and simulation component of a VGE promotes a share and reuse mode of geographic process models while performing simulation tasks. When these geographic process models are shared, the inner geographic knowledge can also be shared accordingly.

Comprehensive and complex geographic research requires collaborative work and process models and geographic knowledge from multidisciplinary experts. One challenge is that different experts often have specific understandings of the problems and are accustomed to conducting their research under their own direction and using tools with which they are familiar. In collaborative working, a workspace that can help to achieve a common and familiar understanding is critical. A VGE can provide users with a virtual environment that corresponds to the real geographic world with visual objects and lively phenomena which are familiar and easily recognized. Compared to tools that use abstract or professional symbols to represent geographic information, the VGE can create a better and more universal understanding to enable multidisciplinary experts to communicate with each other and to encourage knowledge sharing (Lin et al. 2013b). In a collaborative study (e.g., a simulation conducted through setting different parameters or the model is modified collaboratively), existing knowledge can be shared and new knowledge may be produced. A network-based VGE is useful for the knowledge sharing even when researchers are scattered across the globe.

**Big data in GIScience**

In 2007 Jim Gary proposed data-intensive science, also known as the fourth paradigm of science, initiating a new chapter in the development of scientific research. Data-intensive science calls for a special data-centered method that integrates the previous stages of experiment, induction, and simulation into one process. Researchers are encouraged to explore various phenomena and to summarize rules by collecting, storing, analyzing, and presenting these big data, which originate from everywhere and at any time. Nature and Science have published special issues on big data. In 2012 the US government, under the guidance of President Obama, proposed its “Big Data Big Deal,” and the US National Science Foundation (NSF) tried to lead the federal efforts in big data.

The same situation occurs in GIScience, where mass data can be acquired by various means (e.g., remote sensing, surveying and mapping, global positioning system (GPS), and sensor networks). Although various data are acquired from different tools with different formats (some data may even be unstructured or its semantic may be missing), a common feature is that these geodata are from the real world and can be coded with a real location at a point in time. Accordingly, location can be regarded as a special factor for the gathering and sorting of these big data, and is the most important reason for maps being used over the years. Today, data are characterized by three or multidimensions (e.g., time dimension), which require a more powerful tool as the data interface and support further presentation and analysis. A VGE would provide such a workspace because it aims to provide digital mirrors of the real world (Lin et al. 2013b). Based on this background information, all data that exist in the real world can be computerized to form a virtual environment with visible and analyzable
information. Specifically, environmental data that are collected by sensors (e.g., air quality, humidity, and temperature) can be inserted into a virtual environment directly through location matching. Using integrated process models and analysis methods, geoeperiment, geoinduction, and geosimulation can be applied to the same virtual environment that is familiar to human beings.

Moreover, social data are also a type of geographic data because the discipline of geography includes both natural and social factors. Social data can now be easily produced by volunteers, (e.g., travel behavior in a city, networking among friends in different areas, or evaluation of a shop or a school), and these data can be provided through personal digital assistants (PDAs) or smartphones. By these means, citizens can easily be involved in contributing to and using big data. Examples have appeared in OpenStreetMap and Google Earth. A VGE can also provide a visual and accessible interface that allows users to enter mass social data (often in real time) into one virtual environment. Combined with the data collected by professional methods, these data can be displayed in the virtual environment to reflect dynamic situations that occurred in the real world. Thus, the data are more useful and easier to understand, and comprehensive geographic phenomena and rules can also be explored and analyzed in this visual way.

Potential contributions to other disciplines

Potential contributions of VGEs to specific disciplines can be established based on the advantages discussed. Here, remote sensing and global change are presented as examples.

The study of fusing multisource, multiresolution remote sensing data into time-series super-resolution images has become increasingly popular in recent years. These studies explain the natural geographic process using mechanistic models and empirical models. However, remote sensing images do not yet fully reflect dynamic geographic phenomena because of the fixed resolution and the precision problem of remote sensing data. One possible solution is to integrate remote sensing data with geographic process models. Using a VGE, remote sensing data and other geodata can be linked together to form a perceptible environment and human visualized thinking can easily be introduced to contribute to the interpretation of remote sensing images. More importantly, a VGE’s geographic process model base provides a bridge between remote sensing data and geosimulation, which can enhance the efficiency of remote sensing information. On the one hand, multisource, multiresolution remote sensing data can be used as parameters for geographic process models and as comparative data to assist the optimization and validation tasks during the simulation. On the other hand, after simulation, the results can be used as supplementary information to facilitate the interpretation of geographic phenomena using remote sensing data.

Global change is a comprehensive discipline involving many factors such as natural, social, economic, diplomatic, and legal ones. Collaboration between different disciplines and departments and various interest groups is urgently needed to research global change. However, the current situation is not conducive to this. For example, an Earth system model is the most important tool to explain global change and the related impacts of factors. At present, unique terms are associated with different models and specific simulations, so it is difficult for different research teams to conduct collaborative research. The successful application of VGEs in geographic research can provide an opportunity for collaboration in global change studies. The critical task is to integrate Earth system models
VIRTUAL GEOGRAPHIC ENVIRONMENTS

into VGEs. Once the geographic process model base is extended to an Earth system model base, VGEs can provide a suitable workspace for collaborative global change studies.

Conclusion

With the development of geographic science and the progress of geographic understanding, corresponding geographic analysis tools are needed to satisfy the requirements of modern users. From acquiring geographic information to studying geographic objects and their relationships, and then exploring dynamic geographic phenomena and processes, the different phases require different tools, for example, the evolution from the use of maps to GIS and finally to VGEs. The use of a virtual environment for the effective management and analysis of the real world has been shown to be a workable method (Bainbridge 2007), as have VGEs for geographic analysis and research (Chen et al. 2015).

Many tools have been approved after several years (or decades) of evolution, including maps and GIS, and VGEs are still evolving. Detailed information and problems have been discussed elsewhere (e.g., Lin et al. 2013a). This entry has focused on the expectations for future development. A VGE is an integrated workspace based on many theories and various technologies, and critical developments in future may see a greater integration of those theories and technologies. It is very important that multidisciplinary researchers engage in this meaningful work and make their contributions to collaborative efforts. When various types of knowledge originating in the real world can be seamlessly integrated into the virtual world, VGEs can provide us with a better opportunity to explore and understand our intriguing world.

Virtual reality

Weitao Che
Chinese University of Hong Kong, China

The term “virtual reality” (VR) was used for the first time by Jaron Lanier in 1989. Generally speaking, VR is often referred to as a virtual environment and is a computer technology that enables users to view or immerse themselves in an alternate world. VR is the ability of the user of a constructed view of a limited digitally encoded information domain to change their view in three dimensions causing an update of the view presented to any viewer, especially the user (Fisher and Unwin 2003).

By using real-time computer graphics, users can experience a computer-generated environment as if it is real and they are a part of it. Users of virtual reality systems can move about the computer-generated 3-D scene and explore their surroundings. For example, users can walk through the corridors and into the rooms of a virtual museum to view the exhibits. In addition to navigating through the environment, users are able to interact with it. Objects can be touched, lifted, manipulated, and moved (e.g., users could rearrange displays in the museum). Finally, virtual reality systems are often, but not always, immersive. Immersion refers to the perception that the user is fully surrounded by the virtual environment (Pierce and Aguinis 1997; Stuart 2001). The surroundings of the physical environment are blocked out typically through the use of a head-mounted display and many senses are captivated through images, sounds, and touch to create a realistic virtual environment. According to Heim (Heim 1998), there are three I’s of virtual reality: immersion, interactivity, and information intensity. Immersion comes from devices that isolate the senses sufficiently to make a person feel transported to another place. Interaction comes from the lightning ability of the computer to change the point of view of the scene as fast as the human organism can alter its physical position and perspective. Information intensity is the notion that a virtual world can offer special qualities such as telepresence and artificial entities that show a certain degree of intelligent behavior. The immersion of VR depends not only on the display but also on the interaction between computer and human. The interaction devices have evolved from the mouse and keyboard to the joystick, digital glove, digital helmet, and now even the brain (Lécuyer et al. 2008).

VR allows a user to interact with computer-simulated environments and is often used in a wide variety of applications involving immersive, highly visual, and 3-D environments. This computer-generated world may be either a model of a real-world object such as a house or an abstract world that does not exist in a real sense but is understood by humans such as a chemical molecule or a representation of a set of data. This computer-generated world might be in a completely imaginary science fiction world. Further, because input devices sense the reactions and motions of the operator, the computer modifies the synthetic environment accordingly, creating the illusion of interacting with, and thus being immersed within, the virtual environment. A recent development of VR has been in the area of networking and the Internet. Networked virtual environments and 3-D interfaces to the Internet are among the latest applications of
VIRTUAL REALITY

VR in a growing telecommunications market. Most current virtual reality environments are primarily displayed either on a computer screen (Van Oppenraaij et al. 2009) or through wearable displays (Santos et al. 2009; DeFanti et al. 2009). Some advanced haptic systems also include tactile information (Reif and Walch 2008). Users can interact with a virtual environment either through the use of standard input devices such as a keyboard and mouse or through multimodal devices such as a wired glove (Reif and Walch 2008). Some examples of VR definitions are as follows:

The terms virtual worlds, virtual cockpits, and virtual workstations were used to describe specific projects. In 1989, Jaron Lanier, CEO of VPL, coined the term virtual reality to bring all of the virtual projects under a single rubric. The term therefore typically refers to three-dimensional realities implemented with stereo viewing goggles and reality gloves. (Krueger 1991)

I define a virtual reality experience as any in which the user is effectively immersed in a responsive virtual world. This implies user dynamic control of viewpoint. (Brooks 1999)

It is a simulation in which computer graphics is used to create a realistic-looking world. Moreover, the synthetic world is not static, but responds to the user’s input (gesture, verbal command, etc.). This defines a key feature of virtual reality, which is real-time interactivity. (Burdea and Coiffet 2003)

Based on computer science and relevant scientific technologies, virtual reality (VR) produces a digital environment in which visual perception, sense of hearing, and sense of touch are highly similar to those of actual environment within a certain range. With the help of necessary equipment to interact and interfere with objects in a digital environment, users may have feelings and experiences corresponding to those in the actual environment. Virtual reality (VR) is a scientific method and technology created during the exploration of the nature by human beings to understand, simulate, and better adapt and use the nature. (Zhao 2009)

History: chronological milestones

- In the 1860s, VR developed roots when 360-degree art through panoramic murals began to appear. An example would be Baldassare Peruzzi’s piece titled “Sala delle Prospettive.”
- In 1929, Edwin A. Link invented a type of flight simulator to give passengers the feeling of flight, and this was the first attempt by humans to simulate or emulate physical reality. With the constant development of control technology thereafter, a succession of various simulators came into being.
- In the 1930s, “Pygmalion’s Spectacles” (1935) by Stanley G. Weinbaum describes a goggle-based virtual reality system with a holographic recording of fictional experiences, including smell and touch.
- In 1938, the origin of the term “virtual reality” appeared. The French playwright, poet, actor, and director Antonin Artaud, in his seminal book The Theatre and Its Double (1938), described theater as “la réalité virtuelle,” a virtual reality in which, in the words, “characters, objects, and images take on the phantasmagoric force of alchemy’s visionary internal dramas” (Davis 1998).
- In 1956, Morton Heileg developed a simulator called Sensorama, which is a motorcycle emulator that provided the user with a unique combination of 3-D visuals, stereo sound, vibration, wind sensations and city smells. He advanced some basic thought of VR technology in the Sensorama simulator patent in 1962. The development of electronic technology and the miniaturization of computers facilitated the development
of simulation technology and finally computer simulation technology appeared (Zhao 2009). Unfortunately, Sensorama was not a commercial success (Kalawsky 1993).

• In 1965, Ivan Sutherland suggested that a display could be built that would ultimately provide computer-generated images so realistic that they would be indistinguishable from the real thing. Then, he proposed the ultimate solution of virtual reality: an artificial world construction concept that included interactive graphics, force feedback, sound, smell, and taste (Kalawsky 1993).

• In 1966, Thomas A. Furness III introduced a visual flight stimulator for the air force.

• In 1968, with the help of his student Bob Sproull, Ivan Sutherland created the first virtual reality and augmented reality (AR) head-mounted display (HMD) system – The Sword of Damocles. The Sword of Damocles was primitive both in terms of user interface and realism, and the HMD to be worn by the user was so heavy it had to be suspended from the ceiling. The graphics comprising the virtual environment were simple wire-frame model rooms.

• In 1968, Ivan Sutherland produced a device that is considered the first head-mounted display (HMD) device at Harvard University. He based his design on two small CRTs (cathode ray tubes) mounted on a head band. This system was unique in that it also incorporated a head position sensing system (Kalawsky 1993).

• In 1971, the first prototype of a force-feedback system was realized at the University of North Carolina (UNC).

• In 1975, Krueger nominated the phrase of “artificial reality” as “a conceptual environment, with no existence.” In this system the silhouettes of the users grabbed by the cameras were projected on a large screen.

The participants were able to interact with one another thanks to the image processing techniques that determined their positions in the space of a 2-D screen. Due to the constraints of computer technologies during the 1960s and 1970s, the development of these types of technologies was not very rapid. The related thoughts, concepts, and technologies still stayed in the brewing and formation stage (Mazuryk and Gervautz 1996).

• In 1975, a company called LEEP Systems Inc. (formerly known as Pop-Optix Labs) was founded by Eric Howlett to develop wide-angle lenses for 3-D still photography applications. In 1979, he designed the large expands, extra perspective (LEEP) optical system. LEEP optical systems are now used in almost every virtual environment headset manufactured in the world today (Kalawsky 1993).

• In 1977, the Aspen movie map was created at MIT. The program was a crude virtual simulation of Aspen, Colorado in which users could wander the streets in one of three modes: summer, winter, and polygons. The first two were based on photographs (the researchers actually photographed every possible movement through a street grid of the city in both seasons), and the third was a basic 3-D model of the city.

• In the 1980s, with the development of computer technologies, especially the update of the PC and the computer network, VR technology made significant headway. Several typical VR devices and systems came up during this stage, including DataGlove in 1981–1982, visually coupled airborne systems simulator (VCASS, an advanced flight simulator) in 1982, virtual visual environment display (VIVED) in 1984, virtual interactive environment workstation
VIRTUAL REALITY

- In 1989, Jaron Lanier, the founder of VPL Co., put forward the phrase “virtual reality,” which was generally accepted by researchers and became the specific title of this scientific technology field (Zhao 2009).

- In 1989, BOOM, commercialized by the Fake Space Labs, was a small box containing two CRT monitors that can be viewed through the eye holes. The user can hold the box to the eyes and move through the virtual world while the mechanical arm measures the position and orientation of the box.

- In the 1990s, with the breakthrough and rapid development of computer technology and high performance computation, human–machine interaction technology and equipment, computer networks and communication, as well as huge demands in the significant application fields such as military drill, aeronautics, and astronautics and complicated equipment research, VR technology came into a rapid development stage.

- In 1990, VR technology was discussed at the SIGGRAPH conference held in Dallas, USA, where the main contents of VR technology research were settled – formation technology of real-time 3-D graphics, interaction technology of multisensor, high-resolution display technology, and so forth.

- In 1991, the virtual environment configurable training aid (VECTA) was used with one of the fastest available graphics systems and the highest resolution LCD helmet-mounted displays to give a display that compared more than favorably with other virtual environment systems being demonstrated throughout the world (Kalawsky 1993).

- In 1991, cave automatic virtual environment (CAVE) was invented at the Electronic Visualization Laboratory at the University of Illinois (www.evl.uic.edu/pape/CAVE). More recent VR systems based on the CAVE are the ImmersaDesk (www.evl.uic.edu/pape/CAVE/idesk/) and the IWall. Another display device created for virtual reality is GeoWall, which is a practical 3-D display system that combines advanced graphics PCs and specially calibrated digital projectors to display 3-D presentations with ease and versatility. Using 3-D and high-resolution technology, GeoWall allows audiences to view and interact with spatially immersive content.

- In 1994, Burdea and Coiffet published a book named *Virtual Reality Technology*, in which they used 3I (Immersion, Interaction, and Imagination) to generalize the basic characteristics of VR (Zhao 2009).

- In recent years, there was another huge revolution in the field, namely augmented reality (AR), a technology that “presents a virtual world that enriches, rather than replaces the real world” by means of see-through HMD that superimposes virtual three-dimensional objects on real objects (Mazuryk and Gervautz 1996).

Input devices: tracking devices

One of the three I’s defining virtual reality stands for interactivity. To allow human–computer interaction, it is necessary to use special interfaces designed to input commands of a user into
the computer and to provide feedback from the simulation to the user (Kalawsky 1993). That is, input devices allow the users to interact with and control objects in the virtual environment (Denby and Schofield 1999). Commonly used input devices include tracking devices, the 3-D mouse, and data gloves.

A tracking device reports its location or orientation to the computer. Typically, there is a fixed piece at a known position and additional unit(s) attached to the object being tracked. The position and orientation of the head of the viewer is the absolute minimum of information that immersive VR requires for the proper rendering of images. Additionally, other parts of the body may be tracked, for example, hands to allow interaction, chest or legs to allow the graphical user representation, and so forth. Three-dimensional objects have six degrees of freedom (6DOF): position coordinates (x, y, and z offsets) and orientation (e.g., yaw, pitch, and roll angles). Each tracker must support these data or a subset. In general, there are two types of trackers: those that deliver absolute data (i.e., total position/orientation values) and those that deliver relative data (i.e., a change of data from the last state).

These devices monitor the position and orientation of the head, hand, and/or body of the user. When the user turns his or her head, a tracking device located in a head-mounted display or shutter glasses (discussed later) detects the motion, determines the new position of the head, and updates the viewpoint of the 3-D environment to create the illusion that the environment is staying still while the user moves. Trackers attached to the back of gloves or located in a 3-D mouse detect hand position. In addition, body position can be determined with trackers sewn into a bodysuit or exoskeleton. In the future, eye trackers may be available that will update the view when the eyes of the user move. Many types of trackers are available, including mechanical, optical, ultrasonic, and electromagnetic (Aguinas, Henle, and Beaty 2001).

The most important parameters of 6DOF trackers to evaluate the performance of the different types of position tracker for the given application are as follows (Meyer, Applewhite, and Biocca 1992; Bhatnagar 1993).

- **Update rate** – the rate at which position and orientation measurements are reported by the tracker to the host. Higher update rate values support smoother tracking of movements, but require more processing.
- **Lag (latency)** – the amount of time between the real (physical) action of the user and the beginning of transmission of the report that represents this action. Lower values contribute to better performance.
- **Accuracy** – the difference between the actual 3-D position of the object and the position reported by tracker measurements.
- **Resolution** – the smallest change in position and orientation that can be detected by the tracker. Smaller values contribute to better performance.
- **Range** – the working volume within which the tracker can measure position and orientation with its specified accuracy and resolution, and the angular coverage of the tracker.
- **Jitter** – the change in tracker output when the tracked object is stationary.
- **Drift** – the steady increase in tracker error with time.

**Magnetic trackers**

A magnetic tracker is a noncontact position measurement device that uses a magnetic field produced by a stationary transmitter to determine the real-time position of a moving receiver...
VIRTUAL REALITY

element. As the most commonly used tracking devices in VR, magnetic trackers typically consist of three parts: a static part as the emitter (source), a number of movable parts as the receivers (sensors), and a control station unit. The assembly of emitter and receiver is very similar: they both consist of three mutually perpendicular antennae. As the antennae of the emitter are provided with current, they generate magnetic fields that are picked up by the antennae of the receiver. The receiver sends its measurements (nine values) to the control unit that calculates position and orientation of the given sensor.

There are either alternating fields of 7–14 kHz (for AC magnetic tracker) or pulsed fields (for DC magnetic trackers). The fields penetrate the receiver producing a signal that consists of nine voltages (three for each of the orthogonal transmitter fields). DC magnetic trackers add another three voltages obtained when the transmitter is turned off. These voltages correspond to the local value of the Earth’s DC magnetic field. The receiver consists of three small orthogonal coils when AC magnetic fields are used and three magnetometers (or alternatively Hall effect sensors) when DC magnetic fields are used. The receiver voltages are sampled by an electronic unit which uses a calibration algorithm to determine the position/orientation of the receiver in relation to the transmitter. These data packets (three positions and three rotation angles) are subsequently transmitted to a host computer via communication lines. If the receiver is attached to a remote moving object, then the computer can indirectly track the motion of that object relative to the fixed transmitter.

The major advantage of the magnetic tracker is that it has no line of sight restriction and wireless systems have become available thereby reducing encumbrances on the participant. However, there are also some limitations. One of the limitations is that metal in the environment can cause magnetic interference. Another limitation is the short range of the magnetic field that is generated.

Acoustic (ultrasonic) trackers

An acoustic tracker is a noncontact position measurement device that uses an ultrasonic signal produced by a stationary transmitter to determine the real-time position of a moving receiver element. Acoustic trackers usually have three components: a transmitter, a receiver, and an electronic unit similar to their magnetic counterparts. The difference is that the transmitter is a set of three ultrasonic speakers mounted approximately 30 cm from each other on a rigid and fixed triangular frame. Similarly, the receiver is a set of three microphones mounted on a smaller rigid triangular frame (Burdea and Coiffet 2003). There are two types of acoustic trackers. The acoustic trackers either use time-of-flight (TOF) or phase-coherent measurements to determine the distance between a pair of points. TOF trackers (e.g., Logitech 6DOF Ultrasonic Head Tracker, Mattel Power Glove) measure the flight time of short ultrasonic pulses from the source to the sensor. PC trackers compare the phase of a reference signal with the phase of the signal received by the sensors. The phase difference of \(360^\circ\) is equivalent to the distance of one wavelength. The difference between two successive measurements of phases allows computation of the distance change since the last measurement. As this method delivers relative data (so the error tends to accumulate with time), development of PC trackers was abandoned (Mazuryk and Gervautz 1996).

Optical trackers

An optical tracker is a noncontact position measurement device that uses optical sensing to
determine the real-time position/orientation of an object. Of the number of ways this can be achieved, the most common is to make use of a video camera that acts as an electronic eye to “watch” the tracked object or person. The video camera is normally in a fixed location. Computer vision techniques are then used to determine the object’s position based on what the camera “sees.” In some cases, light-sensing devices other than video cameras can be used (Sherman and Craig 2002). Generally, the light sensing can be divided into three categories (Mazuryk and Gervautz 1996).

- Beacon trackers – this approach uses a group of beacons (e.g., LEDs) and a set of cameras capturing images of the pattern beacons.
- Pattern recognition – these systems do not use any beacons, they determine position and orientation by comparing known patterns to the sensed patterns.
- Laser ranging – these systems transmit the laser light that is passed through a diffraction grating onto the object.

The limitation of optical trackers is that the line of sight between the tracked person or object and the camera must always be clear.

Mechanical trackers

A mechanical tracker consists of a serial or parallel kinematic structure composed of links interconnected using sensorized joints. The first tracker used in a VR simulation was the mechanical arm that supported the CRT-based HMD developed by Sutherland. The motion of the head of the user was tracked with regard to the ceiling arm attachment. The dimensions of each link segment are known and used by the direct kinematics computational model stored in the computer. This model allows the determination of the position and orientation of one end of the mechanical tracker relative to the other, based on the real-time reading of the tracker joint sensors. By attaching one end of the tracker to the desk or floor and the other to an object, the computer can track the 3-D position of the object relative to the fixed end of the arm.

Body tracking

Body tracking is the ability of the VR system to sense the position and actions of the participants. The particular components of movement that are tracked depend on the body part and how the system is implemented. The body parts and techniques of body tracking commonly used in VR applications include: (i) head tracking, (ii) hand and finger tracking, (iii) eye tracking, (iv) torso tracking, (v) foot tracking, and (vi) tracking other body parts (Sherman and Craig 2002).

Head tracking allows proper rendering of images from the point of view of the user. The advantage of the head tracking is that a motion parallax cue can be provided, which improves the depth perception. One more important aspect can be considered: the visual acuity of the eye changes with the arc distance from the line of sight.

Tracking the hand and fingers is generally done to give the user a method of interacting with the world. In multiparticipant space, hand gestures can also provide communication between participants. A hand can be tracked by attaching a tracker unit near the wrist or through the use of a tracked handheld device. A glove input device is used to track the positions of the fingers of the user and other flexions of the hand.

In general, most important eye-tracking technologies can be grouped as: (i) limbus tracking; (ii) image tracking, and (iii) electro-oculography (EOG) (Mazuryk and Gervautz 1996).
VIRTUAL REALITY

Very few VR applications actually track the torso of the participant, although when an avatar of the user is displayed, this avatar often includes a torso with certain assumptions made about its position based on head and hand positions. However, the torso is actually a better indicator of the direction the body is facing than either the head or hands. The bearing of torso might be a better element to base navigational direction on than head or hand positions (Sherman and Craig 2002).

Tracking the feet provides an obvious means of determining the speed and direction a user wishes to travel. The obvious method of determining foot movement is to track the position of each foot. The most common way to track the position of each foot is to use magnetic trackers. Other body parts can be tracked and used to control various aspects of a virtual world. These items include body functions, such as temperature, perspiration, heart rate, respiration rate, emotional state, and brain waves, which could be measured simply to monitor the condition of the participants as they experience a world, or they might be used to control the world— to determine what experiences are most relaxing, and so forth.

3-D mice and bats

This basic and simple user interaction tool is in general a joystick-like 6DOF device that can be moved in space by hand, equipped with a tracker sensor to determine its position/orientation, and a few buttons that may trigger some actions. Some 3-D mice may be equipped with a thumb ball for additional movement control.

The 3-D mouse is a handheld device used to navigate the user through the virtual environment and interact with objects. To navigate the environment, the gaze of the user determines the direction and clicking a button on the mouse moves the user forward. The mouse can also lift and move objects in the virtual environment. When the user collides with an object, a mouse button is pushed to lift the object, and the object then moves with the user until a button is pushed to drop the object. As previously mentioned, position trackers located in the mouse determine the hand position of the object and, subsequently, the user.

Data gloves

Gloves are devices that measure the real-time position of the fingers (and sometimes wrist) of the user in order to allow natural, gesture-recognition-based interaction with the virtual environment. The measurement of finger flexion is achieved with the help of various sensors. VPL DataGlove, Virtex CyberGlove, Mattel PowerGlove, Pinch Glove, the 5DT Data Glove, and the Didjiglove are representative gloves that have appeared in VR systems. The use of gloves allows the user richer interaction than the 3-D mouse because hand gestures may be recognized and translated into proper actions. Additionally gloves are equipped with a tracker attached to the wrist of the user to measure the position and orientation of the wrist.

These devices indicate the position of the fingers and hand, interact with the virtual

Other physical input devices

In addition to trackers that capture movements of the users, many other physical input devices were developed to make human–computer interaction easier and more intuitive. For full freedom of movement, 3-D input devices seem the most natural. Attached to our body or handheld, 3-D input devices are generally used to select, move, and modify virtual objects. Devices range from simple handheld objects to large cockpit-style platforms in which the user can sit.
VIRTUAL REALITY

environment, and signal commands to the computer through gestures. Gloves typically have thin fiber optic sensors sewn into the cloth that bend and stretch when the fingers move (Biocca and Delaney 1995) and communicate finger movement to the computer. A position tracker, usually attached to the back of the wrist, monitors the position and orientation of the hand and can be used to create a 3-D representation of the hand of the user in the virtual environment. When the glove collides with an object, the computer can be signaled to lift the object and move it. Gloves can also be designed to provide force and tactile feedback. Finally, bodysuits or exoskeletons are available, which function similarly to the glove, but they track movement of the entire body and display a virtual body to which the users can relate (Mazuryk and Gervautz 1996).

Speech recognition (audio input)

Speech recognition systems are becoming increasingly practical, and they could provide an excellent opportunity for natural communication with computer systems. Some speech recognition systems use speaker-independent speech recognition while others use training where an individual speaker reads sections of text into the speech recognition system (speaker-dependent). These systems analyze the specific voice of a person and use this voice to fine-tune the recognition of the speech of that person, resulting in more accurate transcription.

Output devices and representation

Output devices convey information from the computer to the user about the virtual environment. There are three groups of output devices: visual displays, haptic devices that convey force and tactile information to the body of the user, and audio devices. Virtual environments can be displayed and viewed by users in many different ways. Regardless of the display used, the display must create realistic scenes that correspond to what the user would see as he or she navigates the virtual environment. Common methods are shutter glasses, head-mounted displays (HMDs), binocular omni-orientation monitor (BOOM) systems, and cave automatic virtual environment (CAVE) systems. Shutter glasses create the 3-D effect for some desktop virtual reality systems. A 3-D display monitor shows alternate right and left images at a fast rate and the shutter glasses alternately allow light to reach the eyes. When a left image appears on the display monitor, the shutter glasses receive a synchronizing signal from an infrared device placed on top of the monitor to shut the right lens and when a right image appears, the glasses are signaled to shut the left lens. The right and left images are fused together by the brain to produce the 3-D image. The HMD presents the virtual environment through a device mounted on the head of the user that can resemble a helmet with a visor in front of the eyes or a scuba mask. The HMD contains a separate display for each eye so that each eye sees a different view of the same image. As with shutter glasses, these images are fused together by the brain to produce the 3-D effect. HMDs also have position trackers to signal to the computer the position of the head so that the view of the virtual environment can be updated to match the head movements of the user. HMDs may also have sound devices such as headphones or earphones.

BOOM systems have become a popular alternative to the HMD because users do not support the image display on their heads. Rather, the BOOM involves a viewer mounted on a stand, which the user holds to his or her face to view the virtual environment. The user can
VIRTUAL REALITY

sit or stand and can move the viewer using handles to observe different aspects of the virtual environment. In addition, the user can easily shift between the virtual and real environment because no equipment must be put on and taken off, as with the HMD. Although motion may be slightly restricted due to the design of the BOOM, the quality of the graphics display is higher than the HMD.

A CAVE system allows one or more users to be completely immersed in the virtual environment. Users enter a small room with large video projection walls, which are used to surround users on all sides with computer-generated images. Users wear shutter glasses to view the environment and a position tracker is mounted on the glasses to determine head position. Haptic devices provide output from the computer to the user by simulating force and tactile feedback. Users can “feel” force, tension, friction, pressure, temperature, and speed of objects. Force-feedback devices convey information about the resistance of surfaces (e.g., prevents users from walking through walls) and the gravity, weight, and solidity of objects. This feedback is provided through mechanisms such as joysticks, steering wheels, and handgrips. As mentioned earlier, gloves and exoskeletons or bodysuits can be designed to convey force feedback. Tactile feedback provides information about the surface and texture of objects in the virtual world. Many types of approaches can be used to communicate touch in the virtual environment. Pneumatic devices simulate touch by inflating and deflating air pockets, air jets, or air rings that are attached to gloves and touch the fingers of the user. Vibrotactile methods signal touch through vibration on the skin of the user. Electrotactile devices send pulses of electricity through electrodes touching the skin. Finally, functional neuromuscular devices directly stimulate the nervous system, but are rarely used because of their invasiveness. Audio devices are not a necessary component of most virtual reality applications, but they enhance the reality of the experience and help create immersion by replacing sounds from the physical environment with sounds produced in the virtual environment. Headphones are usually built into head-mounted displays. Additionally, earplugs, which are lighter and less intrusive, can be used. Simple audio systems play back digitally recorded sounds into the headphones of the user or through desktop speakers. Higher end systems use spatialization or 3-D sound that creates the illusion of sound originating outside the head of the user, coming from a particular location away from the user, or moving through the virtual environment.

Visual display devices

Human visual perception is generally considered to be the primary means of gaining information about physical spaces and appearances of objects. Realistic rendering of 3-D graphics and image in real time is the most important means to achieve VR visual perception and a core technology to construct a virtual environment. Realism and real time are two important safeguards for the sensation of system immersion and interactivity in VR, and a pair of prominent conflicts at the same time. Realistic rendering of 3-D graphics and image in real time is mostly about improving realism and real-time capabilities.

The visual interface of VR often provides the most salient and detailed information regarding the virtual world. In general, a complete visual interface consists of two primary components: (i) a visual display surface and an attendant optical system that paints a detailed, time-varying pattern of light onto the retina of the user; and (ii) a system for positioning the visual display surface relative to the eye of the operator. However, the current technical limitations make both the optimal use of normal visual sensory
capabilities and the real-time display of detailed, continuous-motion imagery a difficult challenge for VR developers. In particular, the inadequate optical arrangements between the display and the user’s eyes or the inadequate channel capacity in the display unit may produce spatial distortion and image degradation. For these issues, none of the many display options that currently exist are completely adequate across all applications.

Two major classes of visual display systems are available: head-mounted and off-head displays. Head-mounted displays (HMDs) are physically coupled to the head of the operator by mounting display hardware on a helmet or headband worn by the user.

The most frequently used display type for HMDs is the backlit liquid crystal display (LCD). In many HMDs, all the visual output is generated by computer. The small size of displays used in HMDs brings with it small field of view (FOV). To enhance the viewing range special optics may be used such as LEEP or Fresnel lenses. Both of these approaches require a pre-distortion of the image that will be viewed through the special optics. Wide field optics is used, for example, by VPL Research for the construction of their HMDs. Beyond LCDs, a virtual retinal display (VRD) has been proposed. A prototype of a VRD developed at the HIT-Lab uses a modulated laser light that projects the image directly onto the retina of the user. Although application of this system in practice is currently questionable, VRD offers great potential quality improvement – the goal of the project is to achieve a resolution of 4000 × 3000 and a FOV bigger than 100°.

VR visual output devices

Different types of VR systems – from desktop to full immersion – use different output visual displays that can vary from a standard computer monitor to a sophisticated HMD. The following section will present an overview of the most often used displays in VR.

- 3-D glasses: the simplest VR systems use only a monitor to present the scene to the user. However, the “window onto a world” paradigm can be enhanced by adding a stereo view by use of LCD shutter glasses. LCD shutter glasses support a 3-D view using sequential stereo: with high frequency they close and open eye views in turn, when the proper images are presented on the monitor. An alternative solution uses a projection screen instead of a CRT monitor. In this case polarization of light is possible and cheap polarization glasses can be used to extract proper images for each of the eyes. A head movement tracking can be added to support the user with motion parallax depth cues and increase the realism of the images presented.

- Surround displays: an alternative to standard desktop monitors is large projection screens that offer not only better image quality but also a wider field of view, which makes them very attractive for VR applications. The total immersion demand may be fulfilled by a CAVE-like display, where the user is surrounded by multiple flat screens or one domed screen. Ideally total immersion would support a full 360° field of view. The disadvantage of such projection systems is that they are large, expensive, fragile, and require precise hardware setup.

- Binocular omni-oriented monitors (BOOM): developed and commercialized by Fake Space Labs, BOOMs are complex devices supporting both mechanical tracking and stereoscopic display technology. Two visual displays (for stereo view) are placed in a box mounted to a mechanical arm. The box can be held by the user and the monitors can be watched through
VIRTUAL REALITY

two holes. As the mechanical construction supports usually counter-balance, the displays used in the BOOMs need to be neither small nor lightweight. Therefore, CRT technology can be used for better resolution and image quality.

- **Head-mounted (coupled) displays (HMDs):** HMDs are headsets incorporating two small monitors placed in front of the eyes of the user. The images are presented to the user based on his/her current position and orientation as measured by a tracker. Because the HMD is mounted to the head of the user, the HMD must fulfill strict ergonomic requirements: it should be relatively light, comfortable, and easy to put on and take off. Like any visual display, the HMD should also have the best quality. These demands force engineers to make hard trade-offs. Consequently, the prices and quality of HMDs vary dramatically: from approximately US$800 for a low-cost, low-quality device to about $1 million for a high-tech military HMD.

- **HMDs can be divided into two principal groups:** opaque and see-through. Opaque HMDs totally replace the view of the user with images of the virtual world and can be used in applications that create their own world such as architectural walkthroughs, scientific visualization, games, and so forth. See-through HMDs superimpose computer-generated images on real objects, augmenting the real world with additional information. Most of the HMDs currently available on the market support stereo viewing and can be driven either with PAL or NTSC monitor signals.

**Audio displays**

Hearing is the second greatest source of perception of human beings next to vision and approximately 15% of human perception information of the objective world depends on hearing. Hearing cannot only accompany the sound for visual pictures but also complement information out of vision to enhance the sense of space and realism of the virtual world. Sound greatly enhances the ability of the participant to become mentally immersed in the world. From ambient sounds that give cues to the size, nature, and mood of the setting to sounds associated with particular objects or characters nearby, aural representation is key to user understanding and enjoyment (Sherman and Craig 2002).

Sound can powerfully enhance the human perception ability. As an addition to the visual information, auditory information can offer several benefits like:

- an additional channel for the communication data;
- the ability to perceive information that is outside the visual display;
- the ability to alert the user and focus signals that attract the user or warn him/her;
- spatial orientation cues;
- the possibility for parallel perception of numerous information streams.

In the simplest case, sound can indicate completion of some tasks or signal that some conditions have been met (like collision with objects, placing of bodies, etc.) without cluttering the screen. This technique has been used for a long time in desktop systems and includes click-keyboards or desktop sounds (including speech audio) confirming certain actions or system events. For these purposes a monaural sound is sufficient. In VR, however, more convincing three-dimensional auditory displays can be used to simulate distance, direction, material, and spatial information about the environment. A successful area of application is architectural visualization. Sound cues lead to better
VIRTUAL REALITY

spatial impression and allow visual and acoustic evaluation of building models, which is a significant improvement for walkthrough applications.

To generate these spatial cues convincingly, basic knowledge of the human sound localization system is required. The duplex theory accentuates the two primary hints that play a leading role in this process: interaural time difference (ITD) and interaural intensity difference (IID).

In addition to these two basic cues, other aspects should also be considered. Spatial information reaching our ears depends strongly on the distance from the source, environment geometry, and material properties of objects in the vicinity, which influences the creation of echoes. At least the pinnae (outer ear) of the listener have influence on spectral soundwave shaping by reflecting and refracting it slightly. All these subtle effects altering the sound received by the ear create the effect of spatial sound perception.

To synthesize the sound that matches human perceptual abilities artificially is a complex and computationally expensive task. Moreover, the proper synchronization of sound and visual events is extremely important not to disorient the user by contradictory cues. Three basic steps are required for successful simulation of virtual acoustic environments (Astheimer 1995).

- **Sound generation** – every action in the real world generates some sound (steps, object collisions, etc.). For acoustic simulation sound can be either generated (synthesized) or sampled and played back.

- **Spatial propagation** – this is the most expensive part of the whole simulation. Spatial propagation involves calculation of spatial propagation of sound waves through the environment. Ideally all the reflections (echoes) from different objects and walls should be considered, according to the material properties and surface shapes of these objects.

- **Mapping of parameters** – the calculated parameters should be mapped onto proper sounds that will be delivered to the listener through headphones or speakers. To do this, all rendered chunks (impulses) should be convoluted together by the use of special filters, to produce one sound. The directional effect can be achieved by use of ITD and IID cues and calculation of head-related transfer functions (HRTFs).

Haptic displays

Both vision and audition presentation provide noncontact perception information, while haptic (force/tactility) representation provides contact perception information of virtual objects and the virtual world. The participants could obtain vivid force/tactility experience in contact interaction with virtual objects and their senses of reality, immersion can be directly enhanced and the application field of VR could be expanded.

Haptic representation has the features of: (i) the cues it provides about the world are the ones that are most trusted by the cognitive system when confusing or conflicting information is presented to the senses (seeing is believing, but touching is knowing); and (ii) the perception happens only local to the user, on or near their skin or inside their body.

Haptic sensations perceived by humans can be divided into two main groups.

1. **Kinesthetic (force) feedback** – forces sensed by the muscles, joints, and tendons.
2. **Tactile feedback** – includes feedback through the skin, such as sense of touch, temperature, texture, or pressure on the skin surface.

These perception issues are extremely important when performing some precise manipulation.
VIRTUAL REALITY

tasks. Manipulating every object in the real world always causes a collision between the hand and the object, which is perceived as haptic feedback. Therefore, the many dexterous manipulators and some data gloves are equipped with devices simulating these sensations. A remote interaction with fragile objects (e.g., human eye surgery or laboratory tasks) could not be completed accurately without proper haptic cues.

Kinesthetic or force feedback is used when object placement and manipulation requires a proper force, which is a quite natural phenomenon for humans. To increase the naturalness of interaction in VR, some devices are equipped with force feedback, including a variety of manipulators from simple gloves to sophisticated and mechanically complex exoskeletal hand masters.

In addition to these hand mounted manipulators that are supposed to simulate the real interaction with objects, several studies have proven that presence of force feedback increases efficiency of various placing and manipulation tasks. Therefore, many devices were developed: from the simplest devices such as joysticks or desktop mice with kinesthetic feedback, through force simulation with the help of tense strings in the UNC GROPE project. All of them confirmed qualitative improvements of interaction – haptic display together with visual display can enhance the perception and understanding of natural phenomena such as scalar or vector fields. A recent prototype of GROPE consists of a ceiling-mounted arm coupled with a computer and was used by the chemists for a drug-enzyme docking procedure. The application in other areas such as investigating molecules or protein property seems to bring significant advantages.

Tactile feedback is much more subtle than force feedback and therefore more difficult to generate artificially. The simulation may be achieved with the help of vibrating nodules, inflatable bubbles or electro rheological fluids (fluids whose viscosity increases with an applied electric field) placed under the surface of a glove. All these currently available technologies are unable to provide the whole bandwidth of sensory data we obtain through our skin. They generate the indication of touch with some surface but do not allow the user to recognize its structure.

Modeling methods

The topics of geometric modeling include virtual world space definition, virtual observer location, perspective projection, 3-D modeling and clipping, 3-D space curves, 3-D boundary representation, geometrical transformation, and modeling transformations for translation, scale, reflection, and rotation. The topics of physical modeling include illumination models, reflection models, shading algorithms, radiosity and realism, and collision detection. The topics of kinematics modeling include picking, flying, scaling virtual environments (VEs), and the dynamics of numbers. The topics of behavior modeling include free-form deformation, shape and object inbetweening, the animation of objects, animating the virtual environment (VE), particle systems, interactive using navigation, selection, and/or manipulation for a convincing simulation.

Geometric modeling

Geometric modeling describes the shape of virtual objects (polygons, triangles, vertices, splines) as well as their appearance (surface texture, surface illumination, and color).

- Modeling based on depth range image. Each pixel of range image saves the range information of the first intersection point of
related light and the scene shot, the modeling process of which involves the acquisition, registration, surface reconstruction, and repair of range image.

- Image-based modeling method. The image-based modeling method uses photos to construct vivid 3-D models, which can be divided into active and passive. The active type obtains 3-D information of objects actively through the control of the illumination of the scene, which has high reconstruction accuracy and an easy algorithm. However, artificial reconstruction of clues, whose operating process is complicated, is required. The passive type receives the intensity of the information of scenes passively, and then conducts 3-D reconstruction through analyzing passive clues of images such as tone, shadow, focal length, texture, and parallax. This method barely restricts the scale and position of modeling scenarios, but has a poor accuracy and complicated algorithm.

- Material illumination modeling method. Computer graphics normally uses texture mapping technology to map the 2-D image of the surface reflection property of a reflected object onto the 3-D model surface. This method only represents the color information of the object under certain specified illumination and visual points, but many surface reflection properties of objects possess a large amount of high gloss information. Simple texture mapping technology is unable to realistically present plentiful light reflection and refraction effects of objects. Therefore, the research on acquisition and modeling technology of surface material properties has significant meaning in the realism modeling field.

- Volume illumination model. The volume illumination model is the mathematical description of physical phenomena, such as light intensity change, when the light goes through voxel, serving as the basis for direct volume rendering. The current normal volume illumination models are the active-attenuation model, the varying density emission model, and material classification and hybrid model.

- Field modeling method. Physical fields such as electromagnetic field and gravitational field are all invisible. However, some VR applications often require the distribution, range of action and effects of certain fields in the virtual environment (such as the scanning of a radar beam) to be delivered to users through visualization. Therefore, the research on field modeling could be divided into visualization and appearance modeling. Fields such as vector field and scalar field usually use grids for modeling. The grids mainly refer to a regular grid, rectangular grid, curvilinear grid, nonstructural grid, scattered data, and so forth.

**Kinematics modeling**

Kinematics modeling determines the location of 3-D objects with respect to a world system of coordinates as well as their motion in the virtual world. Object kinematics is governed by parent–child hierarchical relations, with the motion of a parent object affecting that of its child. A further aspect of kinematics modeling is that the camera image needs to be transformed and projected in the 2-D display window in order to provide visual feedback to the user.

**Physical modeling**

Physical modeling integrates the physical characteristics of the object, which include weight, inertia, surface roughness, compliance (hard or soft), deformation mode (elastic or plastic), and
VIRTUAL REALITY

so forth. These features, together with object behavior, bring more realism to the virtual world model. The computation load required by physical modeling is assigned to the haptic rendering pipeline.

- Rigid body motion modeling method. If each point of the object cannot be translated or rotated correspondingly to any other point of this object, then this object is called the rigid body. This modeling method only has to consider the position and direction change of rigid body motion modeling in environment. The object’s deformation can be neglected. The content referred to includes mainly the motion simulation, collision detection, connection, and constraint of the rigid body.

- Flexible object modeling method. In the real world, many objects have no rigid body characteristics. They deform during movement or interaction, namely they are flexible objects. The flexible object modeling refers mainly to geometrically based methods, physically based method, and collision detection of flexible objects. According to the shape and appearance, the modeling of geometrically based method usually adopts a catenary method and the B spline method, resulting in a limited effect on realistic simulation. This section discusses mainly the physically based flexible object modeling method and collision detection.

- Physically based modeling method. This method divides the flexible objects into particles in cells and treats flexible object motion as a particle motion under various physical quantity effects such as force and energy. Grid structures of flexible objects are of discrete type and continuous type. The point particle model, particle model, and spring-point particle model deal with the former type, while the spring deformation model, air aerodynamic model, wave propagation model, finite element model, and so forth, deal with the latter type.

- Virtual human motion modeling method. The virtual human is an important component of the virtual environment. The research on virtual human motion modeling addresses mainly the acquisition and treatment of motion data and control of motion.

Behavior modeling

Behavior modeling is the “modeling of human behaviors or representations required to be expressed in military emulation” (Pew and Mavor 1998). It is the major content of autonomous object research in the virtual environment, which is dated from the research on computer-generated forces (CGFs) in the virtual battlefield (Zhao 2009).

Most of the current VR systems also model virtual humans, called avatars. Avatar is defined as “a user embodiment in a collaborative virtual environment” (Gerhard, Moore, and Hobbs 2004), which has agency (an ability to perform actions) and is controlled by a human agent in real time (Bell 2008). In the sense of shared virtual environment, the more surprising developments are coming from the impressive successes of Second Life (http://secondlife.com; Warburton and García 2009), putting avatars into the 3-D environment and extending their applications via their scripting languages, which have the potential to move how we share, visualize, and communicate geographic data to a new collaborative level (Hu et al. 2010).

New types of virtual reality

Mixed reality

Mixed reality (MR) refers to the merging of real and virtual worlds to produce new environments
and visualizations where physical and digital objects coexist and interact in real time. Not taking place only in the physical world or the virtual world, but a mix of reality and virtual reality, encompassing augmented reality and augmented virtuality (Milgram and Kishino 1994).

In an MR system, the user can interact with and visualize both real and virtual objects in the same context. For example, users could interact with a real-world anesthesia machine as a tangible user interface and visualize an abstract simulation of the gas flows in the context of the real machine. Through this merging of virtual (the abstract simulation) and real (the anesthesia machine) spaces, such a system might also enable the user to mentally merge the different knowledge types – abstract knowledge learned from the simulation and concrete knowledge learned from the real world (Quarles et al. 2008).

Cross reality (dual reality)

Proposed by the MIT Response Environmental Group (ResEnv), cross reality is defined as the ubiquitous mixed reality environment that comes from the fusion of sensor/actuator infrastructure and 3-D virtual environments for an environment resulting from the interplay between the real world and the virtual world, as mediated by networks of sensors and actuators. The difference between cross reality and AR/MR is that the latter is always restricted to head-worn or other wearable/mobile devices, while cross reality is a ubiquitous environment (Lifton 2007).

3-D online virtual world (Second Life, etc.)

As three-dimensional (3-D) virtual worlds such as Second Life and OpenSimulator (OpenSim; http://opensimulator.org) become more mature and technically advanced, they can be used for serious applications that are driven by research (Von Kapri et al. 2009). OpenSim is an open source multiplatform, multiuser 3-D application server that can be used to create a virtual environment (or world) that can be accessed through a variety of clients on multiple protocols. Both Second Life and OpenSim depend on user-created content and have programming interfaces to create new functionality. The networked virtual environment allows for intuitive interaction.

Online 3-D has become increasingly popular in recent years. The 3-D Internet can be defined as one that is navigable in three dimensions rather than two. Instead of websites, you have explorable regions. Instead of 2-D text chatting, you have 3-D avatar chats (Barnes 2010).

Visibility analysis

Juan M. Domingo-Santos
Rubén Fernández-de-Villarán
University of Huelva, Spain

University of Huelva, Spain

The very definition of the word “landscape” characterizes it as “a view or prospect of natural inland scenery, such as can be taken at a glance from one point of view.” Thus, it is clear that for land-use planning and landscape management, visibility is a key factor for decision-making regarding visual impact. In urban areas, dominated by vertical structures, visibility is also a major concern in relation to touristic interest, traffic control, security, and citizen wellbeing, among other issues.

Initially, it is important to recognize that visibility is a complex concept that is used in different fields and deals with multiple factors. As an example, in meteorology, visibility concerns the transparency of the atmosphere, and is defined in terms of viewable distance, whereas in geography it refers mainly to the arrangement of objects in the landscape but it is influenced by other factors, such as the atmospheric conditions, as discussed in this entry.

Thinking of visibility in geographic terms, visibility analyses determine those portions of the landscape that can be seen and the content and composition of available views. With respect to what “can be seen,” it is assumed that the observers have normal vision and there are average-to-good observing conditions. In any case, the “can be seen” idea invites us to think of visibility in probabilistic terms, that is, as a parameter that could be analyzed with a fuzzy approach (Anile et al. 2003), rather than a well-defined deterministic function.

Visibility is based on the existence of a clear line of sight between two points, that is, there are no obstacles that would block light traveling from one point to the other. Beyond this evident requirement, there are many other factors constraining visibility that have a strong influence on what the observer actually “sees;” that is, human perception is a combination of optical physics and atmospheric effects, together with psychological and cultural factors. Gross (1991) identifies the following as the main factors influencing the visual impact of objects on the landscape: visual acuity of the human eye, color contrast with the background, atmospheric extinction (the manner in which light is absorbed and scattered), and surface area covered by the image of the object on the retina. These visibility factors are covered in more detail here.

Visual acuity

Visual acuity is the ability of the eye to see fine detail, technically defined as the spatial resolving capacity of the visual system. This ability is mainly limited by optical aberrations, caused by diffraction in the eye lens and by photoreceptor density in the eye. It is also influenced by other factors including refractive error, illumination, contrast and the location of the retina being stimulated (Kalloniatis and Luu 2007).
VISIBILITY ANALYSIS

Diffraction aberrations

If a point source is taken, the image will be distributed on the retina as a point spread function due to distortions created by diffraction of light passing through the optics of the eye. The point spread function follows an Airy disk pattern that presents a central maximum of light and a series of rings of diffracted orders with very low and decreasing intensity of light (Figure 1).

Two point sources produce two point spread functions at the back of the eye. Rayleigh’s criterion states that two points or lines are just resolved if the peak of one point spread function lies on the first trough of the other point spread function; otherwise, the points are seen as a single element (Figure 2).

Dimension of the retinal mosaic

Retinal cone density is another limiting factor. In this case, two points are resolved if there is a row of unstimulated cones in between rows of stimulated cones (where cones are the basic photoreceptor cells on the retina that enable humans to see). Based on cone spacing, a maximum of approximately 0.47 arc minutes is the best possible resolution, which is well above conventional clinical measures, ranging from 1 to 0.63 arc minutes (Colenbrander n.d.), as this measured spacing does not take into account the optics of the eye or post-receptor neural processing.

Other conditions affecting visual acuity

In addition to the two main limiting factors cited above, there are particular observing conditions and eye disorders that may affect visual acuity. These factors should not be considered in general visibility analysis but they can reduce visibility further. The most significant are briefly described (Kalloniatis and Luu 2007).

- Refractive error: visual diseases such as myopia and hyperopia cause images to be focused away from the retina, affecting resolution.
- Pupil size: a mid-size pupil (3–5 mm) is optimal; smaller or larger sizes decrease resolution.
- Illumination: visual acuity is greatly affected by the level of background luminance.
• Exposure time of the target: although there is no simple function relating acuity and exposure time, this may be significant for detection of linear shapes.
• Area of the retina stimulated: visual acuity is greatest at the center of fixation. At a distance of five arc minutes from the center of fixation, there is a measurable loss in visual acuity, this rising to around a 25% loss at 10 arc minutes (1/6 of a degree).

**Color contrast and atmospheric extinction**

Colors are coded under different standardized systems, or color spaces, which allow the precise reproduction of images and the quantification of differences that will make an object visible against a background. For a given color space, the color difference between two objects is expressed by the Euclidean distance between the color components. More generally, a color space links the physical properties of light, particularly their electromagnetic signatures, to how they are perceived by humans.

Taking the CIE-Yxy color space and considering that color components will be influenced by the atmospheric attenuation, related to distance \( r \) to the observer, the aforementioned Euclidean distance for the color space CIE76, Delta-E or \( \Delta E \) can be expressed as:

\[
\Delta E = \sqrt{C(r)^2 + (\Delta x(r))^2 + (\Delta y(r))^2}
\]  

where the luminance contrast \( C(r) \) depends on the luminances of the object \( Y_O \) and the background \( Y_H \):

\[
C(r) = \frac{|Y_O(r) - Y_H(r)|}{Y_H(r)}
\]

and the color distance between chromaticity coordinates \( x \) and \( y \) in CIE-Yxy color space is given by:

\[
\Delta x = x_O - x_H; \quad \Delta y = y_O - y_H
\]

where \((Y_O(r), x_O(r), y_O(r))\) is the color location of the object in the color space, attenuated by distance \( r \), and \((Y_H(r), x_H(r), y_H(r))\) is the color location of the background, attenuated by distance \( r \).

Atmospheric attenuation of light (Overington 1976) is caused by scattering and by absorption. Specifically, light is scattered by small particles and water droplets suspended in the atmosphere (aerosol scattering), as well as by molecules of air (Rayleigh scattering). Absorption generally depends on atmospheric composition and the wavelength of the light but is generally negligible for the visible region on a clear day when water content is low. Attenuation follows an exponential law in homogeneous air:

\[
F(r) = F_0 e^{-\sigma_e r}
\]

where \( F_0 \) is the original light flux at the source, \( r \) is the distance from the source to the observer, and \( \sigma_e \) is the extinction coefficient.

Scattered light from other light sources entering the viewing path (air light) will increase the apparent luminance of the object. Considering a homogeneous horizontal path, taking \( Y_{Hi} \) as the sky luminance, this apparent luminance of the object may be specified as (Overington 1976):

\[
Y_O(r) = Y_{O0} e^{-\sigma_e r} + Y_{Hi}(1 - e^{-\sigma_e r})
\]

To now consider the contrast of an object against its immediate background, the luminances of the object and background may be subtracted from equation 5 yielding:

\[
(Y_O(r) - Y_H(r)) = (Y_{O0} - Y_{H0}) e^{-\sigma_e r}
\]

Considering

\[
C(r) = \frac{|Y_O(r) - Y_H(r)|}{Y_H(r)}
\]

and
VISIBILITY ANALYSIS

$$C_0 = \frac{|Y_{G0} - Y_{H0}|}{Y_{H0}}$$ \hspace{1cm} (7b)

The apparent luminance contrast may be written as:

$$C(r) = C_0(r) \frac{Y_{H0}}{Y_{H}(r)} e^{-\sigma_e \cdot r}$$ \hspace{1cm} (8)

The extinction coefficient for specific atmospheric conditions can be obtained from meteorological data providing the meteorological optical range (MOR), defined as the length of path of atmosphere required to reduce the luminous flux in a collimated beam from an incandescent lamp, at a color temperature of 2700K, to 5% of its original value (See also Visual variables). From that definition, when \( r = \text{MOR} \), equation 4 will provide the extinction coefficient:

$$\frac{F(r)}{F_0} = 0.05 = e^{-\sigma_e \cdot \text{MOR}}$$ \hspace{1cm} (9)

Then

$$\sigma_e = \frac{2.995}{\text{MOR}}$$ \hspace{1cm} (10)

These equations for attenuation assume horizontal views in a homogeneous atmosphere. In case of nonhorizontal line of sight, attenuation decreases with height and an “equivalent extinction coefficient” must be obtained, by integration along the viewing path considering the standard atmosphere layers involved (Overington 1976).

Line of sight: viewsheds and isovists

Given a topographic surface, two points \( p_1 \) and \( p_2 \) are said to be mutually visible if and only if the interior of segment \( p_1 \) \( p_2 \) lies strictly above the surface (De Floriani and Magillo 2003). The segment is defined as the line of sight (LoS) and both points \( p_1 \) and \( p_2 \) must be on or above the surface.

In natural areas, sloped landforms dominate over vertical structures and normally there is a single height (\( z \) coordinate) for each pair of horizontal coordinates \( x, y \). In that case, the definition given for visibility along the LoS would be correct and, for a given location, the viewshed can be defined by finding the LoS for every other point within the area of interest (the target points). If the land surface rises above the LoS, then the target is out of sight; otherwise, it is in sight and is within the viewshed (De Floriani and Magillo 2003).

Given a viewpoint \( V \) on a terrain, the viewshed of \( V \) is the set of points on the surface that are visible from \( V \). The local horizons for the viewpoint are the loci of points on the terrain that are visible from \( V \) and that block the view of points lying immediately beyond them. The global horizon of \( V \) is the most distant point of the terrain that is visible from \( V \) (Figure 3) (De Floriani and Magillo 2003).

Viewsheds are calculated (Figure 4) from a model of the terrain built up from a finite set of data in Euclidean space \((x, y, z)\), which is called a digital elevation model (DEM); the points can be either defined on a regular \((x, y)\) grid or scattered. A DEM based on the elevations \( z \) of those points represents a surface that is an approximation to the real topographic surface.

GIS consider two main types of DEM: triangulated irregular networks (TINs) and regular square grids (RSGs); a review by De Floriani and Magillo (2003) describes both types, as well as various algorithms that can be used to obtain viewsheds from such models. TIN models provide a better representation of the terrain for the same amount of computer memory but RSG models are easier to operate with different layers of information (Figure 5).

In terms of horizontal visibility, the Earth’s curvature has the effect of decreasing terrain elevation with distance; in flat areas, this effect must be taken into account for long views (Figure 6). GIS
Figure 3  Viewshed in a given direction. Terrain points $q_i$ can be observed as long as more distant points are observed at angles higher than any point nearer the observer. That is, a point, for example, $q_2$, at an angle $(\alpha_2)$ lower than the angle of observations $\alpha_p$ of a point $p_1$ nearer to the observer is not visible. Points $p_1$ and $p_2$ are local horizons; point $p_2$ is also a global horizon because it has the highest observing angle for a visible point. The difference in height $[q_i - k_i]$ is the local offset. When the local offset is negative ($q_2$), the point is not visible and vice versa ($q_3$).

Figure 4  Left: viewshed from viewpoint $V$ (indicated by a yellow arrow), calculated using a GIS. Gray areas are not visible. Purple areas are visible. Right: 3-D recreation of the terrain model from an elevated point of view at a distance from $V$. The viewshed from $V$ is overlaid.
VISIBILITY ANALYSIS

Figure 5  Upper plots: GIS representations of a digital elevation model (DEM) using a triangulated irregular network (TIN) (left) and a regular square grid (RSG) (right). Lower plots: 3-D detail of a TIN model (left) and a RSG model (right).

calculations of viewsheds can be adjusted using the terrain elevation correction:

$$\Delta z = \frac{d^2}{D_e}$$ (11)

where $d$ is the planimetric distance between observed and observation points, and $D_e$ is the Earth’s diameter ($2R_e$) (Figure 6, left).

Light refraction partly compensates for the curvature effect. The combination of the two effects (Figure 6, right) is approximately evaluated in GIS calculations of viewsheds by the equation:

$$z_v = z - \frac{d^2}{D_e} + 0.13 \frac{d^2}{D_e} = z - 0.87 \frac{d^2}{D_e}$$ (12)

where $z_v$ is the terrain elevation value taken for the viewshed calculation, corrected for the $z$ value given by the DEM (ESRI 2008).

In urban areas, where landforms tend to be flat, vertical walls and buildings provide the main restrictions to visibility. In such contexts, the concept of the isovist is used. As illustrated in Figure 7, the isovist is defined as the set of all points visible from a given viewpoint in space with respect to an environment. The analysis of isovist and derived magnitudes (isovist fields) are used in architecture for identifying surveillance paths, generating spatial diversity, by changing sensations such as spaciousness, and identifying inconspicuous viewpoints with good visibility (Davis and Benedikt 1979).

Inspired by isovist, the Viewsphere approach created by Yang, Putra, and Li (2007) uses GIS-based 3-D visibility analysis that integrates buildings and terrain to create a 2.5-D surface model; the algorithm obtains a set of indices based on the volumes of space perceived in relation to the total volume of a hemisphere centered at the viewpoint, with an observation radius decided by the observer. Specifically, the authors use two indices: the Viewsphere index ($I$), which evaluates visible volumes from the 2.5-D model and can be taken as an indicator of perceived density; and the Sky view factor ($F$), a ratio between the volumes under and above the horizon line, giving an indicator of the openness of the view.

A similar approach is called the multiscale implicit TIN; it allows multiscale terrain models to be integrated with 3-D features. The improvements in the analysis of intervisibility achieved through this approach, as well as the limitations, are discussed in Kidner et al. (2001).

The image area on the retina: visual exposure

With reference to the surface area covered on the retina, Llobera (2003) defines visual exposure as “a measure of the visible portion of whatever is the focus of the investigation.” Specifically, visual exposure of an object can be described in terms of the surface covered by its image projected onto the observer’s retina (Figure 8).
Figure 6  Left: effect of distance and the Earth’s curvature on terrain elevation in terms of horizontal visibility. The apparent decrease $\Delta z$ in elevation means that certain points in the line of sight are not, in fact, visible from the viewpoint and this translates to a reduction in the viewshed area. Right: the combined effect (red line) of terrestrial curvature and bending of the line of sight caused by light refraction ($\Delta z_r$).

Figure 7  Zenith view of the isovist of point $x$ in a room. White lines are opaque walls.

Considering that the observer’s field of view can be projected onto a sphere of unit radius, the best way to measure the projection of objects on the view of the observer will be to consider segments of a sphere, which are called solid angles. Equivalent to arcs of circumference, measured in degrees or in radians in 2-D space, portions of a sphere in 3-D space are measured in solid angle units, namely steradian (sr). The sphere subtends $4\pi$ sr and an infinite plane $2\pi$ sr.
The visual exposure of objects is influenced by two main variables, distance and position relative to the observer. These variables are the main constituents of perspective. Regarding distance, Figure 9 illustrates the inverse linear relationship between distance and apparent height of objects. For two identical objects of height $h$, the 1-D vertical viewing angles or apparent heights of the object ($\alpha_1$ and $\alpha_2$, in radians) are approximately given by:

$$\alpha_1 \approx \frac{h}{d_1}; \quad \alpha_2 \approx \frac{h}{d_2}; \quad \Rightarrow \frac{\alpha_1}{\alpha_2} \approx \frac{d_2}{d_1} \quad (13)$$

where $d_1$ and $d_2$ are the distances to the observer. The horizontal component or apparent widths $\beta_1$, $\beta_2$ will change by the same factor. Let $w$ be the average width of the object, then:

$$\beta_1 \approx \frac{w}{d_1}; \quad \Omega_1 = \alpha_1 \beta_1 \approx \frac{hw}{d_1}; \quad \Rightarrow \frac{\Omega_1}{\Omega_2} \approx \frac{d_2}{d_1}$$

$$\beta_2 \approx \frac{w}{d_2}; \quad \Omega_2 \approx \frac{hw}{d_2}; \quad (14)$$

where $\Omega_1$ and $\Omega_2$ are the 2-D surface or solid angles (in steradians) projected on the sphere of unitary radius.

Regarding relative position of the observer and the object, in Figure 10 it can be seen how visual exposure decreases when the object is inclined at an angle $\phi$ from perpendicular to the LoS. The approximate change in visual exposure will be:

$$\alpha_1 \approx \frac{h}{d} \, sen \left( \frac{\pi}{2} \right) = \frac{h}{d};$$

$$\alpha_2 \approx \frac{h}{d} \, sen \left( \frac{\pi}{2} - \phi \right) = \frac{h}{d} \, cos \phi \quad (15)$$
The relative position of the object and the observer has a strong influence on visual exposure. As the angle between the object and the LoS decreases (from \( a_1 \) to \( a_5 \)), so does the vertical component of the solid angle, and with it the visual exposure from high (\( b_1 \)) to very low (\( b_5 \)).

where \( h \) is the height or length of the object and \( d \) is the distance, this being a good approximation when the size of the object \( h \) is small compared to the distance \( d \).

A precise procedure for assessing visual exposure using GIS was developed by Domingo-Santos et al. (2011) using RSG models. This procedure can be applied for single or multiple observation points. For the case of a single observation point, the steps followed are: (i) the division of each cell into two triangles, (ii) the filtering of cells out of the viewshed, and (iii) the calculation by vector algebra of the solid angle of each triangle and the total solid angle of each cell. In terms of raster cells, visual exposure would be the measure of how much each cell occupies the field of view of an individual at any location, measured in solid angle units. In the case of multiple observation points, the total visual exposure of a given cell can be obtained by summing up the set of raster layers obtained for each viewpoint; the result will provide a good indicator of general visibility of each cell. The procedure is briefly described in the following paragraphs.

**Cell division**

As various authors have suggested (De Floriani and Magillo 2003), triangles can be used to
VISIBILITY ANALYSIS

provide a good approximation to a real terrain surface. In Figure 11, each square grid cell is divided along a diagonal to obtain two triangles. The height of each triangle vertex is calculated as the mean elevation of the four cells around the vertex. In this way, triangles give a better approximation to the real terrain than the stepped raster cells.

Obtaining viewsheds

For each viewpoint, $V$, the viewshed of the DEM is obtained using the standard algorithm provided by the GIS software.

Calculation of the solid angle for each visible cell

The calculation of solid angles of each triangle seen from viewpoint $V$ can be performed for the triangulated model using the algorithm of Van Oosterom and Strackee (1983):

\[
\tan(\Omega_1/2) = \frac{|a \ b \ c|}{(abc + (a \cdot b) \cdot c + (a \cdot c) \cdot b + (b \cdot c) \cdot a)} \quad (16)
\]

\[
\tan(\Omega_2/2) = \frac{|a \ d \ c|}{(adc + (a \cdot d) \cdot c + (a \cdot c) \cdot d + (d \cdot c) \cdot a)} \quad (17)
\]

where $\Omega_1$ and $\Omega_2$ denote the solid angles of triangles $ABC$ and $ADC$ (Figure 12); $a$, $b$, $c$, and $d$ are the vector positions of $A$, $B$, $C$, and $D$ taking $V$ as the coordinate origin (that is, vectors $VA$, $VB$, $VC$, and $VD$); $|a \ b \ c|$ denotes the determinant of the matrix obtained by writing the vectors side-by-side; $a$, $b$, $c$, and $d$ are the magnitudes of each vector (origin-point distance); and $(a \cdot b)$ denotes the scalar product of vectors $a$ and $b$.

Depending on the position of the triangles $ABC$ and $ADC$, the values of $\Omega_1$ and $\Omega_2$ can be positive or negative and, hence, absolute values must be used to calculate the total solid angle:

\[
\Omega = |\Omega_1| + |\Omega_2| \quad (18)
\]
where \( \Omega \) is the solid angle of the cell in steradians (sr). Given that the absolute value of \( \frac{1}{2} \Omega_1 \) or \( \frac{1}{2} \Omega_2 \) could be greater than \( \pi / 2 \), the inverse function for the tangent function must be the four quadrant arctangent function (atan2).

This procedure implemented on a GIS platform will produce a new raster grid (the same size as the DEM) with the \( \Omega \) values for each raster cell; this is the visual exposure map from point \( V \).

Whenever multiple viewpoints need to be considered (e.g., along roads or tracks, or in urban areas), one visual exposure map will be produced for each viewpoint. The set of raster maps can be summed using a map algebra tool to obtain a cumulative map (Llobera 2003) of visual exposure for the selected viewpoints.

Due to the uneven distribution and very low values of most solid angles, it may be very useful to change the scale for the visual exposure values, to optimize the visualization of the results (Figure 13) (Domingo-Santos et al. 2011).

**Calculation of visibility values**

The final procedure for the evaluation of visibility may depend on the object that it is intended to identify in the landscape. For instance, a clear-cut forest area or a quarry may produce such a sharp color contrast to the background that only MOR and visual exposure may need to be taken into account for evaluating visibility.

On the other hand, when analyzing visibility of elements like overhead power lines and pylons, the background is a matrix onto which parts of the object are projected, and hence more complex approaches may be required like those proposed by Gross (1991) or Zewe and

---

**Figure 13** Visual exposure calculated from the indicated viewpoint. Gray areas are not visible. All colored areas belong to the viewshed but have different levels of visual exposure: purple areas are highly visible; while exposure decreases in yellow and blue areas; and green pixels are the least visible. Other visibility factors presented in this work, like atmospheric extinction or visual acuity, may have great influence on the visibility of areas with low visual exposure.
VISIBILITY ANALYSIS

Koglin (1995). These authors obtain an estimate of the visual impact of an object, at a particular observer location, referred to as the specific visibility $S''(r)$. This value is calculated as an integral over the solid angle describing the surface area of the retina $\Omega$ taken up by the image of parts of the object $d\Omega$, each of them weighted with the color contrast to the background (influenced by distance $r$ that causes atmospheric extinction), $\Delta E(r)$, and this is normalized by the observer's surface area $\Delta A$ or $dA$ (usually $\Delta A = 1 \text{ m}^2$):

$$S''(r) = \frac{1}{dA} \int_{\Omega} \Delta E(r) \cdot d\Omega \quad \text{(unit } S'' : \text{ sr/m}^2)$$

(19)

Using this specific visibility, the same researchers define the total visibility $S$ as an estimate of the entire visual impact caused by an object in the

Figure 14  Changes in visibility due to vegetation screening and changes in the viewshed defined by the GIS. The line of sight (LoS) corresponds to the maximum vertical angle as read by the GIS software from a corrected digital elevation model (also called digital surface model, DSM). Top: The visible area increases owing to the height added to the terrain level by the vegetation canopy. Bottom: Once the DEM is corrected, the GIS viewshed algorithm will identify cells behind $c_2$ as nonvisible; in reality some of these cells ($c_3 - c_6$) might be visible “through the woods” (red LoS). Domingo-Santos et al. 2011. Reproduced from Elsevier.
landscape. This is obtained by integrating over all possible $S''$ within the viewshed area $A$:

$$S = \int_A S'' \cdot dA \quad \text{(unit $S$: sr)} \quad (20)$$

Zewe and Koglin (1995) also define other useful parameters, namely the region-specific visibility and the route-specific visibility.

### Limitations in viewshed and visual exposure evaluation based on GIS

Using GIS data, there may be several sources of error or constraints in the calculation of viewshed and visual exposure: (i) simplification and aggregation in raster elevation data; (ii) factors that may modify the viewshed, such as vegetation screens near the observer (Figure 14), height of the observer, and the presence of unmapped human artifacts, which cannot be modeled in advance by a traditional DEM model (Anile et al. 2003); and (iii) a data structure that produces a 2.5-D model (there being only one possible $z$ value for any particular $(x, y)$ location) and, hence, an inability to deal with vertical structures such as trees, bridges or buildings (Figure 15) with any accuracy (Bishop, Wherrett, and Miller 2000).

Simplifications and aggregations from the raster model may be overcome by using more accurate DEMs or multiresolution models, which help to reduce computational complexity by adapting the level of resolution in terrain representation to the requirements of specific visibility calculations (De Floriani and Magillo 2003; Kidner et al. 2001).

Unmapped obstacles and vegetation constraints may have significant effects on visibility. Given this, to obtain visibility estimates that are as realistic as possible, the vegetation canopy and other obstacles should be considered as modifiers of the terrain, yielding corrected terrain models, known as digital surface models. The high precision elevation data obtained from airborne laser scanner (LiDAR) data provide extremely accurate tree heights, when available.

**Figure 15** Left: vertical view (aerial photography) of a rock bridge. Right: side view of the same image re-created by means of a 3-D viewer based on a DEM. As can be seen on the right, the DEM is not able to provide an adequate view of two objects with the same $x$, $y$ coordinates (the bridge and the terrain under it). The same viewer provides highly sophisticated 3-D images for many urban areas that overcome these limitations. Reproduced from Google Earth © 2015, Google.
The last of the aforementioned constraints of GIS-based analysis can be overcome through the use of 3-D visualization technologies, which have become useful and popular tools for design purposes, evaluating public preferences, and for making decisions regarding forest management or the visual impact of artificially constructed structures. Indeed, 3-D models can provide an observer at a specific location with the visual magnitude of the visible part of any object. Photorealistic applications like Google Street View® also provide an easy and affordable tool for visibility analysis.

However, 3-D and photo viewers can be very time consuming when dealing with many observation points. In such cases, the fall back is GIS analysis, which can provide maps of all locations from which an object can be seen, as well as cumulative viewsheds of “times seen” or total visual exposure of each cell from a large set of locations.

Overview of the visual variables

The visual variables describe the graphic dimensions across which a map or other visualization can be varied to encode information. The visual variables originally were described by French cartographer and professor Jacques Bertin (1918–2010) in the 1967 book *Semiologie Graphique*. The English translation, *Semiology of Graphics*, was released in 1983 and today is recognized as a seminal theoretical work in both cartography and the broader field of information visualization. The visual variables were inspired by Bertin’s reading of semiotics, or the study of sign systems. Semiotics seeks to understand how one object comes to stand for another object, and therefore helps cartographers think about the way in which a map symbol (the sign vehicle or signifier) representing a geographic phenomenon or process (the referent or signified) comes to mean something (the interpretant) to the map user. French semiotics was developed in linguistics as a method for deconstructing a language into its basic units in order to allow for description and comparison across different language sign systems. Following this approach, Bertin’s visual variables describe the basic building blocks of a map or other visualization. By reducing the map into its constituent graphic elements, unclear or polysemic map symbols can be identified and redesigned, improving cartographic communication. Further, such deconstruction reveals the value judgments and power relationships implicit in the map design process, allowing for critical analysis of the social construction and cultural negotiation of meaning within the cartographic sign system.

Although the visual variables are an influential theoretical framework for cartographic design and research, the contents of visual variable taxonomies vary considerably by scholar (Tyner 2010). Figure 1 synthesizes several notable contributions within cartography into a set of twelve visual variables, adapted from MacEachren et al. (2012). While Figure 1 provides point symbol examples for each of the visual variables, the visual variables can be used to encode information about line and area features as well. Importantly, the twelve visual dimensions described here are only considered visual “variables” when functionally manipulated to encode information. Each of these visual dimensions also can be manipulated as design embellishments to improve the aesthetic quality of the map or visualization.

Bertin (1983) originally identified seven visual variables that can be manipulated to encode information.

1 Location describes the position of the map symbol relative to a coordinate frame. Location is considered an “indispensable” visual variable and takes visual primacy over the others. In cartography, location typically signifies the position of the map symbol relative to a projected spatial coordinate system, meaning that location primarily is used to represent the spatial component of information in cartographic design. However, location can be used to

**Figure 1** Visual variables and their syntactics. Figure derived from Bertin (1983), MacEachren (1995), and MacEachren et al. (2012).
represent attribute information, such as the use of perspective height in prism maps. Further, isoline maps manipulate the visual variable location, interpolating attribute values to produce a spatial surface and then weaving isolines through locations of equal attribute values within this surface. In planimetric, 2-D representations, map symbols near the optical center tend to rise to figure, resulting in more immediate visual interpretation by the map user and, thus, landing them in a higher place of importance in the “visual hierarchy.” In contrast, map symbols near the periphery of the page tend to recede to ground, falling to the bottom of the visual hierarchy. In oblique or 3-D representations, map symbols that are perceived as nearer or taller tend to rise to figure.

2 Size describes the amount of space occupied by the map symbol. Size is the primary visual variable manipulated in proportional symbol maps and value-by-area cartograms. Size also is manipulated in flow maps that scale the thickness of the flow lines to an attribute value. Larger map symbols tend to rise to figure.

3 Shape describes the external form (i.e., the outline) of the sign vehicle. The visual variable shape is essential to the design of qualitative point symbols commonly used in reference mapping. The shape of these map symbols can vary from highly abstract, such as circles, squares, or triangles, to highly iconic, directly mimicking the referent represented by the map symbol. Map symbols that are more complex or less compact tend to rise to figure.

4 Orientation describes the direction or rotation of the map symbol from “normal.” The normal orientation typically is relative to the map’s neatline (either explicitly included or inferred by negative space), but in some cases it can be relative to the projected spatial coordinate system (e.g., relative to the graticule) or another baseline. Multivariate glyph symbols typically make use of orientation to differentiate among the represented attributes. Orientation also is manipulated in flow maps to represent the directionality of flow. Proximate clusters of map symbols that have the same orientation (either aligned or misaligned to normal) tend to rise to figure as a single group. Otherwise, individual map features that are misaligned to normal tend to rise to figure.

5 Color hue describes the dominant wavelength of the map symbol on the visible portion of the electromagnetic spectrum (e.g., blue, green, red) and is one of three visual variables associated with the perception of “color.” Color theory occupies a substantial space in the cartographic canon (Brewer 2005) and is particularly relevant for choropleth mapping as well as other forms of reference and thematic maps that use colors to designate categories or classes. A qualitative or spectral color scheme manipulates color hue while controlling the other components of color; as explained below, such color schemes are appropriate for nominal choropleth maps only. Red map symbols tend to rise to figure while blue map symbols tend to recede to ground.

6 Color value describes the relative amount of energy emitted or reflected by the map symbol. Variation in color value results in the perception of shading, or areas of relative light (high emission or reflectance of energy) and dark (low emission or reflectance of energy). Accordingly, color value is sometimes referred to as “lightness”
in color theory. Manipulation of color value is important for choropleth maps depicting ordinal or numerical information. A sequential color scheme adjusts color value in one direction, sometimes crossing over two or three different color hues to improve discriminability. A diverging color scheme adjusts color value in two directions away from a critical midpoint, with each direction denoted by color value changes within a different color hue. A variation on a spectral scheme with the green hues removed also is effective as a diverging color scheme. The figure–ground relationship for color value is relative to amount of light and dark areas on the map. Map symbols that are dark tend to rise to figure on maps that are mostly light (e.g., with a white background), while map symbols that are light tend to rise to figure on maps that are mostly dark (e.g., with a black background).

Texture describes the coarseness of the fill pattern within the map symbol. It was once common to manipulate texture in choropleth maps using halftone or dithering techniques in order to mimic the appearance of shading; as described above, contemporary choropleth maps instead manipulate the visual variables associated with color due to advances in modern printing and digital display devices. Caivano (1990) describes texture as a higher-order visual dimension with three constituent components: the directionality of the texture units (related to the visual variable orientation), the size of the texture units (related to the visual variable size), and the density of the texture units (approaching the perceptual effect of shading associated with the visual variable color value). Regarding the latter component, map symbols with a denser texture tend to rise to figure.

Bertin’s set of visual variables was extended by Morrison (1974) to include two additional variables used in cartographic design. 8 Color saturation describes the spectral peakedness of the map symbol across the visible spectrum, and is the third of three visual variables associated with the perception of color. Bold or saturated colors emit or reflect energy in a concentrated band of the visible spectrum, whereas pastel or desaturated colors emit or reflect energy evenly across the visible spectrum. From a design standpoint, therefore, color value can be conceptualized as the amount of black in a map symbol while color saturation can be conceptualized as the amount of grey in a map symbol. Color saturation also is referred to as “chroma,” “intensity,” and “purity” in color theory. Bold, saturated map symbols tend to rise to figure while pastel, desaturated map symbols tend to recede to ground.

Arrangement describes the layout of graphic marks constituting a map symbol. The visual variable arrangement varies from regular (i.e., graphic marks are perfectly aligned in a grid-like structure) to irregular (i.e., graphic marks are randomly placed or coalesce into clusters). Arrangement differs from the visual variable texture in that all textures are assumed to be arranged regularly, regardless of the initial direction, size, and density of the texture. Dot density maps vary in both arrangement and texture density, a higher-order visual dimension described as “numerousness” by Nelsen (2000). Map symbols with irregular, and particularly clustered, arrangements tend to rise to figure.
Finally, MacEachren (1995) identified three additional visual variables whose manipulation is made easier through digital production methods. MacEachren (1992) originally grouped these three visual variables under a single technique called “focus” in context of uncertainty visualization, but ultimately acknowledged each component as a visual variable given the potential application to other forms of cartographic representation.

10 Crispness describes the sharpness of the boundary of the map symbol. Crispness also is referred to as “depth-of-field” and “fuzziness” in information visualization. MacEachren et al. (2012) found that crispness was the most effective visual variable for representing uncertainty in the context of point symbolization. Map symbols with a crisp boundary tend to rise to figure while map symbols with a fuzzy boundary tend to recede to ground.

11 Resolution describes the spatial precision at which the map symbol is displayed. The visual variable resolution relates to the topic of generalization in cartographic design, which describes the meaningful removal of detail in the map design as the complexity of the real world is abstracted to fit the reduced scale of the map. Resolution as a visual variable leverages different levels of abstraction to encode information, rather than the typical purpose of generalization. In a raster depiction, resolution refers to the coarseness of the grid size. In a vector depiction, resolution refers to the amount of detail (in terms of nodes and edges) in the linework. Map symbols that are depicted in a relatively high level of detail tend to rise to figure.

12 Transparency describes the amount of graphic blending between a map symbol and the background or underlying map symbols. MacEachren (1992) originally referred to transparency as “fog” to suggest a partially opaque barrier impacting the clarity of the underlying map symbols. Transparency is the primary visual variable manipulated in value-by-alpha maps (the “alpha” channel indicating transparency in computer graphics), an alternative to the value-by-area cartogram that visually equalizes enumeration units by adjusting their opacity rather than their size (Roth, Woodruff, and Johnson 2010). Opaque map symbols tend to rise to figure.

Perceptual basis of the visual variables and their syntactics for mapping

An important characteristic of the visual variables is that they are processed pre-attentively, or in an immediate and preconceptual manner at the sensory level of the human eye. Accordingly, the direct translation of Bertin (1983) is “retinal” variable rather than “visual” variable. Thus, the visual variables are “seen” perceptually rather than “understood” cognitively. Principles of perceptual psychology predict how each visual variable is processed by the eye–brain system, and therefore inform use of one visual variable over others for cartographic design. Bertin postulated four such ways that visual perception may inform application of the visual variables in maps and other visualizations, describing these four properties as “levels of organization.”

Bertin’s (1983) first level of organization is associative perception. With an associative visual variable, variations in the visual dimension are perceived with equal weight, allowing for the eye to perceive all map symbols with the same variation as a group (i.e., as associated). For instance, the eye is not drawn to one color hue
**Figure 2** Visual variable levels of organization. Figures (a)–(d) and (e)–(h) depict the same attribute information. Figure based on Bertin (1983).
over the other in Figure 2a or one shape over
another in Figure 2b, allowing for the perception
of all map symbols having the same color hue
or shape as an associated group; as a result, the
eye is likely to see a series of horizontal rows
in Figures 2a and 2b. Because no variation
dominares, an associative visual variables allows
the eye to attend visually to other visual variables
that also might vary in the visual scene (see the
later discussion on visual variable conjunctions
and bivariate mapping). Bertin believed location,
shape, orientation, color hue, and texture to be
associative visual variables. With a dissociative
visual variable, one variation dominates visual
perception, with the eye drawn to this variation
over others. In Figure 2c, the eye is drawn to
the darker color values due to the contrasting
white background, while in Figure 2d, the eye
is drawn to the larger sizes. As a result, the
eye perceives a vertical gradient in Figures 2c
and 2d, rather than a set of horizontal rows as
in Figures 2a and 2b, despite all four figures
encoding the same information. Variation in a
dissociative visual variable inhibits attention to
other visual variables that may vary in the visual
scene. Bertin believed size and color value to be
dissociative visual variables.

Bertin’s (1983) second level of organization
is selective perception. With a selective visual
variable, the eye is able to focus individually
(i.e., attend selectively) upon each variation of
the visual variable across the visual scene and
ignore the other variations. In other words, it is
relatively easy to isolate visually the distribution
of a particular category of map symbol across the
map when symbolized using a selective visual
variable. For example, it is easier to see the
distribution of red symbols in Figure 2e than the
distribution of hexagonal symbols in Figure 2f,
despite the pair of figures encoding the same
information. Bertin believed shape to be the
only visual variable that was not selective. This
property makes shape useful when each map
symbol should be interpreted individually, such
as in the context of large qualitative point symbol
sets. However, shape is not useful when scanning
for broad patterns across all map symbols, an
important goal of most thematic mapping.

Bertin’s (1983) third level of organization
is ordered perception, while his fourth level
of organization is quantitative perception.
Variations in ordered visual variables are per-
ceived as ranked, with the eye pre-attentively
interpreting one variation as “more” or “less”
than another variation. For example, the green
symbols in Figure 2e are not perceived as
“more” than the purple symbols, just different.
In contrast, the darker symbols in Figure 2g are
perceived as “more” than the lighter symbols,
given the white background. Bertin believed
location, size, color value, and texture to be
ordered visual variables; MacEachren (1995)
later argued that color saturation, crispness,
resolution, and transparency also are strongly
ordered visual variables and that texture is only
marginally ordered. Quantitative perception
extends ordered perception, allowing for the
estimation of numerical values from variations
in quantitative visual variables. For example, the
darker symbols in Figure 2g are perceived as
“more” than lighter symbols, but it is difficult
to estimate how much more without use of a
legend. In contrast, it is possible to estimate how
much “more” the larger symbols in Figure 2h are
than the smaller symbols. Bertin believed quan-
titative perception to be restricted to location
and size only.

Importantly, Bertin’s (1983) third and fourth
levels of organization inform MacEachren’s
(1995) visual variable syntactics. In semiotics,
syntactics describes the relationship of sign vehi-
cles to one another. In cartography, syntactics
prescribes the use of a visual variable given the
level of measurement of the attribute information. Unordered visual variables – such as color hue, orientation, and shape – are appropriate for encoding nominal information. Visual variables that are ordered but not quantitative – such as color value, color saturation, crispness, resolution, and transparency – are appropriate for encoding ordinal information. Finally, visual variables that are quantitative – such as location and size – are appropriate for encoding numerical information but also can be applied for ordinal and nominal information given their visual dominance. Figure 1 reproduces MacEachren’s visual variable syntactics, designating each visual variable as good, marginal, or poor for nominal, ordinal, and numerical levels of measurement.

Visual variable conjunctions and bivariate mapping

Maps or other visualizations can make use of a conjunction of two visual variables. Conjunctions can be applied for redundant symbolization, strengthening the graphic encoding of one attribute, or representing multiple attributes in a bivariate display. For bivariate maps, a conjunction can be homogeneous, using the same visual variable in two different ways, or heterogeneous, using two different visual variables to represent the pair of attributes. In cartography, this distinction also relates to the map symbol’s dimensionality (point, line, polygon, and volume), with a homogeneous conjunction manipulating the visual variables at the same symbol dimensionality and a heterogeneous conjunction manipulating the visual variables at different symbol dimensionalities. The images in Figure 3 encode the same pair of attributes, but Figure 3c represents them using a conjunction that is homogeneous, Figures 3a, 3b, and 3d using a conjunction that is heterogeneous by visual variable, and Figure 3a using a conjunction that is heterogeneous by symbol dimensionality.

As with individual visual variables, perceptual psychology informs the syntactics of visual variable conjunctions. The most promising work to date is based on the sensory characteristic of selective attention, or the ability to attend to only one visual variable while ignoring others. Visual variable conjunctions exhibit one of four conditions of selectivity, each of which is appropriate for a different mapping context (Nelson 2000).

First, a separable conjunction describes a bivariate map or visualization in which selective attention of both attribute encodings is uninhibited. With a separable conjunction, the distribution of each attribute (“X” and “Y”) can be “seen” without one restricting the other. Separable conjunctions are produced when using the visual variable shape, given its status as the only nonselective visual variable. Conjunctions that are heterogeneous by symbol dimensionality also tend to be separable, meaning that a thematic combination of choropleth or isoline (i.e., areas) with dot density or proportional symbol (i.e., points) will result in a separable conjunction. In Figure 3a, it is easy to attend to the distribution of either attribute (“X” and “Y”) but relatively difficult to determine their spatial correlation (“+”). A separable conjunction also is created when combining size and color value on the same symbol dimension, as both visual variables are dissociative; thus, shaded cartograms and shaded proportional symbol maps are considered separable. Elmer (2013) recommends use of a separable conjunction when mapping two independent variables that have incongruous scales (e.g., different units of measure, different methods of normalization, different classification breaks), as there is no assumed correlation and the user is forced to attend to each attribute scale individually.

The conceptual opposite of a separable conjunction is an integral conjunction. With integral conjunctions, selective attention is possible on an
Figure 3  Visual variable conjunctions and conditions of selectivity. All maps depict the same attribute information. Figure derived from Elmer (2013).
emergent – or gestalt – visual dimension (“+”) but selective attention of each original attribute encodings (“X” and “Y”) is inhibited. In this situation, it is easy to “see” where the two attributes are the same or different on their respective scales, but it is difficult to attend to each attribute individually. Recommended color schemes for bivariate choropleth maps make use of an integral conjunction, with the arrangement of colors producing an emergent dimension of increased color value as both attributes increase. In Figure 3b, it is easy to determine where both attributes are high or low in tandem by attending to changes in color value (“+”). However, it is difficult to attend to only one attribute at a time; for instance, both New Mexico and Oregon have the same value in the “X” variable, but this is not easily interpreted due to the integral conjunction. Elmer (2013) recommends use of an integral conjunction when the correlation between dependent attributes is more important than the attributes themselves, as the gestalt dimension will focus the user upon this correlation.

Separability and integrality represent ends of a continuum of conjunctive selectivity, with different conjunctions falling somewhere upon this continuum in terms of visual strength. A configural conjunction describes a situation falling in the middle of this continuum, where a gestalt dimension exists (“+”) but the original attribute encodings are not fully inhibited (“X” and “Y”). Here, it is possible to attend to each attribute but there is also a visual cue aiding interpretation of the correlation between the attributes. Homogenous conjunctions that make use of split symbols are likely to be configural, as they exhibit a gestalt dimension of being “in-phase” (i.e., having the same value for each half of the symbol) or “out-of-phase”. In Figure 3c, it is possible to attend to either side of the split graduated symbol (“X” and “Y”) but also easy to interpret where both attributes are high (e.g., Utah) or low (e.g., Arizona) together, as the two halves reform the original circular shape. Elmer (2013) recommends use of a configural conjunction when mapping two independent attributes that have congruous scales, as the condition of being “in-phase” implies the same attribute value on the same attribute scale.

Finally, an asymmetrical conjunction describes a situation in which a nonlogical gestalt dimension emerges in addition to the positive correlation, as is the case with integral and configural conjunctions. Here, the nonlogical emergent dimension (−) inhibits the ability to “see” one of the two attributes (“X” or “Y”), producing an imbalanced visual effect in which the reader tends to interpret one attribute over the other. Asymmetrical conjunctions tend to be produced when using size or color value with other visual variables, given their status as dissociative visual variables. An asymmetrical conjunction also is produced with a value-by-alpha map (Figure 3d), with the attribute encoded using color (“X”) visually equalized by the attribute encoded using transparency (“Y”). Elmer (2013) recommends using an asymmetrical conjunction when one attribute (i.e., the variable of interest) is more important than the other (i.e., the equalizing variable).

The visual variables remain a central framework for empirical research on cartographic design, informing both the experimental trials and controls. A similar approach rooted in semiotics has been taken to understand dynamic representation in animated maps (DiBiase et al. 1992), sonic representation in multimodal maps (Krygier 1994), haptic representation for handheld devices (Griffin 2002), and interactivity (Roth 2012).

Visuality

Antje Schlottmann
Goethe University Frankfurt, Germany

The term “visuality” is broadly used to describe an individual sensation, or a particular competence of an organism to perceive its environment. In the context of social theory, visuality encompasses visual practices of appropriating (spatial) reality and established ways of looking at the world – by society, cultural and social groups, or disciplines.

The field of visual geographies can be defined with regard to the role of the visual in the study of spatial issues. In this sense, it is not a disciplinary subfield but rather a research perspective focusing on the visual dimension of geographical issues. The theoretical basis of visual geographies provides opportunities for reflection on the relationship between all kinds of mental and material images, visual practices, and space (Schlottmann and Miggelbrink 2009).

Geography has long been understood as a visual discipline in the sense that it (technically) produces and uses material images and relies on modes of observational practice. In recent years, poststructuralist and constructivist approaches have established visual culture as a major field of study. The ensuing visual turn in geography is a manifestation of the attempt to deal critically and reflectively with geographical visualizations (and the associated idea of “pure vision”) and addresses the significance of visuality in the constitution of spatiotemporal realities (Thornes 2004). Subsequently, there has been a growing awareness that producers and interpreters of geographical visualizations are, at the same time, involved in a production of space, which they usually perceive as unavoidable, “natural,” and “obvious.” Cartographic products, maps in particular, have been condemned for claiming objectivity in “pinning down” the material manifestations of social practices. Critical cartography argues furthermore that visual media facilitate the powerful production and fetishizing of space and that they disguise the causes of spatially manifest(ed) phenomena by merely displaying them. On the other hand, increased attention is paid not only to the visible but also to the invisibilities of the sociospatial. Visuality, seen both as the act of seeing and the materialization of views, is referred to as a contingent, selective, and in its core discursively embedded, practice.

Concepts of the relation between image and reality diverge, thus reflecting the underlying social theories and epistemological premises. Poststructuralist approaches emphasize the independence and arbitrariness of signs. Media theory approaches often cling to a similarity theorem, especially when stressing the manipulative character of images, that is, the way in which they “distort” reality. Constructivist perspectives highlight generative and structuring effects of images. Nonrepresentational approaches tend to refrain from determining the relationship between image and reality in support of a performative idea of visuality as an embodied, material, and often politically charged realm.

The interrelation of visuality and spatiality makes room for an infinite set of research foci. Work on the constitution of space through material images focuses on the role of material culture, on images for everyday use or advertising in
structuring of external spaces. Through this lens, associated spatial concepts are metrical with regard to the regulation of bodies and vessels, or social with regard to the structuring of publicity and privacy, of exclusion and inclusion. In contrast, work on the constitution of space “within” images is concerned with the symbolic representation and hence the established sociocultural interpretations of space (e.g., spatial entities such as town, country, home, landscape, inside, outside, etc.). Applied datasets may consist of maps, landscape paintings, press photos, or montages for advertising purposes for instance. In this context, pragmatic approaches relate to spatial images as reflections of contemporary social needs. They put emphasis on (strategic) visual evocations of specific interpretations of space (“natural open space”; “urban transport space”) under social conditions of globalization. Research is centered on hidden locational logics and propositional truth claims of images (“there it looks like this!”) and on representations of discursively formed and conventionalized spatial meanings (“exotic landscape,” “sublime mountains,” “secure residential area,” etc.). Research in this area even includes deconstructing stereotyped constructions of spatial identities in visual media.

Work on the visual constitution of reality also deals with the alleged documentary and informative character of images and their evidential nature, based on a constitutive analogy of perception and image. Related studies analyze the *documentary politics of truth*, in which the image and its appropriation of space are primarily means to the end of creating evidence and legitimation. Images, such as photographs, satellite images, films, or even surveillance videos, often become guarantors of veracity. An image of a place where something is happening or has happened appears to have a certain evidential quality, based on a general sense of objectivity attributed to the mediating technology. Awareness of the fact that images are in principle susceptible to manipulation is only the obverse of the belief in their character as an accurate reproduction of reality and in the authority of vision as an ontological precondition.

Another research perspective focuses on how the production of, access to, and appropriation of space through images affect and alter social relations. Scholarly work on image icons such as “the blue marble,” the ultimate symbol of Earth as a “subjected object” (Cosgrove 2006), investigates to what extent such *visiotypes* penetrate general communication and discursively shape contemporary world views or the idea of the human. A related strand of research (un)covers the interrelation of behavioral patterns and forms of visual surveillance in a wide range of places, for example in public squares and transport, in nursery schools and house entrances. It deals with subject constructions created by video surveillance and with the extent to which new technologies of visual power serve new forms of governance. Other inquiries focus on the visual availability of spaces and places and the people acting in or with them.

Opposing the visual to the embodied and visuality to materiality has been criticized from a non- or more-than-representational perspective in recent years (Rose and Tolia-Kelly 2012). Likewise, phenomenological theorists such as Pierre Bourdieu, Edmund Husserl, Alfred Schütz, or Maurice Merleau-Ponty always claimed that semiotic theories create the problem of representationality by presuming the sign character of images, that is, their referentiality. In this phenomenological point of view, often adopted by human geographers, images exist once material objects confront the viewer (are “presented”) as something that is (solely) visible. On the other hand, Helmut Plessner’s concept of an uncorrupted first-order experience related to the concept of the lived body (*Leib*), as the
ultimate taken-for-granted experience of oneself as an embodied, material being, is questioned. Corresponding work conceptualizes visuality as a powerful agent in the discursive structuration of sensations of, for example, space. In this sense, visuality bears a hidden “somatic power” which is subject to critical research into visual advertising effect.

Geographical research into the visual constitution of sociospatial realities relies on methods originating from the fields of iconology, art history, or, more recently, visual culture. On the other hand, visual methods have traditionally been used for qualitative (ethnographic) research in human geography and its subfields such as cultural, political, or urban geography (Rose 2011). Videotaping the physical performance of politicians, for instance, may highlight issues of gendered spaces. Self-directed photography provides genuine insights into the individual life-worlds (Lebenswelten) of, for example, the inhabitants of a particular urban quarter and the spatial identities they constitute. More inclusive, participatory involvements of academia and the public, for example at the interface of cultural geography and arts, should provide new pathways toward a reflective handling of the representational and natural character of visuality – including the problematic dualism of observers and observed (Urry and Larsen 2011).

In the field of geographical education, participatory visual geomedia such as open street map promise to overcome the dualism of producers and consumers of space. Such visual tools offer creative modes of geographical education and call for more-than-analytical competences. However, there is growing awareness of the fact that all forms of visuality in educational processes – be it the material images offered in school textbooks, the displays of navigation systems, digital maps, or instructed gazes on excursions – demand critical reflective visual literacy as a basic educational goal.

Visualization

Computerized graphics and representation techniques to support information communication and knowledge discovery became known as visualization in the early 1980s, concordant with the development of computing systems that could render complex graphics and support basic forms of interactivity with digital datasets. The fundamental idea behind visualization is to transform data from tabular collections of observations into visual artifacts that can prompt thinking. Where humans may have a hard time interpreting long lists of numbers by visual scanning alone, those same data projected into a graphical representation can help reveal elaborate stories. In that sense, cartography has been a form of visualization for a very long time. Today, we understand visualization to refer to the use of digital methods for representing and interacting with data.

Many of the formative examples in visualization grew from data gathered in scientific experiments and modeling. In 1987, a special issue of the Computer Graphics journal on Visualization in Scientific Computing (McCormick, DeFanti, and Brown 1987) helped crystallize this stream of work into what is now known as scientific visualization. Scientific visualization applications include volume rendering, medical visualization, flow visualization, and chemical visualization. A common attribute of many scientific visualizations is an emphasis on revealing three-dimensional (3-D) structures. As a result, most of the datasets in question represent physical phenomena, and often also include temporal elements to indicate change over time.

Visualization of datasets describing more abstract types of information, including non-numerical data, developed in parallel with scientific visualization, in a topic stream that became known as information visualization. Where scientific visualization focused on representing 3-D phenomena relevant to experiments and modeling, information visualization sought the design of techniques to develop insights from more abstract data sources including financial data, demographic data, and text collections. The lines between scientific and information visualization are not always clear, however, and many relevant problem contexts require the integration of datasets emerging from scientific experiments as well as more abstract information collections. Information visualization has become a significant influence on geographic visualization since the 1990s, and information visualization design patterns for interaction, system components, and representation techniques are commonly found in geographic visualization tools. Ben Shneiderman's work to define a taxonomy for the ways in which different types of tabular data can be analyzed in information visualization (Shneiderman 1996) continues to serve as a strong influence for the general design of geographic visualization tools.

Today, there are thriving academic and professional communities around scientific visualization, information visualization, and a
burgeoning host of subfields that include knowledge visualization and visual analytics. Since a great deal of visualization concerns datasets that include a geographic component, geographers have developed a substantial literature on geographic visualization, frequently referred to as geovisualization.

**From visualization to geovisualization**

The primary connection between visualization and geography has been developed by academic cartographers. References to visualization in the cartographic sciences exist as far back as the early 1950s, but it was the rapid development of scientific visualization in the 1980s that prompted geographers to adopt concepts from that realm and apply them in the mapping sciences. In 1990, David DiBiase was among the first to elaborate on ways in which mapping could support scientific visualization (DiBiase 1990). DiBiase’s so-called swoopy diagram (Figure 1) describing the process of visual thinking and visual communication as a sequence moving from private to public realms is frequently cited as a seminal work in geovisualization. A core aspect of this model is the connection between maps and spatial representations and the process of visually enabled thinking. Maps have the ability to spark knowledge construction and to facilitate

---

**Figure 1** Model of the process of visual thinking and visual communication in cartographic visualization. DiBiase (1990).
problem-solving, not just to communicate what has already been determined through analysis.

Related theoretical developments by MacEachren and Ganter (1990) and Taylor (1994) focused on cognitive models to explain what happens when people use maps to conduct visually led analysis. They emphasized the need for research to understand what prompts people to find patterns using maps, to detect outliers, to understand data quality and uncertainty, and to formulate or confirm hypotheses. In 1995, Alan MacEachren published How Maps Work, which elaborates on these and other aspects of the coupling between cognition, perception, and the use of geographic representations to construct knowledge. A key contribution of this work, first published in an earlier 1994 book chapter, is the Cartography³ theoretical model for geovisualization (Figure 2). This model proposes the realm of possibilities for geovisualization tasks, interaction types, and users. A cross-cutting aspect of this model is its integration of DiBiase’s earlier theory describing the process of visual thinking and communication as facilitated by maps.

Subsequent theoretical developments in geographic information science (GIScience) have drawn further connections between the process of science and the actions one might take with geographic visualization to move between stages in that process. Gahegan (2005) proposed the model shown in Figure 3 which provides for a fully flexible framework in which users could move in sequence through each stage, or move across and between stages in a less prescribed manner. This model offers key leverage points where geographic visualization can be used to support science in its multiple phases of development and refinement.

Geovisualization for exploration and knowledge discovery

The implementation of these theories into practice resulted in an explosion of new tools and techniques in the 1990s and 2000s. Animated maps were particularly popular early on, as emerging computer graphics technologies made it possible to generate animations of spatial data. An important next step was to allow users to control the dynamic behavior of these maps, which saw the development of interactive mapping techniques. Linked displays are another hallmark of many early (as well as contemporary) geovisualization efforts. For example, a scatter plot showing observations may be interactively coupled to a map of where those observations were made, and the interface provides visual linking through user-controlled brushing and highlighting to reveal relationships. Whereas traditional cartographic design ended with the creation of a final product for information dissemination, geovisualization sought the development of interactive maps that could be constantly re-created and manipulated by users as they explore and analyze datasets.

A major emphasis in theoretical models and applications for geovisualization has been on supporting user-driven exploration and knowledge discovery. This corresponds closely to key portions of theoretical models proposed by DiBiase (1990) and MacEachren (1995). The emergence of large spatiotemporal datasets in the 2000s and beyond has spurred the need for new methods by which analysts can make sense out of what they have collected. In many cases, analysts may already have hypotheses in mind that they wish to confirm or refute, but in other instances they may not have any preconceived notion regarding what of interest can be retrieved. Geovisualization provides a

visually led framework for using interactive maps and linked data views to begin unpacking complex datasets and formulate hypotheses about patterns. The underlying theory posits that by approaching problems this way we are able to leverage the enormous power of the human visual system to prompt higher-order thinking and problem-solving. In contrast, manual browsing of raw data tables is an untenable method for prompting this kind of thinking, and only the
most basic outlier detection is possible for most users.

Geovisualization recasts the production of maps from a one-way, intensive design process into an iterative framework that allows users to dynamically create (and re-create) maps and corresponding statistical graphics. As patterns emerge, users can flexibly refine their visualization in order to pursue multiple paths of inquiry. Cartography then becomes a process that happens in real time, and it may be driven heavily by end users who may have no formal cartographic expertise. Many early geovisualization examples grew from a focus on enabling support for animated mapping, a technique that had been proposed in the 1950s and demonstrated as early as 1970. Through animated maps, change over time may be shown, and trends may become evident that are difficult to otherwise discern. As animated mapping matured in the 1980s and 1990s, increased support for user controls to direct animation became more prominent, as did studies to evaluate the impact of these interaction techniques. Animated maps helped push academic cartography toward better solutions for spatiotemporal problems, and this work coincided with the spread of new
datasets that provided temporal as well as spatial dimensions.

As new forms of animated maps were developed to include a wide range of user controls for their parameters, eventually it became possible for a fully dynamic paradigm to emerge. This meant that, instead of deciding when to launch an animated sequence or controlling its speed and other parameters, users could cause the system to display any type of change at any time, in an order of their choosing. Geovisualization at this point adopted what is known today as a coordinated-view interface design, where an input device controls how representations change in a visualization system. The most common manner for coordinated-view systems to operate is for the user to move a mouse cursor around the screen and direct changes to the views by hovering over an observation, clicking on an observation, or selecting multiple observations with a click and drag. To implement this type of interface, visualization tools use brushing, filtering, and other dynamic controls to alter representation methods and analyze data.

A priority for these systems was to support the rapid refinement of spatial information displays, making maps now much less of an ultimate result, and instead more of a transient product that was intended to be changed constantly (Dykes 1997). These coordinated-view systems were the product of a unique synthesis of design patterns from computer science, exploratory data analysis techniques developed by statisticians, and cartographic design and representation methods coming from geographers.

The development of coordinated-view systems also sparked a wave of new research efforts to evaluate their utility and refine their usability. Understanding users became a major priority in this work, and researchers in geography began to incorporate practices from human–computer interaction science in order to evaluate new geovisualization systems and compare them to previous approaches. This work continues today, and it remains a challenge to measure the impact of a fully dynamic coordinated-view environment on problem-solving with real datasets. Traditional measures of efficiency and effectiveness frequently fall short when the goal of an application is to prompt a hypothesis or to help someone interrogate an existing hypothesis.

**Geovisualization toolkits**

The late 1990s and early 2000s saw the growth of several notable geovisualization software systems that implemented both animated mapping methods and coordinated-view interfaces. These systems include CommonGIS, GeoVISTA Studio, the GeoViz Toolkit, and the GeoAnalytics Visualization Toolkit (GAV Toolkit). What these systems had in common is their ability to link together multiple views on spatial data in a fully interactive and dynamic manner. Each of these systems is also data agnostic; they are designed to support visual inquiry into tabular spatial data for any number of possible use-case contexts.

The CommonGIS project began in 1998 at the Fraunhofer Institute in Germany, building on several earlier toolkits with the goal of making a user-friendly geovisualization system that could transform geographically referenced statistical data into actionable information (Andrienko, Andrienko, and Voss 2005). CommonGIS had the ambitious goal of making geospatial data accessible and usable by anyone working from any place. To achieve this goal, CommonGIS was crafted around interactions to support data exploration and the automated creation of maps and statistical graphics. CommonGIS allowed users to explore attributes, dynamically manipulate query parameters, and see the impacts of
these changes in real time through linked maps and statistical representations (Figure 4).

GeoVISTA Studio (Figure 5) began development in the late 1990s in a parallel effort to CommonGIS by researchers at the GeoVISTA Center at The Pennsylvania State University. GeoVISTA Studio, like CommonGIS, was intended to serve as a reconfigurable geovisualization toolkit that could support spatial data exploration and analysis in a coordinated, multiple-view architecture (Takatsuka and Gahegan 2002). A unique attribute of GeoVISTA Studio was its ability to be reconfigured on a component-by-component basis through a graphical user interface that leveraged Java programming technology to automatically link elements and generate new composite applications. This mechanism of geovisualization application construction was made possible in part by the design of common component-level coordination methods that allow visualization elements (a dynamic choropleth map and a scatterplot, for example) to broadcast and receive messages about user-driven highlighting, selection, or other interactions.

Progress on geovisualization technological frameworks, graphics rendering quality, and spatial data handling throughout the late 1990s and early 2000s set the scene for an evolutionary step forward in the late 2000s. The GeoViz Toolkit (Hardisty and Robinson 2011) and the GAV Toolkit (Jern et al. 2007) are two examples of second-generation geovisualization environments that emerged in that era, offering superior performance, tighter integration with the World Wide Web, and improved usability. An important step forward for these toolkits was the complete transition from desktop applications to web-embedded applications. One example of a web-based geovisualization environment is the GAV Toolkit (Jern et al. 2007). The GAV Toolkit features many of the same types of visualization components as its predecessors; however, a key difference is that they are usable inside a web browser. The GAV Toolkit is also designed to be configured in advance of its use, so end users are not deciding which views to display and their general layout. The GAV Toolkit is notable for its deployment in OECD eXplorer, a custom geovisualization application designed to support end-user visual analysis of Organisation for Economic Co-operation and Development (OECD) statistical data (Figure 6).

Coupling computational and visual methods in geovisualization

As available spatiotemporal datasets grew in size and content diversity during the 1990s and 2000s, so too did the need for geovisualization systems to incorporate computational methods to help users detect patterns, isolate outliers, and model possible results. While visually enabled analysis remained (and remains) a key feature of visualizations of all types, today’s tools frequently feature automated or semiautomated mechanisms for determining what users should look at in the first place. Therefore, the intersection between geovisualization and spatial data mining is an active area of contemporary research.

Early examples of coupled computational–visual systems in the geovisualization community sought to suggest potential patterns of interest to analysts through the use of hierarchical cluster detection and correlation matrices (Guo, Peuquet, and Gahegan 2002). In addition to the advantages associated with automated pattern detection methods for very large and complex datasets, a core goal for these early integrative efforts was to help users understand how spatial data mining methods work, and the impacts of changes on their parameters. Through geovisualization toolkits, users can manipulate the settings associated with data mining algorithms and see changes in their results in real time to evaluate their impact.

Computational techniques in geovisualization frequently focus on dimensional reduction tasks. A common problem today is that thematic datasets often contain hundreds of potentially interesting variables, and combinations of those variables may turn out to be significantly correlated (or not correlated) with one another. Visual inspection alone, even with sophisticated geovisualization tools, is not enough for users to discover and explain everything of interest in such datasets. Therefore, researchers have the goal of reducing dimensions to make these complex interrelationships more visible. A notable example of this scenario emerged with work to synthesize the textual content associated with thousands of Association of American Geographers presentation abstracts. Embedded within these data were large numbers of topical keywords, place references, and author affiliations. Skupin and Fabrikant (2003) used a computational method called a self-organizing map (SOM) to reduce this complex data into clusters that could be projected into what looks very much like a typical relief map, albeit with regions, shading, and labels that correspond to thematic similarity inside the text from presentation abstracts (Figure 7). This method is commonly known as spatialization, which is defined as the translation of nonspatial information into a spatial representation such as a map.

In addition to dimensional reduction techniques, computational methods in geovisualization have also included space–time cluster analysis methods, geographically weighted regression analysis, sequence alignment analysis (borrowed from genetic science) for event data, and named-entity recognition methods for identifying place names in text media. In many instances, geographers are adapting computational methods from other domains to account for the complexities of spatiotemporal analysis. In other cases, such as with geographically weighted regression, methods are emerging directly from geographic science. It remains an essential (albeit difficult) goal for geovisualization tools to make it as easy as possible for end users to flexibly manipulate computational methods and see results in real time to evaluate their utility.
3-D geovisualization and virtual environments

The influence of scientific visualization on geographic visualization extended to a focus early on in the development of 3-D representations and virtual environments (Dykes, MacEachren, and Kraak 2005). Many scientific visualizations feature 3-D representations of physical phenomena, and since the subject of geography is quite often the Earth, the use of 3-D virtual globes, landforms, cities, and immersive environments has naturally been a significant focus of geovisualization. For example, imagery from remote sensing platforms and digital elevation and/or building models can be combined to construct graphical representations that simulate 3-D environments. Thematic information can also be integrated into these environments to support analytical work that requires an understanding of all three physical dimensions.

While 3-D virtual environments in geovisualization first emerged in the 1990s, perhaps the most influential example of such a tool came in the form of Google Earth in 2005. Google Earth was the first public release of a virtual globe originally created by Keyhole, Inc., in 2001. Google acquired Keyhole in 2004, and the launch of Google Earth to the general public in 2005 led to the rapid popularization of virtual environment visualization. Its hallmark is its elegant usability, offering aesthetically appealing virtual views of the planet that appear to seamlessly change as you zoom in or navigate. Today, there are many competing virtual globe platforms, nearly all of which allow users to easily pan, zoom, and query areas on the planet. The basic pattern of mouse-driven navigation used in Google Earth is
now a de facto standard for most contemporary 3-D virtual environments.

The temporal dimension is also a major focus for 3-D geovisualization research and technology development. The space–time cube, first proposed by Hägerstrand (1970), added time as a possible third dimension on top of 2-D maps, resulting in a 3-D cube representation. This method has been adapted and extended by many others, and is implemented today in research and commercial geovisualization software for use cases where understanding the temporal dimension of spatial data is particularly important. Most often the interface for a space–time cube allows users to tilt, rotate, zoom, and filter their data.

Virtual environment research in geovisualization also includes a focus on immersive experiences where users wear special equipment or enter into engineered rooms where the perception of going inside a virtual environment can be created. Early work in these areas was promising but heavily limited by the computational power and equipment engineering required to deliver a fully interactive and immersive user experience. Today, such technical hurdles are much less of an issue, and immersive geovisualization is poised for a resurgence in the form of fully virtual as well as augmented reality systems that overlay digital information on top of what we see in the real world.

A key cross-cutting challenge associated with 3-D geovisualization lies within understanding the extent to which 3-D representations and interfaces can help users in real-world analytical tasks. Many studies have attempted to unpack the differences associated with usability and utility in the context of 3-D geovisualizations, and the strongest signal from this work is that three dimensions works well for showing phenomena that are actually 3-D in reality, such as landforms and structures in urban environments. Users have a harder time doing analysis with 3-D representations of thematic data that are overlaid on top of 3-D landforms or cities, so while such methods have a strong visual impact on users, they do not actually perform as well as they might with simpler 2-D representations or multiple 2-D linked views.

Today, 3-D geovisualization is complemented by a variety of new web technologies that support 3-D graphics in web browsers without the need for special software extensions or high-performance computing. Products such as ESRI CityEngine allow designers to construct urban development scenarios to evaluate the impacts of new construction proposals, and the resulting 3-D models can achieve very high levels of realism while retaining fully dynamic interaction in a simple web browser. This stream of work in geovisualization is also intersecting today with a burgeoning range of technical and scientific efforts to improve the ways in which city infrastructure and individual buildings themselves are managed and maintained. As more and more structures become embedded with sensor technology, new roles emerge for the use of virtual environments to help us understand interrelated systems in our world.

The development of geovisualization in academic and professional practice

Formal evidence of the development of geovisualization has come through a substantial body of published research beginning in the 1990s in journals such as Cartography and Geographic Information Science, Cartographica, International Journal of Geographical Information Science, and The Cartographic Journal. In 1995, the International Cartographic Association (ICA) approved the formation of the Commission on Visualization to focus on research on nascent developments in dynamic mapping tools and techniques. This commission, led by Alan MacEachren at The Pennsylvania State University and Menno-Jan
Kraak at ITC in the Netherlands, helped spur the early development of key research themes in geovisualization. In 1999, the ICA approved the continuation of this commission, which was retitled as the Commission on Visualization and Virtual Environments, to signal the inclusion of virtual reality systems as a core theme. In 2007, the Commission was renamed the Commission on Geovisualization to reflect the widespread adoption of that term to describe this stream of research.

Techniques from geovisualization have also made their way into professional practice through implementation in desktop and web-based geographic information system (GIS) software. For example, ESRI’s ArcGIS for Desktop tools include dynamic filtering and linked maps with statistical graphics, as well as 3-D visualization and virtual globe methods. Sophisticated web mapping platforms such as Google Maps, CartoDB, and GeoCommons have featured animated and interactive map methods that were pioneered by academic cartographers in the early 1990s. Whereas those early examples proved conceptual possibilities, contemporary professional systems have implemented these methods with large datasets and made them usable by novices with no technical overhead aside from the use of a standard web browser.

The rise of geovisual analytics

Starting in the mid-2000s, researchers in the information, scientific, and geographic visualization communities began developing a new stream of visualization science around a field named visual analytics. This new field was defined as the “science of analytical reasoning facilitated by interactive visual interfaces” (Thomas and Cook 2005, 4). The development of this new stream of visualization research was heavily influenced by failures to synthesize and understand incoming evidence in the wake of the 9/11 terrorist attacks in the United States. Several of the chief proponents for the first visual analytics research agenda included federal science and homeland security entities from the United States.

A distinguishing characteristic of visual analytics is the focus on explicit support for analytical reasoning. This signaled a deliberate shift from a focus on supporting visual exploration, as had become quite common by the mid-2000s in information and geographic visualization research and applications. Therefore, the aims of visual analytics research could include empirical investigations on how users make sense of their data through the use of visual interfaces, as well as the development of new visual and computational methods that could directly leverage or augment these sense-making processes. The visual analytics movement brought together cognitive and perceptual study methodologies, the development of new visual interfaces for complex data streams, and real-world problem contexts such as crisis management, crime analysis, financial fraud detection, network security, and epidemiology.

A subset of visual analytics work began concurrently in the field of geography, with many geovisualization researchers shifting to what was called geovisual analytics, an extension of visual analytics focused on problems that require geographical analysis and visualization approaches (Andrienko et al. 2007). An early effort was made to connect geovisual analytics to decision support tasks, where relevant problems in crisis management and other domains were most likely to require careful attention to geographic data and analysis techniques. The broader visual analytics community has eagerly embraced the importance of geography in many relevant task domains and datasets. For example, the annual IEEE (Institute of Electrical and Electronics Engineers) Conference on Visual
Analytics Science and Technology has held a synthetic data analysis challenge contest since 2006, with each year featuring at least one dataset that includes a geographical component. Examples of geovisual analytics applications include tools to evaluate cluster results in cancer epidemiology, to extract and geolocate topics from collections of news articles and social media streams, and to detect patterns in movement in very large datasets of mobile phone usage logs. Recent work has also begun to integrate methods for detecting unusual deviations in streaming data sources, and to develop predictive methods for anticipating future events. These aspects represent portions of analytical reasoning that are among the most important to support for end users, but are also the most difficult to develop in interactive visual interfaces. While many early examples of visual analytics work focused on supporting national and homeland security contexts, today there is an increased focus on supporting citizen science and decision-making, business analytics, and digital arts and humanities. Problems in these domains frequently involve the synthesis of complex and imperfect datasets and require systems that can be leveraged by nontechnical subject matter experts.

Research frontiers in geographic visualization

A substantial collection of published research agendas exists today to guide geovisualization and geovisual analytics investigations (e.g., MacEachren and Kraak 2001; Andrienko et al. 2007). What each of these agendas has in common are key aims to develop new geographical representation methods, new forms of interaction with geographic data, novel approaches for evaluating usability and utility, deeper knowledge on cognitive and perceptual processes that humans leverage when doing visually led analysis in geography, and innovative methods for computational analysis that can help identify patterns or predict future outcomes. Emerging contexts for these research aims include the need to understand patterns in complex collections of spatiotemporal data, such as that gathered en masse by satellites or generated in millions of social media messages each day.

The development of new representation methods to visualize spatial data is a primary focus of contemporary visualization research in geography. Innovation in representation has grown from initial discoveries on animated choropleth and point symbol mapping techniques to include new methods that attempt to show diverse data types (such as text, photographs, and video) in their spatiotemporal context. Much work today is aimed at the development of new representational methods that can scale elegantly to help users make sense of massive numbers of observations. Ongoing challenges include the need for new geovisualization tools that can represent and render useful very large collections of text data from social media sources that have location references, and visual representations that help users understand streaming sources of movement data collected by mobile devices.

A key aspect of leveraging geovisualization to solve real-world problems involves the coupling of data representation methods with computational algorithms that have the power to extract potentially interesting patterns, cluster similar groups of observations, or detect and filter significant outliers. Early visualization and geovisualization work focused on making it possible for users to simply use their eyes to detect and interrogate patterns in their data. This is still a key part of the value proposition for visualization today; however, the science has progressed to include a strong focus on the use of computational methods for automatically
suggesting what deserves visual attention. A wide range of pattern analysis, modeling, and cluster detection methods are in development today, with a particular focus on methods that can detect significant changes in streaming data sources. Whereas datasets of interest in the 1980s, 1990s, and early 2000s were primarily static sources, today we are faced with enormous, dynamic data streams. Another major area of growth is in the creation of pattern-matching techniques whereby end users can specify an important general pattern that could be found in a large dataset, and have the visualization system return the patterns that exist that are most similar to that idealized model.

Interaction with geovisualization tools remains a major focus of ongoing research. A long tradition of academic cartography has centered on the interface between people and maps, and recent technological paradigm shifts toward powerful personal computers and mobile devices has raised new and vital questions that require new science investigations to answer. This research stream had its origins in early geovisualization work to explore ways for controlling animated and dynamic maps. Today, there is a great deal of inquiry around touch-based mobile map interfaces and coordinated-view visualization tools that bring together sometimes dozens of representation methods and blend a variety of data types. We have much to learn yet about the limits of human–computer interaction when it comes to manipulating and making sense of mapped information. Today, users can manipulate map interfaces through keyboards, pointing devices, touch, speech, and their eye movements. While some methods are more common than others, there remain many open questions regarding when and how to use each interaction mode to best fit domain-specific tasks.

A related research stream revolves around the empirical evaluation of geovisualization tools and techniques. Drawing heavily from human–computer interaction and usability engineering domains, research on evaluation in geovisualization has attempted to understand the gaps between research prototype methods and what may work in the real world for end users. This work can be broken down into formative and summative studies, with the former focusing on knowledge elicitation to develop designs for new tools with user inputs, and the latter focusing on comparing the resulting tools to existing approaches to measure their utility and usability. Formative approaches in geovisualization evaluation include case studies, focus groups, interviews, card sorting, think/talk aloud protocols, and paper prototyping. Summative approaches in geovisualization evaluation include task analysis, surveys, heuristic assessment, eye movement analysis, and interaction logging. Many geovisualization evaluation efforts involve a series of iterative steps to conduct both formative and summative assessments, blending together a variety of these approaches to triangulate results.

In addition to interaction science and conducting usability or utility evaluations, cognitive and perceptual research helps to characterize and establish the fundamental processes that direct user engagement with geovisualizations and the information that can be derived from them. Visualization is of particular interest to GIScience investigators with cognitive and perceptual research backgrounds as the analysis contexts in geographic visualization frequently place a heavy burden on end users as they attempt to make sense out of large collections of diverse spatiotemporal data. Visualization to support pattern detection and sense-making is often of interest to cognitive scientists, and the visual affordances of these tools provide opportunities for a wide range of perceptual studies as well. Technologies such as skin response measurement and eye movement analysis allow researchers to
explore what stimulates users when they work with geovisualization tools. Frequently, these types of datasets are then used by cognitive scientists to synthesize patterns of interaction, introspection, and exposition by users in order to understand the spatial analytical process and conceptions of spatial knowledge.

Visualizing uncertainty

Kate Beard  
*University of Maine, USA*

The visualization of uncertainty in spatial data was identified as an important topic and an original National Center for Geographic Information and Analysis research initiative in the 1990s. One of the main challenges of this research initiative was to first identify conceptualizations and understanding of uncertainty in its different forms. Uncertainty has many definitions, not all of which fully agree. One understanding of uncertainty is as an expression of confidence in our knowledge about something. In contrast to explicit definitions, uncertainty may be better characterized by identifying its sources. These include lack of data, incomplete knowledge, measurement errors, sampling errors, natural variability in the phenomena being measured, and problems of definition. Fisher (1999) presents a useful categorization of uncertainty centered on the difficulties of defining an object or phenomenon. His categories build on Klir and Yuan (1995) and include three cases. In the first, objects or phenomena are assumed well defined, uncertainty about them stems from errors, and is addressable through probability theory. In the second case, an object or phenomenon cannot be well defined, the uncertainty is attributed to vagueness, and may be addressed by fuzzy set theory. In the third case, uncertainty arises from ambiguity or confusion about how an object or phenomenon should be classified. In such cases, an object or phenomenon may be well defined but disagreement exists over classification or different interpretations of evidence (Klir and Yuan 1995). Such interpretation or classification differences today may be understood as a problem of semantic heterogeneity, a topic being addressed in part by semantic web technologies.

In the mid-to-late 1980s, as interest and technical capabilities in GIS expanded, early work on spatial data quality identified several dimensions of quality which can be equally well be considered dimensions of uncertainty. These dimensions included positional and attribute accuracy, completeness, and consistency. Uncertainty in geospatial data is thus characterized as a multidimensional problem. Uncertainties in the different dimensions (spatial, temporal, thematic) can arise independently, but frequently the dimensions exhibit interdependencies that create extra challenges for characterizing and ultimately visualizing uncertainty.

The balance of concern over dimensions of uncertainty and the interactions among dimensions can vary substantially for particular phenomena of interest, within different domains, and in different context settings. For some spatial phenomena, it is possible to be quite certain about the identity or attributes (identity of a forest fire) yet be uncertain about positional locations or spatial geometry (a forest fire’s location and shape). Change over time introduces temporal uncertainty and limited data sampling in time leaves open substantial temporal uncertainty (e.g., about how a fire progressed). With the introduction and now wide availability of GPS, it is quite easy to obtain precise spatial positions yet be uncertain about attributes at those locations. For example, we could be quite certain about the location and delineation of a town’s boundary, and be quite certain
about the population and other demographic characteristics of the town (a data sampling and collection problem). In other cases the uncertainty in location and identity or attribute are interdependent. For example wetlands are notoriously difficult to delineate thematically and spatially and the task is made more difficult by variations over time. With wetlands the problem is largely one of vagueness although there are also problems in competing definitions and classifications. Spatial autocorrelation, the spatial dependence in a variable over space, is an important dependency that complicates uncertainty assessment. The multidimensionality of uncertainty and the common occurrence of dependencies among uncertainty dimensions in geospatial data has been an on-going challenge in characterizing and visualizing uncertainty.

The different dimensions and sources of geospatial data uncertainty can all be important but, over the last several decades, the relative emphasis on different dimensions of uncertainty has been changing. In the early days of GIS, much attention focused on positional uncertainty. With new technologies, including GPS, more robust and comprehensive spatial reference networks, and higher spatial resolution satellite sensors, positional uncertainty contributed by measurement error has been substantially reduced, making it relatively less critical relative to other sources of uncertainty. Time series data and higher resolution temporal data have become more widely available, heightening concerns about temporal and combined spatial and temporal variability and attendant uncertainties. New data collection technologies have also opened up the potential for average citizens to become data collectors, thereby introducing new sources of uncertainty due to lack of any systematic standards for such data collection. The integration of data from such mixed sources with differing provenance opens new challenges for uncertainty assessment and modeling.

The next sections describe methods for characterizing and modeling uncertainty as a prerequisite for visualizing uncertainty. The entry then moves on to approaches for visualizing uncertainty. The last section reviews some recent evaluations of the effectiveness of these visualizations in conveying uncertainty to users.

Characterizing uncertainty: measures of error

Substantial research has addressed uncertainty representations associated with measurement error and error propagation (Heuvelink and Goodchild 1998; Mowrer and Congalton 2000). When uncertainty is a function of measurement error, several numerical representations in the form of scalars, confidence intervals, and probability distributions are possible. Measures such as root mean square error and circular map error for positional error have been traditional measures used to express uncertainty. These can capture certain aspects of uncertainty but not all. For example, root mean square positional error does not capture shape uncertainty.

Characterization of error-based uncertainty relies primarily on probability models. For a geospatial data object, its dimensional components \((x,y,z)\) coordinates, attributes) are considered random variables whose uncertainty is completely specified by a probability distribution function (pdf). When statistically dependent uncertainties are present, these dependencies must be accounted for; an advantage of probability models is that they can support interdependencies or correlation between dimensions. In such cases, joint probability distribution functions replace separate marginal probabilities distribution functions for each dimension.
Heuvelink, Brown, and van Loon (2007) provide a comprehensive summary of probability models for spatial and temporal dependencies in attribute uncertainties, for correlated attribute uncertainties, and for positional uncertainties that may be statistically dependent in space and time, as well as in their \( x \), \( y \), and \( z \) coordinate dimensions.

Once a probability-based uncertainty model has been specified, it can be used to create multiple simulations of alternative, equally probable realizations of uncertain objects, attributes, or fields.

Spatial uncertainty for example can be modeled through the generation of a set of simulated maps, each of which is consistent with supporting information.

Two recent and useful contributions to the modeling and representation of probabilistic uncertainty include the data uncertainty engine (DUE) (Heuvelink, Brown, and van Loon 2007) and a conceptual model and proposed XML encoding called UncertML. The DUE prototype software tool is applicable to spatial representations that include points, collections of points that behave as rigid objects or deformable objects, and to continuous or qualitative attributes. It supports assessing uncertainties, storing them in a database, and generating realizations for inclusion in Monte Carlo uncertainty propagation studies. The UncertML model is designed to support interoperable uncertainty descriptions for the web environment. Currently the OGC standard web coverage service and web feature service have no way to include uncertainty information with the data. UncertML provides encoding options for summary statistics and probability distributions including joint and marginal distributions as well as mixture models.

Despite several advantages to probability-based models, a number of challenges remain in developing a full suite of models to account for the various cases of interdependencies between spatial, temporal, and thematic dimensions. Also, open questions remain on how to efficiently capture and store the uncertainty information from such models.

**Characterizing uncertainty: representation of vagueness**

Vagueness presents a different form of uncertainty and expectations for different treatment.

Uncertainty related to vagueness has been traditionally modeled using fuzzy set theory. Fuzziness differs from the randomness of probability theory. For example fuzziness measures the degree of occurrence of an event or degree of membership in a class not whether an event occurred or a class exists. Fuzzy set theory supports vagueness or indeterminacy by defining a continuous membership function in the range \([0,1]\) where a value of one signifies definite membership, a value of zero signifies definite nonmembership and intermediate values express gradations of membership. A membership value of 0.2 indicates relatively weak membership while a membership value of 0.8 indicates a stronger degree of belonging to a class. Fuzzy methods have been quite widely used to represent geospatial uncertainty. Early work by Leung (1992) employed fuzzy set theory to model uncertainty in multinomial fields, a common geospatial representation for classified data which includes land cover, soil type, wetlands, and bedrock units. For such data, classes are frequently not well defined or not clearly separated and, thus, well modeled by fuzzy methods.

Fuzzy membership applies most directly to thematic classes but in raster representations, pixel class membership can capture boundary or positional uncertainty as well as classification.
uncertainty. Instead of a single class map (such as a land cover map), fuzzy representations result in the creation of multiple class membership maps, one for each class. Each fuzzy class map conveys one possible version of a categorization. The outcome is thus somewhat analogous with the multiple realizations generated by stochastic simulation from probability based error models.

**Visualization methods for uncertainty**

For geographic information systems which rely heavily on maps and graphics in analyses, visualization provides a logical method for incorporating and conveying uncertainty. Numerous visualization strategies for uncertainty have been proposed and developed (MacEachren et al. 2005). However, it is also the case that no universally accepted standards, best practices, or generally accepted metaphors have yet emerged.

When some measure of uncertainty is available as a variable for display, several graphic symbolizations are possible. Statistical graphics such as boxplots, scatterplots, and histograms can be used to visualize and explore uncertainty but these graphic representations alone do not effectively capture spatially varying patterns in uncertainty. For geospatial data, representation of uncertainty in map form is generally desired in order to convey the spatial location and spatial variation in uncertainty. The depiction of uncertainty borrows substantially from traditional cartographic visualization considerations for selecting an appropriate match between uncertainty measures and visual variables. Of the classic set of visual variables (Bertin 1983) – color (hue, saturation, and value), texture, shape, size, and orientation – the dominant choice for depicting uncertainty has been color and manipulations of its dimensions. Uncertainty representation methods have employed lightness and considered both lighter and darker values for representing uncertainty. Using saturation pure hues are used to represent areas or values with the least uncertainty and desaturated hues to express greater uncertainty. Hengle (2003) manipulated value and saturation jointly to effectively “whiten” areas with greatest uncertainty. These approaches implicitly or explicitly use the analogy of fog in which the data has the appearance of being obscured where it is most uncertain. Other visual variables considered for representing uncertainty include crispness (e.g., contour crispness), focus, and transparency.

Glyphs, compound symbols combining multiple visual variables (e.g., Chernoff faces), have been used frequently to represent multivariate data and have been suggested for representing the multiple dimensions of uncertainty (Pang, Wittenbrink, and Lodha 1997).

All of the above methods face the challenge of how to effectively combine the data representation with the uncertainty representation, which becomes a significant problem for geospatial data. Representation of uncertainty in lower dimensional data is simpler and more common, such as error bars on charts. For geospatial data, the data visualization typically fills the two dimensional space and clever solutions are required to accommodate the uncertainty depiction.

In a GIS context, an uncertainty representation is often viewed as another layer that can be displayed in relation to the data representation. Three alternatives have been identified for relating data and uncertainty in 2-D settings. One option is to display the data and its uncertainty as two separate maps in a side-by-side or adjacent display. In a static context such a display requires a user to make an association between the same locations in the adjacent images. To help users in exploring and assessing the uncertainty, such side-by-side displays need a form of linkage that allows the same object or location in the data
view to be connected to the same object or location in the uncertainty view. For example, selecting a set of pixel locations in the data view can highlight the corresponding pixels in the uncertainty view.

A second option is a sequential presentation in which data and uncertainty views exist as separate maps layered on top of each other and a user can toggle between the two views. The user again has the problem of associating the same positions in the image sequence. The third option is an integrated view in which the data and uncertainty representations are combined in a single representation. In this case data values are mapped to one visual variable and uncertainty values to another. Texture overlays or bivariate color schemes provide methods to accomplish this integration. A hue–saturation–intensity (HSI) color model is a specific example of a bivariate color model in which data values (predictions) map to hues and the uncertainty in the data value (prediction error) maps to saturation of the hue.

Interactive visualizations provide more options to address the display complexity issues. Some interactive methods allow users to select the variable (data or uncertainty) and choose the visual variable to map the variable to depending on what they wish to emphasize. Other interactive approaches allow users to control what data is shown based on setting an uncertainty threshold. As the user interactively adjusts the threshold, data value locations that exceed the uncertainty threshold disappear from the view.

Visual representations of uncertainty become more complex with increasing complexities in the uncertainty representations. The stochastic simulation approach, which offers a conceptually effective means to characterize uncertainty, presents significant challenges for visualization. The Monte Carlo simulations generate large numbers of realizations to capture a full range of variation, leaving the problem of how to synthesize and make visual sense of a large collection of map versions. In the case of Monte Carlo simulation, the uncertainty is not explicitly quantified but implicit in the range of variation expressed across the realizations. The set of simulated maps can be summarized in a static display of the probability of exceeding a particular threshold or some measure of the spread of the posterior distribution. Summary statistics or images, however, lose characterization of the spatial variation. A suggested alternative is to animate the set of realizations but to be effective an animation requires some ordered sequencing of the realizations. These animations should ideally convey an impression of areas that remain stable (have low uncertainty) relative to regions that show large fluctuations.

The visualization of fuzzy set memberships has similar visualization challenges and no widely adopted standard for visualization. The general goal is to visualize multiple class memberships and the confusion between classes. Hengle (2003) describes a color mixture model in which pure classes get a pure hue, locations with mixed but similar classes get transitional hues, and locations with mixed and very different classes transition to white to express the greatest uncertainty about class identity. Pixel mixture methods have also been investigated for fuzzy data representation. In such approaches, pixels are divided into subpixels and each subpixel is assigned a class and the number of subpixels assigned to a class is proportional to the membership value of each class.

Fuzzy classifiers can produce multiple realizations indicating degree of membership. In an example of fuzzy classification of land cover classes, pixels are chosen at random and assigned a cover type based on the membership of the pixel for that cover type and a large number of realizations are produced. Sets of these fuzzy
clairved maps can be viewed one at a time, combined using separate color schemes or animated. Both random and serial realizations have been proposed for such maps. Pixels with dominant membership in one class maintain a consistent color in the animation while pixels with variable membership change color assignments and appear to flicker. The animations are useful for conveying an overall impression of uncertainty. To get more specific uncertainty information for a location, interactive enhancements use a linking strategy to link statistical graphics with image locations.

Assessment of uncertainty visualizations

The goals of visualization methods range from making users aware of the presence of uncertainty to creating quantitative expressions from which an amount of uncertainty can be assessed, to ultimately a deeper spatial understanding. The overall expectation is that visualizations can aid users in better understanding uncertainty, comprehending its possible impacts on their analysis and interpretation and aid in better decision-making.

A number of studies have evaluated the usability of visualizations, user preferences for techniques, and correctness of user interpretation of the intended message (Davis and Keller 1997; Evans 1997; MacEachren et al. 2005). As noted above, visualizations of geospatial uncertainty that attempt to combine data and uncertainty can become very complex and, in many cases, may simply confuse the user, an outcome not always explicitly tested for. Evaluation studies have differed in the number and type of uncertainty visualization methods tested and in the criteria measured (visual appeal, speed of comprehension, correctness of interpretation, ease of use, and overall effectiveness of various visualization techniques). Results have been mixed and because of the wide variation in the test settings no clear patterns on visualization approaches have emerged. Potential dependencies include the user’s level of experience, the task or analysis question, the type(s) of uncertainty, and the user domain. Some studies found that user experience level made a difference in preferences and interpretation while others did not. Some commonalities among the findings suggest that uncertainty as a texture overlay seems to be effective and correctly interpreted by users, and color value (lightness) appears to be more easily interpreted and better associated with uncertainty than saturation. Animations were evaluated in a number of studies and, dependent on the type of animation, some were found to be effective in some contexts, while others were not.

A number of studies sought to test the underlying assumption that inclusion of uncertainty information can contribute to better decision-making by framing the evaluation of uncertainty depictions in decision-making contexts. Leitner and Buttenfield (2000) conducted a study that framed the uncertainty visualization assessment in a site planning decision-making context and their findings indicated that maps depicting uncertainty led to more correct location decisions. However, a comprehensive understanding of the impacts of visualizing uncertainty on decision-making is still an open question.

Unfortunately, several study findings point to limited usefulness of many current uncertainty visualization techniques. An evaluation of multivariate glyphs, for example, found that users were confused and dissatisfied by too much visual clutter imposed by the glyphs.

An analysis by Zuk and Carpendale (2006) of eight uncertainty visualizations suggested a need for greater attention to human factors and cognitive psychology literature on uncertainty and decision-making to better understand the
implications of increased cognitive load in processing complex visual representations.

The empirical studies offer some insights but, unfortunately, many of them are not comparable on task setting, visualization techniques, user experience, and complexity of the data, among other variables, and thus a clear picture of the effectiveness of uncertainty visualization has not been determined.

In studies to date, samples have typically been small and a number of results have been contradictory, leaving a number of open questions. There is, in fact, substantial uncertainty on how well various visualization methods actually communicate uncertainty to the users and the degree to which users are able to assess the uncertainty information correctly.

Conclusions and future directions

Substantial progress has been made in modeling uncertainty and approaches to visualizing it. However, routine use of uncertainty visualization in geospatial analysis contexts remains rare. A general consensus among researchers in the field is that no single visualization method is sufficient to convey all the dimensions and subtleties of geospatial uncertainty.

Assessment studies collectively have not yet provided clear guidance on best practices for communicating uncertainty visually. Because of domain specific aspects, task dependencies, high dimensionality, and difficult to model interdependencies among uncertainty dimensions, uncertainty visualization remains very challenging. Context dependencies are a significant issue and more systematically designed experiments would help to assess the performance of uncertainty visualizations in different contexts.

Experts in visualization and experts in uncertainty modeling have perhaps not interacted as closely as they might in addressing the problem as well as working with cognitive scientist and psychologists in evaluating human factors. A fairly substantial gap still exists between visualization techniques developed largely independently of specific characteristics of uncertainty models and similarly uncertainly models developed largely without visual representations in mind.

The context dependencies may be such that greater attention to the dimensions of uncertainty and their relevance for different data, domains, and tasks warrant very flexible methods for users to indicate and prioritize methods for uncertainty depiction. Many of the approaches are able to indicate a presence of uncertainty but do not yet help with discriminating different types and forms of uncertainty. In other words, uncertainty due to vagueness cannot be discriminated from uncertainty due to errors. Because of the many different dimensions and types of uncertainty this is another challenging problem.

Couclelis (2003) makes the important point that information or knowledge products such as maps do not carry evidence of their own inadequacy. She notes that, “Bad knowledge and erroneous beliefs do not necessarily look or behave differently from good unless and until some special situation arises.” This point argues for continued proactive development of methods to better convey data, information, and knowledge uncertainty through visual means or otherwise.

Volcanic processes and landforms

Saeideh Gharehchahi
Texas State University, USA

Volcanoes are among the most spectacular landscapes on the Earth. They have enormous impacts on human life, ranging from providing fertile soil to producing fatal catastrophes. Volcanic mountains are mainly considered a potential threat for the population living around them. The presence of unconsolidated materials accompanied by the possibility of seismic activities and explosive eruptions make them a potential threat for populations living in their vicinity.

As they are a part of geomorphic systems, geomorphologists have played an important role in studying and classifying the processes and landforms related to volcanic activity. All geomorphic systems can be considered the result of endogenous (tectonic and volcanic) or exogenous (geomorphic) processes. Endogenous variables or tectonic processes are the result of internal energy originating from the Earth’s core, which ultimately influences the processes and structures on the Earth’s surface.

Intrusive and extrusive volcanic processes are associated with the modern theory of plate tectonics. In this model, the hard outer layer of the Earth is a set of broken plates that interact along the margins. These plates include the African, North American, South American, Antarctic, Australian–Indian, Eurasian, and Pacific plates (Huggett 2006) (Figure 1). Some of these plates are covered by oceans and the others carry continents.

There are three types of boundaries through which tectonic plates converge or diverge. Divergent boundaries are those in which plates are being extended by divergent forces as new materials create new oceanic crusts causing the plates to develop. In transform boundaries plates move along main faults or fractures, whereas at the convergent boundaries or active margins two plates collide and subduction occurs. In fact, as a result of this subduction, extreme pressure and heat melt the rock and push the resultant magma toward the surface (Figure 1). The active margins are the location of volcanic mountain belts and high rates of earthquakes; however, some volcanic activities can be found in the middle of the plates. To explain this type of activity, scientists postulate a hypothesis which relates its origin to hot centers known as mantle plumes (Goudie 2004). A volcano above a hotspot is not active forever, because plate motion will carry a volcano past the hotspot and the volcano becomes inactive; however, a new volcano may develop over the hotspot. The most active volcanic regions to which this theory applies are Hawai‘i, Réunion, Yellowstone, and Iceland.

Volcanic and plutonic processes

Volcanic processes refer to the extrusion of molten rocks, known as magma, onto the Earth’s surface or intrusion of magma into crustal material beneath the surface. Volcanoes and the resulting landforms vary depending on the
eruptive behavior. Explosive or pyroclastic volcanoes blow pieces of solid rock from the vents, whereas effusive eruptions contain molten rocks, which extrude less violently onto the surface in the form of lava flows.

The nature of a volcanic eruption is determined by the chemical composition of the magma (molten subsurface rocks), its temperature, and the amount of dissolved gases within it. All of these factors have a large influence on the ability of magma to flow, which is associated with the viscosity of magma.

Silica-rich felsic magmas have a tendency to be cool in temperature, which directly results in high-viscosity magma (resistant to flow), whereas mafic magmas tend to be extremely hot and less viscous. Thus, high temperature causes lower viscosity and high silica content leads to a high level of viscosity. As molten rock rises toward the surface, the pressure and temperature decrease and gases release. This process results in violent eruptive explosions (Petersen, Sack, and Gabler 2010). Granitic (or rhyolitic) magmas consist of 70% silicate. Andesitic magma contains 60% silicate and has a substantial content of incorporated gas with a moderate tendency to flow, whereas basaltic magmas contain 50% silicates which tend to vent gas more readily. These lavas are more effusive. As the basaltic lava solidifies, a network of cracks develops, resulting in columnar features that are roughly hexagonal (Figure 2b).

Silicic, viscous, and cooler magmas expel solid material into the air in various sizes. These rocks, called tephra, are explosive fragments of volcanic
rocks or lava ejected by eruptive processes and classified into three types of pyroclastic material. Ashes are sands or gravels less than 4 mm in diameter, lapilli are between 4 and 64 mm in diameter, and blocks are larger than 64 mm (Huggett 2006).

**Volcanic landforms**

Lava flows are outpourings of magma that result from effusive eruptions and flow with low viscosity and high temperature over a broad area. The mineral composition of lava is a determining
factor in the type of resulting landforms. Basaltic lava is the most dominant form of lava that contributes to the creation of surface features (Figure 2c).

Extremely fluid lava can easily spread across the surface for long distances before cooling. In this case, the outer surface layer comes in contact with the atmosphere and solidifies while the moving body underneath results in a rosy and wrinkling crust called pahoehoe (Figures 3 and 4). With increasing distance from the source, pahoehoe breaks into sharp-edged tubes. This accretion along margins due to less heat and great viscosity is known as aa, which is a common effusive form in the Hawaiian Islands. Lava flows do not always pour out from volcanoes, but can erupt without any explosive activity through linear vents called fissures. Very fluid basaltic lava erupted from fissures is able to scatter over a large area before solidifying, which creates geomorphological landscapes called flood basalts. In some continental regions, these flat surfaces are elevated and result in basalt plateaus. The Deccan Traps of central India, the Siberian Traps, and the Columbia River Plateau of western North America are examples of basaltic plateaus.

Figure 3  Ropy pahoehoe lava. Photo by Garry and Susan Hayes, 2004. Reproduced by permission of Garry and Susan Hayes.
The accumulation of lava flows results in a type of volcano with a low slope and convex profile like a shield, which is accordingly named a shield volcano (Figure 5a). Unlike the more explosive volcanoes that are more dangerous, shield volcanoes are built by relatively quiet effusive eruptions. The most prominent shield volcanoes in the world are located on the Hawaiian Islands, with the largest being Mauna Loa. It reaches 4170 m above sea level and is 17 km from the Pacific floor to its summit.

The smallest type of volcano is the result of an explosive eruption of pyroclastics, rather than an accumulation of lava from repetitive eruptions. These are known as cinder cones (Figure 5b). They have a bowl-shaped crater made of pyroclastic materials. At the time of eruption, because of high levels of gas, cinder fragments blast into the air and accumulate around the volcanic vents. Distinctive cinder cones can be found in Mexico, Idaho, and New Mexico. The most famous one, named Paricutin, in central Mexico, grew out from a new vent in 1943 to a height of 100–400 m in a year.

The most common type of volcano, named stratovolcanoes or composite cones, are conical volcanoes made of accumulated layers of pyroclastic materials (tephra, ash) and lava (Figure 5c). They are distinctive, with a simple symmetrical cone and a concave profile as seen on Mount Damavand (Figure 2a), the highest volcano in Iran and Asia (5610 m), and Mount Fuji (3776 m) in Japan. Stratovolcanoes are common...
features where an oceanic plate subsides below a continental plate or another oceanic plate.

Silica-rich magma forms acid lava which is extremely viscous. Where this type of lava moves toward the volcanic cone due to high silica content and outgassing of fluid magma, the viscosity will increase and magma will not be able to travel far from the vent (Figure 5d). As a result, a steep-sided and jagged dome-shaped volcano emerges with a collar of unstable debris around it. Due to the growing pressure of gas over time, this type of volcano, called a plug dome, often erupts explosively.

In 2008, Mount Chaitén, a plug dome in southern Chile, erupted for the first time in more than 9000 years. The eruption began with the emission of ash, seismic activities, and pyroclastic flows while two vents developed in the old dome. The government evacuated the city when defensive works failed. From July 2008, Chaitén continued to erupt, with a growing lava dome and ash columns up to 3000 m. In 2009, the dome collapsed, and pyroclastic materials flowed 5 km from the central vent. The risk of mudflows and flooding is still high in this area, so the government has abandoned the city and relocated the residents.

The most common feature of all volcanoes are the chambers through which magma rises to the surface. The main chamber is the central vent. During the eruption, the volcano chamber may evacuate enough to trigger the collapse of the volcanic structure, leaving behind a distinct depression crater called a caldera. Yellowstone Caldera, the best known example, erupted most recently approximately 650,000 years ago during which released materials covered a substantial part of North America.
Intrusive processes

Intrusions or plutons include those molten rock materials that solidify or cool before reaching the surface of the ground. These igneous processes are collectively referred to as plutonism.

Large intrusions are sited deep and appear on the surface by the uplift of the land they intrude or by the process of erosion. They become a distinctive landscape because of their resistance to erosion compared to the other, weaker surrounding rocks. These resistant rocks often form the core of mountain chains.

Intrusions are classified by their shape and their location in relation to the rock layers they intruded (Figure 6). Large intrusions are circular in shape. Small intrusions without any particular shape are called stocks and cover an area less than 100 km². Large ones that cover an area greater than 100 km² and mostly have granite in their composition are known as batholiths. They are associated with metamorphosing or melting adjacent rocks while they develop under the land surface. The best examples of batholiths can be found in California; for example, the Sierra Nevada Batholith is a continuous granitic form. Another larger batholith is located in the Coast Mountains of western Canada, and stretches for about 1800 km to southeastern Alaska.

The other type of intrusion is related to the injection of magma into fractures and between two layers of sedimentary rock without changing the surrounding rocks. A laccolith is associated with the horizontal flow of magma between two layers of rock in a bump shape. These sedimentary layers are often eroded and leave a resistant feature of mountains or hills. They form like a pipe in which the cap is connected to the source of magma by a stem. The Henry Mountains of Utah are one of the typical laccolith sites in North America.
There are also other smaller intrusive features that can be exposed by erosion. One of those small forms is termed a sill, created by intrusion of magma in a flat shape between rock layers without pushing overlaying layers upward. Sills are known as harder strata in geology. They may develop to be hundreds of meters thick, such as some unique sills in Tasmania, but usually they are between 10 and 30 m thick.

The pressure on magma can cause a vertical injection into the fractures within a rock body. These wall-shaped structures, named dikes, are always younger than their surrounding rocks. However, tectonic processes can change the form of dikes from vertical to horizontal sheets. Volcanic necks are a kind of dike which results from magma solidifying in the central vent with the weak layers of cone eroded over time and the neck exposed as a resistant remnant standing above the Earth’s surface. In Europe, volcanic necks are used as a unique place for constructing castles or chapels, such as Saint Michel d’Aiguilhe chapel in France or Trosky Castle in the Czech Republic.

Volcanic hazards

Volcanoes are a collection of processes and hazards in mountain regions, but they also include further hazards involved with eruptive activity. Direct hazards are the result of explosive activity whereas indirect hazards are the by-product of volcanic activity. Volcanoes may remain dormant for many years, but at the time of activity the consequences of hazards are severe and enormous. They contribute to the rapid change of the landscape and cause disruption by interrupting drainage systems and slope processes. Because of the combination of unconsolidated materials, such as pyroclastic fragments and ashes, and steep slopes that are highly fractured and faulted, slope hazards are common (Thouret 2010).

Pyroclastic flows are one of the direct hazards that are caused by explosive eruptions. They are among the most dangerous volcanic hazards because they are a moving body with high velocity and contain a large amount of pyroclastic materials and gas which can reach a temperature of 1000°C. In 1902, the eruption of Mount Pelée completely flattened the town of St Pierre in Martinique and killed some 30,000–40,000 people. Despite enormous eruptive activity prior to the event, the government did not take defensive measures. At that time the wrong perception of risk caused the death of the entire population.

Rockfalls, landslides, and debris avalanches accompany or follow eruptive activity. They are the collapse of a section of slope in which a huge mass of deposits moves rapidly downslope and destroys everything in its path. One of the largest debris avalanches recorded in history is associated with the eruption of Mount St Helens, in the United States, in 1980. An initial earthquake caused the north side of the mountain to bulge. A second earthquake, of magnitude 5.1, led to a massive collapse.

Lava flows move slowly, but some of them can be sufficiently fast to cause destruction and fatalities. In 2002, Goma, in the eastern part of Congo, was destroyed by lava which spread through the center of the city. Lava destroyed 4500 houses and buildings and killed some people.

Tsunamis are the other deadly events resulting from seismic activity prior to or simultaneous with the incidence of volcanic eruptions, which transfer a high level of energy to sea waves. Because many shorelines are densely populated, they can severely affect coastal populations. The 2011 earthquake off the coast of Tohoku in Japan triggered powerful seismic waves which reached...
heights of up to 40 m. In this catastrophic event, 15,893 people lost their lives.

Lahars are a mixture of hot pyroclastic materials and rock debris, which start flowing down a steep slope and are able to melt snow and glaciers on their way. This will result in a muddy and fast-flowing stream. The rock boulders carried by lahars make them devastating while the muddy flows spread over the populated plains and far away from the source. The eruption of the Nevado del Ruiz volcano in 1985, in Colombia, South America, resulted in a tragic event. Pyroclastic flows melted the glaciers on the way and formed a lahar moving down the slope at a speed of 60 km per hour. It buried the town of Armero, killing more than 20,000 people.

Voluntarism and the voluntary sector

Mark Skinner
Trent University, Canada

Andrew Power
University of Southampton, UK

The voluntary sector is a complex and increasingly complicated sphere of twenty-first-century society. It comprises a myriad of diverse and heterogeneous self-governing associations of people who have a mutual interest in providing services, support, education, advocacy, self-help, and, in some cases, activism and resistance. The sector is also referred to, often synonymously, as the third sector (in between the state and market), nonprofit sector (versus the for-profit sector), community sector (alongside government and business), nongovernmental sector (alongside government and business internationally), or the social economy (in between the private and public spheres of activity). Each term is derived from particular historical–geographic contexts, such as the prevalence of the nonprofit sector in North America, social economy in continental Europe, and nongovernmental (in relation to international) development in the Global South.

Some, but not all, within the voluntary sector are charities. Many have statutory sources of funding. Some rely primarily on voluntary fundraising and/or grant-in-aid funding, while others have detailed contracts/service agreements with state agencies. Given the heterogeneous nature of voluntary organizations, they can be differentiated by their size and organizational structure, and range from small community groups to international development organizations.

Volunteers, those individuals who contribute their time freely, are essential to the voluntary sector. Most voluntary organizations involve volunteers formally in some fashion, in front-line and/or governance roles. Although not established for financial gain, many voluntary organizations also have paid employees and can be highly professional. There is, however, growing recognition of the scope and importance of individuals who volunteer their time informally, without association to voluntary organizations. Taken together, the actions of the voluntary sector and volunteers, both formal and informal, are rooted in the broader philosophy of voluntarism – that is, noncoerced action, usually for public benefit, outside the constraints of the state. In principle, this means that voluntary bodies do not depend on statute or the market for their existence or purpose.

Yet, as has become evident over the past quarter of a century, voluntarism and the attendant activities of the voluntary sector and volunteers are increasingly intertwined with the state and private interests as welfare societies have evolved. Given the importance and complexity of the sector, the study of voluntarism involves understanding the spatially uneven and place-specific nature of the voluntary sector and volunteering. Interest in geographical dimensions is long-standing and was renewed recently as part of a broader voluntary turn across the social sciences over the past two decades. At the heart of what is
now referred to as “geographies of voluntarism” has been an effort to tackle the multidisciplinary challenge of understanding voluntarism in an era of globalization, welfare state restructuring, and demographic ageing. Such work is set against the backdrop of a widespread rediscovery of voluntarism within political debates on the role of the voluntary sector. Largely confined to the Global North, debates on where the voluntary sector is positioned vis-à-vis the state have long been a focus in many countries, particularly within the context of welfare and care systems worldwide. In the early twenty-first century, national and subnational governments are increasingly turning to voluntary organizations for the delivery of many services, including local transport, libraries, information and advocacy, and health and social care. Debates over how the voluntary sector operates have become increasingly relevant. At the same time, the voluntary sector (and volunteers) in many countries has always played a role parallel with the state. Nonetheless, for much of recent history, the sector has operated outside the state’s remit, as family and friends’ associations, and community (parish)-based and mutual charities. The increasing ways that the sector has become involved – and invoked, even co-opted – by the state has led to a growing recognition of the crucial importance of understanding how voluntary sector activities are manifest geographically. The new scales, places, and spaces that the sector increasingly occupies give rise to wholly new spatial dimensions, as well as prompting new theoretical and methodological debates about the sector’s future role in society. Such debates, however, remain predominantly focused on the Anglo-American-Australian/New Zealand context of voluntarism in the Global North.

Evolution of voluntarism and the voluntary sector

The voluntary sector has evolved from the primary to a supplementary and even subservient provider of welfare services and support alongside the state. Historically, the voluntary sector has had a long-standing role within the provision of support for those in need in society, including many who were poor, destitute, sick, or old. Partly in resistance to state involvement in the lives of individuals and families, voluntary services traditionally have included almshouses, private philanthropy-based institutions, and religious-based charities, as well as extending to the administration of hospitals and early mental health asylums. This primary faith-based role in alleviating destitution continues today, especially in countries of the Global South.

The widespread repositioning of the state as the primary provider of welfare, with the voluntary sector playing a more supplementary role, began in the early nineteenth century with the establishment of publicly funded asylums across the United Kingdom, Europe, Scandinavia, and North America, as well as the Soviet Union. It was further entrenched in the welfare states that were established across Anglo-America and Western Europe following World War II. Even in strongly Catholic countries such as Spain, Portugal, and Ireland, state provision of services gradually extended into many areas of public life. In essence, the policy of viewing voluntarism as the “extension ladder” was promoted, with the idea that the voluntary sector would provide specialist services or add-ons to those provided publicly; however, this supplementary role within the welfare state would change with the growing mistrust in what many saw as paternalistic public services in the postwar era.
In the last quarter of the twentieth century, a further repositioning of the voluntary sector was sparked by fiscal crises and a broader neoliberal-inspired rolling back of the welfare state via restructuring of health-care and welfare systems. Attendant devolution, divestment, and downloading within welfare states coincided with deinstitutionalization and other community-oriented policies to create more demand and responsibility for voluntary sector support. For instance, people with mental health and other issues, who had previously been cared for by the state in public institutions, now had to rely on the “patchwork quilt” of volunteer-based community services that became the prominent form of service delivery throughout the 1980s and 1990s. The patchwork model of voluntary support was emulated throughout health and social care, leading to policy concerns about service coordination and accessibility, as well as uncertainty about the sustainability of volunteer-based support in general.

Interest in the geographical implications of the evolving position of voluntarism vis-à-vis the state began to emerge as geographers, initially in North America, then in the United Kingdom and elsewhere, traced how volunteer services in the neoliberal era were located in ghettoized, inner-city metropolitan areas, which were often stigmatized places, given the punitive view of the welfare class that used their services. Out of this situational work arose a major contribution to the political economic critique of public service restructuring – Wolch’s (1990) pivotal conceptualization of the voluntary sector as a shadow state, with attendant questions about its role in, and capacity for, delivering health-care and welfare services. The term “shadow state” refers to the repositioning of the voluntary sector from providing a complementary or supplementary role to being seen as an alternative and, in some cases, a subservient (or co-opted) provider of health and community care services. Underpinning this work was a wider belief that public welfare retrenchment was eroding the centralist and universalist foundations of support services. In turn, many scholars argued it would lead to a more fragmented, decentralized, and ad hoc provision of support, reliant on a piecemeal voluntary sector. Wolch’s conceptualization provides a critical, and still relevant, appraisal of how far voluntary sector providers may come to look more like public sector providers. This trend is particularly apparent in the increasing professionalization of much of the voluntary sector, and its corporate positioning within or alongside the state that is evident across the range of voluntary organizations today.

The shadow state phenomenon has arguably become more pervasive since the turn of the twenty-first century, as public service restructuring and the emphasis on a greater role for the voluntary sector has emerged as a defining feature of welfare state reform across Europe, North America, and elsewhere. It is possible to identify the macro-level shifts in how the sector has been recognized and co-opted through different political governance models, including neoliberal contexts. For instance, the United Kingdom’s “third way” agenda in the 1990s and early 2000s sought to reconcile right-wing and left-wing politics by advocating a synthesis of right-wing economic and left-wing social policies. Under this political project, which has been emulated elsewhere, the voluntary sector was to encompass all nonprofit organizations, including social enterprises, cooperatives, and charities of all shapes and sizes. This development coincided with a large rise in the profile of the sector and an upward shift in the scope and scale of voluntary action. Alongside this change in policy and discourse came structural changes to support state and voluntary sector partnerships, which marked a new “settlement” (or compact) in the
voluntary–state relationship, one that promises a further repositioning of the voluntary sector as partner in the provision of services.

In response to the renewed focus on the voluntary sector, a growing number of geographical studies in Canada, New Zealand, the United Kingdom, and the United States have focused on the implications for voluntarism of the rationalization, privatization, and devolution of health-care and welfare services. These effects have been borne out in terms of how and where organizations operate and with whom they work. This particularly productive body of work, exemplified in the groundbreaking book by Milligan (2001), has explored the implications of restructuring processes for local communities and individuals, and traced the changing roles and responsibilities of voluntary organizations, volunteers, and families. The impacts of this evolving context have been examined through a range of voluntary sector services, including home care, community support, counseling, literacy, sport and health promotion, HIV/AIDS care, hospices, hospitals, long-term care, mental-healthcare, urban homeless shelters, and rural elderly care.

As noted, most of the current literature is focused on the Global North context of voluntarism, even though the positioning of the voluntary sector is known to have evolved quite differently in many countries across the Global South as well as in post-Soviet countries. In Eastern Europe, for instance, the voluntary sector remains a primary provider, as the state has continued its residual “last resort” role in the form of institutions and comparatively punitive welfare services. In contemporary communist countries, such as China, the role of voluntarism and the voluntary sector traditionally has been restricted to state-sanctioned activities, mostly in relation to culture and the environment. In the broader Global South context, voluntarism has evolved to comprise primarily nongovernmental organizations (NGOs) that, in some countries, fund and/or provide the majority of health-care services. The development of a voluntary sector comprised of NGOs in the Global South, however, has seen phenomenal growth and proliferation. Their contribution has been linked primarily with development projects but they also have opened up a political space at the local level as an alternative to state-led structures and mechanisms. At the same time, NGOs are often integrated into national and global systems in ways that voluntary organizations in the Global North often are not. In addition, there is the phenomenal growth of “volunteer tourism,” as explored through the work of Sin (2010), driven by social initiatives like sustainable development, ethical consumerism, and “first world responsibilities to the third world.”

Scales, places, and spaces of voluntarism

The previous discussion offers an account of the ways in which voluntarism and the voluntary sector have evolved around the world and the different positions they have occupied in relation to the state, and the ways in which such positioning has been conceived and critiqued. Turning to geographical dimensions, the voluntary sector has been “mapped” empirically in comparative contexts, for instance, in the interdisciplinary Johns Hopkins University “Global Civil Society in Comparative Perspective” project. As noted by Milligan and Conradson (2006) in their seminal anthology of the field, this interdisciplinary work confirms the spatially uneven landscapes of voluntarism and volunteering that have emerged between and within the Global North and Global South at the turn of the twenty-first century. This comparative work also reveals important gaps in knowledge around volunteering internationally, most notably
in regards to gender and development studies, population ageing and community development, and environmental governance.

Alongside these international comparisons is a body of work that has sought to trace the scales, places, and spaces of the voluntary sector and volunteering within national borders, and the resulting “geographies of voluntarism” that have materialized at the national, local, and individual levels. Geographers have been attuned to the process of voluntary organizations “jumping scale” from local to national and, indeed, from national to international scales (e.g., European Union, United Nations). At each scale, there are varying benefits and risks involved in terms of funding, level of political involvement, and ability to make change. This work usefully illustrates the varying spatial practices and strategies of voluntary organizations, and how such organizations try to best adapt these to suit the needs of their clients. Some organizations are very sensitive to scale: for instance, some disability groups feel their activities become diluted and/or they become too distant to their client groups by jumping scale from local and more service-driven activities to national and more political activities.

At the national scale, various attempts at mapping the voluntary sector have been undertaken within new, nationally focused research initiatives, such as the Birmingham (UK) Third Sector Research Centre. This work reveals discernible patterns of voluntary sector activity on the landscape, shaped by different political contexts. For example, Mohan and Bulloch (2012) point to the dispersed and fragmented nature of the “civic core” of voluntary activity across the United Kingdom, which they found to consist of one-third of the population, which provides the vast majority of volunteering hours and participation in civic associations, as well as the amount given to charity. Members of the civic core, they discovered, are drawn predominantly from the most prosperous, middle-aged, and highly educated sections of the population, and are most likely to live in the least deprived parts of the country. This is a crucial point, as governments are increasingly turning to the sector to fill the gaps in welfare support for the most needy. The concept of civic core is used to reveal the gap between the government rhetoric associated with policy and the reality on the ground, where many “charity deserts” occur. In the UK context, for instance, the current “big society” government agenda has sought to redefine the relationship between voluntarism and society by calling on individuals to play a larger role in volunteering. This political project deploys a narrative associated with the middle-class volunteer of the Victorian “golden age” of voluntarism, and of all parts of society contributing regardless of class, religion or gender. It also emphasizes and seeks to champion the ubiquity of “everyday” volunteering, as seen in support of libraries, school activities, and sports, for instance, which account for a significant proportion of volunteer hours within national surveys.

In other national contexts, such as Canada and the United States, this rhetoric has become a typical narrative alongside (and perhaps associated with) the wider welfare retrenchment and restructuring of the voluntary sector discussed in the previous section, and is having profound material outcomes for voluntarism and the shape of the voluntary sector on the ground. At the subnational scale, there have been growing expectations and pressures to fill gaps in urban welfare services and to occupy an increasingly public stage in terms of having to provide wider community services. There has also been a corresponding push towards individualism, which has been propelled by the rise of self-directed support. Self-directed support refers to growing expectations that welfare service recipients will
become more autonomous and responsible for their own care and wellbeing. Such expectations are arguably characteristic of neoliberal constructions of economic life and have implications for expectations of volunteers. As DeVerteuil (2012) argues, however, the supportive approaches by volunteers and voluntary organizations to groups deemed vulnerable (e.g., people with mental health problems, the homeless, the elderly) have been downplayed by many mainstream accounts that have become largely fixated on the punitive accounts of injustice in the city – particularly within contexts where the residual neoliberal welfare state reigns. In this sense, injustice must coexist with and depend upon more supportive, charitable currents within urban space. Voluntary sector support at a very fundamental level can be seen to facilitate the broader processes of neoliberal capitalism to continue.

At the local scale, the role of voluntarism has emerged as a means of explaining disparities in local manifestations of health and care, as well as spaces of resistance to structural changes in health-care systems. Geographic work has also examined how voluntary organizations and volunteering have become embedded in particular places. There is an underlying concern for understanding the importance of “place” in explaining how and why the voluntary sector is manifest quite differently among and within various types of communities, locales, and environments. Geographers have increasingly advocated for a nuanced understanding of the role of voluntarism in the formation of places, for instance, in the World Health Organization (WHO)’s global age-friendly cities initiative, which identifies volunteering as a key determinant of successful community development in an era of population ageing. Attention to the compositional and transformative nature of place (as a physical and social phenomenon) has led to a greater understanding of the local dynamics of voluntarism. This development is seen not only in metropolitan and urban settings but also in various rural and more remote areas, where volunteer-based support is seen to be a crucial community and individual asset. Indeed, the place-embeddedness of the voluntary sector and volunteering is fundamental for understanding the uneven landscapes of voluntarism that have emerged in recent decades. Key studies have also examined the physical, representational, and emotional aspects of place in relation to voluntary care activities from the household, to the community, to the school or clinic, and beyond. As seen in work by Skinner and Joseph (2011), the underlying emphasis is on the social construction of place and the transformative potential of voluntarism in place formation, such as the role of older volunteers in leading initiatives to create age-friendly rural communities, thus advancing understanding of the place-embeddedness of voluntarism. It also reveals the ways in which people respond to the power dynamics associated with health and care in their particular locales, such as in resistance to health-care restructuring (Milligan 2001).

At the micro (individual) scale, the embodied dimensions of volunteering at the individual level have also garnered research, from accounts of front-line volunteers in urban homeless shelters, to the experiences of volunteer health promoters in rural parts of South America, and to biographical accounts of the life stories of volunteer activists. As is evident in the contributions to a special issue of *Health & Place* edited by Skinner and Power (2011), the underlying emphasis is on understanding how voluntarism shapes, and is shaped by, the experiences of people and the places in which they volunteer. For instance, Milligan, Kearns, and Kyle (2011) reveal how those involved in and committed to voluntarism invoke memories and develop strong personal narratives about place-based
struggles, and reflect on the importance of place in shaping their activist roots.

To further understand the (uneven) landscape of the voluntary sector across scales and within places, an appreciation of the different spaces the voluntary sector occupies is required, as well as of the place-specific ways in which voluntarism occurs. There are myriad spaces and places which the voluntary sector occupies, uses, manages, and resists. Understanding voluntarism as a multifaceted process that operates across urban, economic, political, and social spaces has become increasingly useful for the development of informed policy at various levels, from the national state to the regional government and even more locally. In terms of the spaces of welfare within the city (e.g., voluntary homeless shelters, drop-in centers), for instance, geographers have argued that these sites have a lot more to offer marginalized groups than basic survival or a “last resort” service. They are also a “space of refuge” away from stigma and where normal rules do not apply and it is claimed that everyone is welcome regardless of their background. These spaces also serve other purposes: to utilize facilities (relevant for those with more complex and multiple challenges); to socialize; to kill time and to gain information. It must be acknowledged, however, that these settings can also be problematic, where clients can often experience infantilization, stigmatization, patronization, and exclusion due to the complex codes of behavior and subtle forms of policing that are often interwoven within these sites. Other work has focused on understanding how the voluntary sector can occupy a “space of resistance” to the growing pressure to take on new and greater roles in services provisioning on the ground as well as on wider social justice issues. Building on the seminal work of Wolch (1990), Milligan (2001), and others, there have been increasingly sophisticated theorizations of, and empirical inquiries into, voluntarism as a response to structural and socioeconomic changes, such as restructuring health-care systems, urban homeless shelters, and ageing rural communities, as already noted.

Expanding on these lines of inquiry, new forms of voluntarism are being observed within a range of social movements that are responding in different ways to state practices around the world. For instance, scholars examining volunteer activism in the wake of the 2007–2008 global financial crisis – and the attendant calls for austerity measures among Western governments, the IMF, and the World Bank – have highlighted the varying and contested spaces of participation and resistance that have evolved in response to the further rolling back of the state in terms of social welfare provisioning in different societies, and in different socioeconomic climates. Movements such as Occupy and Anonymous often reject the notion that twenty-first-century state restructuring policies are simply governmental responses to the hardship associated with fiscal crisis (as in the rhetoric of “keep calm and carry on”). They argue rather that policies such as austerity are neoliberal political projects in their own right that exacerbate this hardship. Much of this work has been informed by (post-) Marxist geography, led most prominently by the seminal work of David Harvey. He has examined the resistance movements and revolutionary urban struggles that have mobilized in reaction to the effects of global capital accumulation, including volunteer-based activist groups. Work in this vein, including studies of the Arab Spring revolutions in the Middle East and North Africa, has examined how resistance movements have collectively taken over public space and, through their actions, made it more inclusive and accessible. In this way, what makes a space public is often not its preordained “publicness” but is the result of various strategies and acts of resistance that often involves volunteers.
and volunteering. While broader in scope than voluntarism, this work nonetheless illustrates how civil society (and the voluntary sector) can mobilize in response to utopian visions of society, as well as to issues concerning the organization of everyday economic and social life.

Geographers have also become more attuned to the democratic spaces opened up by volunteers, activists, and organizations seeking to represent the identity of, and make claims for rights and recognition for, constituent groups (e.g., lesbian, gay, bisexual, and transgender (LGBT) people, ethnocultural minorities, older persons). This relational geography reveals a complex set of voluntary spaces where small charitable bodies and highly professionalized nonprofit organizations coalesce. A core concern of this work is how such spaces of voluntarism seek to reshape the citizenship status of individuals, and to examine the motivations and strategies behind the coalescence of different interest groups around, for example, defense, mutual support, culture or language preservation, and resistance. These varying motives often relate to the broader civil society context that voluntary groups occupy. For example, during the “troubles” in Northern Ireland, local people sought to withdraw from the hostility of wider society and create mutual societies based on strong religious grounds. Meanwhile, gay people have often mobilized for mutual support and resistance (for example, groups such as Stonewall), in an attempt to cultivate more safe spaces and to maintain the notion of queer lifestyles. While work has focused on the importance of voluntarism in these fields, others have criticized these movements for their essentializing tactics of creating group identities and their political positioning in relation to the state. As an indirect outcome of their identity politics, to fit in within these groups often involves performance of certain roles. Often they create duties and obligations for members, who may feel under constant surveillance to ensure that they behave in an appropriate way (e.g., Muslim women).

Conclusion

The growing interest in and research into volunteering across the social sciences in the early twenty-first century is evident in the multidisciplinary and widespread policy concern about the implications of the uneven landscapes of voluntarism. This concern has been propelled, in no small part, by the enduring gaps in knowledge about the geographical dimensions of voluntary sector activities and volunteering. In response to this gap, much work has sought to understand voluntarism in an era of globalization, welfare state restructuring, and demographic ageing. As part of this work, the evolution of geographical conceptions of and empirical investigations into voluntarism (from the shadow state to spaces of resistance) has highlighted the crucial differences that “scale,” “place,” and “space” make to understanding the processes, outcomes, and implications of voluntary sector activities. This recognition of the place-specific ways in which voluntarism occurs is evident within particular contexts (from metropolitan to remote) and among various scales (from household to global). Underlying the contributions of geography and geographers, however, are the implicit connections to concepts of scale, place, and space that link geographies of voluntarism and provide the foundation for the emerging and, arguably, increasingly explicit spatial turn in voluntary sector studies more generally.

Despite, or perhaps by virtue of, this work, the lack of consensus surrounding the defining scope and character of the voluntary sector remains a challenge. Given its broad range, there are myriad ways in which its constituent organizations, groups, and volunteers (both
formal and informal), can shape and be shaped by the wider changes occurring in the early twenty-first century. This recent period offers both challenges and opportunities for the sector, in terms of how it responds to socioeconomic, demographic, and environmental change. Looking forward, the idea of the postwar welfare state’s supplementary positioning of the voluntary sector is rapidly becoming a distant memory. Yet, given the now ubiquitous nature of welfare reform and the ongoing political project to roll back the state, debate over the role of the voluntary sector and volunteering will continue to be at the forefront of public policy worldwide. Geographical knowledge, especially in regards to other aspects of voluntarism, such as gender and development studies, population ageing and community development, ethnocultural and religious identities, and the environment, will be an essential part of understanding the proliferation of new forms of voluntarism in response to these challenges.

Volunteered geographic information: quality assurance

Mordechai (Muki) Haklay
University College London, UK

Volunteered geographic information (VGI) originates outside the realm of professional data collection by scientists, surveyors, and geographers. Quality assurance of such information is important for people who want to use it, as they need to identify if it is fit for purpose. Goodchild and Li (2012) identified three approaches for VGI quality assurance: the “crowdsourcing” approach, which relies on the number of people that edited the information, the “social” approach, based on gatekeepers and moderators, and the “geographic” approach, which uses broader geographic knowledge to verify that the information fits into the existing understanding of the natural world. In addition to the approaches that Goodchild and Li identified, there are also the “domain” approach, which relates to the understanding of the knowledge domain of the information, the “instrumental observation” approach, which relies on technology, and the “process-oriented” approach, which brings VGI closer to industrialized procedures. First we need to understand the nature of VGI and the source of concern regarding quality assurance.

While the term “volunteered geographic information” is relatively new (Goodchild 2007), the activities that this term describes are not. Another relatively recent term, “citizen science” (Bonney 1996), which describes the participation of volunteers in collecting, analyzing, and sharing scientific information, provides the historical context. The collection of accurate information by nonprofessional participants has been an integral part of scientific activity since the seventeenth century and likely before (Bonney, Shirk, and Phillips 2013). Therefore, when approaching the question of quality assurance of VGI, it is critical to see it within the wider context of scientific data collection and not to fall into the trap of novelty. Thus, approaches to ensure that such information is of suitable quality, and the handling of information about quality aspects, can be based on well-established methods that were developed in the past.

Yet, this integration needs to take into account the insights that have emerged within geographic information science (GIScience) research over the past decades. Within GIScience, it is the body of research on spatial data quality that provides the framing for VGI quality assurance. Van Oort’s (2006) comprehensive synthesis of various quality standards identifies the following elements, which are commonly considered when spatial data quality is discussed.

- **Lineage** – description of the history of the dataset and how it was collected and evolved.
- **Positional accuracy** – how well the coordinate value of an object in the database relates to the reality on the ground.
- **Attribute accuracy** – as objects in a geographical database are represented not only by their geometrical shape but also by additional attributes, this measure evaluates how correct these values are.
- **Logical consistency** – the internal consistency of the dataset, in terms of topological
correctness and the relationships that are encoded in the database.

- **Completeness** – a measure of the lack of data; that is, an assessment of how many objects are expected to be found in the database but are missing, as well as an assessment of excess data that should not be included. In other words, how comprehensive the coverage of real-world objects is.

- **Semantic accuracy** – linking the way an object is captured and represented in the database to its meaning and the way in which it should be interpreted.

- **Usage, purpose, and constraints** – this is a fitness-for-purpose declaration that should help potential users in deciding how the data should be used.

- **Temporal quality** – this is a measure of the validity of changes in the database in relation to real-world changes and also the rate of updates.

Naturally, the definitions above are shorthand and aim to explain the principles of geographical information quality. The burgeoning literature on spatial data quality provides more detailed definitions and discussion of these aspects.

While some of these quality elements might seem independent of a specific application, in reality they can only be evaluated within the context of use. For example, when carrying out analysis of street lighting in a part of town, the question of completeness becomes specific regarding the recording of all street-light objects within the bounds of the area of interest; whether the dataset includes these features for another part of the settlement is irrelevant for the task at hand. This is true for all other quality elements. The scrutiny of information quality within a specific application to ensure that it is good enough for the need is termed “fitness for purpose.” Fitness for purpose is a central issue with respect to VGI.

To understand the reason that geographers are concerned with quality assurance of VGI, we need to recall the historical development of geographic information and, especially, the historical context of geographic information systems (GIS) and GIScience development since the 1960s. For most of the twentieth century, geographic information production was professionalized and institutionalized. The creation, organization, and distribution of geographic information was completed by official bodies such as national mapping agencies (e.g., France’s Institut géographique national) or national geological bodies (such as the British Geological Society) which were funded by the state to carry out mapping activities. As a result, the production of geographic information became an industrial scientific process in which the aim was to produce a standardized product – commonly a map. Due to financial, skill, and process limitations, products were engineered carefully so they could be used for multiple purposes. Thus, a topographic map could be used for navigation and also for urban planning and many other purposes. Because the products were standardized in terms of scale or the type of geographical features that were recorded, detailed specifications could be drawn against which the quality elements could be tested, and quality assurance procedures could be developed to ensure that the surveyor collected the necessary information on the ground and the cartographer tested her map before sending it to the printing press. This was the backdrop to the development of GIS and to the conceptualization of spatial data quality.

The practices of centralized, scientific, and industrialized geographic information production lend themselves to quality assurance procedures that are deployed through organizational or professional structures, and explain the perceived challenges with VGI. For example, procedures for appropriate calibration
VOLUNTEERED GEOGRAPHIC INFORMATION: QUALITY ASSURANCE

of photogrammetric equipment can be drawn up and then applied every time an operator starts a work session. Centralized practices also support employing people with the focus on quality assurance, such as going to the field with a map and testing that it complies with the specifications that were used to create it. In contrast, most of the collection of VGI takes place outside organizational frameworks. The people who contribute the data are not employees and seemingly cannot be put into training programs, asked to follow quality assurance procedures, or expected to use standardized equipment that can be calibrated from time to time. The lack of coordination and top-down forms of production raises questions about ensuring the quality of the information that emerges from VGI.

To consider quality assurance within VGI requires understanding of some underlying principles that are common to VGI practices and so differs from organized and industrialized geographic information creation. For example, some VGI is collected under conditions of scarcity or abundance in terms of data sources, number of observations, or the amount of data that is being used. As noted, the conceptualization of geographic data collection before the emergence of VGI was one of scarcity, where data is expensive and complex to collect. In contrast, in many applications of VGI the situation is one of abundance. For example, in applications that are based on microvolunteering, where the participant invests very little time in a fairly simple task, it is possible to give the same mapping task to several participants and statistically compare their independent outcomes as a way of ensuring the quality of the data. Another area where the abundance concept can be useful is in the development of software for data collection. While in previous eras there would be inherently one application that was used for data capture and editing, in VGI there is a need to consider multiple applications, as different designs and workflows can appeal and be suitable for different groups of participants.

Another underlying principle of VGI is that, since the people who collect the information are not remunerated or in contractual relationships with the organization that coordinates data collection, a more complex relationship between the two sides is required, with consideration of incentives, motivations to contribute, and the tools that will be used for data collection. Overall, VGI systems need to be understood as sociotechnical systems in which the social aspect is as important as the technical part.

In addition, VGI is inherently heterogeneous. This is due to the principle above – because the process is not controlled in a top-down manner it cannot follow attempts to capture all the information in an orderly way. In large-scale data collection activities such as the census of population there is a clear attempt to capture all the information about the population over a relatively short time and in every part of the country. In contrast, because of its distributed nature, VGI will vary across space and time, with some areas and times receiving more attention than others. An interesting example has been shown in temporal scales, where some citizen science activities exhibit “weekend bias” as these are the days when volunteers are free to collect more information. For more details, see Volunteer geographic information.

Because of the difference in the organizational settings of VGI, a different approach to quality assurance is required, although, as noted, in general such approaches have been used in many citizen science projects. Over the years, several approaches have emerged and these include “crowdsourcing,” “social,” “geographic,” “domain,” “instrumental observation,” and “process-oriented” approaches.
The “crowdsourcing” approach builds on the principle of abundance. Since there are a large number of contributors, quality assurance can emerge from repeated verification by multiple participants. Thus, if several participants deliver Global Positioning System (GPS) tracks for the same road while driving their car and all the tracks contain the evidence of fast driving, we can be confident that the road is there and suitable for private vehicles. Even in projects where the participants actively collect data in an uncoordinated way, such as the OpenStreetMap project, it has been shown that, with enough participants actively collecting data in a given area, the quality of the data can be as good as authoritative sources. The limitation of this approach is when local knowledge or verification on the ground (“ground truth”) is required. In such situations, the crowdsourcing approach works well in central, highly populated or popular sites where there are many visitors and therefore the probability that several of them will be involved in data collection rises. Even so, it is possible to encourage participants to record less popular places through a range of suitable incentives.

The “social” approach also builds on the principle of abundance in terms of the number of participants, but with a more detailed understanding of their knowledge, skills, and experience. In this approach, some participants are asked to monitor and verify the information collected by less experienced participants. The social method is well established in citizen science programs such as bird watching, where some participants who are more experienced in identifying bird species help to verify observations made by other participants. To deploy the social approach, there is a need for a structured organization in which some members are recognized as more experienced and are given the appropriate tools to check and approve information.

The “geographic” approach uses known geographical knowledge to evaluate the validity of the information that is received by volunteers. For example, by using existing knowledge about the distribution of streams from a river, it is possible to assess if mapping contributed by volunteers of a new river is comprehensive or not. A variation of this approach is the use of recorded information, even if it is out of date, to verify the information — for example, by comparing how much of the information that is already known about a location also appears in a VGI source. Geographic knowledge can be potentially encoded in software algorithms that evaluate new information in light of existing knowledge.

The “domain” approach is an extension of the geographic one and, in addition to geographical knowledge, uses a specific knowledge that is relevant to the domain in which information is collected. For example, in many citizen science projects that involve collecting biological observations there will be some body of information about species distribution both spatially and temporally. Therefore, a new observation can be tested against this knowledge, again algorithmically, to help ensure that it is accurate.

The “instrumental observation” approach removes some of the subjective aspects of data collection by a human, who might make an error, and relies instead on the availability of the equipment that the person is using. Because of the increase in availability of sufficiently accurate equipment, such as the various sensors that are integrated in smartphones, many people keep, in their pockets, mobile computers with the ability to collect location, direction, imagery, and sound information. For example, image files that are captured in smartphones include,
in the file, the GPS coordinates and time-stamp which, for a vast majority of people, are beyond their ability to manipulate. Thus, the automatic instrumental recording of information provides evidence of the quality and accuracy of the information.

Finally, there is a “process-oriented” approach, which brings VGI closer to traditional industrial processes. Under this approach, the participants go through some training before collecting information, and the process of data collection or analysis is highly structured to ensure that the resulting information is of suitable quality. This can include provision of standardized equipment, online training, or instruction sheets, and a structured data recording process. For example, volunteers who participate in the US Community Collaborative Rain, Hail & Snow Network (CoCoRaHS) receive a standardized rain gauge, instructions on how to install it, and online resources to learn about data collection and reporting.

Importantly, these approaches are not used in isolation and any given project is likely to see a combination of them in operation. Thus, an element of training and guidance for users can appear in a downloadable application that is distributed widely; therefore the method that will be used in such a project will be a combination of the process-oriented and the crowdsourcing approaches. Another example is the OpenStreetMap project, which, in general, gives limited guidance to volunteers in terms of information that they collect or the location in which they collect it. Yet, a subset of the information collected in the OpenStreetMap database about wheelchair access is completed through the highly structured process of the WheelMap application in which the participant is required to select one of four possible settings that indicate accessibility. Another subset of the information, recorded for humanitarian efforts, follows the social model in which the tasks are divided between volunteers using the Humanitarian OpenStreetMap Team (HOT) task manager, and the data that is collected is verified by more experienced participants.

The final, and critical, point for quality assurance of VGI is fitness for purpose. In some VGI activities the information has a direct and clear application, in which case it is possible to define specifications for the quality assurance elements that were listed above. However, one of the core aspects noted above is the heterogeneity of the information that is collected by volunteers. Therefore, before using VGI for a specific application, there is a need to check for its fitness for this specific use. While this is true for all geographic information – and even so-called authoritative data sources can suffer from hidden biases (e.g., lack of update of information in rural areas) – the situation with VGI is that variability can change dramatically over short distances – so while the center of a city will be mapped by many people, a deprived suburb near the center will not be mapped and updated. There are also limitations that are caused by the instruments in use – for example, the GPS positional accuracy of the smartphones. Such aspects should also be taken into account, ensuring that the quality assurance is also fit for purpose.

Jonathan Cinnamon  
*University of Exeter, UK*

Origin and meaning

Volunteered geographic information (hereafter VGI) is defined as “geographic information acquired and made available to others through the voluntary activity of individuals or groups, with the intent of providing information about the geographic world” (Elwood, Goodchild, and Sui 2012, 575). The growth of VGI in the past 10 years is a result of several related technological advances and scientific practices, such as Web 2.0, Geoweb, spatial media, neogeography, citizen science, crowdsourcing, and open science (Rice *et al.* 2012). Goodchild (2007) coined the term VGI to describe what he viewed as a different form of spatial data production that contrasted with more conventionally produced geographic information, and to emphasize the potential role of VGI in augmenting our knowledge of the geographic world. VGI often differs from conventionally produced forms of geographic information, including the types of information produced and the approaches used to acquire it, the methods and techniques for working with it, and the social processes that mediate its creation.

Despite the increased attention to VGI in recent years, voluntary spatial data collection efforts are not new and can be traced back before the age of Web 2.0. A host of related movements have helped enable VGI as a phenomenon. One of the earlier examples was the Christmas Bird Count starting back in 1900. In geography, Bill Bunge’s “Geographical Expeditions” involved local residents in counter-mapping and spatial data production efforts in Detroit in the 1970s (Bunge 1971). In the United Kingdom, the BBC’s Domesday Project in the 1980s used volunteers and community groups to assemble a digital spatial data archive (Openshaw, Rhind, and Goddard 1986). The explosive growth of VGI in the past decade is a result of several converging technological advancements. The traditional high cost of spatial data collection—which necessitated its production either by government agencies or corporations—has now been vastly reduced due to broad access to the portable global positioning system (GPS) devices, location-aware smartphones and other handheld/wearable devices, broadband Internet, and the availability of user-friendly mapping software.

In addition to declining costs and the emergence of accessible mapping technologies, another catalyst of VGI in the past decade has been the desire and need to produce user-generated content and maps about phenomena that are not covered by conventional data production activities. These include transient and ephemeral phenomena in time-sensitive situations, information that is less-readily quantifiable, or phenomena of interest to individuals and groups, but which have perhaps less significance to national mapping agencies and other traditional producers of spatial data.
Furthermore, during the past five years, interests in VGI have been merging with research agendas of the broader phenomenon of big data. As part of the big data deluge, VGI is also of interest to the private sector, which has taken an increasingly significant role in the production, archiving, dissemination, and use of geographic information in general. The private sector is also beginning to cash in on citizen data production efforts. This new trend raises a series of social, economic, and political issues regarding the production and use of VGI in society.

Types of VGI

There have been several efforts to develop VGI typologies according to the purpose of VGI (allocentric vs egocentric) or the nature/content of VGI (implicit vs explicit) (Craglia, Ostermann, and Spiniatti 2012; Engler, Scassa, and Taylor 2014). However, in the age of big data, the boundary between VGI and other types of geographic information/spatial data is rapidly blurring. In fact, as a special type of geographic information, VGI shares multiple commonalities with the traditional geographic information we have been dealing with so far. In general, VGI can be loosely grouped into three types: geospatial framework data, gazetteer/place name data, and miscellaneous geotagged content data (text, audio, photo, video, etc.) about various places/points of interest. Furthermore, VGI can be used to augment existing authoritative geospatial databases of various kinds.

A growing number of VGI initiatives are developing geospatial framework data. In general, framework data are the most common data themes geographic data users need and typically include seven themes: geodetic control, orthoimagery, elevation, transportation, hydrography, governmental units, and the cadaster. The framework data cover relatively static phenomena and are commonly used for municipal services and administration, geopositioning, and wayfinding. Until recently, the production of geographic framework data has been the exclusive responsibility of government agencies. Not all seven types of framework data are particularly well-suited to the VGI or crowdsourcing approach. For example, maintenance of the primary geodetic control system and the compilation of accurate elevation data require a high level of expertise in surveying, mapping, and advanced photogrammetry. Major investments in equipment are also a prerequisite for performing these tasks successfully. Furthermore, delineations of land tenure and ownership of governmental units such as voting districts or school districts are structured by laws and government policies. As such, citizen volunteers can only play limited roles (if any) in producing most types of geographic framework data although road network data is a notable exception. The primary responsibility for data compilation for most framework data will likely remain with professionals such as licensed surveyors with advanced training in mapping and photogrammetry.

The production of transportation and road network data using the VGI approach has been successful. OpenStreetMap (OSM), perhaps the best example of geospatial framework data collected by volunteers, is a collaborative global effort to produce a detailed, full coverage digital map of the world’s road networks (and some other features) through voluntary effort. Volunteers capture the locations of transportation infrastructure and topographic features by using GPS and tracing satellite imagery. Once compiled, these data are freely available as rendered online maps or for download as data files under the framework of creative commons. Users are free to use these data and to develop their own
In addition to the abovementioned VGI projects that have been designed to parallel conventional data collection efforts, there exists great potential to harness VGI as a data source for improving existing products. The impact of VGI on this process could be profound with potentially billions of sensors around the globe contributing to improving existing maps and databases. Instead of intermittent coverage by professionals when time and funds allow, VGI could offer more timely observations by distributed volunteers acting as an early warning system for local changes. There are a few examples that provide a template for how this approach could be more widely applied, by both the private and public sectors. The United States Geological Survey (USGS) has a program called the National Map Corps (http://nationalmap.gov/TheNationalMapCorps), which encourages members of the public to update the National Map. Corporations are widely using this model as well, including Google who are enlisting the help of the public through their MapMaker program and “report a problem” feature. These hybrid spatial data production activities could be particularly valuable since they could benefit from the strengths of both approaches, the low-cost and distributed nature of VGI and crowdsourcing initiatives and the oversight and quality control of conventional data production methods (Cinnamon 2014).

In addition to framework and gazetteer related data, VGI has also been used to produce attribute data – information about local phenomena. These nonframework VGI initiatives assemble data about some phenomenon for which the spatial distribution or patterns are significant and compile the observations of many contributors. This may be one of the most exciting aspects of VGI, the ability to produce data on any theme or phenomena of interest, including information
that has not previously been recorded (Cinnamon and Schuurman 2013). An emerging source of VGI may exist due to the emerging popularity of Apple iHealth, Google Fit, Jawbone UP, and other products that are producing personal health data (such as heart rate, calories, weight) that are geotagged. Although these types of data are personal and private, they could become a goldmine for health-related research if producers are willing to share and forgo privacy concerns.

Many VGI efforts produce thematic data using interactive mapping interfaces on the web, such that users of the site may contribute information to the map and dataset or gather information from it. Well-known platforms such as Google Maps and the Google API (application programming interface) can be modified to create map-based data collection interfaces for use in these projects. Although these platforms are a very commonly used data production tool, this type of VGI can be produced with more analog methods including text messaging. The Ushahidi platform can collect VGI contributed via text messages, which is then compiled and disseminated via an online map interface. In addition to interface and text message based strategies, VGI is also produced by georeferencing user-generated content online, typically through the practice of geotagging existing media such as audio/sound data (murmurtoronto.ca), photos (http://queue.acm.org/detail.cfm?id=2212756), and videos (Mills et al. 2010). Flickr, for example, encourages users to contribute geotagged photographs that can then be retrieved through a map interface along with text descriptions and links to other sources. This method of VGI production has grown significantly due to the automated georeferencing procedures in apps such as Twitter and due to the locating capabilities of handheld multimedia devices that automatically assign coordinates, location information, and attribute data to photos and other media.

Perhaps even more significantly, Google’s new mantra “Google Maps = Google in Maps” has made all the geotagged online VGI content searchable through Google Maps, which is revolutionary not only for geographic data production, but also for the design and development of search engines. More than just an easy way to georeference photos, this is potentially a valuable source of VGI. Twitter enables users to tag their tweets with locational information, a function that has already fostered interesting new possibilities for understanding the spatial patterns of very immediate or quickly changing situations, such as threat from wildfires or student-led occupying central protests in Hong Kong. A recent popular social media-based video collecting site is Vine (https://vine.co), a site that allows users to geotag all videos collected. While this type of VGI production typically occurs through users applying geotags to their own content, a growing number of geosocial networking applications are passively recording location information from their users, which requires very little if any input from the user. Many of these services are “opt in” meaning the user has to agree to share their location and activities (e.g., FourSquare, Instagram, Path, Vine, etc.), however, it is not always clear what the location information produced by the app’s users will be used for by the company. Given the range of ways that VGI is produced and the potential for producing new, previously unrecorded datasets, VGI has become an important area of geographic information science (GIScience) research. This represents a “wikification” of GIS (Sui 2008), a broader societal transformation in how geographic information is created and used. Exciting research both about and with VGI has been reported in recent years, as illustrated below.
Research about VGI

VGI quality assessment

Crowd-sourced data and VGI have been labeled by some as the scientific equivalent of fast-food, due to its ubiquity and relatively low cost to produce (Spielman 2014). This conceptualization poses an interesting question for the scientific community: is it healthy and safe to consume crowd-sourced data for research purposes given the limited ability to know its accuracy and credibility? The general consensus within the research community is that VGI offers an alternative mechanism for acquiring and compiling geographic information, but suffers from a general lack of quality assurance. Before applying VGI in any meaningful way, one must understand steps to assess the quality of VGI in hand.

In general, spatial data quality includes the following seven elements: position accuracy, attribute accuracy, logical consistency, completeness, lineage, temporal quality, and usage/purpose constraints. Goodchild and Li (2012) described three approaches for VGI quality assurance, which are described as the crowdsourcing, social, and geographic approaches respectively. As an extension of these three approaches, Haklay (see his entry in this volume on Volunteered geographic information: quality assurance) further articulated three additional approaches for VGI quality assurance – the domain approach, the instrumental observation approach, and the process-oriented approach. Bordogna et al. (2014) reported a linguistic approach for VGI quality assessment. It should be pointed out that the boundaries between these different approaches for VGI quality assurance are not so clear cut. One of the major problems among the existing approaches for VGI quality assurance is that they are blind to the sources of errors and do not differentiate at which stage of the data life cycle these errors occur.

To further address the VGI quality issue, VGI quality assurance research should be tied to the big data quality assessment techniques for maximum data usability (Loshin 2014). Like other types of big data, errors of VGI can be introduced in any stage of VGI life cycle, and they may be attributed to protocol and participants errors. In the broader citizen science literature, Wiggins et al. (2011) identified a total of 18 mechanisms for data quality control and validation in citizen science. These 18 mechanisms consider stages of data life cycle and sources of errors. The existing VGI quality assurance approaches as reviewed by Haklay (Volunteered geographic information: quality assurance) focus on the data collection stage and participants’ errors only. Additional work is needed to develop approaches to assess errors introduced in other stages of the data life cycle beyond the data collection stage. Moving beyond the participants’ errors, efforts are also needed to tackle the various protocol errors (e.g., poor sampling) in VGI production.

As spatial data quality assurance is shifting towards a more user-centric perspective, the precise meaning of data quality, accuracy, and uncertainty may be quite different from their traditional meanings in the context of surveying and mapping. Spatial data accuracy 2.0 (Goodchild and Hill 2008) and spatial metadata 2.0 (Kalantari et al. 2014) emphasizes more on the fitness of purpose in assessing the quality of VGI. In addition to the technical quality and accuracy (Esmaili, Naseri, and Esmaili 2013), social and political credibility is also becoming increasingly important in assessing VGI quality (Flanagin and Metzger 2008). All these new developments may further complicate the VGI quality assessment process.
VGI use methodology: from mapping parties to GeoHackathon

VGI use methodology has exhibited a few defining characteristics that are quite different from the traditional use of spatial data. The new emerging VGI practices are not only now increasingly conducted in the mode of open science and open GIS (Sui 2014), but they are also closely tied to Daniel Pink’s (2006) six senses of the whole new mind (design, story, symphony, empathy, play, and meaning). Sui (2015) documented that new GIS themes (of which VGI is an integral part) in geodesign, map stories, synthesis, critical GIS, geogames, and platial GIS coincide with Pink’s whole new mind remarkably well. Conventional GIS development has predominantly concentrated on cartographic, quantitative, computing, and spatial database-oriented with the goal of efficiency, which tends to be closely associated with the left-side/slow thinking capabilities of the human brain. In contrast, the uses of VGI focus more on narrative, qualitative, story-telling, and synthesis-oriented with the goal of equity, which tend to be more closely associated with the right-side/fast thinking capabilities of the human brain. Evidently, the increasing VGI applications have the potential to enable GIS users to transcend the enframing nature of technology and lead them to explore new territories with greater sensitivities.

The diverse information that is being generated as VGI presents a number of challenges for developing methodologies to make use of it. Although conventional methodologies for spatial analysis and modeling are still useful and used for VGI applications, a major shift in VGI use methodology is the transition from traditional analysis to mashup and synthesis (Elwood, Goodchild, and Sui 2012). Admittedly, synthesis is much more challenging than analysis from a methodological perspective, due to its involvement with data in multiple formats and media (number, text, oral story, photo, video, simulation, etc.). Geographers’ current efforts to develop a more eclectic approach by linking diverse quantitative and qualitative methods may be tapped for VGI applications. Unlike the spatial analysis of a previous era that was often conducted by a lone analyst, synthesis of VGI tends to be much more participatory, through a mixing and remixing of multiple data and methods, as demonstrated in VGI applications in several recent disaster-relief efforts. Instead of seeking truth, the new mashup efforts focus more on developing narratives about various locales. VGI production and use have evolved from the mode of mapping parties (http://wiki.openstreetmap.org/wiki/Mapping_parties) during the early days to GeoHackathon in most recent years (www.upsingapore.com/geohackathon; www.cura.umn.edu/visualizingneighborhoods). As more and more people, both GIS professionals and citizens, are getting involved in VGI production and use, we have witnessed the growth of a new level of volunteerism and civic activities within the broader geospatial community, as demonstrated by voluntary organizations such as giscorps.org or mapaction.org.

VGI use and legal issues

Similar to many other advances in geospatial technologies, the development of VGI has also brought in a new set of legal issues, ranging from intellectual property to liability, and from defamation to concerns about privacy. According to Scassa (2013), these legal VGI issues may manifest in different ways depending on the stakeholders concerned. The operator or producer of a product, website, or application that relies upon VGI will need to be aware of various potential legal issues, and should take
care to address these issues in licenses and other documentation related to the site. The extent to which they need to do so and how they do so may depend on whether they are public or private actors, or whether they operate commercially or noncommercially. VGI contributors should be aware of the license terms under which they provide content. Although they are unlikely to hold copyright in small quantities of information, creative material provided in other forms, most notably photographs, video, or text, is likely protected by copyright. In some cases, contributors of VGI may be institutions or organizations that provide data sets, and there may be a copyright that can be asserted in an original selection or arrangement of data.

Sites that incorporate VGI typically have terms of use or licenses that function as a contract with the user. The terms of these documents are important as they may govern issues such as the right to use or incorporate the information on the site into other works/products/websites and whether users may use the material for commercial purposes. For example, Creative Commons (2012) and Open Data Commons (2012) each have licenses that limit users to noncommercial uses of licensed content. Such licenses may require that any downstream uses of the contents of the site be licensed under the same terms and conditions. Other license agreements may set out the rules regarding attribution: a user of licensed data may be required to attribute the source of the data or to do so in a specific format.

Privacy and surveillance are significant concerns associated with the phenomenon of VGI. Geographic information contributed by users to a website or database enables the ability for location tracking and monitoring, which may lead to an invasion of privacy and the potential for harm (Andrejevic 2007). Many social media sites and location-based services record the locations of their users in space, which is sometimes actively provided by the user, however, in other cases it is produced passively without the user fully understanding this or its consequences. Some location-based services such as FourSquare utilize this location information in developing their service, while others compile it for use by other companies for targeted geo-demographic marketing purposes (boyd and Crawford 2012; Wilson 2012). Willingly or unwillingly sharing one’s location – whether for the purposes of contributing VGI or not – is a serious safety concern, and presents one of the most serious issues implicated with the recent integration of mobile and location technologies (Elwood and Leszczynski 2011). In crowdsourcing and VGI projects, users should be made aware of what the data will be used for, and any potential privacy infringement related to their contributions.

Research with VGI: using VGI as a data source for various applications

A wide variety and rapidly increasing number of projects have been developed in recent years to take advantage of the phenomenon of VGI and crowdsourcing. In some cases, the projects have been developed in order to produce geographic information where none existed before, and in other cases they are motivated by a desire to augment or complement existing formalized sources of data. A range of examples of each motivation is provided below. For more examples, refer to the report by Haklay et al. (2014), a comprehensive collection of crowdsourcing examples including VGI projects from around the world.

Four wildfires in 2010 in California provide an interesting example of this type of activity, and serve to emphasize the value of VGI as a mechanism for creating and sharing geographic
information in time-critical situations, a point made earlier in the context of framework data (Goodchild and Glennon 2010). The Jesusita fire (May 2009) generated large amounts of Internet traffic, as citizens posted text descriptions, photographs, and other kinds of information within minutes of the fire’s outbreak. Individuals and groups of citizens used the framework to compile this information on a minute-by-minute basis into situation maps, showing the location of the fire front, areas under evacuation orders, and other relevant information. These maps served for many citizens as the timeliest source of information, supplanting official sources that could not keep up as well with the rapidly evolving situation. By linking various wildfire VGI with Twitter, social media has been proven to be an effective way to disseminate early warnings in emergency situations (http://newscenter.sdsu.edu/sdu_newscenter/news.aspx?newsID=75219).

“Road Watch in the Pass” is an example of a citizen science project that produced VGI about wildlife sightings along a stretch of highway in British Columbia, Canada (Lee, Quinn, and Duke 2006). The project was set up to allow citizens to share sightings of wild animals including deer and moose for the purposes of conservation and public safety, given the problem of collisions between wildlife and vehicles in this area. Locations along the highway where wildlife was sighted were identified on a web-based map. The data produced was used to augment reports from conventional sources, therefore increasing knowledge about solutions for mitigating animal–vehicle collisions at high-risk locations.

The Geo-Wiki platform (www.geo-wiki.org) is a VGI project that enables volunteers from around the world to contribute to a global land classification project (Fritz et al. 2012; Fritz et al. 2009). Participants evaluate the accuracy of land-cover classification in existing land-cover maps, by comparing them with Google Earth imagery and through their own knowledge of local areas. This project has been successful in harnessing the wisdom of the crowd to settle disputed land-cover classifications in existing maps. The value in this approach is the speed by which land-use classification can be verified and the low cost compared to conventional approaches.

The United States Geological Survey has a crowdsourcing program that collects local reports of seismic activities from the public. The Did You Feel It program was set up to provide an additional source of information that could be collected quite rapidly in the aftermath of an earthquake event. Any web user can provide reports of local seismic activity on the website (http://earthquake.usgs.gov/earthquakes/dyfi/), which can then be used for logistical planning and recovery. This program was initially restricted to the United States only, but is now set up to collect reports worldwide.

FixMyStreet is a website and mobile app that allows citizens to report various urban infrastructure problems such as potholes, graffiti, and abandoned vehicles in the United Kingdom (www.fixmystreet.com). This project – operated by the civil society organization mySociety – uses a web-based platform to allow members of the public to produce VGI pertaining to observations in their local area. The user enters the postal code of the area in which they wish to report an observation, selects the specific area on the map, and then adds a textual description of the problem. Users can also view reports made by other users and all reports are then forwarded on to local councils.

A project organized by the City of Boston is using a passive crowdsourcing approach to produce VGI related to street conditions called StreetBump, in which citizens are contributing information about potholes and other road quality concerns (www.streetbump.org). StreetBump
is an app that the user runs while driving, which is able to automatically collect information on bumps in the road through a smartphone’s built-in GPS and accelerometer. The app is designed around the idea of “gamification,” in which contributors score points if the pothole is fixed. If three bumps are recorded at the same location, this site is identified and added to the list of locations to be addressed by the city.

The US National Park Service is developing the Places of Interest project (www.nps.gov/npmap/tools/places), which will utilize a VGI approach to produce geographic information that will be added to their park maps to keep them up to date and accurate. The project will also contribute VGI to the development of OpenStreetMap, which the National Park Service already uses in their digital mapping projects. The plan is to develop an interface for the public to contribute geographic information related to the national parks – such as trails, tourist sites, and park infrastructure – and have a data validation procedure in place to ensure the quality of data. If relevant and accurate, the data produced will be added to the databases of both the National Park Service and OpenStreetMap.

Map Kibera is a VGI project started in 2009 that empowered local residents of the Kibera informal settlement in Nairobi, Kenya to produce a detailed local area map (http://mapkibera.org). Despite the extensive size and number of people living in this area, no previous, comprehensive map existed, which made planning and community organization a challenge. Prior to this project, Kibera was a “blank spot on the map,” which visually underscored the socioeconomic disparity in access to and provision of geographic information in Nairobi. The project provides local residents with GPS receivers to record streets, buildings, and points of interest, which are then added to the OpenStreetMap database.

The Humanitarian OpenStreetMap Team (HOT) has carried out a number of projects that demonstrate the value and credibility of VGI produced by trained volunteers in a structured way. A number of projects have been undertaken around the world, including recently in Ulaanbaatar, Mongolia (http://hot.openstreetmap.org/projects/mongolia_mapping_ulaanbaatar). The local government in Ulaanbaatar has teamed up with HOT to engage local residents to produce a comprehensive map of roads and urban infrastructure such as street lighting, bus stops, buildings and landmarks, parks, schools, and hospitals. Training and oversight is provided by HOT to increase the accuracy and potential value of the data and maps produced.

Summary and conclusion

Rapid advances in technology, along with changing demands for geographic information, have dramatically altered the environment within which this information is produced and accessed, effectively removing the economies of scale and assured patterns of use that allowed national mapping agencies such as the US Geological Survey (USGS) or Ordnance Survey (OS) in the United Kingdom to evolve and flourish. Perhaps the most important contributor to the advancement of VGI is the growth of the web, particularly the increasing participation of its users in generating its content in the age of Web 2.0 along with the development of mobile technologies and handheld devices such as portable GPS devices and smartphones. Through the successful stories of VGI reported so far, it is abundantly clear that VGI is rapidly becoming a valuable data source in low-resource areas or time-sensitive situations.
VOLUNTEERED GEOGRAPHIC INFORMATION

In addition to its contributions to environmental monitoring via citizen science, VGI has also promoted transparency in government operations and fundamental changes in business practices and models in various industries with the emergence of the sharing economy. Citizen sensors all over the world have rejuvenated a higher level of volunteerism.

With the growing heterogeneity of VGI and its contributors, the quality, credibility, and uncertainty of VGI also increase. This can be challenging to communicate with the public or for people who are used to working with authoritative data sources in a traditional top-down model (Haklay et al. 2014).

As this entry is written (late 2014), it is believed that the development of VGI and its applications so far have followed the storyline of a long tail along multiple dimensions according to the anecdotal evidence we observed. Despite the lack of quantitative measures, the long-tail nature of VGI has manifested at least in the following two aspects. First, as far as the spatial data infrastructure is concerned, traditional authoritative data collected by government agencies still serve as the “head” (large data for several key application areas) whereas VGI is serving the “long tail” (a variety of relatively small data for a diverse range of applications). Second, as far as the VGI production as a whole is concerned, contributors or players in VGI production also follow a power-law distribution: a relatively small number of contributors account for a disproportional percentage of the VGI production. One interesting development during the past five years is that VGI is, in fact, only a branch of the big data stream and is also merging rapidly with the big data deluge. Not surprisingly, as more and more big data with spatial and temporal stamps are available, boundaries between VGI and non-VGI are increasingly blurred day by day. Perhaps we are rapidly approaching the day when VGI will be synonymous with big data or will be largely indistinguishable from more conventionally produced spatial data. VGI has proved to be a valuable source of data for multiple exciting applications, but at the same time it also raises profound legal, ethical, social, and political issues regarding its collection, retention, dissemination, and use.

Vulnerability

Robert McLeman
Wilfrid Laurier University, Canada

Vulnerability refers to the potential to experience loss or harm. The term appears widely across the natural and social sciences. In geography and related disciplines, vulnerability is commonly used when describing the relationship between humans and the natural environment from a socioecological systems perspective, where changes in one part of a human–environment system have the potential to stimulate changes elsewhere in the same system or in other, linked systems. Vulnerability is employed in a relational sense, that is, the vulnerability of something to something else, such as the vulnerability of a farming population to drought. Vulnerability (of a system, or a unit or actor within a system) is determined by the nature of the adverse stimulus (often referred to as exposure); the sensitivity of that system, unit, or actor; and its capacity to adapt (Smit and Wandel 2006). In the UN Framework Convention on Climate Change (UNFCCC) the term “vulnerability” has important legal implications, including an obligation that signatories will assist vulnerable countries in adapting to the impacts of climate change. The UNFCCC has consequently had a significant influence on the volume and direction of vulnerability research by geographers, and will continue to do so. The International Geographical Union’s (IGU) Commission on Population Geography has a strong, ongoing interest in demographic dimensions of vulnerability, which reflects new directions in vulnerability research being pursued by geographers.

Ecologists began using the term “vulnerability” in the early twentieth century to describe potential stimulus–response relationships in natural systems (e.g., effects of predation on bird populations (Errington 1934)). By the 1970s the term had been adopted by researchers studying the human impacts of natural hazards, with human ecology (or political ecology) scholars advancing its development in the 1980s through research on the causes of soil erosion, land degradation, and famines (e.g., Blaikie 1981). In the 1990s vulnerability became a key concept for describing the human impacts of anthropogenic climate change. Current vulnerability research reflects these combined influences of natural science–derived systems theory and social science–based human ecology (Adger 2006). In socioecological systems approaches to vulnerability, the human world and the natural environment are seen as being interconnected sets of complex and dynamic systems, where changes experienced in one have consequences for the other. The ability of a system to successfully absorb perturbations or to adapt to changing conditions without experiencing significant disruption, or changing from one state to another, is described as resilience (Holling 1973). Resilience, which has its own associated scholarship focusing on system transformation and learning (Miller et al. 2010), helps in the identification of vulnerability. For actors, groups, or populations within a given socioecological system, a condition of vulnerability develops when potential perturbations or changes exist that exceed the resilience of the system. Vulnerability increases positively with the strength or force
of the perturbation; similarly, the greater the sensitivity to that perturbation, the greater the vulnerability. Conversely, the better adapted systems (or actors or units within them) are to perturbations, the lower their vulnerability (Figure 1). Because human and natural systems are continually changing in response to internal and external stimuli, the nature of and degree of vulnerability are also continually changing.

A simple example of the impacts of climate change on farming illustrates the functional relationship between exposure, sensitivity, and
adaptation in the formation of vulnerability. Most farms are potentially vulnerable to droughts, given the inherent nature of agriculture, but not all farms are equally so. Some types of farm operation are more sensitive than others to temporary shortages of water, such as dairy farms, because cattle must consume large volumes of water daily. Similarly, fresh vegetables require larger, more regular amounts of water than most grains. The degree of exposure to drought varies according to local and regional climatic conditions and patterns, and to site-specific factors such as soil quality and drainage. Farmers may employ a range of adaptations to reduce their exposure and sensitivity to drought, such as planting drought-tolerant crop varieties, using groundwater for irrigation or watering livestock, buying crop insurance, pooling resources with other farmers, or supplementing household income through off-farm employment. The availability and accessibility of adaptation options vary from one place to another depending on governance structures, institutional arrangements, market prices, technologies, and other factors operating across multiple spatial, temporal, and jurisdictional scales. With climate change threatening to increase the frequency and severity of droughts in many regions, the vulnerability of farmers will increase in the absence of building greater adaptive capacity (Smit and Wandel 2006).

This functional understanding of vulnerability, and the related concepts of resilience and adaptation, have been used by geographers to explore contemporary socioenvironmental challenges including food (in)security, the spread of HIV/AIDS, disaster risk reduction, environmentally related migration, and the potential impacts of climate change. Such applications have brought attention to the uneven social distribution of vulnerability and its root causes in the unequal access of individuals and households to resources, wealth, social capital, and other assets (Bohle, Downing, and Watts 1994). The least powerful, most marginalized members of society are often the most highly exposed to environmental risks and have the least adaptive capacity. This susceptibility is regularly seen following natural disasters, when rates of death, injury, property damage, and displacement show distinct patterns along lines of race, gender, age, and poverty. For example, when Hurricane Katrina struck New Orleans in 2005, the poorest residents (disproportionately composed of African Americans and minorities) were living in neighborhoods most damaged by flooding, were most dependent on underprepared government authorities for assistance, and had the least individual capacity to adapt to post-storm increases in the cost of housing. They were consequently more likely to be permanently displaced (Fussell, Sastry, and VanLandingham 2010).

Theoretical and empirical research continues to grow in the study of the physical vulnerability of locations and infrastructure to natural hazards, the social dimensions of vulnerability, and their interactions. An emergent area of research investigates how vulnerability to environmental change can be both a driver and an outcome of human population processes. It has long been known that human population growth (and accompanying demand for resources) is an important driver of environmental change. A disproportionate amount of that growth is occurring in regions with high rates of land degradation and where exposure to natural hazards and climate change risks are high. Within exposed populations, rapid changes in age distributions, fertility rates, and migration behavior affect social networks, social capital, gender roles, and related attributes that influence the adaptive capacity of households and communities (McLeman 2010).
VULNERABILITY

Vulnerability researchers employ many different qualitative and quantitative methods, often mixing them to achieve particular results. Because vulnerability research is often aimed at supporting policy and planning, there is growing emphasis on creating tools that enable the visualization of vulnerability. GIS-based technologies are particularly valuable for these purposes. The UNFCCC negotiation process generates ongoing demand for research on regional and sectorial vulnerability to sea level rise, ecological changes, increased frequency/severity of extreme events, and other impacts of climate change, with increasing attempts being made to measure and quantify vulnerability. Researchers also seek to develop future vulnerability and adaptation scenarios that incorporate more sophisticated models of future socioeconomic and demographic trajectories (Stern et al. 2013).

Coming decades will see continued growth in vulnerability-based research generally, a result of its conceptual simplicity, methodological utility, and widespread acceptance by policymakers. High rates of urbanization in developing regions will demand greater research attention on urban vulnerability to environmental risk and change. The linkages between environmental vulnerability and mobility, food security, and political instability will receive growing research attention, as will questions of governance structures best suited to deal with such challenges. Vulnerability research is unlikely to consolidate around a particular set of methodological approaches anytime soon, but is instead likely to see ongoing expansion and innovation in methods and techniques being used. Rapidly evolving technologies like mobile computing, online social media, and crowdsourcing apps are opening new avenues for data collection and analysis, and for public participation in vulnerability research.

War

Benedikt Korf
University of Zurich, Switzerland

It has been proposed that geographers – or geography as a discipline – have been better at studying war than peace. The French geographer Yves Lacoste famously titled one of his books on geopolitics: *La géographie, ça sert, d’abord, à faire la guerre* (Lacoste 1976) – that geography serves primarily to wage war. This statement might partially apply to certain “geographic” techniques, such as cartography, geographical information systems, and remote sensing, which are all important tools in waging war, even though this was not necessarily the original purpose of their development. But the complicity of geographers with agendas of war-making has often been more deeply implicated in political projects of colonialism, imperialism, Nazism, and territorial expansion in the nineteenth and first half of the twentieth century. These geographers have been explicitly apologetic to the pursuit of war. It is fair to say, however, that this might have been true for some geographers, but not for all, as there have also been important figures in geography promoting peace rather than war (Megoran 2011).

While there continues to be a group of military geographers who explicitly provide analysis for military establishments, critical geographers today rather seek to provide an analysis of the phenomenon of war as a contribution to a critical theory of society, state-making, capitalism, imperialism, and globalization. Such critical theory requires a careful analysis of war and its relation to peace, to politics, to society, and to capitalism.

Clausewitz’s puzzle and beyond

“War is the continuation of politics by other means,” wrote the Prussian military general and theoretician of war Carl Clausewitz in 1832 – as an afterthought to the Napoleonic wars (Clausewitz 2005/1832). These wars had rampaged through most of Europe’s landscape, causing death and destruction. But they had also triggered political reform in some countries, caused national awakening, fostered democratic and republican movements across Europe, and, finally, had brought the restoration of monarchical order as a result of Napoleon’s defeat on the battle ground. Not surprisingly, then, for Clausewitz, war was a chameleon: depending on context and perspective, its effects can be colored very differently. But Clausewitz suggests that war is even more than a chameleon; it is a total phenomenon, composed of a trinity of (i) violence, hatred, and enmity, (ii) the play of chance and probability, and (iii) subordination.

Much controversy has emerged around the question of whether Clausewitz is still relevant in the twenty-first century, and although it is not our task here to write a critique of Clausewitz, this controversy indicates the complexity of the phenomenon of war. Clausewitz developed his theory of war in a historical era when wars were often fought between states, or rather dynasties, as many of these states were not yet nation-states in a modern sense but rather dynastic monarchies. This type of warfare reached its height in the two world wars of the twentieth century, with large armies confronting each other on the battlefield. This is also how “conventional” war is usually defined:
WAR

as a military confrontation between two or more countries, states, or political collectivities, and their combat forces. In line with this state-centered view of war, there is a set of legal prescriptions in international law on how to fight such wars: how to declare them, how to end them, and how to conduct them. An important distinction in these prescriptions is that between combatants and civilians, and there are legal definitions of what a “proper” war is. Proper war is also subject to moral philosophical debates to distinguish “just” from “unjust” war, by defining conditions and causes that do or do not justify the pursuit of war.

There are at least three problems with this view of proper war: first, there are many wars (they have in fact become the vast majority in recent decades) that do not fit into these categories. These “other” wars are then often attributed with additional labels to distinguish them from “conventional” war: for example, civil wars (intrastate wars, fought out between a government and insurgents, or between different opposing militant groups), partisan wars (fought by resistant groups against an occupying force), wars of liberation (fought against colonial powers, for instance), and terrorism. With the end of World War II, and more so after the end of the Cold War, many observers suggest, this latter type of war has become dominant, while the number of interstate (conventional) wars has decreased significantly.

The second problem with the definition of “proper” war is that many, if not most, interstate, conventional wars were much messier than the categories attributed to describe them. Many of them displayed elements of civil war, partisan war, counterinsurgency war, and so on, besides and beyond the combat field of the conventional armies with their tanks, soldiers, artillery, aircraft, and other military technologies.

The third problem is that the definition of proper war also defines the antithesis of war: peace. This definition marks a clear boundary between war and peace: as soon as war is declared, peace is over, and as soon as a ceasefire is declared, peace has returned. But in reality this boundary is often fuzzy – we might find ourselves in a situation of not war anymore but not (yet) peace either, or of simmering, low-intensity warfare, or of gang violence, of militant rule. David Keen (2000) therefore asked: War and peace – what’s the difference? In many situations today, this difference has become blurred.

For the philosopher Michel Foucault, “peace itself is a coded war” (2003, 51). Foucault suspected Clausewitz to have inverted the original proposition that politics is the continuation of war by other means, rather than, as Clausewitz had suggested, that war was the continuation of politics by other means. Foucault writes: “Right, peace, and laws were born in the blood and mud of battles” (2003, 50). According to Foucault, war is not something that comes after politics has failed, but politics itself is war. War is not a remnant of a premodern past, but continues to permeate societies – to purify their inner social body and polity. To understand the full extent of Foucault’s provocation, we need to contrast his argument with that of Thomas Hobbes in Leviathan (1996/1651). Hobbes saw the question of war as an institutional problem. War would inevitably emerge in a “state of nature” – a presocietal condition where nobody holds a monopoly of violence. Intrastate war, to Hobbes, was a problem to be solved by state building that would bring about a monopoly of violence and thus security and social peace. Here, we can see how Foucault and Hobbes differ: for Foucault, war continues to permeate society even after a state has established a monopoly of violence.
Warscape

With the end of the Cold War, many observers expected an end to armed conflict. But surprisingly, the number of armed conflicts increased after 1990, at least in the realm of public media attention. Many of these wars of the 1990s and thereafter irritated modern observers. They were subsequently called “new wars”: new not in the sense of hypermodern or advanced, but rather new as different from conventional (“old”) wars. Paradoxically, these new wars brought the premodern past back onto the battlefield in the sense of a return of “archaic” forces of “primitive” or “primordial” warfare. These new wars were often labeled as “asymmetric”: they were not fought between states, but between states and a variety of violent nonstate actors; they were archaic, brutal, and primitive, involving large-scale massacres (Rwanda, Bosnia), mass-scale sexual harassments, and erratic violence against civilians (Congo, Sierra Leone, etc.). These new wars were said to be predatory, involving rampant warlords (Congo, Sierra Leone, etc.), and a blurring of the distinction between combatants and civilians, between war and business, between war and peace. Yet, at the same time, it became clear that these wars were not an exception to, or disconnected from, globalized modernity; in fact, the flows and forces of globalized capital were intricately related to the political economies of “new wars” (Kaldor 2012). Then came 9/11 and with it the two US-led wars in Afghanistan and Iraq, which have consumed much attention of critical geographers interested in war. Many observers see this as an asymmetric war between a global power (the United States and its allies) and nonstate actors (Taliban, insurgents, tribal groups), where the former has a super-hegemony in terms of military technology and nevertheless fails to systematically control the battlefield and bring the war to a sustained end. Violence has continued to unsettle large parts of Afghanistan, northern Pakistan, and Iraq, despite the presence of military personnel, and the utilization of hypermodern military and intelligence technologies and counterinsurgency tactics.

What we find in those battlefields, and in different figurations in other wars, is a complex “warscape”: a landscape of violence, destruction, coercion, suppression, fear, suffering, and of excitement, enrichment, opportunity, technological advancement, and social transformation. Amid and besides the struggles on the battlefield, there is a more silent space of struggle; this is the space of all sorts of noncombatants who happen to live in warscapes. Violence has ambiguous, often contradictory, effects on agency at different times, in different places, and for different individuals: war is not a matter of “all terror all the time all over the place” (Korf, Engeler, and Hagmann 2010, 386). Inhabiting a warscape is thus not simply a question of coping with violence or adapting to new power holders; it is entangled in multiple and differentiated agendas of social struggle, life projects, and negotiations over livelihoods. It is therefore difficult to draw a clear line between the social conditions of war and those of nonwar as social actors continue to struggle throughout both conditions in a peace-to-war continuum, which has become fuzzy in many of today’s wars: there is no clear beginning or end to a war, but rather a diffuse grey zone of hidden, erratic forms of violence and more open combat. Similarly, it is often not possible to distinguish neatly between perpetrators and victims, as some noncombatants may take profit out of war, while others might experience tremendous suffering, and the same individual might at some point in time belong to the former and at another to the latter category.
Synchronicity of the nonsynchronous

Warscapes are not confined to a locale, but are embedded in transnational networks of accumulation, financial capitalism, technological grids, and blurred boundaries between “archaic,” “modern,” and “hypermodern” (futurist) subjectivities, objects, technologies, and practices of warfare. These blurred boundaries encapsulate what the German philosopher Ernst Bloch has described, in a different context, as “synchronicity of the nonsynchronous”: all these objects, elements, and subjects ought to be in different historical times; they seem to belong to different historical eras of warfare – the past, the present, the future. But they are all co-present in the same historical moment – the present condition; and they may even be co-present in the same warscape (e.g., Afghanistan, Iraq), while in others, one particular historical time may dominate our perception of the battlefield: for example when violence in the Rwandan genocide was labeled as “archaic” or when drones are seen as futurist elements in present-day warfare.

This synchronicity of the nonsynchronous can be mapped along a continuum from the body to the drone. The most “archaic” subjectivity in these warscapes seems to be encapsulated in the figure of the suicide bomber, and her object of war: the body. At the other end of this continuum is the drone that wages war through an unmanned robot vehicle that is steered from afar – where the warrior operates from a distance. The “heroic” dimension of manly combat that has been an important element of “archaic” warfare has thereby escaped into the grids of the technologies of the cyborg warfare of a “post-heroic” society. Warfare is steered from afar, but modern technologies make the battlefield present on the computer screen – an intimacy from a distance that is mediated through hypermodern technology (Gregory 2010). It links the messy warscape of blood, dust, and struggle with the clean office of the drone operator at a safe distance from the place of combat.

The geography of war

Geographers have been involved in studying warscapes from a variety of angles – and there has been a proliferation of geographical work on war and violence in the last decade. Not surprisingly, there have been differentiated approaches, methods, and theories guiding different geographical scholars in studying warscapes – and they have also focused on different types of warscape. One group of geographers has focused on warscapes with a heavy involvement of the US military, in particular on the battlefields of Afghanistan and Iraq. The Palestine–Israel conflict, the escalation of violence in Gaza, and violence in the Middle East more broadly have also attracted the attention of geographers. But there are many other contemporary warscapes – beyond these hotspots – that geographers have studied: Sri Lanka, Nepal, East Timor, the Horn of Africa, Sierra Leone, Rwanda, Colombia, Mozambique, Angola, and many more. Some geographers have studied past atrocities and warscapes: for example, the legacy of Cold War violence, the geography of civil war, mass violence, and other atrocities in countries such as Cambodia during the Khmer Rouge and Rwanda and its genocide, but also East Timor, Vietnam, and Laos. In these latter sites, mass-scale violence has been a historical, often traumatizing experience.

The US intervention in Afghanistan and Iraq as part of the global war on terror has drawn a lot of attention from geographers during the past decade. These wars have been high up in global media discourses and in the critical, self-reflective engagement of geographers who
felt obliged to challenge their home countries’ implication in massive military operations in various countries and sites across the globe. In these warscapes, where the United States has sustained a massive military presence over a long time period, fighting an asymmetric war against Taliban or other insurgents, the synchronicity of the nonsynchronous objects, technologies, and subjectivities has been pronounced in its most peculiar way. In the Afghan warscape, for example, hypermodern technologies (drones, cyberwarfare) were deployed on the battle-ground amid the troops and machinery of “conventional” modern armies (soldiers, tanks, aircraft) with “tribalist” elements of war, the Kalashnikov fighting of warlords and elements of partisan war (road blocks, insurgents’ attacks, counterinsurgency). The “archaic” mode may also include blood killing, revenge, and “irrational” violence: in the case of Rwanda, killing with machetes rather than with guns. At the core, these objects and technologies of warfare appear to belong to different historical times. But also the subjects fighting war are attributed to different historical epochs, with tribal leaders and warlords being consigned to a “premodern” era, soldiers representing the modern (the present), and the “cyborg” of hypermodern technologies blurring the boundaries between human and nonhuman and bringing the future into the present.

A number of geographical studies resonate with these observations. A growing field of study in geography has looked into the emerging battlespace of the war in Afghanistan as a network-centric warfare, where hypermodern or “futurist” military technologies are mobilized to produce a “surgical” type of warfare that combines military intelligence from remotely sensed surveillance with targeted killings, often through drones or robots. Derek Gregory calls this the deadly embrace that reconfigures the relation between war, distance, and intimacy: the soldier is not immersed physically in the battlefield. The battlefield is now digitized on the computer screen. It is distant and yet intimate, as modern surveillance technologies appear to bring the battlefield’s configuration back to the operator’s office. These new technologies of warfare foster an unbounding of military activities across the war – what Gregory calls “everywhere war” (Gregory 2011). But this type of war occurs alongside other types of military technologies and violence, such as paramilitary and terrorist violence, as well as more conventional military operations, which require large-scale logistics to transport troops and weaponry for large distances. For Gregory, this “everywhere war” can break out and emerge in very different sites and in different types of war, beyond the battlefields of US interventions in the Middle East.

The proliferation and increasing fuzziness of war is captured in the concept of “battlespace,” which “prefigures a boundless and unending process of militarization where everything becomes a site of permanent war … [It] has no front and no back and no start and no end” (Graham 2009, 389). For Steve Graham, permanency signifies the emergence of a new military urbanism: the world’s main battlegrounds are now becoming urban, rather than the dusty, remote, rural frontiers that are normally associated with warfare (Afghanistan, Iraq, Somalia, Sierra Leone, etc.). The everyday spaces, sites, and infrastructures of the urban have become the main targets and threats for attacks. Insurgents, terrorists, and other nonstate militant actors lurk invisibly in the everyday spaces of urban life; they exploit and target the circulation and flows within and between cities – air travel, the Internet, financial flows. The new urban militarism represents a process of insidious militarization of urban life, a securitization of the city and an urbanizing of security. Urban everyday life becomes
WAR

the Achilles heel of irregular and asymmetric warfare – the urban becomes a target of violence, but it is also transformed to garner possibilities of violence through it, for example in the attempts of the US military or Israeli forces to demodernize urban societies through the destruction of infrastructure. Graham identifies a militarization and securitization of modern urban life in the proliferation of surveillance technologies, in the increasingly militarized dealing with immigrant sites as potential dangerous spaces in the city, and in the militarized veins of popular culture. For Graham, then, war is everywhere and everything. If we accept such a position, there is, however, a certain danger that the concept of war loses its value as an analytical category: if everything is war, the thing that is not war becomes not only blurred and indistinguishable from war but vanishes from political life – as a social reality and as an aspiration.

Another influential study, by James Tyner (2009), *War, Violence, and Population: Making the Body Count*, has invited population geographers to embrace more systematically structural forms of violence and war in the study of populations. Tyner studies the politics of violence in the genocidal atrocities of Rwanda and Cambodia as well as in the Vietnam War. He frames this violence as a form of biopower in a Foucauldian sense: death and destruction are often seen as being productive as a politics of life that protects or enables certain lives and populations. Tyner’s work resonates with feminist geographers’ insistence on and careful study of the body politics and the gendered geographies that warscape produces (Giles and Hyndman 2004): bodies count (i.e., the politics of the body) rather than simply a body count (of how many people are dead or injured, i.e., an aggregate sum of war’s collateral damage). Geographers have analyzed the geographical imaginations framing this politics of the body, which can take various dynamics and forms: gendered subjectivities might become un-settled and re-enforced through warrior images of female fighters or child soldiers. Postcolonial inequalities might be reasserted through differential practices of implementing security for “different” bodies – “local” versus “international” personnel, military versus civilian (Fluri 2011) – or in the media attention and public grief attributed to “different” bodies – the loss of individual US soldiers, missing or dead, is acknowledged, while the dead or missing Afghan or Iraqis are reported in the hundreds or thousands.

Another prominent field of study among geographers has been the problematic “resource wars” (Le Billon 2008). These are wars where the accumulation of resource rents from high-value mineral resources (diamonds, oil, etc.) have provided incentives for warlords to keep war ongoing, but in a way that does not disturb, but rather promotes, their business interests. War enables those warlord entrepreneurs to monopolize resource rents, through securing access both to the sites of exploitation and to the sites of transnational trading. The convoluted transnational entanglements of Western consumers, international companies, and “local” warlords has been captured in the concept of “blood diamonds”: the consumer good of diamonds have a past that is rather bloody, excavated in the minefields of some of the most protracted wars in West and Central Africa. Again, there seems to be a kind of nonsynchronicity at play here: in the liberal minds of Western observers, trading is thought to promote peace rather than war. These bloody resource wars are “archaic,” a savage type of “premodern” business practice, that is nevertheless part of global capitalism, its production networks, and its consumer culture.

The problem with the literature on “resource wars” has been that some of this work has been found to purport a soft or “quasi” environmental
determinism by linking resource abundance with political violence – or by overemphasizing the economic incentives of warfare, while downplaying other dimensions of political struggle. Again, the analytically interesting point in this form of political violence is the entanglement of political struggle, insurgent logistics, and battleground dynamics with the highly complex transnational spaces of the marketization of mineral resources, such as oil, diamonds, and gold, which links the global borderlands of capitalism with its metropolitan centers. And yet, the local battlegrounds within which those mineral resources are exploited retain their own characteristics and dynamics, which can be described as the “telluric geographies” of partisan, insurgent warfare, requiring a terrain of operation, a complicated entanglement of insurgents and civilian population with often fuzzy boundaries, shifting sites of control, violence and atrocities, and the affective geographies of fear, hope, and collectivity (Korf 2011). One important element in these geographies is the often persistent ungovernability of these sites, which are characterized by overlapping and contradictory governable spaces with different rules, governing logics, and claims to loyalty (Watts 2003).

This brief survey of geographers’ work on war highlights some of the most innovative contributions of geographers to the interdisciplinary field of war and conflict studies. Three characteristic features can be identified: first, most geographers engage with warscapes. The word “scape” signifies the fluid and irregular shapes of warscapes across different sites, including their transnational entanglements of spaces of militarization with the global capitalist frontier. Second, in one way or another, they reflect the synchronicity of the nonsynchronous that shapes such “scapes” – the moral imaginations of past, present, and future that are ascribed to different technologies, objects, and subjectivities in these sites. And third, they engage and weave together the three elements of war that Clausewitz branded as the “trinity” of violence, chance, and suppression.

Clausewitz wrote that war is a total phenomenon. For geographers studying war, there is an epistemological challenge in capturing this totality of the phenomenon, while not neglecting the intricate entanglements of localized social practices that are spread across different sites and that are deeply implicated in the everyday experiences of warfare. Geographers have contributed significantly to better understand, empirically and conceptually, different sites, practices, and technologies pertinent in these complex warscapes. While much work has emphasized that such entanglements exist and has started to conceptualize them, studying these intricate entanglements empirically remains a challenging task to be accomplished more fully.

After Clausewitz: the irritation about an irritation

Clausewitz wrote that war is more than a chameleon. In late-modern wars, it seems that what makes war a chameleon is the synchronicity of the nonsynchronous. This nonsynchronicity is irritating to the eyes of the Western observers. It reminds the late-modern (Western) subject about some remnants of a premodern past that is co-present in contemporary wars. And these remnants of the past are not “neutral” in normative terms: the (cognitive) irritation about their presence comes from the (negative) normative ascription of these pasts, their subjectivities, objects, technologies, and practices. This “past” warfare is said to be “irrational,” “inhuman,” “archaic,” “brutal,” “uncivilized”: the seemingly “futile” heroism of the suicide bomber
who sacrifices his (or her) body and life in war appears to be an expression of madness. There is a latent racism at work here, because those brutal, uncivilized fighters are primarily located in the Global South, in Africa (the “dark continent”) and some parts of Asia. Modern armies, and especially the futurist technologies, tend to remove the bodies of their own soldiers from the battlefield (the drone approach) or surround the body of the soldier with the newest technologies to protect it from physical harm. And yet, the presence of the premodern warrior subjectivity, objects, and technologies forces even the most modern and futurist army to keep the soldier subject on the battleground.

It is not only the phenomenon of this synchronicity of the nonsynchronous in warscapes that is troubling; the fact that it troubles us should invite critical geographers to uncover the moral imaginations tied to these representations of wars. The question is why certain technologies of killing are attributed with normative superiority. These moral imaginations that cause irritation about the nonsynchronous elements in the present place the “premodern” elements of warscapes onto an inferior normative level (primitive, cruel, brutal, inhumane) compared to the “regulated” space of conventional warfare that is represented as “rational,” “legal,” and “humane.” This representation all too often justifies Western military interventions in the name of security, democracy, development, and humanitarianism – to protect the inhabitants of these warscapes from their own “lack of civilization.” These normative imaginations should be irritating – but are not necessarily surprising. As Foucault reminds us, politics itself is war – and global politics often amounts to a war over the geographical imaginations of our postcolonial present.

Waste and waste management

Josh Lepawsky
Memorial University of Newfoundland, Canada

What is waste?

In everyday language waste usually refers to something to be discarded as unwanted, unusable, or as a byproduct of some process. It may also be used to describe careless, frivolous, or extravagant behavior. But waste defies easy definition. We may know it when we see it, but presupposing a universal definition would be a mistake. Waste is always situated and infused with a vast range of value judgments that are at once ethical, spiritual, political, and economic as well. Thus, as much as waste may seem mundane, it is also of cosmological significance.

Types of waste

There are several broad categories of waste generally recognized: industrial waste, municipal (or household) waste, and hazardous or special wastes such as radioactive and biohazardous waste notable for their particularly problematic risks. These broad categories of waste can each take solid, liquid, and gaseous forms which have their own attendant management approaches and infrastructure.

Broadly speaking, industrial waste refers to any discards resulting from heavy-duty manufacturing activities that cannot be reused and must be handled for disposal in some manner. Sometimes the term also includes waste arising from resource extraction and processing (e.g., mining and smelting). Municipal waste refers to the materials discarded as part of daily life by individuals and households. It is often synonymous with “garbage” and “trash.” Hazardous waste is any material deemed to pose a substantial risk of harm to people and environments. As might be expected, what counts as “substantial” is a source of considerable uncertainty and debate. “Special” wastes often refer to byproducts of nuclear power generation and of medical applications because of the severe risks for harm posed by the materials involved (e.g., radioactive waste or pathogenic material), the protocols for handling them as waste, and the management techniques used to mitigate their risks once placed in some form of disposal facility.

Specific definitions of each of these waste types vary between countries. For example, in Canada, the major categories of solid waste include oil sands tailings (645 million metric tons), mine waste rock (256 million metric tons), mine tailings (217 million metric tons), livestock manure (181 million metric tons), and municipal solid waste (34 million metric tons) (Statistics Canada 2012, 11). Thus asking how much waste is produced in Canada reveals absolute numbers, but it also reveals that what counts as solid waste in these figures includes waste from only some activities of primary production (e.g., mining and livestock agriculture) and excludes manufacturing altogether.

It also reveals that the portion of the waste stream that is typically understood as garbage (municipal solid waste, or MSW), makes up a mere 2.6% of the total. In the United States, similarly MSW makes up only about 2.1% of
disposed solid waste (MacBride 2012, 242), while in the European Union (EU), household MSW is 8.8% of waste totals. There are difficulties in making such side-by-side international comparisons because countries use different categorization schemes. However, these figures highlight that the majority (between 91% and 97%) of waste generated or disposed of in these regions is attributable to sources such as primary production, agriculture, and manufacturing, rather than what individual consumers and households throw in the trash bin.

Management strategies typically treat each type of waste as separate waste problems. Yet relying on such divisions has consequences for how waste is framed as a management problem. For example, when MSW data are tallied separately from industrial solid waste (ISW), vast amounts of waste arising from energy production, manufacturing, and distribution are left out of the picture. In this sense, distinguishing between ISW and MSW reinforces a false separation between industrial systems that produce commodities for individual consumption.

Per capita measurements used to make different populations comparable do their own work in terms of making certain versions of waste as a management problem visible in particular ways and not others. They do this by dividing waste arising over an entire population, and combining vastly different processes (e.g., personal consumption, byproducts of manufacturing, institutional, commercial, and construction activities) into an undifferentiated mass that is then divided equally among the population of a given territory (usually a city, region, or a country). One of the results is that individuals become the bearers of responsibility for masses of waste that they have little or no control over. At the same time, the idea that waste generation is an individualized postconsumer problem is reinforced while obfuscating the role of waste arising from raw material extraction, manufacturing, and distribution, processes that occur well before consumers even purchase commodities.

Waste generation grows as economies grow, and the prospects for separating waste generation and economic growth remain ambiguous (Fell, Cox, and Wilson 2010). In broad terms, international comparisons reveal that, as income increases, so does the amount of waste. The evidence suggests this relationship is stepped. In other words, instead of waste generation increasing linearly or exponentially with economic growth it increases in a series of rather abrupt jumps. Furthermore, the largest increases in waste generation occur in the shift from “low” to “medium” income or from “medium” to “high” income situations; “high” income countries, generally speaking, produce more overall waste than low or medium income countries do, but the rate at which waste generation increases is more rapid in low and medium income countries whose economies are growing. Also, generally speaking, as income level increases the composition of the waste stream changes: organic matter declines but metals, plastics, glass, and especially paper increase. As national income increases, there is a corresponding shift in waste management practices toward recycling and incineration. Future projections of waste generation indicate that it will increase most in low income and upper-middle income countries. As their wealth and populations increase, low income and middle income countries are respectively projected to experience an annual increase in per capita waste generation of more than 56% and 48% over 2010 levels by the year 2025. In contrast, annual per capita waste generation growth rates in high income countries will likely be below 10% of 2010 levels by the year 2025.

The designation of wastes as hazardous raises its own complexities. For example, many household wastes meet or exceed toxicity thresholds
for industrial hazardousness (e.g., paint, batteries, cleaning fluids), yet they are often excluded from hazardous waste lists for practical reasons – if all municipal household waste were treated as hazardous waste, it would vastly outstrip the financial capacity of municipalities to deal with it (Wynne 1987). Indeed, the thresholds used to define hazardous waste are themselves subject to discretionary decision-making. In the 1980s, for example, the United States Environmental Protection Agency (US EPA) had to decrease by tenfold its standard threshold for toxicity of waste lest almost all domestic sewage count as hazardous waste and massive costs to manage it would be incurred. This is an example of the effects of pragmatic management where definable thresholds of harm can be determined. However, in many cases such thresholds cannot be determined: for example, for endocrine disruptors such as bisphenol-A (BPA) in common plastics. With these chemicals any level of exposure has observable effects that can be considered a form of harm.

Waste management

In its contemporary forms, waste management refers to the governance and handling of solid, liquid, and gaseous materials externalized by some actor (e.g., a person, group, organization, or economic sector). The need to handle the discards of human activity is an ancient one, but waste management in the contemporary sense of the term emerged with the urbanization and industrialization of the nineteenth century. Even in Canada and the United States, contemporary norms of municipal waste management such as curbside pickup are of very recent origin.

The postwar period of industrialization in the United States and Europe witnessed profound shifts in economic production in industry and the household that in turn led to broad-scale shifts toward the acceptance by consumers of increasingly disposable products. One of the key indicators of this shift was the emergence of prepared preserved and frozen foods and their attendant packaging (see Figure 1). Paper, aluminum, and, later, plastic posed new challenges for waste management beyond their increase in overall and relative volume. Plastics in particular added material and chemical complexity to the waste stream, making such strategies as recycling and composting more complicated and costly.

The post-World War II period saw rising incomes with attendant changes in waste generation. Substantial changes in the waste management industry also ensued. Up until the 1960s, garbage handling in US and Canadian municipalities was done by a mishmash of public and private enterprises; cities were their own garbage markets and little integration existed across business segments (e.g., hauling versus disposing) or geographical territory. But postwar urbanization presented a serious waste management problem for cities as the growth of business and apartment buildings resulted in large quantities of waste in densely populated areas. The era also saw an increasing trend toward disposable packaging.

A key technological innovation that partially facilitated the shift from garbage business to waste management industry was containerized collection. In 1939, George R. Dempster patented what would become known as the “Dumpster” – a trade name often used interchangeably with the now familiar metal container with which municipal and other garbage is stored prior to collection (see Figure 2). Containerization of garbage collection meant a single driver could collect, empty, and return each container, thereby cutting collection costs by as much as 50%.
More critical examinations of waste management point out that most waste management strategies do not seriously challenge the underlying economics of growth within which they are situated. Treatment and disposal (T&D) of waste can in principle be part of an integrated waste management scheme that works to reduce the tonnage, toxicity, and heterogeneity of produced wastes, but in practice this is difficult (Liboiron 2013). Reliance on T&D infrastructure, especially when private in whole or in part, reduces or eliminates incentives to reduce waste put through the system. One only has to imagine the paradox of a private waste hauling firm actively finding ways to reduce the material throughput of the waste its customers contract it to haul to a landfill, or a privately owned landfill operation actively discouraging the use of its facilities by helping to reduce the amount of waste sent to it by its customers.

At issue here is that customers of T&D-based waste management systems are buying a service. The T&D operator is paid to provide that service and, in so doing, receives both money and the wastes to be dealt with. This arrangement can create a situation in which the customer has no knowledge of whether the waste has been handled properly after it has been collected. At the same time, T&D operators are confronted with the problem of a lack of control over the quality of the materials they handle: their customers are trying to rid themselves of materials that are of zero or negative value to them, so they have little incentive to incur additional

Figure 1  Composition of municipal solid waste, 1960–2012. Source: United States Environmental Protection Agency.
WASTE AND WASTE MANAGEMENT

costs by sorting those materials. Moreover, if and when technological or price changes emerge that increase the economic value of the materials T&D systems manage, the materials can shift from being waste to being valuable commodities and can thus become exempt from waste management regulations, despite no change in tonnage or toxicity (see Wynne 1987).

It might seem ideal to organize waste management schemes such that waste production is avoided altogether or the tonnage, toxicity, and heterogeneity of the wastes so produced are minimized and their costs internalized to those that manufacture the products that will eventually become waste. Legislation in the EU and elsewhere (e.g., Canada and Japan) has gone some distance to instituting extended producer responsibility and the “polluter pays” principle. But remainders of some sort will inevitably be produced, not all or even most of which may be reusable as inputs into other production processes. Consequently, ideals such as extended producer responsibility and the “polluter pays” principle – where manufacturers internalize the costs of waste management and pollution related to their products – often meet with limited success.

Critics also argue that current schemes such as curbside recycling are small compared to the scale of waste production by industrial manufacturers or by industrial consumers. For example,

Figure 2  Dumpster in Los Angeles. Source: commons.wikimedia.org.
since municipal solid waste comprises about 3% of total waste arisings in Canada and the United States, and less than 10% in Europe (see above), household recycling can achieve little in terms of overall waste reduction. Some argue an emphasis on recycling results in the “recycling trap,” a situation in which gains are not made from waste prevention and reduction because emphasis is placed mostly or entirely on recycling. When this happens, waste prevention or reduction strategies such as making products longer lasting, more repairable, and/or more modular (which would permit ease of replacing components, rather than whole products) fall by the wayside (Ackerman 1997; MacBride 2012).

More broadly, recycling rates can increase and the recycling of materials can become more efficient, but such changes do not necessarily lead to reduced waste generation, as a consequence of the so-called Jevons’s Paradox. The phenomenon is named after William Stanley Jevons, a nineteenth-century English economist. He observed how technological changes that increased the efficiency of coal burning led to increased coal consumption resulting from those very gains in efficiency – since less coal was needed to do the same work, it became cheaper to use coal, thus total demand for coal increased and outstripped the savings gained from efficiency. Similarly, even as contemporary industrial processes become less materially and energy intensive, aggregate growth in those processes typically outstrips gains from efficiency. Thus while each unit of economic activity might generate less waste, the overall amount of economic activity grows and so does the overall amount of waste.

Types of waste management

Contemporary waste management is typically framed using a hierarchy of options. In order of preference, these options include waste reduction, reuse, and recycling, with disposal (usually by landfill) being the least preferred. Each option includes a wide range of possible management techniques.

Landfilling

One of the oldest and most common forms of waste management is open dumping on land. Today, landfill is still the most common form of waste management in many countries, though considerable variation occurs (see Figure 3). A modern landfill, however, involves significant technological engineering and intervention and is a relatively recent occurrence. In 1965 the United States passed the Solid Waste Disposal Act which made open dumping illegal and mandated regulations and standards for landfills. In Canada, where solid waste is primarily a provincial jurisdiction, Ontario passed the Waste Management Act in 1970 with similar implications as the US legislation. Together these laws precipitated a “garbage crisis” in the sense of a manufactured scarcity by making landfills far more expensive, when they had previously been cheap and plentiful. Municipal governments, largely responsible for managing household waste, were suddenly confronted with legislation that drastically affected their budgets. Larger firms had spent years acquiring landfill space in the run-up to the passage of the US law. These larger firms were able to present themselves as a solution to the “garbage crisis” faced by municipal authorities which were unable or unwilling to finance the costs of new landfill facilities required by the new regulations. The business of handling waste, once fragmented between thousands of small operators typically serving single urban markets, increasingly became a vertically integrated and international industry of multibillion-dollar firms (see Table 1).

Though landfills might be thought of as final resting places for solid waste, they too produce
their own gaseous and liquid waste products in the form of landfill gas and leachate. Landfill gas is principally comprised of carbon dioxide and methane, but the material complexity of landfill constituents and their interactions with microbes and other conditions in the landfill can result in a wide range of other gaseous constituents as well. With appropriate technology at least some methane, a potent greenhouse gas, can be captured for use as an energy source in electricity generation.

Leachate is any liquid with dissolved and/or suspended substances that may cause environmental harm. Leachate is mostly formed from precipitation or groundwater sources that subsequently percolate through a landfill. Like landfill gas, leachate can be particularly problematic because of the material complexity of landfill constituents. For example, in the

![Figure 3](image-url) Management of municipal waste in the OECD, 2011. Source for data: OECD.
late 1980s approximately 7,000,000 chemicals were known to exist, of which 80,000 were used commercially, and 1,000 new chemicals entered commercial use each year. Yet, even if all available laboratory testing capacity on Earth were devoted full-time to testing the toxicity of those chemicals newly entering commercial use, only about half could have been tested (Wynne 1987). Today there are over 85,000,000 known organic and inorganic chemical substances potentially available for industrial uses. Thus, the chemistry of manufactured things that are eventually discarded and which may end up in landfills involves great uncertainty about the impacts of those chemicals in action with biological and geological processes long into the future.

It is commonly understood by waste engineers that even a well-designed landfill will need to be properly maintained in perpetuity to avoid all the possible risks associated with the biological and geological changes its contents will undergo.

**Air pollution abatement**

Air pollution abatement techniques involve neutralizing or mitigating the release and/or toxicity of gaseous waste byproducts of a variety of activities such as smelting, manufacturing, power generation, and transportation. Catalytic converters on cars, for example, reduce the toxicity of car exhaust through a chemical reaction. So-called scrubbers are used to control the particulate and/or chemical composition of exhaust from industrial processing and energy generating stations. Scrubbers work via wet or dry means. Wet scrubbers use water or other chemical solutions to remove particulate matter and thus reduce or eliminate the toxicity of exhaust effluent. Dry scrubbers use some form of material that can absorb acid gases and a filtering system to remove particulates.

Air pollution abatement techniques have their own waste generation problems. Catalytic converters, for example, rely on precious metals like gold, palladium, and platinum which must be mined. Those mining activities entail their own implications for waste generation (e.g., the production of waste rock or “overburden”) and waste management (e.g., for mitigating acid mine drainage). Scrubbers eliminate or reduce air pollution at the source, but their byproducts are solids and liquids that themselves must be

treated and/or disposed of if they cannot be reused in some way. In this sense, air pollution abatement turns one kind of waste management problem – airborne pollution – into other kinds of waste management problems – solid or liquid pollution – and moves them around (e.g., from the exhaust source to a landfill). This kind of transformation and transposition challenge is a feature common to many forms of waste management.

**Waste water treatment**

Waste water treatment includes a vast range of applications. Like air pollution techniques, they all involve neutralizing or mitigating the effects of releasing water deemed to have harmful consequences for people and/or ecosystems. Probably the most important and familiar form of waste water treatment is that for sewage. Strategies to keep waste water separate from potable water have had major benefits for human health. Though often invisible, engineering for sewage has significantly impacted the built form of some of the most iconic urban settings. For example, in the mid-1850s the flow of the Chicago River was reversed and much of the city’s built landscape was raised by ten feet to accommodate a new sewage system.

Waste water management solutions developed in the nineteenth century were influenced by the miasmatic theory of disease (Melosi 2008). The theory held that noxious air from rotting organic matter was responsible for the outbreak of various epidemics sweeping burgeoning industrial cities. In England, reformers such as Edwin Chadwick were advocates of Jeremy Bentham’s utilitarian philosophy. Bentham believed that right action is that which delivers the most happiness for the most people. Utilitarianism in this form provided a philosophical basis for a variety of state-based interventions into waste management for public health, such as the separation of potable water sources from sewage. In turn, these major infrastructural projects entailed the organization of new administrative structures to govern hygiene and disease prevention through waste management. For example, the Metropolitan Sanitary Commission, created for Greater London in 1847, replaced the seven existing and separate sewer commissions with a single administrative body. Later, in 1875, the Public Health Act was a key event representing the first time that the British national government took responsibility for protection of its citizens’ health. Waste water management and state formation, then, are tightly linked (more broadly, see Goldstein 2013).

**Incineration**

Incineration involves the combustion of waste materials to reduce their mass and volume. Incineration schemes for managing industrial and urban waste streams emerged in the United Kingdom in the late 1860s. Known as “destructors,” they quickly became synonymous with poor air quality, but as early as the 1880s technical improvements led to higher incineration temperatures, which improved air quality and enabled the production of steam for energy generation. Today’s industrial incinerators involve high-temperature combustion and can significantly reduce both the mass and volume of waste material, thereby substantially reducing, but not eliminating, the need for landfills. They may also be especially important for mitigating the hazardousness of particular waste streams with pathogenic and/or toxicological risks since high temperatures can destroy pathogens and chemical bonds.

The use of incineration as a waste management approach is on the rise in Europe, where bans against landfills untreated solid waste have been
enacted. It has also been granted tax exempt status as a form of renewable energy generation by the US Environmental Protection Agency. Nevertheless, incineration is also highly controversial. Though the high temperatures of modern incinerators can destroy the chemical bonds of particularly toxic substances such as dioxins, those temperatures are reached using furnaces burning oil. Thus, the status of incineration as a renewable and sustainable form of energy generation is questioned by some. Also, though incinerators can break down chemicals such as dioxins, those same chemicals can reform from exhaust gases as they cool and are released into the air. For these and other reasons, new incineration plans often face resistance in the locale where they are to be sited. They are also increasingly resisted in transnational networks of activism (Davies 2005).

Recycling

Recycling describes a variety of practices that divert discards away from waste streams and toward various reuse applications. The diversion of materials is done using one or a combination of strategies including separation at source (e.g., by private citizens) or in a materials recovery facility (MRF) where employees sort recyclables from nonrecyclables. The term “recycle” first entered into use in the 1920s to describe the reuse of oil byproducts in the petroleum industry, and now recycling has become one of the most common forms of environmental behavior among households and individuals. Rates of individual and household participation in recycling climbed quickly in the United States, more than doubling between 1960 and 1990, but since then the rate of increase has stagnated. Currently, around 34% of all US municipal solid waste arisings are recycled but other countries claim higher (e.g., Germany, Austria, and Korea) and lower (e.g., New Zealand, Turkey, and Chile) rates (see Figure 3).

Understood in broader terms, recycling has a rich geohistory. For example, scavenging for potential value in waste has been an important practice throughout human history (Medina 2007). It would be a mistake to assume that scavenging, even in its contemporary forms, is solely a response to extreme poverty and inherently defined by exploitation. In many instances around the world scavengers who collect and return various materials to the production stream can regularly earn several times the legally mandated minimum wage, although the work is often precarious and risky. Many industrial processes, both historically and today, substantially depend on scavenging to recover what others have cast off as waste and return it to production (Minter 2013; Figure 4). For example, in 2011 the US scrap recycling industry processed 135 million metric tons of material, which is more than the amount of material recycled by US households. Scrap steel accounted for at least 83% of inputs to iron and steel foundries globally between 2008 and 2011. Globally, scrap metals comprised the inputs for production of more than 40% of copper, 35% of lead, 33% of aluminum, and 30% of zinc (Bureau of International Recycling, n.d.).

Recycling can also play more than an economic function during times of material scarcity. For example, the salvaging drives by civilians in the United Kingdom and the United States during World War II that were designed to supply material for those nations’ war efforts were as much about material recovery as they were about encouraging the morale of civilians on “the home front” (Cooper 2008; see Figure 5). Similar uses of recycling and its affective or emotional geographies underwrote communist nation-building efforts in Hungary and other Soviet satellites between 1948 and 1984 (Gille 2007).
Biodegradation

Biodegradation is the chemical breakdown of waste materials by micro-organisms under aerobic (i.e., in the presence of oxygen) and/or anaerobic (i.e., in the absence of oxygen) conditions. Familiar forms of biodegradation include composting and anaerobic digestion. Composting has been a key component of agricultural systems for centuries. Today it is an increasingly popular form of municipal waste management. Industrial-scale composting of organic municipal solid waste began to emerge in the 1980s, mostly in Western Europe. The European Commission claims, for example, that over 14% of per capita municipal waste generated in the EU was treated via composting and digestion in 2012. Anaerobic digestion has been a common part of sewage treatment processes since the nineteenth century. More recently it has been applied as a management approach for organic industrial and municipal solid waste. Both forms of biodegradation are useful on a number of fronts: they divert waste from landfills, saving space and mitigating the production of landfill gases and leachate. They can be added to soil to improve agriculture and home gardening; and they can have synergies with solid waste and waste water treatment systems when biodegradation is used to treat the organic fractions of these
two waste systems. One of the challenges facing biodegradation as a management practice is the difficulty of keeping out contaminants (e.g., plastics and chemicals) that reduce the efficiency of the biodegradation process itself and/or result in outputs with toxic characteristics, making them unsuitable for reuse in agriculture.

Waste trading

At its most general, waste trading is a commercial transaction involving the movement of waste arising in one place for treatment and/or disposal in another. The term is usually used to indicate movements that cross jurisdictional boundaries either within countries (i.e., as a form of domestic trade) or between countries (i.e., as a form of international trade). The waste trade can involve many steps of treatment that recover materials for reuse. It is not simply a matter of moving material to where it is cheapest to dispose of it, though that is an important aspect of waste trading. New York City, for example, treats around 5 billion liters of sewage per day. Once treated and dewatered, the remaining solids are sold to private firms, which trade them domestically and internationally for use as fertilizer.

Like other forms of waste management, the waste trade can be controversial. Indeed, a key international agreement known as the Basel Convention was a response to international concern raised over ocean dumping and the dumping of waste from “developed” countries in “developing” countries (Kummer Peiry 1995). The convention intends to halt transboundary shipments of hazardous waste from what it calls Annex VII countries (OECD, European Community, and Lichtenstein) to all other signatory countries, but various issues complicate the picture. First, that portion of the convention that seeks to halt Annex VII to non-Annex VII shipments (called the Ban Amendment) is not yet in force. Second, while Annex VII signatories would be prohibited from shipping hazardous waste to non-Annex VII signatories, nothing in the convention prohibits waste trading between countries within each category. Given that non-Annex VII territories include a very wide diversity of countries in terms of wealth and technological capacity for waste management (e.g., much of Asia and all of Africa), the convention is limited in its ability to stop waste trading from “rich” to “poor” countries.

International regulations like the Basel Convention are promulgated in an attempt to halt or reduce undesirable international trade in waste by making it illegal. Yet the very presence of national or international regulation on waste
treatment and disposal opens up the potential for profit to be made from skirting those laws and thus the potential for waste crime. Estimates suggest that organized crime syndicates earn US$20–30 billion annually from illicit trade in waste. Passing and enforcing stronger regulations may help to reduce the problem; however, any such efforts also have to overcome the substantial challenge of detection. The world’s major ports handle millions of containers per year and properly inspecting them for illegal waste shipments, even in a single port, is impossible.

Geographic research on waste and waste management

Geographic research on waste and waste management engages with a wide diversity of issues, reflecting the discipline’s breadth (see Moore 2012 for an excellent review). Among the most important themes is environmental justice (EJ), a broad concept that captures the idea that every person has an equal right to a safe and healthy environment. Research in this vein examines whether there are consistent patterns in the spatial distribution of a variety of activities related to waste and waste management, such as trading, treatment, storage, and disposal, that vary systematically with sociodemographic variables such as race and class. Results have been very mixed. Some studies contend that cause–effect relationships between the location of undesirable waste management activities and the location of particular sociodemographic groups are not consistent and cannot be clearly linked to systematic prejudice (Cutter 1995). One key complicating factor is that widely different results can be obtained merely by changing the geographical scale used in the data analysis. This involves the modifiable area unit problem (MAUP) which arises from the aggregation of data from one scale (e.g., households) to another (e.g., census tracts) and can make it more difficult to identify the effects on different economic or racial groups. Another complicating factor is the broader issue of problem definition: for example, whether inequality can be understood to have a generally applicable geographic unit of analysis, or even why hazardous waste management problems should inherently be specified as problems about locating facilities rather than problems derived from capitalist accumulation and externalization strategies (Lake and Disch 1992).

A second key area of geographic research on waste and waste management focuses on various aspects of both individual and collective environmental behavior and its governance. Briefly, environmental behavior is action construed by individuals and groups to be environmentally beneficial (e.g., recycling) while governance in this context refers to the regulation of that behavior through the daily practice of norms and/or formal governmental policy. A key finding from this kind of research is that a diverse set of environmental values, along with situational and psychological variables, influences or motivates actual environmental behaviors (e.g., recycling, waste minimization, and reuse). These findings are notable for their importance for governance since they suggest the possibility of, and need for, a variety of subtle policy approaches that might be employed to nudge individual and collective behavior toward more environmentally beneficial ends (Barr, Gilg, and Ford 2001).

An important focus of the environmental behavior research is recycling and waste minimization. Like other areas of geographic research about waste and waste management, the work on recycling and waste minimization is highly diverse. One stream of such research attempts to understand the underlying factors that might account for the observable gap between people’s stated support for environmental action and their
actual behavior. Recycling has become widely accepted as a positive environmental action, but the degree to which individuals and households actually undertake it strongly depends on the ease and convenience with which it can be done.

Related to this stream is research documenting links between recycling, citizenship, and identity. Research along these lines tends to examine recycling as part of a gamut of practices that perform personal and civic identities deemed to be ethically good. Here, practices may or may not be specifically about attitudes toward nature or the environment, but may instead be understood as part of broader conceptions of being a good person or citizen. An associated area of research takes recycling and community-based waste management strategies, particularly but not exclusively in the Global South, as examples of paths toward greater socioeconomic inclusion and justice (and, as such, it resonates with environmental justice research). This line of research challenges the received wisdom that modern consumer societies are thoughtless throwaway societies. Indeed, people engage in a wide variety of practices that route discarded items away from the waste stream, even if achieving environmental ends is not necessarily the point. These practices include hand-me-down and hand-around relations of exchange for things such as clothes (particularly for children) and other household items. These practices typically occur outside formal recycling systems and may or may not be explicitly framed as environmental behaviors by those who engage in them, but may instead be about generating and maintaining relations of care, community, and the like. Indeed, some studies have found procedures that route materials away from the waste stream to be a widely practiced norm (rather than an exception) for most classes of discards except food and packaging.

Research on recycling and community-based waste management practices in the Global South document the key role such practices play as livelihood strategies and paths out of poverty. It also challenges assumptions that the lives of those who engage in scavenging for recycling are defined by marginalization and victimization. This research area also documents the tangible environmental benefits achieved by the work performed by people in these circumstances, which are often informal and undervalued (Gutberlet 2013).

A third area where geographic investigations of waste and waste management have offered novel insights is industrial ecology. Industrial ecology describes an interdisciplinary approach to understanding the industrial economy, in whole or in part, as networks of material and energy flows in which the byproducts of one process are incorporated as resource inputs into another, thus generating zero waste. Practitioners in this field are typically devoted to finding technological solutions to maximize the efficient use of those material and energy flows underpinning industrial activity, while simultaneously achieving goals of sustainable development. The main contributions by geographers to the industrial ecology literature have been critical assessments of its history and of the very large gaps between industrial ecology ideals and their actual implementation (Gibbs and Deutz 2005). For example, industrial agglomerations of Victorian England exhibited features of what would today be called industrial ecology. Such agglomerations were fueled by coal, residuals from which included coke, ammonia-rich water, and coal tar. Victorian era blast furnaces producing iron left behind slag at a ratio of 2:1. Initially managed as forms of unwanted discard, commercial uses were eventually found for each of these materials (Desrochers 2009). Carbon-rich coke powered railway engines;
ammonia-rich residual water became a basic input to the pharmaceutical, dyeing, printing, and fertilizing industries; coal tar was found to be useful as a wood and metal preservative and as an intermediate input to rubber production and dye making; and blast furnace slag could be used in copper smelting, road building, building materials, and steel production. Indeed, the commercial uses of slag turned the massive accumulations of it on the British countryside (the “slag heaps”) into a lucrative export.

Geographers have also challenged as flawed abstractions the tropes and metaphors of nature, ecology, and natural systems that typically underpin the intellectual and policy justifications for industrial ecology. One problem underlying the actual implementation of industrial ecology is that the costs of standard forms of waste management are minimal relative to overall business operating costs and thus do not provide enough of an incentive to change; for example, by co-locating and/or sharing inputs and outputs with other businesses. Also, generating the interfirm trust necessary for taking on the financial risks of industrial ecology projects is difficult to instigate through policy. Where relatively successful industrial ecology projects have occurred, it seems that initial gains were made via firms willing to participate in initiatives that were economically low risk, but with environmental benefits (e.g., shared waste water treatment). Cooperation developed during these low risk initiatives then forms a basis for riskier and more substantive interfirm cooperation to achieve broader industrial ecology goals. In contrast, in the Global South, industrial ecology agglomerations manage flows of waste sourced globally rather than locally and exist in circumstances where waste management costs are minimal (e.g., ship breaking in Bangladesh, see Gregson et al. 2012). These examples strongly contrast with the metaphors and tropes about nature and ecology commonly associated with industrial ecology projects in the Global North, such as being “clean and green.” By comparison, recovering secondary materials from waste in the Global South, such as ship breaking and electronics recycling, can be quite dirty and messy.

A fourth and more recent theme of geographic research on waste and waste management focuses on tracing the “afterlives” of particular classes of commodities, such as clothes, cars, electronics, food, and container ships cast off or discarded as waste (Alexander and Reno 2012). Following the trajectories of such things, geographers have analyzed patterns of exchange premised on the rekindling of value out of waste. The empirical results have also been used to push and challenge major theoretical concepts and approaches that cut across a variety of substantive areas of research in geography and beyond. For example, global production networks (GPNs) and global value chains (GVCs), two major theoretical approaches in economic geography and economic sociology respectively, typically trace value creation from the point of manufacture to the point of sale. But studies of the trade in discarded clothing, cars, electronics, and ships have demonstrated that the usual conceptualization of value in these approaches needs to be substantially modified to account for additional rounds of value capture and creation that occur after the final sale of new commodities. These studies also suggest differences in governance between the coordination found in global recycling networks and the firm-driven commodity chains for products consumed in the Global North.

In a different vein, studies of the afterlives of food shift the analytical focus toward infrastructure and away from individual attitudes, behaviors, and awareness (Evans 2012). Thus, instead of food waste being a problem stemming from lack of awareness that could be ameliorated by informational campaigns, researchers document food
Waste and waste management raise far-reaching and fundamental questions that have ethical dimensions, such as what is a good or right action with respect to waste and waste management (Hawkins 2006). Such questions involve both spatial and temporal dimensions. Spatially, questions about good or right action might involve investigating concerns for justice around siting decisions for waste treatment and disposal facilities; or they might examine the ethical implications of the mobility of waste for treatment (e.g., recycling) or between source(s) and sink(s) (e.g., persistent organic pollutants into food webs). Temporal dimensions focus on the ethical questions raised by the implications for future generations of waste management strategies being practiced today. Such temporal questions are at first glance most acute with respect to nuclear waste. For example, the Waste Isolation Pilot Plant at Yucca Mountain, New Mexico, was approved under regulations that mandated a 10,000-year time horizon. More common forms of waste and waste management, such as the landfilling of household waste, raise similar issues. This is because landfills agglomerate such a wide range of organic and inorganic matter and lifeforms (especially bacteria) in combination with biophysical and geophysical processes that the potential consequences for future human and/or other forms of life is essentially unknowable and necessitates long-term management (Hird 2013).

Two broad approaches to the spatial and temporal aspects of waste ethics exist. The first proposes to avoid waste altogether and is exemplified by the zero waste movement. Zero waste is an ideal that aims to prevent waste from being generated in the first place. It derives its intellectual and practical inspiration from conceptualizations of cycles of energy and material in natural systems. It focuses on upstream practices such as design for durability, repairability, and reusability; it also advocates for lifestyle changes that reduce consumption. As such, achieving zero waste would entail fundamental shifts in the production and distribution of commodities. Substantive policy proposals that would achieve such ideals already exist. Two
important examples are steady-state economics and degrowth. Steady-state economics entails matching population, consumption, and carrying capacity. Degrowth entails equitably downscaling production and consumption while supplanting efficiency with sufficiency to increase human wellbeing and ecological conditions.

A second approach to the spatial and temporal aspects of waste ethics claims that avoiding waste altogether is unrealistic, thus the solution is to “waste well” (Lynch 1990). This approach to waste ethics also draws conceptual and practical inspiration from understandings of nature and is compatible with the ideals of zero waste. Wasting well would entail designing commodities for durability, modularity, ease of reuse, repair and recycling, ease of disassembly, and benign disposability (e.g., by mandating “green” chemistry, which designs toxicity out of products before they are put on the market, as an industrial norm).

WASTE AND WASTE MANAGEMENT

Further reading

The water system is highly dependent on the climate system. As precipitation and air temperature are the main inputs of the water system, changes in the spatial and temporal distribution of precipitation and air temperature will change how much water goes back to the atmosphere and how much remains in the soil, and thus be available for runoff. Rising air temperature increases evapotranspiration over water bodies and land surfaces, which will further reduce the water level of lakes and streams, soil moisture, groundwater flow, and thus streamflow. Even without changes in precipitation, warming can alter the whole water cycle, thus lowering runoff in dry, warm months. Changes in the volume of water in different reservoirs within the cycle have significant impacts on water-dependent industries and ecosystems. Indeed, climate change affects many different aspects of water resources, and the impacts will vary over space and time, reflecting the affected region’s land use and management conditions. Hence, climate adaptation strategies in the water sector should consider each location’s unique social and environmental conditions (see Figure 1).

Climate change impacts on water quantity

Water supply is projected to change as the spatial and temporal distribution of precipitation shifts. However, the impacts of climate change on regional water supply depend on the response of each basin to the direction of climate change. The sensitivity of each basin is largely a function of the location of the basin that influences the climate regime, basin soils and geology, land cover, and basin morphometric characteristics such as shape and slope.

Global hydrologic model simulation results show that climate change is likely to amplify the existing uneven distribution of water supply, both spatially and temporally. In humid temperate climates in mid-latitudes, where the basin runoff process is largely controlled by snow accumulation and subsequent melt, rising air temperature is projected to increase spring streamflow but reduce subsequent months’ streamflow as snowpack reduces in the late spring and summer months (Chang et al. 2012). In the equatorial wet tropics, annual streamflow is projected to increase in general, while in the dry tropics and in the Mediterranean climate, it is projected to decline. These changes are associated with change in the precipitation amount in these areas as the wet tropics are expected to receive more precipitation overall, which
can cancel the effort of evaporative loss due to rising air temperature. In glacier-fed rivers such as those in the Himalayas, the Andes, and the Sierra Nevada, warming can temporarily increase summer flow in the next few decades, but it will eventually decline as glacier ice contribution diminishes (Cisneros et al. 2014).

Changes in precipitation seasonality will also increase the temporal variations of streamflow in mid-latitudes. Seasonality of flow is likely to be amplified with drier summers and wetter winters. In humid marine west coast climates, the wet season flow is projected to increase, while the dry season flow is projected to decrease further. With increased evapotranspiration and reduced soil moisture, the recharge rate will decline, reducing groundwater supply. While there is high uncertainty in estimating the potential changes in groundwater availability from climate change due to groundwater’s long residence time, groundwater-dependent regions, typically already water-stressed in drier climates, are vulnerable to changes in the timing and magnitude of precipitation (Georgakakos et al. 2014).

**Climate change impacts on water quality**

Changes in air temperature and streamflow characteristics will affect the physical, chemical,
and biological aspects of water quality. Stream temperature is particularly sensitive to such changes in flow amount and timing. Together with warmer air temperature, decreased summer flow will raise stream temperature, reducing dissolved oxygen content in the water, thus negatively affecting the survivability of cold-water fish species such as salmon and trout. In lakes and reservoirs, as hot days extend, thermal stratification increases, lowering the mixing of top warm waters with cold bottom waters, which results in the excessive growth of algae in the top layers, which in turn depletes oxygen and kills fish (Georgakakos et al. 2014). When higher water temperatures are combined with calm and warm dry spells, it can increase the formation of blue-green algae (Arnell 1996). However, groundwater-fed streams or lakes may be less affected by climate change because summer baseflow is likely to be maintained, even though some reductions of the absolute amount of summer flow are inevitable.

Increased seasonality resulting from increasing streamflow variability will also increase sediment and nutrient loads during high-flow seasons (Praskievicz and Chang 2011). As channel erosion increases, sediment will be deposited in areas further downstream. During the low-flow season, reduced flow can, together with rising air temperature, increase pollutant concentrations because a higher water temperature can precipitate the chemical reactions of these pollutants. After a prolonged dry period, a small rainfall or snowmelt can transport a large amount of nutrients that have accumulated in the soil (Whitehead et al. 2009). Wastewater treatments may need to be upgraded to cope with such climate change-induced alterations in water quality. As some climate models predict higher tree mortality and more frequent wildfires, additional nutrients or sediments may be delivered to streams after forest fires. Changes in flood frequencies and magnitudes resulting from climate change will increase the capacity of streams to carry large sediments, exponentially increasing sediment loads during high-flow events.

Climate change impacts on droughts and floods

Climate change not only means changes in flow but also implies more frequent droughts and floods. Climate models predict increases in the number of dry days while the intensity of precipitation increases in mid-latitude humid climates. Such changes in precipitation patterns will bring more frequent urban flash floods in already developed areas that have high amount of impervious surface areas. As urban development continues in the coming decades, the magnitude of urban flash flooding is likely to increase. In large watersheds, riverine flooding, which occurs when channel capacity can not hold the excess water and thus spills over to the river bank and adjacent low-lying areas, is also likely to increase when prolonged wet periods saturate soils (Georgakakos et al. 2014). The 1993 Mississippi River flood exemplifies such a case. As the intensity of tropical storms is likely to increase under warming scenarios, coastal areas are prone to flooding that results from storm surges. Cities located at the mouth of large river basins will be exposed to more frequent coastal flooding as sea level rises and storms bring inland as well as coastal flooding. Many infrastructures such as power plants, roads, drinking water, and wastewater treatment plants, which are located near rivers or coastal areas, are particularly vulnerable to flooding.

While extended extreme droughts (multiyear droughts) may not necessarily increase in humid temperate climates, short-term droughts (3 or 6 months) are projected to increase under some
climate change scenarios (Cisneros et al. 2014). Even without changes in annual flow, changes in the timing and magnitude of seasonal flow will exacerbate summer droughts in some areas, particularly where the gap between water supply and demand is already high. In arid climates, extreme droughts are more likely to occur under a warming climate, as evidenced by the American southwest and southeast in the past decade. The social impacts of such prolonged droughts can be severe in areas where alternative drought mitigation strategies are not available.

Climate change impacts on water demand

Rising air temperatures will also increase municipal and irrigational water demands. Historical analysis of some large municipal water providers shows that daily water production is highly positively associated with daily maximum temperature and negatively related to antecedent precipitation amounts (Miller and Yates 2006). The effects of this climate variability and change on water demand will vary by region. The sensitivity of water consumption to warming is higher in arid climates than in humid temperate climates (Breyer, Chang, and Parandvash 2012). Outdoor water use in these hot arid climates will increase further as urban residents attempt to reduce the temperature by applying more irrigation water. As the temperature rises, soils get drier earlier in the growing season, so crop water needs to be increased as well. Thus, irrigation water demand will rise, although plants may use water more efficiently to minimize transpiration under harsh climates. Water withdrawals for cooling power plants can be affected, as warmer waters can reduce the efficiency of cooling. With an expected decline in summer water supply, an increase in competition between different water users is likely in many river basins that are already stressed by other nonclimatic factors such as ongoing development and population growth.

Climate change impacts on water-related ecosystem services

Changes in water quantity and quality and in the frequency of floods and droughts will affect water-dependent ecosystems and thus water-related ecosystem services, the benefits that people obtain from nature. Changes in the timing and magnitude of flow will shift water-provisioning ecosystem services, such as drinking water supply and hydropower generation. Additionally, regulating ecosystem services will be affected. Changes in sediment and nutrient loads or concentrations will increase the cost of water treatment for drinking or irrigation. Increased sediment supply from upstream may fill in reservoirs or dams quickly, adding to the cost of dredging and reducing the lifespan of dams. During flood events, water-borne disease may spread over wider geographical areas quickly, adding to the cost of public health care. During the low-flow season, the increased concentration of sediment can block navigation or irrigation channels, adding to the cost of removing silts. Diminished groundwater supply will increase the cost of pumping for irrigation and desiccate wetlands, limiting wetland functions and services. Particularly in areas where hydrologic and thermal regimes shift abruptly, increased stream temperature will negatively affect aquatic species and thus diversity because of the limited time allowed for species to adapt to such rapid change. In those areas, invasive species may take advantage of the changing climate and replace native species. Other water-dependent cultural ecosystem services such as skiing, sport fishing, kayaking, and waterscape aesthetics may
degrade as snow, water availability, and water quality decline. While there is high uncertainty in estimating the value of these water-related ecosystem services, as society’s demand for these services increases in the future, their value is also likely to increase.

Possible climate change adaptation strategies in water resources

While climate change is occurring at a global scale, the impacts of climate change will vary by region and will be realized differently across different scales. Therefore, effective climate adaptation strategies should consider the regional and scalar differences of each region’s environmental and social systems. A wide combination of structural and nonstructural policy may help relieve the potentially negative consequences of climate change in the water resource sector. New dam operation rules can minimize the disruption of hydropower generation while maintaining environmental flow and preventing downstream floods. Aquifer recovery storage can draw excessive winter water into the groundwater system and pump out during the low-flow season for meeting the needs of irrigation water. Best management practices in farmlands can reduce nonpoint source pollution, while urban green infrastructure can retain more storm runoff and nutrient or sediments during storm events. Smart land-use planning and landscaping practices in urban areas can reduce residential outdoor water consumption in the summer. Early flood or drought warning systems can prepare communities to cope with extreme hydrologic hazards. Some portions of floodplains can be restored by planting trees, reducing peak flow in downstream areas while providing habitat in stream bank areas. Floating homes or amphibian houses can be more proactive adaptation strategies in coastal areas where both sea level and storm surges are projected to increase in a warming world. For these adaptation strategies to be successful, concerted coordination across different sectors at different levels is essential.

Drinking water and water for personal sanitation are essential for human life, health, and dignity. Access to water for these purposes is the focus of an evolving international human right. In 2010 the United Nations (UN) General Assembly passed a resolution recognizing water as a human right (United Nations 2010). The vote on this resolution was 122 in favor with 41 abstentions. The United States, Canada, and some members of the European Union were among those abstaining. The abstentions occurred because the full parameters of this right are still being developed, and the impacts are uncertain.

The need for a specific human right to water has evolved for several reasons. In the various declarations of human rights made since 1945, water has not always been explicitly singled out, though it is mentioned in some conventions. An explicit human right would encourage investment in water and sanitation services. Access to water is a global problem with 768 million people lacking safe drinking water and 2.5 billion without adequate sanitation facilities (WHO 2013). Framing water as a human right recognizes water’s importance to human dignity and the need for equal access. If water is a human right, then investments will be made equitably. Another reason for the evolution is the backlash against private service providers that propelled a series of confrontations starting in the 1990s. The protestors asserted that *water is a human right, not a commodity*. This anti-privatization movement has been very vocal in bringing a human right to water to global attention.

A human right to water is often a polarizing issue. This is partly because the *right* is associated with specific local conflicts. Even though the conflicts that focus attention on the issue are local, a human right to water is an international right. Human rights must be accepted by the international community, and this often requires compromise.

### Water as a human right in context

The issue of access to drinking water has deep roots, especially in arid areas (Salzman 2006). In traditional Jewish water law, surface waters were common property (open access) available to anyone for drinking water purposes (see also Water rights). Wells on the other hand were the common property of the community (limited access common property). Although everyone had a right to drink before water was used for agricultural purposes, community members had a preference over outsiders if there was an extreme shortage. Islamic traditions also give drinking water a preference over other uses, with drinking water available to everyone. Australian Aboriginal traditions required outsiders to *ask first* for drinking water, with permission usually granted. Other parts of the world have similar traditions. Although the provision of drinking water as a human *need* has a strong tradition, treating it as a *commodity* also has a long history.
WATER AND HUMAN RIGHTS

The growth of large urban areas created water supply problems which local wells and surface sources could not overcome. Solutions were often expensive and a variety of public and private (sometimes both) supply systems developed depending on circumstances. In ancient Rome citizens were provided free water in a variety of public basins, but almost half the total supply went to private destinations where a fee was paid (Salzman 2006). By the late 1500s London licensed a water delivery system that delivered water for a fee. The system was built mostly with private money. By the late 1700s cities in the United States were sufficiently large to require more sophisticated delivery systems. Philadelphia, New York City, Boston, Chicago, and Cincinnati developed a variety of fee-based water supply systems. Some were public and others were private (Armstrong, Robinson, and Hoy 1976). Today, urban water delivery supported by user fees is the norm, with both public and private systems supplying water.

Many parts of the world have difficulty funding the kinds of water supply and sanitation systems needed to meet health standards. International sources can provide the needed capital, but this often comes with strings attached. By the 1980s the International Monetary Fund and the World Bank had adopted neoliberal policies promoting the privatization of public services such as water utilities. Some of the private firms, after investing in water supply and sanitation systems, raised the prices charged to a level beyond the consumer’s ability to pay. In Bolivia and Argentina protestors refused to pay their bills and took to the streets. Eventually, the private firms were ousted. The protestors claimed a human right to water under international law. But their anti-privatization and anti-commodification rallying cries do not represent current trends in international law. A human right to water is neutral over public or private delivery systems (Murthy 2013). A description of international law will help in understanding the current situation.

International law

International law, and in particular that associated with human rights, differs from the law that governs nations. In general, international law governs the relationships between States (countries). International human rights law goes one step further, creating an obligation governments have to their own citizens. Human rights bring individuals into international law. Because States are sovereign, international law is largely (not completely) consensual. This means States must agree to be bound by the international law in question. Without this consent enforcement is problematic.

International law comes from four sources. Not all are of equal importance and some are not recognized by all States (countries). Conventions and customary international law receive the greatest amount of acceptance. The other two, general principals and secondary sources such as the writings of legal scholars, have persuasive value in some instances. Only the first two will be discussed here. Conventions are written agreements (treaties and other international instruments) where the parties have expressly consented to be bound by the terms. A treaty can be between two or more parties, and only those parties are bound. In contrast, customary international law is based on the common practice of States (what they actually do), and the belief they are bound to behave that way by international law (opinio juris). Consent is implied in this instance. If a State behaves contrary to what some consider customary law, it shows lack of consent. Acquiescence, doing nothing to object, can be used to infer consent. Thus when a right is claimed under international law, States frequently object in order to show they do not consent.
Statutory law binding all States is not common internationally, although the European Parliament creates binding statutory law for member states. The UN Security Council does have power to create binding law, but each permanent member has veto power. A UN resolution may or may not be binding and certainly would not be on States voting against such resolutions. The language of a particular resolution controls, and many are considered soft law since they do not have language forcing any action. Declarations or resolutions containing nothing more than an aspirational goal or a statement of principle are not hard law (enforceable law). Even if resolutions are soft law, they can show a trend toward an emerging customary international law.

A common way for customary international law to emerge is through the use of UN conventions. A UN convention, unlike a treaty between two States, is meant to be agreed to by a large number of countries, at which point it shows evidence of customary international law. For example, through a lengthy process of negotiation a draft convention is created. This draft is reviewed by UN member States, and those that agree will sign and ratify the convention. After a specified number of States have ratified a convention it is considered to be in effect, although it may not be binding on all. This is typical for the human rights conventions that implicitly recognize a human right to water.

Human rights

Human rights, as a legally binding obligation States have toward their citizens, date from the end of World War II. Although the concept of natural law has been around much longer, states were not bound to any particular standard of behavior. Natural law recognizes that all people are entitled to specific rights and freedoms regardless of man-made laws. Natural law can include a right to self-determination, life, liberty, property, or the pursuit of happiness, depending on the philosophical interpretation. The US Constitution’s Bill of Rights recognizes many of these natural rights and others. In 1948 the UN adopted the Universal Declaration of Human Rights (UDHR), which includes 30 articles defining fundamental freedoms and liberties. Although this is not a binding treaty, the signatory States (all members of the UN) pledged themselves to achieve this aspirational goal. As such, the document presumptively has legal effect whether it is enforceable or not. A right to a standard of living adequate for health purposes is included. This right can only be achieved with access to water, which by implication is included in the right.

Subsequent to the UDHR, several other UN human rights conventions addressed specific aspects of human rights with water either implicitly included or with some explicit reference to water. The International Covenant on Economic, Social, and Cultural Rights (1966) declares that people cannot be deprived of means of subsistence. Water is implicitly included in a right to subsistence. The Convention on the Elimination of All Forms of Discrimination against Women (1979) recognized a right to adequate living conditions, including access to water and sanitation. The Convention on the Rights of a Child (1989) recognizes a right to clean water to protect children’s health. The Convention on the Rights of Persons with Disabilities (2006) assures equal access to clean water. All but the last convention have entered into effect because a sufficient number of countries have ratified them. This does not mean they are universally binding and enforceable, although they may represent aspirations for what customary international law should include. For example, the United States
WATER AND HUMAN RIGHTS

has not ratified any of these conventions. Two problems exist. One is with the uncertainty created by the convention language, and the other is with different importance States assign to the meaning of a human right.

Not all States mean the same thing when they use the term human right. One position looks on human rights as an acknowledgement of an important human need that ought to be addressed. Another views human rights as a legal entitlement obligating a government to act, even though it means a reallocation of scarce resources (Donoho 2012). There is a significant difference between a need and a legal entitlement. A legal entitlement gives an individual a mechanism for enforcing the right against the government. Needs are aspirational, as reflected in most human rights conventions where the government obligation is limited to available resources or all appropriate means. This language allows governments to interpret the convention as a goal rather than an entitlement.

Current status as customary international law

The 2010 UN resolution expressly declares water as a human right. The resolution is nonbinding but is an expression of high aspiration. No treaty or convention expressly creates this human right. The real issue is whether a human right to water has reached the point where it is customary international law (Cavallo 2012). Commentators argue either that customary law status has already been achieved or that it is in process. The main issue is whether the right will be defined in terms of a need or an entitlement. Enforcement changes depending on the approach (Beail-Farkas 2013) as do obligations between States. The parameters of customary international law are determined by examining state practice (how States actually behave). State practice is used to establish opinion juris (a State’s belief that it has an obligation to follow the law) and requires consistent and uniform behavior.

State practice can be determined by both State behavior and the actions of international bodies. For example, ratification or failure to ratify the human rights conventions discussed above shows an individual State’s position with regard to state practice. The reasons for non-ratification or the exceptions made as part of the ratification process are important in determining the contours of an individual state’s acceptance or denial. Also, state practice can be determined by examining the international soft law created by international bodies. International soft law includes resolutions by the UN Human Rights Council and other UN documents, statements from international conferences, and regional or national human rights documents. All these together provide evidence of state practice. At present, the lack of uniformity and consistency makes it difficult to determine the parameters of the human right to water. Several examples will be used to illustrate the complexity in establishing customary international law.

The right to safe drinking water and sanitation has been recognized expressly or implicitly in regional and national legal instruments. Regional treaties in Asia, Africa, America, Europe, and the Middle East are one example (Cavallo 2012). Typically, these are in regional human rights agreements and obligate a state to provide basic services, eliminate discrimination, and provide equitable access. A right to water is also being recognized in national constitutions. South Africa, Uganda, Argentina, and others have explicitly recognized the right while in India it is implicit in their constitution. Court decisions in South Africa have extended this to include a duty to provide free water under some circumstances (Bluemel 2004). California joined
this growing movement in 2012 by legislatively enacting a bill establishing a right to “safe, clean, affordable, and accessible water” sufficient for “human consumption, cooking, and sanitary purposes” (California Water Code 2013).

International conferences have generated a large number of declarations and resolutions addressing this issue. When these conferences have official State representation they reflect state practice and build the case for an evolving customary international law. Additional weight is added when the conference is sponsored by the UN. For example, the UN Water Conference in Mar del Plata (1977) recognized that all people have a right of access to drinking water sufficient for their basic needs. This was reaffirmed in Agenda 21 (1992), the Programme of Action of Cairo (1994), the Istanbul Declaration of Human Settlements (1996), the Johannesburg Declaration (2002), and most recently the Rio + 20 Conference (2012).

The UN has made many declarations on drinking water and sanitation (Cavallo 2012), but the most recent is an explicit recognition of a human right. In 2010 the UN General Assembly recognized “the right to safe and clean drinking water and sanitation as a human right that is essential for the full enjoyment of life and all human rights.” The resolution recognizes the body of soft law discussed above, and then calls upon the international community “to provide financial resources, capacity-building and technology transfer, through international assistance and cooperation” (United Nations 2010). Although 122 States voted for this resolution, 41 abstained. Some of the States voting for the resolution qualified their vote by saying it was subject to domestic legislation or to resource limitations (Cavallo 2012). Many of the states voting against the resolution felt it would interfere with the work by the Human Rights Council in Geneva. The Council is in the process of fleshing out the parameters of this human right, as will be discussed below.

Although the discussion above is not exhaustive of the number of statements made declaring a human right to water, it shows sufficient state practice to confirm the existence of the right. The elements of the right are also beginning to take shape mostly within the UN Human Rights Council. Any convention solidifying this right will probably be proposed by that source.

**Attributes of a human right to water**

The General Assembly resolution does not have much detail describing the elements of the human right. The details are most fully developed in General Comment 15 (Committee on Economic, Social, and Cultural Rights 2002) and Human Rights Council Resolution 15/9 (2010). The Committee on Economic, Social, and Cultural Rights and the Human Rights Council are part of the administrative structure of the UN. Although neither the resolution nor General Comment 15 is binding, together they foreshadow what might appear in a proposed international convention.

General Comment 15 defines freedoms and entitlements associated with the right. It outlines governmental obligations, defines what acts violate the right, and requires a process for enforcement. Freedoms include a right of access to existing supplies. Arbitrary disconnections, interference with existing delivery systems, and contamination violate the freedom of access. Entitlements include equal opportunity to enjoy water and water adequate for human dignity. Adequate water depends on the circumstances but includes a consideration of availability, quality, and accessibility. Availability includes sufficient water for drinking, personal sanitation, and domestic uses. Quality includes both
health-based standards and palatability requirements such as taste and odor. Physical, economic, nondiscriminatory, and information accessibility are all required. Physical accessibility is based on distance to the supply (immediate vicinity), quality of the facilities and services, and personal safety of the users. Economic accessibility requires that services and facilities be affordable to everyone. Nondiscriminatory accessibility promotes equality and prohibits discrimination for any reason. The list is extensive and includes sexual orientation, social status, HIV/AIDS (human immunodeficiency virus/acquired immune deficiency syndrome), and other discriminatory grounds. Special attention must be shown to groups who traditionally have had difficulties accessing water. Information accessibility includes a right to both receive and give information during water management decisions.

General Comment 15 creates government obligations designed to achieve the freedoms and entitlements. Two obligations are effective immediately: governments must guarantee the right can be exercised without discrimination, and steps must be taken to fulfill the right. The language describing implementation gives governments some flexibility. Implementation must be “deliberate, concrete, and targeted” toward achieving the goal. Governments have a duty that is “constant and continuing” and must “move as expeditiously and effectively as possible.” This language requires constant progress, but does not require governments to exceed their financial capability. Obligations to respect, protect, and fulfill are included. The respect obligation grants equal access to adequate water, recognizes customary and traditional water rights, and prohibits pollution from government facilities or actions. The obligation to protect requires governments to pass legislative measures that will prevent third parties from interfering with the right. This is aimed specifically at nongovernmental service providers, and requires legislation that guarantees equal access to safe and affordable water. This provision does not prevent the privatization of water services, but does provide consumers protection against inequities. The obligation to fulfill suggests a broad range of actions, including water planning, education on hygiene, and water conservation. Most importantly it addresses the issue of affordable water. Payment for water services must be equitable regardless of whether services are publicly or privately provided. Income supplements, low-cost and subsidized water rates, or even free water may be required depending on circumstances. It should be noted that subsidized or free water is a government obligation and not the obligation of a private service provider.

States are required to adopt a national water strategy in order to achieve the level of services required by the right. A process must be put in place that can monitor progress. States must take “necessary and feasible steps” in order to be in compliance. A distinction is made between inability and unwillingness. A State that is unwilling to use resources to achieve the right violates the requirements of General Comment 15. Resource constraints can make it impossible for a State to comply. This inability to comply requires justification, but States have discretion in determining the suitability of specific measures. Progress reports must be given to a UN committee who will evaluate whether goals are being achieved. Any person or group who is denied this right should have access to a legal remedy at the national and international levels. Legal remedies include compensation, restitution of prior conditions, and guarantees that the violation will not reoccur.

Obligations can extend beyond a country’s boundaries. Technical and financial assistance should be provided to other countries, especially by States that are economically developed.
The operative parts of the Human Rights Council Resolution 15/9 are less than two pages long. Several things are made clear by their repeated emphasis. While drinking water and sanitation services can be delegated to third parties, States are not exempted from their obligation to protect a human right to water. Non-State or third parties can provide services, but they must do so in a way that is transparent, nondiscriminatory, and accountable. Planning and implementation processes must be transparent and have meaningful stakeholder participation. A regulatory framework is needed to insure all providers fulfill the obligations, with regulatory institutions being given the ability to monitor and enforce the regulations. Non-State service providers are specifically singled out and required to engage stakeholders proactively and to actively incorporate human rights into their operations. Non-State providers must also provide a grievance process.

Clearly, States have the primary responsibility for protecting human rights, but third-party, non-State service providers are allowable. Although the terms “privatization” and “commodity” are not used, private service providers are acceptable. But States must regulate and enforce regulations to ensure non-State providers protect human rights and ensure stakeholder participation and protection.

**Consensus, ratification, and enforcement**

The above description provides insight on the current parameters of the international human right to water, but General Comment 15 and Human Rights Council Resolution 15/19 are not binding international law. Both were produced within the administrative structure of the UN. Neither of them is an agreement that can be ratified by individual States. At best they illustrate evolving customary international law. When the human right to water was specifically adopted by the General Assembly, the resolution recalled (acknowledged) General Comment 15 but not in the active part of the resolution. Acknowledgement (recalling) is not the same thing as a full discussion and the creation of a convention. Consensus on the shape of this human right has not yet been achieved. A draft convention is needed to stimulate discussion that in time can form a consensus. Once a proposed convention is in place, States must consent by ratifying it before a binding legal obligation is created. Even if a convention receives sufficient support to be in effect, human rights conventions have a weak record of enforcement.

Reaching a consensus may be difficult, as was shown by the 41 abstentions in the General Assembly vote. Many States, including the United States, felt the Resolution was premature because there were many uncertainties and a lack of consensus. Problem areas include: private service providers, obligations a State has to other States, philosophical differences States have in defining human rights, and international supervision. One reason for the 41 abstentions on the General Assembly Resolution (United Nations 2010) was the lack of clarity on the private sector role in service delivery. Anti-privatization and anti-commodification were rallying cries to bring world attention to a human right to water. From that perspective the private sector has no role in delivering water and sanitation services. Human Rights Council Resolution 15/19 (2010), which came out after the General Assembly Resolution (United Nations 2010), makes it clear that private sector service delivery is compatible with a human right to water. States have an obligation to ensure compliance regardless of the delivery mechanism. In fact many corporations are in favor of a human right to water because they view the investments this will require as a
business opportunity. In spite of the current UN position the debate is not a closed issue.

Inter-State obligations are unclear. General Comment 15 requires States that are more developed to provide financial and technical assistance to others. In addition, States should provide water to other countries to help them realize the right to water. Many countries are already involved in providing international assistance and are uncertain if more will be required. In voting in favor of the General Assembly Resolution (United Nations 2010) a few countries made an exception, stating the provision would not apply to them (Cavallo 2012). If this obligation survives into a final proposed convention, it will most likely be stated as an aspiration rather than an obligation. States are not likely to agree to provide water to another State. Such a reallocation could interfere with existing rights and have substantial costs (Donoho 2012).

States have substantially different philosophical approaches to human rights. Three examples are used with a realization that there are many nuances that fall in between. In one view a human right is an individual entitlement enforceable against the government with sanctions possible. The right is judiciable in an international or national forum, with real consequences including a reallocation of resources. From a different perspective, the right is an expression of human need best fulfilled by creating safety nets negotiated by a country’s political institutions. This approach uses available resources to progressively achieve specified goals. It allows the consideration of economic needs other than drinking water and sanitation. These two approaches are not completely compatible, but both are found in General Comment 15. The third approach views an endorsement of human rights as window dressing that can be ignored. Governments do not always mean what they say.

International supervision is also problematic. General Comment 15 envisions a process with States reporting progress to the UN where it can be evaluated. Enforcement by international judicial bodies is also proposed. Both these have elements that can be viewed as infringing on a State’s sovereignty.

Any proposed convention must reach some form of consensus on these items, making it unlikely that everything currently in General Comment 15 will be included. General Comment 15 was drafted by an unelected body without full debate. Ratification will be difficult in some countries, depending on the final convention language. Consensus and support for ratification will need to give States flexibility to protect their sovereignty. For example, the United States seldom consents to human rights conventions. A convention is a treaty which requires ratification in the US Senate. Even if the President signs the treaty/convention, consent cannot occur without Senate approval.

If a convention is negotiated and ratified by a sufficient number of countries to be in effect, enforcement is still a difficulty. Human rights conventions are notoriously weak on enforcement provisions, giving each State substantial freedom to make their own interpretation of a convention’s meaning. Convention terms tend to be malleable with substantial wiggle room. In addition, economic and social human rights are generally nonjudiciable, meaning individuals cannot get redress in a national or international forum. The weakness of international enforcement of human rights is well known even for States that have ratified conventions. But declaration of a human right has moral authority, and can be persuasive in influencing political processes and investments. Ultimately, if a State has the political will, enforcement will occur.

At the national level more progress has been made. The South Africa Constitution of 1996
recognizes a human right to water. Subsequent court decisions have upheld this right, leading to investments in infrastructure. In India a right to water and sanitation has been implied by the courts. Other States have made similar choices. The trend toward bottom-up national approaches will likely continue as negotiations on an international human right to water progress. Most commentators classify the right as soft international law or arguably customary international law. The real challenge is establishing the parameters of the right and reaching a consensus.

Water banking

Sheryl Luzzadder-Beach
Jonathan M. Flood
University of Texas at Austin, USA

Water banking enhances the storage component of the water budget, to overcome times of water shortage, when human water use demand exceeds the available water supply. This is most critical in arid regions where there is high demand both for drinking water and for agricultural uses. Water banking is also necessary for reducing water withdrawal impacts on natural terrestrial and aquatic habitats. California is a prime example of a US state with numerous water banking programs. Other states with major water banking programs include Texas, Colorado, Idaho, Nevada, and Arizona.

Physical water banking programs

Physical water banking involves the actual transfer of water from one region to another, or capture of excess surface runoff into storage in a groundwater aquifer or surface reservoir. It may also involve retention of water from one season to use in a later season, to meet the restrictions of water law. For example, in Texas, California, Arizona, and Nevada, groundwater banking is practiced for a number of reasons (Maliva 2014; Megdal and Dillon 2015). It is a form of artificial aquifer recharge that stores water that may not be put to beneficial use until a later date. The water is stored in an aquifer in order to maintain a future right to withdraw the water (Maliva 2014; see Water rights). Water is introduced into the aquifer either by injection wells or by spreading the water over the surface and allowing infiltration and percolation to the water table (Maliva 2014). Banked aquifer water may also be treated to meet use quality criteria (Megdal and Dillon 2015). The physical benefit of this system is that water is stored in overdrawn freshwater aquifers, and, by adding water, the aquifer’s pore spaces are prevented from collapsing, which helps to avoid ground subsidence (see Aquifers). Another benefit is to even out the supply when water is seasonally scarce. There may be impacts on stream flow that is connected to the water table, so coordinating with surface water management is important, especially in times of drought. Because groundwater law can be different from surface water law even in the same jurisdictions, care must also be taken in regulating, measuring, accounting for, and monitoring groundwater banking activities (withdrawals and deposits), especially if surface water is part of the equation. Water banking is also used for ecological habitat restoration, as applied on the Snake River in Idaho, where instream flows are managed for endangered species (Green and O’Connor 2001).

Virtual water banking programs

Unlike physical water banking, virtual water banking programs involve trading water use credits or water withdrawal rights on a market. Water banking matches buyers and sellers, and follows the market value of water across and between regions (Maliva 2014). For example, urban and agricultural waters have different prices, values, markets, and desired qualities. Lepper (2006,
368) further differentiates water markets into exchanges, transfers, and groundwater “augmentation” programs. Transfers involve a change of ownership or the lease of water rights, whereas exchanges involve temporary trades or changing the timing of the use within the frame of water rights law, as practiced in the Arkansas Valley (Colorado) water banking program (Lepper 2006). Likewise, Southern California has a complicated system of conjunctive water use to follow demand and exchanges between surface water systems, reservoirs and groundwater systems, and multiple water districts (Pulido-Velasquez, Jenkins, and Lund 2004). This is conceptualized using economic engineering network flow models, since multiple uses and outcomes in geography and time are optimized. California sees urban water demands alone growing from 10.8 km$^3$ in 1995 to a forecasted 14.8 km$^3$ in 2020. Conjunctive uses in Southern California provide about 3.1 km$^3$ a year, in comparison to the urban demand (Pulido-Velasquez, Jenkins, and Lund 2004). Conjunctive use and water banking occurs in Southern Idaho, with the one of nation’s earliest water banking programs formed in the droughts of the 1930s and formalized by law in 1979 (Lepper 2006; Ghosh, Cobourn, and Elbakidze 2014). This system marketed water rights or entitlements by sale or lease (Lepper 2006, 367). Many orders of magnitude less than California’s urban water demands, the number of trades or exchanges in Idaho grew from less than 0.001 km$^3$ of water in 1995 to nearly 0.071 km$^3$ of water in 2013 (Ghosh, Cobourn, and Elbakidze 2014).

Water markets are also practiced internationally, as exemplified in Spain (Palomo-Hierro, Gómez-Limón, and Riesgo 2015). Spain’s water markets became legally possible over the last two decades, in response to higher water demands and a growing economy. Informal markets had existed for a long time prior to the 1999 legislation. The Water Law of Spain formed water centers, and allows for transfers between users, and the transfer of rights for private water use, although water itself is in the public domain. Water rights cover both groundwater and surface water use, and are usually granted for 75 years. The transfers can be time-limited, and water authorities can intervene for the greater good. Transfers can benefit urban, agricultural, and industrial (e.g., hydropower) uses. Droughts in Spain in 2005 and 2008 drove a large number of transfers, and interbasin transfers were also accomplished in these trades (Palomo-Hierro, Gómez-Limón, and Riesgo 2015).

Conclusions

Although water itself may be in the public domain, its use and distribution can be bought, sold, leased, and lent. Physical and virtual water banking can alleviate conditions of water shortage, protect aquifers from collapse, and prevent ground subsidence. Water banks can form a market of exchange and balance of water costs between users and regions. Water banking can also alleviate unevenness of water in time, and allow users to put water to beneficial use in later times than the normal water cycle and water law might allow. Interactions of surface and groundwater must be considered by careful management of water resources that are physically banked in aquifers, and virtually traded and applied.

References

“What happens to the rain” is a fundamental topic for geography. Rainwater, as freshwater, is essential for human and almost all of terrestrial plant and animal life. With the exception of seafood, nearly all human food is directly, or indirectly, produced through natural vegetation or forage crops, dependent on rainwater. Public water supply through surface water, and groundwater, is dependent on rainfall, in many dry locations from tens of thousands of years ago during the cooler, often wetter episodes of the Pleistocene epoch. With the exception of eolian processes, water is a fundamental agent in sculpting the Earth’s terrestrial surface, whether as flowing water or ice, or as an agent in the physical or chemical weathering of surface materials.

Placing time and quantitative values on the components of the hydrological cycle is critical for managing water resources. This is exactly what is entailed in generating a “water budget” or “water balance” for a site or an area. Thus, the water budget involves placing quantitative values on the destination of the precipitation ($P$) that is evapotranspired ($ET$), becomes surface runoff ($RO$), becomes groundwater ($GW$) plus a change in surface or groundwater storage ($\Delta S$). Over a longer term the water balance is thus (Dunne and Leopold 1978):

$$P = ET + RO + GW \pm \Delta S$$

However, over the shorter term additional components need to be included:

$$P = I + ET + OF + SM + GW \pm \Delta S$$

where $I$ is interception, $OF$ is overland flow, and $SM$ is soil moisture in the vadose zone (Gurnell 2000). Over the longer term, those three items are evapotranspired, become runoff, or become groundwater.

Water budgets can be calculated for a point location, in which values are in water depth (mm or inches) or can be calculated for an area such as a stream drainage basin or an aquifer in volumes of water ($m^3$ or acre-feet).

In the context of time, water budgets can be calculated for any specific period depending upon the purpose of the analysis. When calculating specific irrigation needs for a crop, water budgets are often calculated for a day, a week, a season, or a year. When analyzing water supply or climate, water budgets are typically calculated for a specific year or for “mean annual” conditions which in the United States is the preceding three decades, for example 1981–2010.

The basic outlines of the hydrologic cycle have been commented upon since antiquity. Jewish King Solomon wrote in Ecclesiastes 1:7 that: “All the rivers run into the sea, yet the sea is not full. To the place from which the rivers come, they return again.” In Greek civilization, Plato relied upon a giant, underground reservoir called Tartarus, that desalinized seawater and then, drawn by the sun, lifted the water to sustain springs and stream baseflow. Aristotle rejected his mentor’s model and described the outlines of the hydrologic cycle, but without quantitative data fit their concepts into pre-existing models about the symmetry of nature. In Roman times, Vitruvius postulated the “hot bath model,” in which water vapor rose from the hot water and...
condensed on the cool ceiling above (Biswa
1970).

In the early scientific era, Bernard Pallisy in *Discours admirables* (Admirable Discourses) qualitatively describes the precipitation-based hydrologic cycle. Taking that concept, Pierre Perauiq measured precipitation, stream flow, and spring flow in the Seine River basin and stated that precipitation alone was sufficient for those water outputs. A generation later, Edmond Halley measured evaporation rates providing the final component for generating a quantitative whole Earth hydrologic cycle (Biswa 1970).

Detailed hydroclimatic analyses began in the 1800s. Rain gauges and methods for measuring stream flow provided quantitative values for analysis, but were limited by the inability to calculate land surface water losses through soil evaporation and plant transpiration (Mather 1991). Initially estimates of combined evaporation and transpiration, “evapotranspiration,” were obtained by simple accounting of liquid water inputs and outputs, with evaporation (*ET*) being: $ET = P - RO + GW$ (Thornthwaite and Mather 1955).

Developing methods for calculating evaporation and combined evapotranspiration has been more difficult. Lysimeters, in effect a flowerpot on a scale, were first used in the late 1880s, where evapotranspiration was equal to the loss of the weight of the “flowerpot” over time. Since then lysimeters up to the size of small buildings have been used to measure evapotranspiration for specific types of vegetation and crops. In the twentieth century infrared spectrometers and cameras have been used to measure evapotranspiration.

Because of the difficulty in actually measuring *ET*, the development of models to estimate *ET* has been critical to the application of water budgets. The agricultural motivation of these efforts resulted in the concurrent desire to calculate optimal water need for vegetation, that is, potential evapotranspiration (*PET*). A critical step in the development of water basin studies was the incorporation of potential evapotranspiration into water budget studies. By developing models to estimate potential evapotranspiration, hydroclimatologists could calculate the supplemental irrigation needs for a given crop.

In a series of papers beginning in 1931, C.W. Thornthwaite developed methods for calculating potential evapotranspiration and actual evapotranspiration based upon temperature, latitude, precipitation, and day of the year. This work facilitated the development of classification systems, first based upon temperature and the ratio of precipitation to evaporation, and then precipitation to potential evapotranspiration. Based upon precipitation and potential evapotranspiration he developed water budgets that included actual evapotranspiration that was supported both by direct precipitation and by soil moisture utilization. In the 1950s, Thornthwaite developed water budget models that provided values for soil moisture recharge, soil moisture utilization, deficit, and surplus over varying time periods. The developed water budget models were directly applicable to irrigation applications, as they calculated the water deficit as the difference between actual and potential evapotranspiration. These later methods were then developed into the WATBUG Fortran IV computer program in the late 1970s (Mather 1991). In the “Internet age” there are online water budget calculators for Thornthwaite methods and others such as Penman *PET* (Ponce 2014).

Developing water budgets has provided an essential tool for analyzing the size of closed lakes in dry regions. Edmond Halley (1715, 298) stated: “Now I conceive that as all of these lakes receive rivers, and have no exit or discharge, so it will be necessary that their waters rise and cover the land, until such time as their surfaces
are sufficiently extend, so as to exhale in vapour that water which is poured in by the rivers, and consequently that lakes must be larger or smaller according to the quantity of the fresh water that they receive …”

Lake size is a function of basin runoff plus lake precipitation and evaporation from the lake surface as a function of its size and the lake evaporation rate. This reasoning has been used to calculate lake sizes during the Pleistocene “pluvials” and to analyze the effects of inflow diversions to modern closed lakes such as the Salton Sea, Aral Sea, and Dead Sea.

Human impacts on natural water budgets, initially inconsequential in pre-domestication times, have dramatically increased. Initially irrigation distributed and hastened the evapo-transpiration of local stream flow from within a basin. More recently, major water imports and exports have created highly altered budgets and hydrological regimes. For example, in the western United States, water of the Colorado River basin is diverted from the tributary Animas River to the Rio Chama of the Rio Grande basin. Farther north in Colorado, Colorado River water is transferred to the Plate River to supply water for the burgeoning Denver metro region. One of the largest water transfers involves the importation of water into coastal Southern California that receives water from the Colorado River, the Owens River of the eastern Sierra Nevada., and the Feather River of the northern Sierra Nevada. Linton (2008) observed that such dramatic water transfers limit the utility of simple regional applications of water budgets because such water transfers create entirely non-natural environments in both the source and the destination regions.

The recent increase in municipal use of groundwater has provided impetus to generate water budgets for aquifers. Aquifers can be considered the subterranean equivalent of drainage basins with inputs, outputs, and changes in storage. However, the difficulty in directly measuring these amounts justified resistance to managing groundwater resources until recently. In a famous case decided in 1904 involving a suit to receive compensation for a lowered water table, the Texas Supreme Court ruled that “Because the existence, origin, movement, and course of such water, and causes which govern and direct their movement are so secret, occult, and concealed … an attempt to administer any set of legal rules in respect to them would be involved in hopeless, uncertainty, and would therefore be practically impossible” (Kaiser 1986, 31). Gradually agencies responsible for aquifers and scientists studying them have developed at least reasonably accurate water budgets for aquifers. Initially these budget models were based upon solving for surface water inputs and outputs and the concurrent changes in aquifer volume. Fluorescent dye studies facilitated the calculation of relative inputs and outputs from aquifers.

The power of geographic information systems (GIS) to analyze and model three-dimensional space facilitated the development of GIS-based groundwater models to quantify components of groundwater budgets. The legal mandates to manage the water resources of specific aquifers have sponsored the development of “water availability models.” Such models are by nature complex as they need to accommodate different hydrologic heads, waters of different densities, and aquifer units of varying specific yield and conductivity. In an echo of the 1904 Texas Supreme Court decision, and in spite of significant technological progress, Kresic (2007) warns that such models remain simplifications of reality and can never be 100% accurate on account of the myriad of variables and uncertainties affecting groundwater.

Water conflicts

Jacob D. Petersen-Perlman
Aaron T. Wolf
Oregon State University, USA

Water has been the source of disputes since the Neolithic revolution, when humans settled down to cultivate food between 8000 and 6000 BCE. This is reflected within the English language: the word “rivalry” is derived from the Latin rivalis, meaning “one using the same river as another.” The ancient roots of the word are still evident today in many situations, as riparians – countries or provinces that have the same river in their territories – are often rivals over shared waters. This is evident today with countries downstream complaining of upstream users, such as Pakistan about India, Iraq and Syria about Turkey, and Egypt about Ethiopia.

Rivalries such as these lead to water being managed for mitigating conflict, as all water management serves multiple objectives and navigates between competing interests. Within a nation, these interests – domestic users, farmers, hydropower generators, recreational users, ecosystems – are often at odds, and the probability of a mutually acceptable solution falls dramatically in proportion to the number of stakeholders. Add international boundaries and the odds fall farther still.

Without a mutually agreed solution, parties with interests in shared water resources can find themselves in dispute or even violent conflict, either with each other or with state authorities. Still, these water-related disputes must be considered in broader political, ethnic, and religious contexts. Water is rarely the single or even the dominant cause of conflict, but competition for scarce or shared water resources can exacerbate existing tensions between countries and therefore must be considered within the larger context of conflict and peace.

The nature of water conflicts is often similar across disparate spatial and temporal scales. So too are many of the solutions to these conflicts, which humans have developed to address water shortages and to cooperate in its management. In fact, cooperative events (water-related events between riparian countries ranging from minor verbal support to voluntary unification into one nation) between riparian states outnumbered conflicts by more than 2:1 between 1945 and 2008. Water has also been shown to strengthen ties, develop cooperation, and even prevent conflict. In some cases, water has been one of the few paths for dialogue in otherwise heated conflicts. In regions that are politically unsettled, water may serve as an essential component of regional development plans, which serve as de facto conflict-prevention strategies.

While the underlying reasons for controversy related to water may be numerous, including power struggles and competing development interests, all water disputes can be attributed to one or more of three issues: quantity, quality, and timing (Figure 1). No matter at what scale the conflict occurs, the key to managing, understanding, and preventing future water-related conflicts can be found in the institutions established to manage water resources.

WATER CONFLICTS

Understanding conflicts over water is particularly relevant, as many basin boundaries do not conform to political boundaries. The world’s 276 international surface water basins that include political boundaries of two or more countries constitute 47% of the Earth’s land area. These basins are also home to around 40% of the world’s population. Many of these basins have more than two countries that contribute to its area, demonstrating the high level of interdependence; for example, the Nile is shared by 12 countries, while the Danube has 19 riparian countries. Thousands more basins are divided at subnational levels.

The nature of water conflict

Because of the prevalence of these water bodies spanning boundaries across the globe, scholars have debated whether disputes between nations due to the transboundary nature of water may lead to violent conflict; the debate appears to be centered on how “transboundary water conflict” is defined. Wolf (2000) has argued that, while there is a growing literature describing water as a historic and, by extrapolation, a future cause of warfare, a close examination of case studies cited in this literature reveals looseness in the classification categories; in other words, it is often unclear how authors define water “wars.” De Stefano et al. (2010) found only 38 acute disputes (i.e., those involving water-related violence) between 1948 and 2008; of those, 31 were between Israel and one or more of its neighbors, with no violent events occurring between Israel and its neighbors after 1970. This means that most of the disputes were (i) political tensions or instability rather than formal acts of warfare, and (ii) instances where water was a

Figure 1 Reasons for transboundary water-related conflictive events and cooperative events (TFDD 2011).
tool, target, or victim of armed conflict. While these disputes are certainly important, they do not constitute water “wars.” Wolf (2000) also cited many incidents of violence related to water at the subnational level; these incidents were generally between indigenous peoples, water-use sectors, and/or provinces. Others suggest that, while the likelihood of war over water is small, a long history of violence associated with transboundary water resources exists, and that future pressures, including (but not limited to) population and economic growth and climate change, could increase tensions. A few characteristics that make water likely to be a source of strategic rivalry between nations include the degree of water scarcity; the extent to which the water supply is shared by more than one region or state; the relative power between basin states; and the ease of access to alternative freshwater sources (Gleick 1993). Nations have cut off access to shared water supplies for various political and military reasons; they have also aimed for new water supplies through aggressive military expansion. Gleick (1993) cited inequalities in water use as another source of many regional and international frictions and tensions.

Though water supplies and infrastructure have often served as military tools or targets, no states have gone to war specifically over water resources since the Mesopotamian city-states of Lagash and Umma fought each other in the Tigris–Euphrates Basin in 2500 BCE. Instead, official cooperation over water has been much more common, with more than 3600 treaties signed between 805 and 1984 CE. Though most of those treaties concerned navigation, treaties signed more recently have addressed water management, including flood control, hydropower projects, or allocations in international basins. Since 1820, more than 680 water treaties and other water-related agreements have been signed, with more than half of these concluded since the mid-1960s.

The likelihood of international water conflict

With the proliferation of water-related agreements, especially in recent years, the likelihood of escalated, even violent, conflict over water resources is one that scholars have debated over the past decades. This debate falls within the framework of hydropolitics (Waterbury 1979), which relates to the ability of geopolitical institutions to manage shared waters in a manner that is politically sustainable, that is, without tensions or conflict between political entities (McNally, Magee, and Wolf 2009).

Examining transboundary water system resilience within a hydropolitical context leads to the concept of hydropolitical resilience, defined as the complex human–environmental systems’ ability to adapt to permutations and change within these systems. In contrast, hydropolitical vulnerability is the risk of political dispute over shared water systems (Wolf 2005). Characteristics of a basin that would tend to enhance hydropolitical resilience to change include international agreements and institutions, a history of collaborative projects, generally positive political relations, and higher levels of economic development. At the same time, facets that tend toward vulnerability include rapid environmental change, increased hydrologic variability, rapid population growth or asymmetric economic growth, major unilateral development projects, absence of institutional capacity, the potential for the “internationalization” of a basin, and generally hostile relations (Wolf 2005). When examining characteristics that would tend to enhance or detract from hydropolitical resilience in combination, it becomes clear that the settings
WATER CONFLICTS

of hydropolitical conflict are most likely with major water projects, such as dams, diversions, or diversion schemes, built in the absence of agreements or collaborative organizations, that can mitigate the transboundary impacts of these projects (Petersen-Perlman et al. 2012).

Variables that increase the likelihood of conflict

The aforementioned variables (or combination of variables) may cause actors in the river basin to move from nonconflict into conflict. Wolf, Stahl, and Macomber (2003, 2) suggested the following relationship between change, institutions, and likelihood of conflict: “The likelihood of conflict rises as the rate of change within the basin exceeds the institutional capacity to absorb that change.” This suggests that two important dimensions exist in transboundary water disputes: (i) a high rate of change in the system; and (ii) a low capacity of institutions in the system to absorb change, for example, low hydropolitical resilience.

Change that may lead to low hydropolitical resilience is manifested in several ways, one of which is the unilateral construction of large water infrastructure in transboundary basins. One prominent example of this unilateral construction occurred in the Tigris–Euphrates Basin, where in 1990 Turkey finished construction of the Ataturk Dam, the largest of 21 dams constructed for the Southeastern Anatolia Project (GAP), and interrupted the flow of the Euphrates for a month to partly fill the reservoir. Despite the Turkish government’s warning of a temporary cutoff of flow, Syria and Iraq’s governments protested that Turkey now had a water weapon that could be used against them. Those fears were prescient, as later that year the president of Turkey, Turgut Ozal, threatened to restrict water flow to Syria to force it to withdraw support for Kurdish rebels operating in southern Turkey (Gleick 1993). Another example of water infrastructure-related conflict is the 1986 case of North Korea announcing plans to build the Kungansan Dam on a tributary of the Han River upstream of the South Korean capital of Seoul. Gleick (1993) suggested that this led to fears in South Korea that the dam could be used as a weapon to flood Seoul through sudden releases of the reservoir. South Korea built a series of levees and check dams upstream of Seoul to try to mitigate potential impacts. More recently, rhetoric from leaders of downstream nations has escalated over Ethiopia’s construction of the Grand Ethiopian Renaissance Dam, arising from concerns over how the dam would impact flows of the Nile for downstream countries. These are strong examples that feature how water management decisions from an upstream riparian can be used (or viewed) as a political weapon to impose its will on downstream co-riparian nations.

Dam construction alone, of course, may not be the only condition for interstate water conflict to occur. Wolf (1998) hypothesized that the aggressor would have to be both downstream and the basin’s hegemon. He also stated that the upstream riparian would have to launch a project which decreases either water quantity or quality, knowing that their actions will antagonize a stronger downstream neighbor. The downstream power would then have to decide whether to launch an attack, and would have to weigh not only invading, but also occupying and depopulating, the entire watershed to prevent any retribution (Wolf 1998). Also, both countries in this scenario would most likely not be democracies, as two democracies have never been at war with one another (Wolf 1998). Climate change may also heighten hydropolitical
tensions within countries, between countries, and/or within river basins. In addition to climate change possibly altering the quantity and timing of flow within river basins and increasing water scarcity, there may also be detrimental indirect, negative effects of reducing food availability and increased exposure to new disease vectors. In combination, these can undermine the legitimacy of governments, damage local and national economies, and have adverse effects on human health. These direct and indirect changes may alter the hydropolitical resilience of the basin; as a consequence, river basins without robust water-related treaties and institutions may be more vulnerable to tension and conflict.

Variables that decrease the likelihood of international conflict

Now that the causes of hydropolitical conflict have been explored, it is natural to discuss what may lessen its likelihood. It is important to note that water cooperation may still happen in times of international tensions; there are several examples of countries actively at war with one another that may still concurrently find a way to cooperate over water. For example, the Mekong Committee, established by the governments of Cambodia, Laos, Thailand, and Vietnam as an intergovernmental agency in 1957, exchanged data and information on water resources development throughout the Vietnam War. Israel and Jordan held secret “picnic table” talks regarding the Jordan River following the unsuccessful Johnston negotiations of 1953–1955, even though they were at war from the time of Israel’s independence in 1948 until they signed the 1994 peace treaty. The Indus River Commission, created by the signing of the Indus Waters Treaty between India and Pakistan in 1960, survived two major wars between the two countries in 1965 and 1971. All 12 Nile Basin riparian countries are also currently involved in senior government-level negotiations to develop the basin cooperatively, despite disagreements.

Building institutional capacity by signing treaties and creating river basin organizations is described as a mechanism to decrease the likelihood of hydropolitical conflict. Giordano and Wolf (2003) cited characteristics that would make a treaty over water effective:

1 an adaptable management structure (including flexibility, allowing for public input, changing basin priorities, and new information and monitoring technologies);
2 clear and flexible allocating criteria;
3 equitable distribution of benefits;
4 detailed conflict resolution mechanisms.

Though there is certainly evidence to support these observations, there may also be inherent weaknesses of certain consent-building relations in water. Riparians can exploit treaties in a number of ways; treaties are not easily enforceable, can be structured to reflect (or exacerbate) existing inequalities between riparians, and can lead to a lack of participation from nonsignatory riparians (Zeitoun and Warner 2006). Perhaps the mere presence of a treaty or treaties does not indicate hydropolitical resilience alone; indeed, perhaps Zeitoun and Warner’s declaration that “the absence of war does not mean the absence of conflict” (2006, 437) may also extend to how the presence of agreements does not signify the absence of conflict. It may also be the parties engaged in treaties/institutions themselves, rather than institutional content or presence, that are at the heart of their success. These assertions are healthy critiques but, within the context of violent conflict, the relationship of institutional
WATER CONFLICTS

capacity and decreased violent conflict still stands (e.g., Wolf, Stahl, and Macomber 2003).

The nature of intranational disputes

The principles for avoiding international water conflicts have been discussed; but it is also important to see how the nature of water conflict changes at the national scale. While the literature on transboundary waters often treats political entities as homogeneous monoliths – “Kyrgyzstan feels …” or “Syria wants …” – analysts have recently identified the pitfalls of this approach, showing how subsets of national actors have different values and priorities for water management. In fact, the history of water-related violence includes incidents between water-use sectors, tribes, urban and rural populations, and states or provinces. Some research even suggests that the likelihood and intensity of violence increases as the scale becomes more local. Worldwide, local water issues revolve around core values that often date back generations. Groups such as irrigators, indigenous populations, and environmentalists, for example, may all view water as tied to their way of life, which is increasingly threatened by new demands and uses for cities and hydropower.

Interstate water conflicts have led to fighting between downstream and upstream users, such as between Native Americans and European settlers and along the Cauvery River in India. These water-related disputes can engender civil disobedience, acts of sabotage, and violent protest. In 2001 the United States Bureau of Reclamation closed the headgates of the Klamath Project in order to protect an endangered fish. This cut off water deliveries to irrigators, leading to large protests. In the Indian state of Orissa, 30,000 farmers clashed with police in December 2007 as a result of the government’s decision to allow a large number of industries to source water from the Hirakud Dam, while the farmers depended on this water for irrigation. Fifty protesters were injured in the confrontation with police. From 1907 to 1913, in California’s Owens Valley in the United States, farmers repeatedly bombed an aqueduct diverting water to the fast-growing city of Los Angeles.

National instability can also be provoked by poor or inequitable water services management. Disputes may arise over system connections for suburban or rural areas, service liability, and especially prices. In most countries, the state is responsible for providing drinking water. Even in cases where concessions are transferred to private companies, the state usually remains responsible for the service. Water-supply management disputes therefore usually arise between communities and state authorities. Protests are particularly likely when the public suspects corruption in water services management or that public resources are being diverted for private gain.

There are both similarities and distinct differences inherent in national and international water conflicts. The differences are more often stressed, but just how different the two settings are is open to debate. The following subsections deal with some common assumptions.

Institutions and authority

National cases are often played out in relatively sophisticated institutional settings, particularly in the West, while international conflicts can be hampered by the lack even of an institutional capacity for conflict resolution. It has been argued, though, that even sophisticated institutions have often not been amenable to relinquishing the traditional, usually legal, approaches to resolving water conflicts, effectively presenting the same challenges as the international setting.
Law and enforcement

The United States and other countries have, over the years, established intricate and elaborate legal structures to provide both guidance in cases of dispute, and a setting for clarifying conflicting interpretations of that guidance. International disputes, in contrast, rely on poorly defined water law, a court system in which the disputants themselves have to decide on jurisdiction and frames of reference before a case can be heard, and little in the way of enforcement mechanisms. One result is that international water conflicts are rarely heard in the International Court of Justice. Likewise, of the international cases presented here, only the Mekong Committee has used the legal definition of “reasonable and equitable” use in its agreement.

In the legal realm too, it has been argued that the differences between national and international disputes are more apparent than real. Given the myriad of legal venues open to disputants, and ambiguities of court jurisdiction, creative lawyers can effectively hamstring legal challenges for years, essentially creating a de facto lack of legal authority.

Presumption of equal power

“All are equal in the eyes of the law” is a common phrase describing national legal frameworks. No such presumption exists in international conflicts, where power inequities define regional relations. Each of the watersheds presented here includes a hegemonic power which brings its power to bear in regional negotiations, and which often sees agreements tilt in its favor as a consequence. Here, too, it has been argued that unequal resources, usually financial or political, result in real world inequities finding their way into the national settings of conflict resolution.

The best alternative to a negotiated agreement (BATNA)

A difference commonly pointed out between national and international disputes is that, in national water conflicts, war is not usually a realistic BATNA. While it may be true that intranational water wars are not likely, the same is increasingly accepted as being true of the international setting. While shots have been fired, both nationally and internationally, and troops have been mobilized between countries, no all-out war has ever been caused by water resources alone. As one analyst familiar with both strategic issues and water resources has noted, “Why go to war over water? For the price of one week’s fighting, you could build five desalination plants. No loss of life, no international pressure, and a reliable supply you don’t have to defend in hostile territory” (personal communication).

While real differences do exist between the national and international settings for water conflict resolution, these distinctions may not be as great as is often thought. The fortunate corollary to this is that many of the successes of alternative dispute resolutions in the national realm may be more applicable to the international setting than is commonly argued.

The difference makers: strong institutions

Strong institutional capacity that can adapt to change can prevent conflict at both the intranational and international scales. Institutions responsible for managing water resources have to be strong to balance conflicting interests over allocation and to manage water scarcity, which is often the result of previous mismanagement. These institutions can even become a matter of dispute themselves. In international river basins, water management typically fails to manage conflicts when there is no treaty spelling out each
nation’s rights and responsibilities with regard to the shared river, nor any implicit agreements or cooperative arrangements.

Similarly, at the national and local levels, it is not the lack of water that leads to conflict but the way it is governed and managed. Many countries need stronger policies to regulate water use and enable equitable and sustainable management. Especially in developing countries, water management institutions often lack the human, technical, and financial resources to develop comprehensive management plans and ensure their implementation.

Institutions may help to solve disputes

Most disputes, regardless of scale, are resolved peacefully and cooperatively, even if the negotiation process is lengthy. Cooperative water management mechanisms can anticipate conflict and solve smoldering disputes, provided all stakeholders are included in the decision-making process and given the necessary information, trained staff, and financial support to act as equal partners. Cooperative management mechanisms can reduce conflict potential by:

- providing a forum for joint negotiations to occur, thus ensuring that all existing and potentially conflicting interests will be taken into account during decision-making;
- considering a variety of perspectives and interests to reveal new management options and to offer win–win solutions;
- building trust and confidence between parties through collaborating and joint fact-finding; and
- making decisions that have a much higher likelihood of being accepted by all stakeholders, even if consensus cannot be reached.

Cooperation-inducing design

Building an environment for cooperation may prove difficult, especially in an environment where a history of cooperation is absent or lacking. Wolf (1995) listed general guidelines for cooperation-inducing implementation, using the pre-peace treaty Jordan Basin as his case study.

- Control of one’s major water sources: It is necessary to address both past and present grievances as a prerequisite for market-driven solutions. As such, an initial “disintegration” of the basin is recommended.
- Cooperation opportunities may be hidden in the details of each party’s bargaining mix.
- Water basin development can proceed from “small and doable” projects to ever-increasing levels of cooperation and integration, remaining always on the cutting edge of political relations.

One step that is often proposed in the beginning stages of cooperation is data and information exchange. Yet, it is important to remember that data collection should be purposeful, as data collection for its own sake may not be particularly useful. Strategic joint fact-finding between parties engaging in a project may serve as an important catalytic tool for developing political buy-in and fostering participation. Joint fact-finding also lowers the perceived risks of cooperation, as it has low sovereignty infringement and transaction costs. Factors that promote this exchange of data and information include the presence of compatible needs, absence of legacies of mistrust, increasing water resources stress, perceptions of mutual benefit, external pressure and funding, comparable levels of institutional capacity, popular and political concern about water resources management,
and functional formal or informal cooperative arrangements (Chenoweth and Feitelson 2001).

**Track I and track II diplomacy**

While any project can be designed to induce cooperation, it is also necessary for all parties involved to go through diplomatic processes to agree on a framework. This is where an outside party may help to play a role in the process. Though third parties alone cannot create a conducive political environment, they can provide incentives to cooperate both directly and indirectly through playing a brokerage role, by:

- providing technical competence and examples of best practices;
- assisting in negotiation and mediation skills, including the provision of legal and other water experts; and

Four different strategies of third-party support can be identified (Mostert 2005): track I diplomacy (cooperation); track II diplomacy (collaboration); track III diplomacy (transformation); and continuing support. Track I diplomacy involves supporting the conclusion of a formal agreement between parties, typically through mediation and facilitation. Track II diplomacy aims at arriving at feasible development strategies on the ground through promoting informal dialogues, research and studies, and capacity building. Track III diplomacy addresses policies at both national and local levels, which are typically at the root of transboundary water problems. Finally, third parties may provide the financial support necessary to sustain cooperation, through funding for a river basin organization or loans for development projects. None of these strategies is mutually exclusive; for instance, track II diplomacy efforts may build the pathway to more formal track I discussions.

WATER CONFLICTS

Water conservation

Heejun Chang  
*Portland State University, USA*

Water conservation means efficiency in use or all measures to reduce water consumption. The goal of water conservation is to use water more efficiently in order to meet the needs of humans and ecosystems. Water conservation is a pressing global environmental issue because the world freshwater supply is likely to diminish as the planet warms up and precipitation decreases in some parts of the world, while urban, agricultural, and environmental water demands continuously increase as population and income grow. Additionally, in some parts of the developing world, access to safe drinking water is very limited. Because water conservation implies any institutional, technological, and behavioral changes in water use as they relate to broad social changes, and drivers of these vary by each water use sector, changes by individual sector must be identified. Additionally, the spatial dimension of water conservation needs to be examined because the determinants of water use and conservation vary over space, and reduced water use in one area may induce increased water use in another region.

Urban residential water conservation

Urban residential water use is tightly associated with both macroscale factors (e.g., land use or institution) and microscale individual factors. These factors also interact with each other across scales, which shape complex water use and conservation patterns in urban areas. Densely developed urban areas use less water per household than sparsely developed suburban areas. In many old European compact cities where small lots and green spaces are typical, water consumption rates are two or three times lower than those of other relatively new North American or Australian cities (Sauri 2013). Therefore, changing the density of new development can have significant potential for water conservation.

Even within the same metropolitan area, a wide range of spatial variations in water use exists. Relatively affluent suburban residents in newer developed areas use more water than old dense inner city residents (House-Peters and Chang 2011). This is tightly associated with larger outdoor spaces in suburban houses that require lawn maintenance and irrigation during the summer. Lawn irrigation accounts for approximately a third of the total residential outdoor consumption in North American cities (EPA 2012). In some instances, neighboring residents or neighborhood organizations (e.g., homeowners’ associations) are under pressure to maintain green lawns, which contributes to higher household outdoor water consumption.

However, progress in water conservation has been made in some cities through the introduction of mandatory (regulatory) or voluntary (incentive) water conservation programs. Mandatory conservation programs include water curtailment during severe droughts. A case study of Seattle, Washington, shows that water curtailment is most effective with higher income, larger lot size, larger living space, and smaller household size (Polebitski and Palmer 2013). Institutional change such as changing building code may help...
achieve some water conservation programs; for example, installing new water-saving devices are now mandatory in new homes. Additionally, some cities encourage denser development in newer homes to reduce outdoor water consumption.

Voluntary water conservation programs include customer incentives to reduce outdoor water consumption by promoting the use of weather-sensitive water meter or lawn aeration programs (through rebate in the next water bill from a water provider). Other voluntary programs include the promotion of xeriscape landscaping that uses local native plant species that are adapted to local climate and thus require little water for maintenance. Another approach to achieving water conservation is capacity building that provides necessary information on water-saving devices to the target population that is interested in improving water use efficiency. A study in Santa Clara Valley in California, United States, shows that program participants were able to reduce water consumption by 18% (Reed 2012).

Technological changes have reduced water consumption. New dishwashers, washing machines, low-flush toilets, low-flow showerheads, and faucet aerators can substantially reduce indoor water consumption, while smart water meters or drip irrigation devices can help decrease outdoor water use. Such changes need to be linked to institutional or behavioral changes to be effective, as the adoption of such new technology depends on a wide array of institutional and behavioral factors. Water metering for individual household can be implemented so that urban residents are fully aware of their water consumption patterns and can identify potential water leakage problems.

Other behavioral changes help achieve water conservation targets. Changing water use habits rather than replacing existing water use devices enables urban residents to use water more efficiently. In arid climates, residents can avoid automatic lawn irrigation by applying water more sensitively in response to fluctuating local weather conditions. This will result in substantial reduction in outdoor water consumption. Other behavioral changes in indoor water use include using dishwashers and washing machines when they are full instead of partially filled. Since a wide difference exists between household perceptions of water use and actual water use efficiency, there is much room for new conservation practices in residential water use.

As urban water consumption is closely associated with water infrastructure and urban development patterns, a distributed approach has been suggested for achieving water conservation goals. Urban areas typically rely on transferred water outside of the city, so implementing an on-site water reuse systems can promote alternative sources of water for indoor and outdoor water consumption. These relatively small-scale structures include rainwater harvesting, storm water harvesting, graywater reuse, and on-site wastewater purification systems. Rainwater harvesting is one of the most common practices that is gaining population. Graywater, which comes from household wash water from kitchen, bathtubs, or washers, can be reused for other applications. On-site wastewater treatment systems can minimize evaporative loss and replenish groundwater.

Industrial water conservation

Globally, industrial water use makes up less than 10% of total water use, and the consumption has leveled off or declined in most developed countries. Most of industrial water is returned back to the water system, but the quality of water is typically degraded. Since the enactment of the Clean Water Act of 1972 in the United States,
many industries have started using water more efficiently and discharging less polluted water by recycling and reusing wastewater, which typically accompanies a pretreatment of wastewater (Vickers 2002). Water recycling is the reuse of water for the same purpose, which may require treatment before reuse (EPA 2012). Water reuse is the use of wastewater or reclaimed water from one use (treated wastewater) to another use (landscape watering).

The amount of industrial water used in one region is subject to the specific type of industry in the region because each industry has different water needs. Food-processing, paper mill, chemical, refined petroleum, or metal industries use a large amount of water, while service or knowledge-intensive creative industries use less water. Additionally, while water use generally increases with industrial production, the relationship between water use and production may be either linear or nonlinear depending on the type of industry (Vickers 2002). As such, any changes in regional industrial restructuring have implications on the amount of industrial water that can be saved. Some industries (e.g., food processing) incorporate water into a product (consumptive use), while others (e.g., power plants) return water back to the environment once it is used.

Together with new regulations on water efficiency requirements, technological changes have allowed many industries to conserve water. New improvements in water efficiency in heating and cooling systems, plumbing fixtures, and appliances, as well as federal mandates in water conservation at federal facilities have contributed to the reduction in industrial water consumption. Because a large amount of industrial water is used for cooling, recycling such water has a big potential to save industrial water. A modern recirculating cooling system uses water multiple times for cooling (EPA 2008) rather than using a single-pass cooling system.

Other behavioral and economic incentives can help reduce industrial water use. Like residential water conservation, industrial water conservation can be achieved by monitoring its uses regularly and applying water at the right amount when needed. Metering individual equipment that uses water can also help to identify water use efficiency over time. Increasing the cost of water service has somewhat mixed results. While increasing the costs of water and sewer service offers incentives to promote water conservation, some firms may divert their main water supply from public to private wells, which may not necessarily lead to the reduction in industrial water use (Vickers 2002).

**Agricultural water conservation**

Agriculture is the largest sector of human use of water, with world irrigation water withdrawals accounting for approximately 70% of the total human use of renewable water resources annually. The share of agricultural water in total water consumption is declining, with the absolute amount of water used for agriculture falling in some parts of the world. Approximately half of irrigation water is lost either by evaporation during water transfer or by leaking from infrastructure. Because demand for food production continuously increases and climate change can further increase crop water demand (see Water and climate change), conserving water in the agricultural sector has been a major issue.

The efficiency of irrigation depends on irrigation technology. Surface irrigation (also called gravity or flood irrigation) typically pumps water to the upper end of a field, allowing water to move downward by gravity, but it wastes a lot of water in runoff (Pimentel et al. 2004). This is the most common irrigation method, which
WATER CONSERVATION

has been practiced since ancient times. Sprinkler irrigation applies water through the air from sprinkler heads, distributing water more evenly than gravity systems. While it helps reduce runoff, sprinkler systems are more expensive than gravity systems (Vickers 2002). Drip irrigation uses much (up to 50%) less water than surface irrigation because water drips slowly to the plant root zone through narrow tubes. While drip irrigation minimizes evaporative loss and eliminates runoff and thus helps in water conservation, it is expensive, requires a constant water supply, and needs filtration to avoid clogging up the narrow water delivery tubes (Pimentel et al. 2004).

Improved irrigation technologies and their adoption have contributed to the efficiency of agricultural water use in most developed countries around the globe. A shift from gravity flow irrigation to center-pivot sprinkler or micro-irrigation has decreased the amount of irrigation water, particularly in the dry western United States since the late 1990s. More efficient pressure irrigation systems such as drip, low-pressure sprinkler, or low-energy precision application systems contributed to the reduction in agricultural water use. Even though the total irrigated area increased, total agricultural water use declined in the western United States. Additionally, in gravity-irrigated areas, which account for a relatively small area, less water-intensive management practices have been implemented. These practices include special furrowing techniques, shortened furrow lengths, and laser leveling of fields.

Agricultural practices as they relate to crop production and irrigation behavior can help achieve water conservation. First, farmers adjust water needs to specific crops because each crop has a different irrigation need during the growing season. Second, farmers apply organic mulches or leave biomass to minimize water loss from the soil surface and improve water percolation to the soil (Pimentel et al. 2004). Finally, farmers can reduce irrigation water by carefully selecting the timing and amount of water application using weather information, soil moisture monitoring, and rainfall sensors.

Other practices can also reduce the amount of water needed for irrigation. For example, crop residue management can capture precipitation more effectively and reduce runoff, thus reducing the water requirement for crop irrigation. Additionally, conservation tillage can increase percolation and infiltration, and decrease the amount of water evaporated from the soil surface. Applying these land-based best management practices can work better with pressurized sprinkler irrigation systems than with gravity irrigation systems since farmers apply water when they plant crops in traditional fields operated by gravity irrigation systems.

Educational, financial, and regulatory incentives can encourage farmers to adopt such water-efficient irrigation and farming practices (Vickers 2002). When farmers are well informed about the economic and environmental benefits of water conservation and are given direct technical assistance, they are more willing to adopt new irrigation technology and to change their water use behavior to achieve water conservation. Economic incentives such as the establishment of new pricing structures that reflect the true cost of water delivery and water uses (e.g., multiple block rates) and water rebate programs, help farmers reduce irrigation water use. Regulatory incentives include the flexible supply of water, facilitation of a water market that allows voluntary transfer of water between users, and the promotion of the conjunctive use of groundwater and surface water supply and recycled water.
Scale of effective conservation

When water conservation programs are launched, it must be considered that household- or farm-level conservation may or may not conserve water at another scale such as the sub-basin or the whole watershed scale. Given that some portions of lost water from lawn or farm irrigation may end up with either returning surface runoff or recharging groundwater, water conservation at the individual household or farm level may actually reduce the amount of water available for other purposes such as environmental flow or navigation. This is particularly the case in arid climates where water-saving irrigation technologies can actually increase water depletions at the sub-basin scale, limiting the utility of water conservation programs (Ward and Pulido-Velazquiz 2008). However, when agricultural runoff is polluted, increasing irrigation water-use efficiency at a farm scale can help achieve multiple benefits for farmers, ecosystems, and society. Farmers can draw less water for irrigation, lose less water, and return less polluted water while maintaining both crop yields and water quality in main streams.

Definitions, availability, distribution of, and access to drinking water

Water that is made fit for human consumption with minimal short- or long-term harm is called potable or drinking water. Waters in lakes and rivers with surface runoff from rain and snowmelt are referred to as surface water, whereas, water below the ground with rain and snowmelt infiltration and percolation is referred to as groundwater or aquifers. Groundwater and surface water serve as the two major sources of drinking water.

Geologic evidence indicates that water of volcanic origin has been flowing on Earth for most of its 3.8 billion years of existence. Water is essential for all life forms and thus makes the Earth unique in many ways compared to other planets in the solar system. As shown in Table 1, over 96.5% of the Earth’s water is contained in the 1.34 million km³ of the oceans (Shiklomanov 1993). All the ocean water is saline. For an aqueous water sample, concentration of other substances in it, such as salts, is often measured as mg/L (milligrams per liter) or ppm (parts per million), and for low concentrations also as μg/L (micrograms per liter) or ppb (parts per billion). The salinity of ocean water is around 3.5% or 35 000 ppm. For practical purposes, this water without significant modifications is unfit for human consumption and for most agricultural and industrial uses.

In general, dissolved salt in fresh water is less than 0.1%, brackish or estuarine water is in the range of 0.1–3%, and ocean water is in the range of 3–5%. As shown in Table 1, ocean and saline groundwater comprise 97.5% of Earth’s water, which is unfit for human consumption without major treatment. The remaining 2.5% of the Earth’s water, which has low salinity, is termed “fresh water.” Over two-thirds (68.7%) of this fresh water is inaccessible and locked up in polar regions, and the remaining 31.3% is made of fresh groundwater (30.06), ice/permafrost (0.86), lakes (0.26), soil moisture (0.05), atmospheric water (0.04), swamps (0.03), rivers (0.01), and biological water (0.003). Due to the presence of rivers across the global landscape, a column of other water components in relation to the total global river volume (unit of 1) is constructed and presented in the last column of Table 1. For every single drop of fresh river water, there are 43 drops in lakes, 4967 such drops in groundwater, and 637 243 drops of saline water (Table 1).

After rivers, the second largest visible component of fresh water is the lakes. The 91 000 km³ held by freshwater lakes constitute a mere 0.26% of total fresh water. The spatial distribution of the 10 largest freshwater lakes on this planet, Lake Erie, and the remaining lakes as a group is shown in Table 2.

Collectively, Lake Baikal (25.93), the Great Lakes (Superior, Michigan, Huron, Ontario, and Erie combined, 25.06), and Lake Tanganyika...

WATER: DRINKING

Water in its three major forms of solid (ice), liquid (water), and gas (vapor), has been cycling the Earth’s surface and subsurface for billions of years influenced by physical, chemical, and biological processes. This water movement process is referred to as the water or hydrological cycle, as shown in Figure 1 (Ohio DNR 2011). This cycle is one of the most important natural phenomena and serves as the driving force behind many other life cycle processes on this planet. The heat energy from the sun is the main external fuel that gets this process going on a continuous basis.

One of the most contested debates in recent decades is the influence of human activities (especially carbon emissions), as opposed to nature, on changes to Earth’s surface temperature. A concomitant debate also surrounds the impact of such changes on spatial and temporal variability and uncertainty of extreme weather events such as floods, hurricanes, and droughts.

Drinking water, to varying degrees, may be obtained from several components of the hydrological cycle (Figure 1). Key components of the cycle include evaporation, transpiration, condensation, precipitation, snowfall, surface runoff, infiltration, percolation, and groundwater seepage (USGS 2014). Solar heat enables evaporation of water from oceans, lakes, and rivers and also enables the release of water as vapor from vegetation to the atmosphere through transpiration. As moist air rises in the atmosphere, it cools and condenses to form clouds which then fall to oceans, freshwater bodies, or land surfaces as precipitation/rain and snow. Of the precipitation falling on land, a portion becomes surface runoff that finds its way to creeks, streams, rivers, and lakes, eventually evaporating or emptying into oceans. The remainder infiltrates the Earth’s surface to become groundwater, the majority of
which percolates and seeps into surface water bodies such as rivers, lakes, and oceans. This entire process has been repeating for billions of years with some uncertainty and significant variability over space and time. For example, at Cherrapunji, India, it rained 2300 cms in 1861, whereas at Arica, Chile, there was no rain for 14 years (USGS 2014).

Creeks, streams, and rivers are characterized by their watersheds. The watershed of a river is the area of land that contributes to the river’s flow. The final outfall from the river to a higher order river or the ocean will be represented by waters from the entire watershed. The term “watershed” is used to describe smaller units of land that drain into creeks, streams, and rivers, and the term “river basin” is considered to include many watersheds that are a part of a larger river such as the Mississippi, Nile, Amazon, or Ganges. Hydrologically and spatially defined catchment areas such as watersheds and river basins have played a major role in the administration, planning, protection, and management of freshwater resources based on landform and landscape characteristics and use, in addition to politically derived administrative boundaries.

**Drinking water and regulations**

**Drinking water and public health**

Sanitation, drinking water, and public health are closely connected. On this planet, 2.5 billion people do not have access to adequate sanitation,
783 million do not have access to clean water, and 85% of the population lives in the driest half of the planet. An estimated 3.5 million die each year due to inadequate sanitation, water supply, or hygiene. Up to 90% of wastewater in developing countries flows untreated into rivers, lakes, and highly productive coastal zones. Industry dumps an estimated 300–400 million tons of polluted wastes into water bodies, and nitrate from agriculture is one of the most common chemical contaminants in surface and ground waters (UN Water 2013). Mining, forest operations, power generation, rapid urbanization, land-use change, climate change, and population growth have also become serious stressors on the quality of available fresh waters.

In addition to human wastes, naturally occurring contaminants such as fluoride and inorganic arsenic are found in high concentrations in a number of countries such as Argentina, Chile, China, India, Mexico, the United States, and Bangladesh. In Bangladesh, 20 million and 45 million people are at risk of being exposed to arsenic concentrations greater than their national standard of 50 \( \mu \)g/L and the WHO guideline value of 10 \( \mu \)g/L, respectively (WHO 2011; Flanagan, Johnston, and Zheng 2012).

Combined with the sewer systems of the mid-to late nineteenth and early twentieth centuries, filtration and eventually disinfection of water contributed to near-elimination of diseases such as cholera and typhoid that annually killed significant numbers of urban dwellers. Although it was nearly eradicated by the mid-1900s, cholera has recently reemerged as a pre-eminent public health threat in certain densely populated developing nations: cholera and other diarrheal diseases cause up to 5% of deaths worldwide. Acute waterborne illnesses are relatively uncommon in developed nations, where the focus is on reducing exposure to low concentrations of organic and inorganic chemicals.

### Drinking water treatment

Through the early to mid-1800s drinking water systems in developed nations consisted mainly of pipes for delivering water (e.g., New York and London). Modern technologies for contaminant removal and remediation include filtration, flocculation and sedimentation, and disinfection. Flocculation is utilized to coagulate particles that settle out of the water as sediment in the treatment process. Alum, metal salts, and synthetic organic polymers are often used as flocculants. The clear water above the sediment is filtered to remove smaller particles. Typical filters are gravel, sand, and charcoal. Public water systems are often further treated with a disinfectant such as chlorine, chloramines, chlorine dioxide, ozone, and ultraviolet (UV) radiation to control biological contaminants in the distribution system. Additional treatment such as ion exchange may also be used to remove inorganic ions and activated carbon to remove organic contaminants (US EPA 2016a).

Various small-scale or household treatment systems may also be utilized to treat private well water or provide further treatment of tap water. These systems include simple particulate filters, water softening devices to remove hardness or carbonates, anion exchange to remove contaminants such as nitrate, and activated carbon filtration, distillation, reverse osmosis, and others to treat specific contaminants (State Hygienic Laboratory at The University of Iowa 2013).

Strategies for providing safe drinking water include source water protection and treatment of drinking water to meet health-related water quality standards. A form of pollution prevention, source water protection has been increasingly employed in international and
WATER: DRINKING

national water protection legislation including the European Union’s Water Framework Directive and the United States’ Safe Drinking Water Act. As was the case in historical hydraulic empires, large cities worldwide have continually expanded their influence over available water resources nearby to develop and sustain supplies for their growing populations. Some, such as New York City, have opted for a watershed protection approach which has proven more cost effective than filtering the 1.2 billion gallons provided to its 9 million residents each day.

Despite significant advances in water treatment technologies, drinking water quality is still strongly linked to the quality of the source water. Many countries actively promote source water protection to prevent pollution of groundwater, lakes, rivers, and streams that serve as drinking water feeders for local communities.

In developed countries, only a very small part of the treated piped water is consumed or used in food preparation. Most of the rest is used for toilet flushing, washing, bathing, and landscape irrigation. As a conservation and/or economic measure, dual water supply systems are employed by some for separating such uses.

Drinking water standards

Most if not all nations have adopted some form of health-based drinking water standards that specify the maximum allowable concentration of various classes of contaminants, including inorganic and organic compounds, pathogens, sediment, and radioactive substances. In the United States, drinking water standards are set by the Safe Drinking Water Act (US EPA 2002), in the European Union by the Drinking Water Directive (EU 1998), in Canada by Guidelines for Drinking Water Quality, in India by the Bureau of Indian Standards, and in Australia by Drinking Water Guidelines. Many nations in South America base their drinking water standards on WHO guidelines, and drinking water standards in China are also based on WHO guidelines (WHO 2011). Regulated contaminants include metals such as lead, mercury, and chromium, volatile organic compounds (VOCs) such as benzene and 1,2-dichloroethane, semi-volatile organic compounds including pesticides and polycyclic aromatic hydrocarbons (PAH), and bacteria such as coliforms and E. coli, as well as viruses and radionuclides.

Table 3 compares selected drinking water standards published by the US EPA (2016b), the WHO (2011), and the European Union (EU 1998). Review of the comparison chart shows that there are many similarities in regulated contaminants, but there are also differences in compounds regulated as well as regulatory concentrations allowed. For example, the compound atrazine, a common agricultural triazine herbicide, is included in the US national primary drinking water regulations at a concentration of 0.003 mg/L and in WHO guidelines for drinking water quality at a concentration of 0.002 mg/L, yet it is not a regulated parameter in the European Union. Arsenic is a regulated contaminant by all regulatory bodies at a concentration of 0.01 mg/L.

Drinking water: current and future challenges

There are numerous current and future challenges in the realm of drinking water, including issues of access to resources, available quantity of water, and threats to water quality. Gleick and colleagues (2012) peg the basic human daily need for water at 50 L per person, which includes 5 L of water for drinking and the balance for hygiene, sanitation, and food preparation. In 2010, the United Nations recognized the human
right to clean drinking water and sanitation via Resolution 64/292. The human right to water contrasts with the legal right to use water, which, with some notable exceptions, is often determined by ownership of overlying or adjacent land, connection to an official water supply system, or purchase of a vessel containing water. Societies worldwide developed local approaches to protecting source waters and allocating drinking water, but most modern legal principles for water access and use are based on prior appropriation, riparian rights, or permit systems.

More than 80% of people without access to improved drinking water reside in slums and rural areas of developing nations (WHO/UNICEF 2013). For some, drinking water is often obtained by walking several kilometers carrying containers weighing 20 kg or more. This burden often falls on women and children whose health, education, and general wellbeing suffer as a result (Gleick et al. 2012; Holden 2014).

Lack of access is partly due to mismatches in distribution of fresh water and human populations: for example, India and China together account for nearly a third of global population but possess less than an eighth of global freshwater resources. Access to safe drinking water also varies widely with level of economic development, ranging from less than 50% in many developing nations (sub-Saharan Africa and Oceania) to nearly 100% in many developed nations. Large populations in South Asia, Southeast Asia, sub-Saharan Africa, and Oceania lack access to improved drinking water (Figure 2). In addition to differences in access, average per capita consumption also varies widely between developed (500–800 L/day) and developing (60–150 L/day) nations, and in some extreme cases may be as low as 20 L/day (WHO/UNICEF 2013).

Access to drinking water may also be affected by conflict over freshwater resources. There are several current and longstanding disputes over international river basins including the Nile, Jordan, Tigris-Euphrates, and Colorado. In some cases, there are productive international agreements (e.g., Nile River Basin Initiative) and related processes in place.

Climate change is likely to impact drinking water quality and quantity in at least two ways: (i) via changes in precipitation patterns, and (ii) via sea level rise. General forecasts for impacts of global climate change invariably include an intensification of climate extremes and more rapid circulation of water within short-term components of the water cycle (e.g., precipitation and evaporation). Increased average temperatures are forecast to reduce snow pack in high elevations of the Rockies (United States), and to continue rapidly melting glaciers in the Alps (Europe), Andes (South America), and Himalaya (Central Asia), which will reduce the storage capacity of these “water towers” that provide a significant part of major rivers’ (e.g., Amazon, Colorado, Ganges, Brahmaputra, Rhine, and Yellow) flow. For low-lying small island nations and coastal regions, sea level rise increases the risk of inundation of drinking water infrastructure and fouling of scarce drinking water resources.

Regulation, governance, and economics of drinking water are also significant factors in determining access to and quality of drinking water. There is no standard regulatory practice to protect drinking water supplies; prevailing community norms suggest that local participation in protection and provision of drinking water may be ideal. In many cases, pollution of drinking water sources is regional or global in scale, and is thus outside the control of state, national, river-basin or watershed-level governance. Expensive centralized treatment and distribution systems are but one model for protecting public health and providing reliable drinking water.

* US EPA – Each water system must certify annually, in writing, to the state (using third-party or manufacturers certification) that when it uses acrylamide and/or epichlorohydrin to treat water, the combination (or product) of dose and monomer level does not exceed the levels specified, as follows: Acrylamide = 0.05% dosed at 1 mg/L (or equivalent); Epichlorohydrin = 0.01% dosed at 20 mg/L (or equivalent).
† Pesticides means: organic insecticides, organic herbicides, organic fungicides, organic nematocides, organic acaricides, organic algicides, organic rodenticides, organic slimicides, related products (inter alia, growth regulators), and their relevant metabolites, degradation, and reaction products. Only those pesticides which are likely to be present in a given supply need be monitored.
‡ The parametric value applies to each individual pesticide. In the case of aldrin, dieldrin, heptachlor, and heptachlor epoxide the parametric value is 0.00003 mg/L.
§ Polycyclic aromatic hydrocarbons – specified compounds are: benzo(b)fluoranthene, benzo(k)fluoranthene, benzo(ghi)perylene, and indeno(1,2,3-cd)pyrene.
|| US EPA National Secondary Drinking Water Regulations are nonenforceable guidelines regarding contaminants that may cause cosmetic effects (such as skin or tooth discoloration) or aesthetic effects (such as taste, odor, or color) in drinking water.
# US EPA Action Level, if more than 10% of tap water samples exceed the action level, water systems must take additional steps.
** US EPA surface water treatment rules require systems using surface water or groundwater under the direct influence of surface water to (1) disinfect their water, and (2) filter their water or meet criteria for avoiding filtration so that the following contaminants are controlled at the following levels: Cryptosporidium – 99% removal for systems that filter. Unfiltered systems are required to include Cryptosporidium in their existing watershed control provisions, and Giardia lamblia – 99.9% removal/inactivation, viruses – 99.99% removal/inactivation, Legionella – no limit, but EPA believes that if Giardia and viruses are removed/inactivated according to the treatment techniques in the surface water treatment rule, Legionella will also be controlled. Turbidity – for systems that use conventional or direct filtration, at no time can turbidity (cloudiness of water) go higher than 1 nephelometric turbidity unit (NTU), and samples for turbidity must be less than or equal to 0.3 NTU in at least 95% of the samples in any month. Systems that use filtration other than conventional or direct filtration must follow state limits, which must include turbidity at no time exceeding 5 NTU. HPC – no more than 500 bacterial colonies per milliliter.
Source: Data from US EPA 2016a; WHO 2011; and European Union 1998.
Other decentralized approaches that draw upon traditional knowledge and experiences in collective water resource management and strategies, such as rainwater harvesting for household use, may be necessary in urban areas in both developing and developed nations. Unfortunately, such approaches are often not supported or encouraged by existing legal frameworks. A wider array of reliable means and flexible policy frameworks for providing safe drinking water may be necessary to meet future demands.

Treated wastewater is increasingly viewed as a “new” source of water for industrial, agricultural, and domestic use. Treated wastewater makes up more than 10% of total water demand in Kuwait, Israel, Cyprus, Qatar, and Singapore, and some 20 million m$^3$/day are reused in 43 nations. In the United States, treated municipal wastewater has the potential to account for up to a quarter of domestic supply. Beginning in 1969, Windhoek, Namibia, has had a history of using treated wastewater for potable use. In 2002, the reclamation plant capacity was increased to 5.5 million gallons per day (MG/D) or 21 000 m$^3$/day. Singapore also has systems in place for the direct reuse of treated wastewater for potable use, but this practice is relatively uncommon. Indirect reuse of treated water (e.g., injection into an aquifer prior to use as drinking water) is much more common; as of 2005, more than 2000 European cities had indirect reuse systems.
Desalination is a major technology that has been employed to remove salts from seawater, brackish water, or saline groundwater. It is energy intensive, costly, and creates significant environmental impacts. Often, it is employed by regions and nations with access to plenty of energy, such as the Middle East, wealthy nations, such as the United States, Japan, Spain, Australia, and Israel, and nations with large coastal populations and water scarcity, such as India and China. In mid-2015, over 300 million people in 150 countries were estimated to obtain 87 million m$^3$/day of treated water (23 billion gallons per day) from over 18,400 desalination plants (IDA 2015). In recent years, the desalination capacity of various regions has grown considerably with much of the increase devoted to industrial, agricultural, or municipal users, based on the needs of the particular region.

Privatization of water supplies may also affect access to improved drinking water. Water has been viewed through much of modern history as both commodity and public good. During Roman times, for example, those paying for household piped water subsidized the construction and supply of water to public wells. There is considerable contemporary debate concerning private versus public ownership of drinking water systems, particularly in developing nations. Some argue that private corporations would be able to operate systems more efficiently and effectively, while others assert that privatization leads to violations of the human right to drinking water. Notable examples of both failures (price increases, decreased access to drinking water, and ultimately protests and violence leading to cancellation of contracts, as in Cochabamba, Bolivia) and success stories (significant reductions in child mortality in poor areas of Argentine cities in the 1990s) make privatization fertile ground for debate.

Drinking water quality issues include biological (e.g., reemergence of cholera) and chemical threats that are exacerbated by ever-expanding industrial activity, growing human population, increased consumption, and land-use changes. Many if not most commercially significant compounds can be found in surface waters, and therefore in drinking water drawn from these sources. More than 100,000 substances are in regular commercial use, and health effects of many compounds are not known, as toxicological studies have only been completed on a small fraction of the total universe of substances. Combined or synergistic effects of consuming combinations of low concentrations of myriad substances are also unknown.

There continues to be significant concern associated with contaminants that may be present in drinking water that may not be removed by standard water treatment processes, or that are not regulated and thus not included in regulated monitoring programs. These contaminants include, but are not limited to, pharmaceutical compounds, personal care products, pesticides, flame retardants such as polybrominated diphenyl ethers (PBDEs), fabric protectors such perfluorinated compounds (PFCs), and the environmental degradates or these, as well as pathogens. Of particular concern are contaminants that have been characterized as endocrine disruptors, which are associated with adverse developmental and reproductive effects on fish and wildlife, and possibly humans. Some persistent compounds may travel via the food chain or atmospheric circulation to contaminate drinking water thousands of miles from their origin. Treating drinking water to remove substances such as pharmaceuticals is partially effective with conventional treatment technologies such as coagulation and filtration, and higher removal rates can be achieved with advanced techniques.
such as ozonation, nanofiltration, or reverse osmosis (WHO 2010).

Existing as well as new forms of fossil fuel exploration must be balanced with the protection of drinking water sources. Hydraulic fracturing in particular poses significant threats to drinking water sources via contamination of aquifers and surface water bodies with methane and injected fluids. Existing regulatory frameworks may be inadequate for coping with the long-term and potentially irreversible damage to some drinking water sources.

Due in part to public concern about the safety of drinking water, bottled water has become a rapidly growing industry. Global bottled water consumption nearly tripled between 1997 and 2011, from 21 billion to over 60 billion gallons, with the top 10 nations consuming nearly 75% of bottled water and the fastest growth in China, Mexico, the United States, and Brazil. In 2011, the highest per capita consumption, of nearly 65 gallons, was in Mexico. In general, there is less regulatory oversight of bottled water than of piped drinking water, but there may be some cases in which bottled water is the only viable alternative.

Water is a special resource vital for human survival and has long been considered a human right. Recognition of this fact has been established in several international conventions (United Nations 1992). However, increases in water scarcity have led to calls for using economic tools to quell demand. This has resulted in attempts to reconcile these two seemingly disparate viewpoints. The Dublin Statement on Water and Sustainable Development recognized that “Water has an economic value in all its competing uses and should be recognized as an economic good,” which seemingly put to rest the debate over whether water is an economic good. At the same time, the Statement recognized (Principle Four): “Within this principle, it is vital to recognize first the basic right of all human beings to have access to clean water and sanitation at an affordable price. Past failure to recognize the economic value of water has led to wasteful and environmentally damaging uses of the resource. Managing water as an economic good is an important way of achieving efficient and equitable use, and of encouraging conservation and protection of water resources.”

Since its ratification, considerable attention has been placed on determining what constitutes an “affordable price” for water in developing nations. Considerable efforts have been made by nongovernmental organizations to build capacity in developing nations to allow individuals to attain adequate amounts of water per day for drinking and sanitation purposes. Often this takes the form of public wells and low-cost mechanisms to purify surface water to make it potable. The projected impacts of climate change are leading to increased calls to strengthen these efforts. These goals were also codified in the United Nation’s Millennium Project. The goals of providing adequate drinking water have been integrated in the larger Millennium Project Goal 1: “Eradicate extreme hunger and poverty.”

The benefits of using economic tools to manage water demand have strong theoretical support. However, transfers of water between voluntary parties is often undermined or complicated by a series of difficulties, including the lack of infrastructure to move bulk water, excessive legal fees associated with gaining approval to transfer, and temporal delays (Matthews 2003; Gould 1988).

Water economics can be classified into three general categories: domestic use, municipal and industrial use, and agricultural uses. Each category has its own managerial issues associated with pricing structures. For example, cities struggle with determining appropriate pricing for water for domestic purposes. The goal is to maintain availability of a minimal amount of low-cost water for those with limited incomes. The emerging trend is to provide an economic incentive for conservation. Traditional water pricing was often fixed per unit or decreased per unit with additional water used. Newer research suggests water has been priced suboptimal in the past. To promote conservation, newer systems with rapidly escalating pricing based on quantity of use are being adopted; these maintain a low cost for initial water use, followed by a rapidly increasing cost per unit used.
In semiarid areas agriculture represents the largest use of water diverted from a watercourse. Because of the quantity of water extracted for agriculture, water economics plays a substantial role in shaping not only food production but also water availability for all other purposes, including ecosystem protection. At the same time that water pricing can encourage water conservation when the price of improving efficiency is lower than the price of water, agricultural subsidies can distort market signals.

Water pricing can impact what crops are grown in a given area. Agricultural subsidies provide artificially low-cost water to farmers in an effort to keep food prices low. However, they simultaneously discourage conservation by distorting the true value of the water. The result is artificially high levels of production, and a reduced incentive to conserve water. The increase in production has an economic benefit for some areas. However, this practice distorts water allocation schemes, and can reduce the amount of water left in river systems for ecological protection. The overutilization of water for agriculture also has impacts on water quality, as runoff from agricultural fields often contains high levels of fertilizer and pesticide residues.

Numerous concerns and pitfalls exist in the transfer of bulk water. These include carriage losses, or loss of water in transit from the basin of origin to its new location, ecological impacts in the basin of origin, and the socioeconomic impacts of the basin “losing” a portion of its water supply. This creates a difficult paradox: as Tregarthen (1983) once quipped, “An economist might be defined as someone who doesn’t see anything special about water”; however, the needs for reallocation are pronounced. Every reallocation is unique, meaning the exact impacts are not always clear when a transfer is proposed. The ideals of the market economy call for goods to be homogenized as much as practicable for economic efficiency. For market signals to work properly, market participants must fully understand what they are buying or selling—without this understanding an “informational asymmetry” develops (Cooter and Ulen 1997).

Water is unlike many other resources because of its fungible nature. Its ability to move in time and space, and change forms from liquid water to water vapor, makes defining ownership problematic. In the case of water, the myriad property rights criteria (i.e., when a user can use water, from where the water can be taken, how much must return to the stream), along with the uncertain ecologic and socioeconomic impacts of transfers, preclude a homogeneous water market. Research efforts have codified the difficulties in standardizing water transactions (Krutilla 2010; Gould 1988). Brennan and Scoccimarro (1999) cited the lack of clear water rights as a primary deterrent to water transfers in Australia. With similar issues apparent in other semiarid areas such as Spain and the United States, it is clear this is not an issue unique to one particular nation’s property rights laws.

Commoditization of water, along with the subsequent reallocation, poses threats to third-party users by reducing the quantity of water that returns to a stream. To prevent such harm, water managers can impose requirements necessary to ensure the transfer will not impair other water users. Treating water like any other commodity does elicit some rational concerns. Considering the “public interest” before approving water transfers can raise issues of equity and fairness. Critics claim such an imposition constricts an individual’s property rights, and impacts their return on investment.

Restrictions on transboundary reallocations often have a protectionist slant requiring legal intervention to determine the legitimacy of the prohibition. For example, most western
states in the United States imposed restrictions on transfers of water across state lines. These statutes have been the subject of considerable legal review and in most cases have been ruled an impermissible burden on commerce. Such protracted legal battles are not limited to intranational disputes. Many nations have similar restrictions on water transfers. Debate and legal wrangling over international water marketing efforts are likely to be an increasingly frequent occurrence in the twenty-first century.

Impacts to third parties are rarely considered when other commodities are bought and sold—it is logical to ask whether water should be held to a different standard (Sax 1965). Management of water is necessary at least to the level required to ensure downstream water users with vested property rights are not unfairly injured by another party’s water transactions. Beyond this standard the role of government in the spatial and economic use of water is unclear. Most nations have some level of zoning ordinances for land use. At issue is whether restrictions on water use, which have an impact on the broader landscape, are just a natural extension of these kinds of land-use regulations. Still, many critics question the appropriateness of government intervention over water use if the uses in question are “reasonable” (i.e., not wasteful). Also in question is whether it is the responsibility of government to decide what the rural landscape should “look like.” These are simultaneous philosophical and resource management questions that will substantially impact water use and pricing in the twenty-first century. The open-ended nature of these questions will lead to different approaches taken in different political jurisdictions, be it across national or provincial boundaries. While the lack of standardization may be problematic, these natural case studies will provide water resource managers with opportunities to study the efficacy of various techniques, and use adaptive management to enhance water management.

Geographers have long played a critical role in managing water scarcity and studying water usage patterns across the globe. Enhanced technologies within the geographic information sciences allow more robust tracking of water use, and monitoring of areas experiencing water shortages. Coupled with the increased use of economic tools, allocation of water in both rural and municipal areas impacts how and where water is used. Water demand is predicted to intensify to meet the growing needs of rising populations and increases in per capita food consumption. It can be argued that all commodities markets are “messy” with constantly oscillating valuation of the resource. Pricing water at a level that maintains its availability as a basic human right for the poor, while still encouraging water conservation and protecting minimum streamflows, will be a primary natural resource management issue in the twenty-first century.

Water engineering

Paul F. Hudson
LUC The Hague, Leiden University, Netherlands

Water engineering has been a fundamental dimension of anthropogenic impacts on the environment since humans first started to live upon river banks. The subject spans a range of topics and is especially divided into coastal and freshwater environments, with the latter primarily focused towards hydraulic engineering. This entry considers the subfields of water engineering from the perspective of surface water, and especially alluvial rivers. Hydraulic engineering involves a multitude of discreet actions and structures designed to alter the functioning of flowing rivers for the benefit of humans. Alluvial rivers are physical systems which adjust to changes in sediment and energy, both of which are impacted by water engineering structures.

The earliest comprehensive and large-scale water engineering occurred in the Middle East and North Africa for crop irrigation within the Tigris–Euphrates and Nile Deltas. New sophisticated approaches to water engineering continue to rely upon some of the same principles laid out centuries or even millennia ago. Surface water engineering requires knowledge of basic fluid mechanics to computationally analyze the force of water and its interaction with sediment and the channel boundary layer. Additionally, hydraulic engineering requires knowledge of statistics to forecast time series of stream discharge and suspended sediment data. Common analytical tools apply mathematics and statistics in computer-based hydraulic models (e.g., Hydrologic Engineering Center - River Analysis System (HEC-RAS)), which combine hydrologic, topographic, and channel geometric data within the framework of a geographic information system (GIS). Additionally, much water engineering requires fieldwork, including topographic surveying and leveling, in addition to more job-specific tasks such as stream gauging and sediment sampling. These tools may be applied to, for example, estimating stream power, reservoir storage capacity, sediment transport, or irrigation potential, or to forecasting the impact of dam removal on downstream channel geometry and aquatic habitat.

Inventory of major water engineering structures and impacts

Surface water engineering includes a comprehensive range of activities and structures (Table 1), such as dams and reservoirs, groynes (wing dikes), meander cutoffs and channel straightening, dikes (levees), dredging (cut and fill), bridges and culverts, bifurcations, flow diversions and sluice gates, and revetments. As such, actual engineering structures may range in size from the smallest of culverts (<1 m) placed within small first-order channels in headwaters, to dams and reservoirs, among Earth’s largest human-constructed features.

Groynes

Groynes are elongated rigid structures extending outwards from the river channel bank, emergent at low stage but inundated at moderate to high water levels. The goal of engineering groyne
WATER ENGINEERING

fields is to create a deeper self-cleaning channel, such that it maintains a navigable channel with minimal need for dredging. Morphologically, groyne are oriented nearly perpendicular to stream flow and most often located in shallow channel reaches on the inside of elongated bends and riffles, whereby they trap coarse sediments. Groyne are often placed in a series of relatively closely spaced sets. Groyne are usually semipermeable, constructed from concrete, granite, or basalt. Along large rivers intensively utilized for economic activities, such as the Ohio River, groyne are an ever-present component of the riverine environment.

In addition to reducing fish habitat, because of their resistance to flow, groyne also increase flood stage levels. Indeed, an important measure of the new integrated flood management program along the Dutch Rhine entitled “room for the river” requires that groyne fields are lowered from 0.5 m to 1.0 m to reduce flow resistance at high flow events, which is expected to lower flood stages by between 6 cm and 10 cm.

Dikes (levees)

Floodplain embankment by dike construction for flood control is among the oldest and most common forms of water engineering. Earthen dikes have been constructed for millennia along large rivers, providing flood control and access to agricultural lands, water resources, transportation, and aquatic environments. Development and increased population density follows floodplain embankment, such that dikes are also associated with increased flood risk. Dike construction should be informed by a thorough understanding of flood frequency, floodplain hydraulics and sedimentology, and subsidence, in addition to the ecological values of the local floodplain environment.

Underseepage is a major geotechnical concern along dikes underlain by highly permeable sands and gravels, especially with long duration floods, and can result in sand boils and local flooding along the backside of dikes. Environmentally, dikes are associated with a multitude of negative impacts, such as restricted hydrologic connectivity, degradation of aquatic habitat, and subsidence of local floodplain reaches on the backsides of dikes. A major component of many modern integrated floodplain management plans is to create more “room for the river” by moving dikes further away from the channel, thereby increasing storage capacity for floodwaters while also restoring exchanges of nutrients and fish between rivers and floodplain aquatic habitat.

Revetments

Channel revetments are constructed to prevent bank erosion and are placed along the eroding channel bank, especially cutbanks. Revetments should extend from above the average high water line to between the toe of the river bank or channel thalweg to prevent scour and undermining. Revetments are often constructed of natural materials, such as willow saplings, for small rivers, or of articulated concrete pads for large rivers. Concrete revetments increase local channel velocities and shear stress, and are mainly detrimental to fish diversity. Their effectiveness in maintaining channel stability has resulted in revetments being a major component of the environment along intensively utilized alluvial rivers.

Dams and reservoirs

The most substantial water engineering projects are dams and reservoirs. The purpose of riverine dam construction varies, and includes hydroelectric generation, flood control, agriculture, recreation, and consumption by humans and industry (Graf 2006). Dams are constructed from concrete or earthen materials, with the latter being particularly important along lowland

rivers. Dams may also be created by natural processes, such as earthquake-triggered mass wasting events which result in large volumes of material blocking river valleys. Several general categories of dams include check-dams, low flow dams, and large main-stem dams. While large main-stem dams constructed upon large rivers receive much publicity, small dams located on low-order rivers are nearly ubiquitous across many parts of Earth’s riverine landscapes.

Dams alter the downstream hydrologic regime by reducing high flows and increasing low flows. Dams also trap sediment behind reservoirs, with sediment trap efficiencies commonly exceeding 95%. The altered hydrologic regime and reduction in sediment load result in downstream channel incision, degrading aquatic habitat. Simulated flow events and sediment flushing can be an effective management regime, but are dependent upon the physical setting and dam operation.

Globally there are currently two main contrasting trends concerning dams: construction of large dams in Asia, Africa, and South America, and removal of small dams in North America and Europe. The science of understanding the downstream impact of dam removal on rivers is in its infancy, with important questions pointed towards understanding the effects of released sediment on channel and floodplain habitat, including the magnitude of change and the timescale for recovery.

Meander bend cutoffs

Meander cutoff for channel straightening is among the most commonly utilized engineering procedures for flood control, but is also used to increase the navigability of rivers heavily utilized for commerce (Gregory 2006). Many meandering rivers in the Northern Hemisphere have been straightened by the process of artificial cutoff. Cutoffs are created by dredging and cutting a ditch across a point bar, especially at an elongated meander neck, during the low flow season. Because the sandy point bar material is noncohesive, the ditch rapidly enlarges as stage levels increase, further accelerating inflow and subsequent incision and widening of the new channel cut. Within several years the cutoff is usually complete, depending upon the sedimentology and subsequent streamflow events. Well-known examples of rivers straightened by artificial meander cutoffs include the Yangtze, the Rhine, the lower Mississippi, and the Kissimmee River in Florida. Meander bend cutoffs were an especially common engineering practice in the United States during the early half of the 1900s, and were seen as part of a broader management program for river “improvement” to reduce flood risk and increase the depth of navigable waterways. Along many meandering rivers, cutoffs have achieved their desired goal of reducing flooding. Unfortunately, the practice has had profound unintended geomorphic and environmental consequences, requiring further management and engineering.

Meander bend cutoffs reduce channel length (and sinuosity) and locally increase channel gradient, thereby causing a channel knickpoint. Hydraulically this is important because the increased channel gradient increases shear stress. The combination of the greater shear stress and higher velocity results in channel bed incision, dependent upon the channel substrate and bed material. Along many rivers which have undergone multiple cutoffs within a relatively short period of time, knickpoints migrate upstream and result in extensive channel degradation. Following channel bed incision, channel banks then become over-steepened and subsequently erode and input large volumes of sediment into the channel. Thus, upstream migration of knickpoints frequently results in downstream channel bed widening and aggradation. This
presents a new problem to river management authorities, which may now need to increase both the frequency of dredging and the construction of revetments to prevent bank erosion and groynes to “train” the channel.

Because meander cutoffs for flood control result in reduction in overbank hydrologic events, the natural hydrologic connectivity is substantially diminished, resulting in significant adverse consequences to floodplains and associated aquatic environments. Management strategies to reconnect rivers to their floodplains are oriented towards increasing freshwater pulse events into aquatic environments. This may involve a gamut of engineering options, including sluice gates, diversion structures, side channel creation, and floodplain lowering, as well as breaching of floodplain dikes.

**Sequence of water engineering**

The timescale for engineering to occur ranges greatly according to the sophistication and scale of the feature, as do the benefits to humans and the adverse impacts to the river environment. Planning should take into account several distinct phases, including (i) initial planning, (ii) construction, (iii) implementation, and (iv) abandonment and/or removal of structures.

The **planning** phase should include a multidisciplinary team of scientists and stakeholders, and establish hydrologic and environmental baseline conditions of the setting. This often includes a review of hydrologic and sediment databases from government agencies, as well as of the geomorphic and environmental setting. The **construction** phase is completed by engineers with heavy machinery, and should be organized with a view to minimizing the construction footprint. Many water engineering activities are closely synchronized to the hydrologic regime, implying a seasonality of construction activities. The **implementation** phase awaits actual hydrologic events to test the effectiveness of the structure, which may then require further calibration. Constructing sluice gates, for example, to manage or restore freshwater inputs into floodplain water bodies often requires additional calibration to optimize sediment inputs. **Abandonment** of structures is common and unfortunately many rivers are littered with relict engineering structures (local dikes and bank protection works), which may continue to influence active hydrologic processes and effectively become part of the modern environment. In some instances prominent features are being removed, such as dikes and some dams, but this depends on the budget and management priorities of government agencies which oversee such activities.

Water quality

Susanna T.Y. Tong
University of Cincinnati, USA

Water is a precious and limited resource. It covers 75% of the Earth’s surface, of which 2.5% is fresh water, and only 0.77% is accessible. But it is essential to all life forms. Not only does it support aquatic ecosystems, but also human survival is intricately related to the availability of clean water supply for both consumptive and nonconsumptive uses. By supporting domestic, industrial, agricultural, recreational, and other economic activities, such as power generation, transportation, and waste processing, the quantity and quality of water is of paramount importance to a society.

Under natural ecosystems, the quality of water is related to an array of physical, chemical, and biological attributes of the watershed and the waterbody. But with anthropogenic disturbances to the natural environment, the quality of many surface water bodies is deteriorating. Water pollution is a state in which the water has an excessive amount of a certain type of constituents that render the water harmful to human health and the environment and is unusable for humans.

Since the Industrial Revolution, more affordable products have been manufactured, and our standard of living has been improved, but we have generated many forms of wastes. Without much treatment, chemical wastes from industry and domestic sewage were directly disposed of in the receiving water bodies. The American waterways became cesspools and open sewers. The drinking water was contaminated.

In 1972, to address the water quality problems and to ensure that the nation’s waters are swimmable and fishable, the United States enacted the Clean Water Act (CWA), which was subsequently amended in 1977 and 1987. Under the auspices of the Act, the US Environmental Protection Agency (USEPA) is authorized to regulate the quality of the nation’s water. The legislation has provided administrative controls, stipulated regulations for controlling water quality, and provided funds to defray the costs of establishing treatment facilities. The paradigm of water quality management has gradually shifted from the human use strategy to the ecological integrity strategy. The earlier strategy is based on the assumption that water bodies have certain assimilative capacities. The common notion is that dilution is the solution to pollution. The new strategy is to restore and maintain the biological, physical, and chemical integrity of the waterways. In 1976, the USEPA set up the National Recommended Water Quality Criteria, providing standards to assess pollutants to protect aquatic life and human health. Since then, the criteria have been revised. The current criteria provide standards to assess 150 pollutants. Under the Safe Drinking Water Act, the USEPA has set standards for drinking water quality. It requires states to conduct source water assessments for each drinking water intake. The National Pollution Discharge Elimination System (NPDES) was also created, and all industry and wastewater treatment plants are required to have permits to discharge any form of pollutants to water bodies. Moreover, the CWA requires the establishment of the Total Maximum Daily Load (TMDL) program. If a water body is impaired, the states are required
to identify the sources of the pollutant, estimate assimilative capacity of the water body to the pollutant, and determine the maximum allowable discharge pollution load. However, even with these regulations, water pollution in the United States is ubiquitous. According to the 1998 National Water Quality Inventory report to the Congress (USEPA 2000), 40% of the surface water bodies in America do not meet the water quality standard. Contaminated by pathogens, nutrients, and chemicals, they are unfit for fishing and swimming. In the developing world, more than 780 million people do not have access to improved water (UNICEF and WHO 2012).

Types and sources of pollution

There are two major types of water pollution: point source pollution and nonpoint source pollution. Point source pollution comes from identifiable sources and is easier to monitor and regulate. An example is the chemical wastes from industry. It often contains various types of organic and inorganic chemicals, such as polychlorinated biphenyls (PCBs), cleaning solvents, detergents, and metals. Many of these chemicals are toxins and are not soluble in water. Instead, they are soluble in fats. They tend to adhere to soil colloids and reside in the substrate of the aquatic ecosystem. They are persistent and prevalent in the environment and can bioconcentrate in the ecosystem and bioaccumulate in the food chain. When contaminated fish are consumed, they can cause human health problems. Lead and mercury, for example, can affect the nervous system in humans.

In addition to industrial discharge, commercial and domestic wastewater is another important point source pollutant. Wastewater contains debris (grit, sand, gravel, plastic), particulate organic matter (fecal matter, toilet paper, food wastes), dissolved organic and inorganic matter (soaps, detergents, urine, nutrients, and wastes from the degradation of bacteria, algae, and zooplankton), pharmaceuticals, and personal care products. In developing countries, the wastes may be minimally treated or may not be treated at all. Hence, the most common pollutants in these areas are waterborne disease-carrying vectors. Examples are bacteria, viruses, parasites, and pathogens, which are commonly found in human and animal excrements. According to the World Health Organization, 3.4 million people die every year from waterborne diseases. Typhoid and cholera are rampant in developing countries. Coliforms, *Escherichia coli*, and fecal streptococci have been used as fecal indicators for sewage contamination and the presence of other harmful pathogens. Besides diseases, organic matter from human and animal feces and other biodegradable wastes, such as leaves and grass, can cause water pollution problems. During biodecomposition, while the bacteria and detritus feeders consume the organic wastes, they also use up the dissolved oxygen (DO) in the water. When dissolved oxygen is consumed faster than it is replenished from the atmosphere, the amount of oxygen will be depleted. Most fish and macroinvertebrates require an oxygen concentration of more than 4 mg per liter. The lack of DO will result in hypoxia and a dead zone, and the aquatic ecosystem will not be able to support sensitive and endemic species. Many higher aquatic life forms will die and the water will become turbid. Biological oxygen demand (BOD) is a measure of the amount of organic matter in water. A high BOD in a water body signifies not only a high amount of organic matter but also a high probability of low DO. Similar to BOD, chemical oxygen demand (COD) is an indirect measurement of pollution and an indicator of the amount of DO in water.
It measures the amount of oxygen consumed during the chemical decomposition process of the organic and inorganic contaminants.

Although the wastewater in the industrialized world is collected and treated, sewage treatment is not a thorough process, and discharge from municipal treatment plants and onsite septic tanks is often a major source of contamination. In America, municipal sewage typically undergoes two processes. The primary treatment employs mechanical methods and sedimentation to remove debris and other suspended matter. The secondary treatment is a biological process. It allows aerobic or anaerobic micro-organisms, including bacteria, decomposers, and detritus feeders, to biologically disintegrate the organic wastes. When the effluent is discharged, it may still contain contaminants. For instance, the discharge from electric utilities often contains chromium, which in its hexavalent species is carcinogenic. But because of cost, chromium is not treated by water treatment facilities. Instead, the treatment of industrial contaminants is left to the industry, and its discharge is regulated by NPDES. Likewise, without tertiary treatment, nitrogen and phosphorus are not treated. In small watersheds, point source discharge from the municipal sewage treatment plants can be a dominant contributor of nutrients (NRC 2008). Pharmaceuticals and personal care products are emerging contaminants, which are yet to be regulated. When disposed from the sewage treatment plants, some of these products are found to affect aquatic fauna. For example, high levels of estrogen have been attributed to infertility in alligators in Florida. In Europe, the Urban Waste Water Treatment Directive (UWWTD) requires member states to implement tertiary sewage treatment for cities with a population larger than 150,000. Today, many Nordic countries and Western European countries employ tertiary sewage treatment. Consequently, there is a marked decrease in nitrogen and phosphorus discharge from the sewage plants in these countries.

In many older cities in the United States, storm water is routed through the combined sewers, which collect both the sanitary sewage and the urban runoff. This technology originated in England. While it will work well if the amount and intensity of rainfall are relatively consistent throughout the year, the system may fail if the precipitation patterns are irregular. In times of heavy rain, excessive precipitation may flood the combined sewer system, and the discharge may overwhelm the sewage treatment systems. Combined sewer overflow (CSO) can cause serious point source pollution as it may contain not only surface runoff from rain but also untreated raw sewage. This has been a major problem for many cities in the Eastern United States and in the Midwest, such as Cincinnati in Ohio.

Another point source pollutant is hot water discharge from utility plants, which can cause thermal pollution. A plume of hot water can act as a barrier for migration of aquatic organisms. While it may promote the growth of micro-organisms, such as algae, it can affect the metabolic rate or cause stress to other aquatic species. Besides, it can change the thermal stratification, lowering the thermocline below the compensation point where light cannot pass through. As a result, the depth of the nonproductive zone with warm water but no light and oxygen will increase. Moreover, a higher temperature may affect the chemical reactions and change the solubility of gas. The DO in streams will be decreased. Hot water release is a common water pollution problem in many industrialized countries. In the United Kingdom, half of the waterway is used for cooling in power generation and other industrial processes. Although thermal pollution is often related to hot water release, cold water discharge can cause thermal pollution.
as well. When cold water from the bottom of the reservoir is discharged into a nearby stream that is warmer, it can upset the ecosystem. In New South Wales, cold water pollution affects almost 3000 river kilometers.

In the United States, the regulation of interstate transport of oil is vested in the Federal government; it is beyond the jurisdiction of states. But seepage from oil wells and oil pipes and accidents of oil tankers may occur within local communities and can lead to oil pollution. Many petrochemicals, such as benzene and toluene, are toxic to aquatic organisms. Through ingestion, inhalation, or absorption, aquatic life can be harmed. In contact, oil can clot the gills of fish and coat the feathers of water fowls. A layer of oil covering the surface water will also reduce gaseous exchange between the water and the air as well as the amount of sunlight infiltrating into the water.

Since the enactment of the CWA, pollution from point sources has been greatly reduced, and the nation’s water has been improved. The levels of toxins in many water bodies, such as the Great Lakes, have been reduced (ASIWPCA 2004). Some rivers and lakes have also been restored. To cite an example, Chesapeake Bay used to have problems of hypoxia, and eutrophication was a commonplace during the summer months. In 1996 and 1997, *Pfiesteria* was found in the Bay. In partnership with the local states and the USEPA, concerted basin-wide efforts have been dedicated to the reduction of nutrient and sediment loadings. It was an expensive program, but the Bay is gradually recovering. Moreover, throughout the process, new knowledge has been gained in terms not only of scientific discovery but also of the efficacy of various legislative regulation programs and restoration efforts.

Nevertheless, the CWA is not adequate to protect water quality as its goal is mainly concerned with regulating point source pollution, and it does not provide any enforcement mechanisms for controlling nonpoint source pollution. Nonpoint source pollution occurs when rainfall scavenges the contaminants from the land surfaces and washes them to the receiving water bodies. Since nonpoint source pollution is more scattered and may be derived from a large watershed encompassing various states, it remains a challenge to monitor and control.

In the United States, the leading source of nonpoint source pollution and surface water impairment is from agriculture. Depending on the tillage, cropping systems, fertilizer and chemical use, animal stocking intensity, and methods of disposing of animal wastes, runoff from farmlands and feedlots is often contaminated by nitrates, ammonium, phosphates, pesticides, herbicides, bacteria, animal wastes, and sediments. As more wetlands are being drained and the riparian buffer strips removed for urban development, runoff from farmlands is not intercepted and retained and flows directly downstream. In many watersheds, such as the Mississippi, where fertilizers are commonly used, runoff from farmlands is the most dominant source of nitrogen and phosphorus, about six or even 10 times greater than the background natural levels. Nutrients are essential to both aquatic flora and fauna. But excessive amounts of nutrients can stimulate undesirable growth of photosynthetic algae, dinoflagellates, protists, and cyanobacteria. These phytoplankton and zooplankton consume an abundant amount of oxygen, and when they die, oxygen will also be used by bacteria to biologically degrade their dead remains. Known as cultural eutrophication, this process of nutrient enrichment can lead to algae bloom and the depletion of DO. Moreover, some phytoplankton may secrete toxins. The dinoflagellate *Pfiesteria* has been found to cause ulcerative lesions on fish. By damaging the skin, it can predispose the fish to other pathogens.
The cyanobacterium *Microcystis* also produces the liver toxin microcystin, which when ingested or exposed can cause adverse human health effects.

Sediment is another common pollutant in American streams, rivers, and lakes, much of which has a nonpoint source origin. Soil erosion from farmlands and barren soils contribute a large amount of sediments and debris. When washed to the waterways, suspended matters and total dissolved solids will increase the turbidity of the water, deterring the penetration of light into a water body and reducing the amount of primary productivity. Water will become murky, and aquatic animals will not be able to locate food. Sediments can also clot the gills of fish, suffocate eggs, larvae, and young fish, and destroy the habitat and breeding grounds for many aquatic fauna.

Together with nutrients and sediments, herbicides and pesticides are often leached from farmlands to receiving water bodies. In the United States, about 90% of the wells sampled by the US Geologic Survey (USGS) are contaminated by pesticides. The agricultural pesticide dieldrin is highly toxic to aquatic organisms. It affects the immune system of fish, and in high concentrations it can kill them. If contaminated fish is consumed by humans, it can cause headache, dizziness, vomiting, convulsion, and even kidney damage. Atrazine, a commonly used herbicide in cornfields, is found to cause reproductive problems and tissue abnormalities in fish. In humans, methaemoglobinemia (blue baby syndrome), gastric cancer, and non-Hodgkin’s lymphoma have been linked to ingesting water contaminated by fertilizers and pesticides.

In urban areas, storm water runoff from construction sites and impervious surfaces, including rooftops, roadways, and lawns, also contains debris, rubber fragments, heavy metals, road de-icer, gasoline, motor oil, and nutrients. First flush phenomenon is the condition of the first few inches of urban runoff after the commencement of a rain event. The runoff is usually highly contaminated. But as the rain continues, the runoff will generally become less polluted.

Drainage from coal and mineral mines can also contaminate surface and groundwater supplies. Sediments and toxic chemicals in mine ores, such as heavy metals, when exposed during and after the mining activities, can be scavenged and washed to surface water. Recently, hydrofracking has become more popular as a means to obtain an alternative energy source. But the use of chemicals to fracture deep rock strata to collect natural gas, and the disposal of such chemicals, can instigate water quality problems. Besides toxic chemicals, drainage from mines and landfills (commonly known as leachate) can be highly acidic.

Atmospheric deposition can contribute to nonpoint source pollution as well. It may contain contaminants from natural (such as volcanic eruptions and forest fires) or anthropogenic sources. Transportation, fossil fuel combustion, electric power generation, fertilizer production, and other industrial activities emit various species of sulfur and nitrogen in the air. When washed out by rain and deposited on waterways, they form acid precipitation. Acid runoff and acid rain can dissolve other heavy metals and can disrupt growth and reproduction of aquatic organisms. In aquatic systems, a pH value below 5 or above 10 often signifies some form of pollution.

Salinization can be another form of nonpoint source pollution. In many coastal areas, a high water table keeps pressure in the aquifer. Because of the difference in salinity and density between the fresh water and the seawater, fresh water from the groundwater table extends to the ocean, thereby acting as a buffer between the salty water and the fresh water and protecting the underground water from contamination. However, with the abstraction of groundwater or subterranean fluid, the water level in the
groundwater table drops, reducing the pressure in the water table. Consequently, seawater will intrude into the aquifer, causing salinization and contaminating the groundwater. Over-irrigation under a hot and semiarid or arid climate can cause salinization as well. As water is evaporated from the highly soluble sodium and calcium compounds, their residues will be left behind in the soil. Together with the less soluble sulfates and carbonates, soils can become saline. Urban runoff from roadways may be enriched with salts from road salts and de-icers. The excessive amount of salts in soil and surface runoff will ultimately be transported to receiving waters, which can affect stream biota, ecosystem health, and drinking water supply.

Measurement and assessment of water quality

To measure water quality, the traditional method is to conduct in situ water quality samplings and chemical analyses. Although these methods can provide good records of the water constituents, the measurements will only reflect the water quality conditions in one location at one time. Automatic ambient water quality sampling can overcome some of this problem by providing continuous temporal measurements. However, many water quality data loggers will be required to provide a large spatial coverage.

To have better spatial and temporal coverage of the water quality conditions, some scientists use remote sensing imagery. By mounting different sensors, such as Landsat Thematic Mapper (Landsat TM) and Enhanced Thematic Mapper Plus (ETM+), Moderate Resolution Imaging Spectroradiometer (MODIS), Satellite Pour l’Observation de la Terre (SPOT), National Oceanic and Atmospheric Administration – Advanced Very High Resolution Radiometer (NOAA-AVHRR), IKONOS, Quickbird, Advanced Spaceborne Thermal Emission and Reflection Radiometer (ASTER), Airborne Visible/Infrared Imaging Spectrometer (AVIRIS), and Hyperion, on board airplanes or satellites, a constantly updating and almost continual coverage of the landscape and water body in different wavelengths and spatial and temporal resolutions can be captured. The images acquired from these sensors can be used in the detection of snow cover, evapotranspiration, land use, crop type, and vegetation change, as well as in water availability and consumption analyses. Additionally, when the spectral signatures of the imagery are related to the ground-truth water quality data, a near real-time registry of the water quality can be attained. This method works particularly well as the first approximation of the amounts of sediments and chlorophyll in the water body and can be used to monitor soil erosion and algal bloom and facilitate water quality management.

Since analytical chemical information collected from field surveys cannot reflect internal exposure and body burden, some scientists prefer to use biotic data. They are simpler to use and acquire. Biosurveys of flagship or umbrella species can provide valuable information on pollution exposure–response relationships. When multispecies are examined, the information on species composition and abundance in a biotic community can be compiled into metrics and indices. One such index is the Index of Biological Integrity (IBI). The Ohio EPA has derived an IBI consisting of a matrix of 12 criteria of fish communities, including the presence and abundance of sensitive and tolerant species, to depict the instream water quality in Ohio. Other states in America also have similar fish indices to indicate the quality of the aquatic environment. Another index, the Invertebrate Community Index (ICI), uses data on benthic invertebrates to portray the water quality conditions. It consists of 10 metrics depicting the health of the
macroinvertebrate communities. In addition, some scholars have used the community structure and the richness of bacteria taxa to reveal the health of water bodies and catchments. These indices are constructed based on the established knowledge of the ecology and synecology of the biotic communities. The assumption is that the presence and performance of biotic organisms are indicative of the environmental conditions. At a subspecies level, the body burden of the contaminant found in the biota is used to depict the water pollution level. It is also used as the basis for decision-making by the food advisory committees. Visual symptoms in the biotic organisms are good indicators of the water pollution status. Indices, such as DELTA (which denotes deformities, erosion of fins, lesions, tumors, and abnormalities of fish), can be used to indicate the presence of toxins, fungus, and nutrients in water.

Biosurveys and bioassessments are good tools for rapid biotic evaluations. The data collected can be used in empirical, statistical, and stochastic analyses to determine the degree of contamination, the causes of pollution, and the biotic response to the impacted environment. The results are useful in understanding the causal pathways.

With the advent of computer technology and the availability of metadata sets, a variety of empirical and processed-based hydrologic and water quality computer models have been used to simulate the fate and transport of pollutants, water quality, and the potential consequences of various water planning schemes. Commonly used watershed-scaled models are the Hydrologic Simulation Program – Fortran (HSPF), Soil and Water Assessment Tool (SWAT), Spatially Referenced Regression On Watershed attributes (SPARROW), Agricultural Non-Point Source model (AGNPS), Areal Non-Point Source Watershed Environment Response Simulation model (ANSWERS), MIKE-SHE (System Hydrologique European), Water Evaluation And Planning System (WEAP), and Long-Term Hydrologic Impact Assessment (L-THIA). Underpinning the conceptual framework of these models are the hydrologic principles and empirical interrelationships of different variables, including climate, soil, geology, land use, vegetation growth, latitude, topography, basin hydrology, channel morphology, water chemistry, and pollutant transport. Some of these models are integrated with geographic information systems (GIS), expediting data acquisition and processing. The models are often used to assess the current water quality conditions, ascertaining whether or not the water body is meeting the water quality standards.

Future challenges in water quality management

According to the Intergovernmental Panel on Climate Change, the increase in fossil fuel burning and deforestation is causing an increase in atmospheric carbon dioxide, a greenhouse gas, and inducing global warming. At local scales, a higher summer temperature and consequently greater evaporation may increase convective precipitation. A higher winter temperature may lead to a lower amount of snow in higher latitudes and altitudes and earlier snow melt. The changes in global circulation patterns may affect the precipitation regimes in different parts of the world. Some regions may have a higher amount of precipitation, while others may experience a lower precipitation. The variation in precipitation will change the amount of surface runoff and the concentration and loading of pollutants. Hence, climate change is anticipated to affect the hydrologic and nutrient cycles and impact not only water supply, demand, and availability, but also water quality. Furthermore, climate change is likely to change the frequency and
WATER QUALITY

severity of extreme hydrologic events. Intense storms, hurricanes, droughts, and floods may exacerbate water quality problems. Storm events may have a shorter duration, but they may be more intense with a higher erosive power. Dilution, flushing, and delivery of sediments, nitrates, and phosphorus will be increased. The higher temperature and the changes in flow regime can also modify the fate and transport of pollutants.

Other anthropogenic activities, such as channelization, installation of storm drains, and land-use/land-cover changes from forested lands to farmlands and urban areas, can affect the porosity and permeability of the land surface and the retention, interception, and infiltration of water. As such, the surface and subsurface water pathway (surface runoff, groundwater recharge, evapotranspiration, the flashiness of storm hydrograph, and the magnitude of peak flow) will be altered. As the water balance in the catchment is changed, water quality will also be degraded. With the increase in population, many watersheds are urbanizing at a rapid rate, and it is inevitable that there will be more bacteria and higher levels of COD, BOD, and phosphate in these areas, which unequivocally will affect water quality and impair aquatic ecosystems.

Moreover, future urbanization may work in concert with climate change or other changes, amplifying or moderating the frequency and magnitude of floods and droughts, leading to concomitant changes in water pollution. The rise in the use of biofuels to meet the increasing energy demand may also increase the use of fertilizer and the risk of nitrate contamination. In the face of global environmental changes, there is a need to predict the plausible hydrologic and water quality conditions under different future scenarios. However, due to uncertainties of the future as well as in the quality of data and accuracy of the analytical methods, formulation of appropriate future water management plans remains a difficult endeavor.

Mitigation strategies and sustainable water resources management

To mitigate and adapt to the future hydrologic and water quality impacts of global changes and ensure quality water for future use, both point source pollution and nonpoint source pollution have to be controlled. More stringent regulations for industrial and sewage discharge have to be implemented. Improved sewage treatment to remove nutrients or other contaminants can be helpful to reduce pollution from municipal sewage plants. Best management practices (BMPs) can be employed to control nonpoint source pollution. For farmlands, conservation farming practices, such as no till and crop rotation, may help to reduce the amount of sediments and nutrients leached to the streams. To entice the farmers to practice conservative measures, the BMP strategies can be integrated with incentive programs or payments for agricultural services. In urban areas, porous pavements, rain barrels, retention ponds, and buffer strips can be installed to reduce the amount of urban surface runoff and improve its quality. Though expensive, distillation, microfiltration, and reverse osmosis can be used to desalinate saline water.

Today, many watersheds in America do not have a coordinated program for water quality management that involves different states and institutions. But a watershed transcends political boundaries. Hence, better coordination is needed. To meet the challenges of future demand of high quality water in a cost-effective manner and to ensure an adequate supply of clean water, it is essential to link water management with water needs arising from changes in population, energy generation, economy, land use, and climate. Long-term
regulatory programs should be established. Such programs should couple monitoring and water sustainable assessments with management goals. Water policies should involve plans for water appropriation, water-use management, and water conservation, for example, grey water reuse and recycling and the use of water-saving faucets and trickle irrigation systems. Strategies may include water pricing, water trading, and return flow credits. Moreover, it is essential to protect the quality of water, which may entail sustainable landscape management, riparian zone restoration, river management, and pollutant reduction. Green techniques that emulate natural processes, such as the restoration of wetlands, should be considered in tandem with the traditional hard engineered solutions to derive water management decisions so as to optimize the results and achieve water quality objectives. More importantly, there is a need to have a better understanding of the interplay of the biophysical, water quality, and socioeconomic variables in a watershed. Data, knowledge, and skills from different disciplines should be integrated. As such, a holistic and systematic water quality monitoring program and a unified national approach for sustainable water resources management can be implemented.

Water resources and hydrological management

James L. Wescoat Jr
Massachusetts Institute of Technology, USA

Water resources refer to surface waters that flow across the land and groundwater that percolates beneath the surface, which are subject to various types of human activities and hydrological management (i.e., human measurement, use, modification, and control). Key hydrologic processes in the water cycle include precipitation as snow and rain, interception of rainfall by plants, infiltration into soil surfaces, evaporation and transpiration by plants, snowmelt and runoff of these fresh waters into streams, lakes, and wetlands, along with erosion and sedimentation of those surface water bodies, recharge of groundwater aquifers, and ultimately discharge into saline coastal waters (Figure 1). Hydrology has close relationships with climatology, glaciology, geomorphology, and oceanography. Each hydrologic process is shaped by regional interactions between the Earth’s energy budget, climate, landforms, and land uses which themselves range from forests to grasslands, croplands, industrial areas, and urbanizing landscapes. Each of these types of human settlement modifies hydrologic processes in ways that affect water quantity, quality, and use. Although the distribution and flows of water resources change in dynamic ways, water is not lost from Earth’s hydrologic cycle. It remains as part of the world water balance.

Human activities convert hydrologic processes into “resources” that serve various social purposes. Water resources are therefore defined as systems of supply, demand, treatment, use, recycling, and reuse, until water returns to the atmosphere or ocean. Water supplies are obtained by collecting rainfall, impounding water in upland reservoirs for distribution to lowland areas, pumping groundwater, or desalinating saline waters for various human uses. While such supplies are sometimes regarded as the resource, it is human water demands that drive the search for supplies and transform hydrologic processes into water resources.

In economic terms, water demand can be defined as the quantities of scarce water resources that are required by competing water uses. However, this formulation is complicated in most places by the absence of water markets, objections to treating water as a commodity, and distorted water pricing. Some water uses are highly subsidized while others, such as in-stream flows for ecosystem protection, have no markets or policies that assign a value to them.

Water policies and politics may thus subsidize some uses and undervalue others, which can increase water withdrawals, inefficiency, and waste. Conservation policies seek to establish standards of water use, pricing, and pollutant discharge. Such policies fit within complex frameworks of water governance that comprise water regulations, institutions, and politics that reflect and respond to changing social values. Some societies have developed elaborate systems of private water rights while others rely on state regulation, community governance, or a combination of public, private, and community control. New water demands and values are continually created. For example, demand for bottled beverage products is expanding, as are the aesthetic values associated with water conservation.
Modern domestic water use usually requires treatment through filtration, disinfection, pH control, and contaminant removal prior to use. The growth of municipal and industrial uses has led to increasing withdrawals of water for drinking, power plant cooling, and waste disposal. Although these uses consume little water through evaporation, they alter water quality in ways that require wastewater treatment. Irrigation agriculture by comparison consumes a large proportion of the water withdrawn through evapotranspiration by crops, and it returns a relatively small proportion to streams and aquifers, along with increased concentrations of salts and agricultural chemicals. Recreational and ecological uses of modified rivers require that some level of minimum in-stream flows be maintained.

Water management strives to mitigate hazards, especially floods and droughts. Hydrologic processes also contribute to mudslides, accelerated erosion, land subsidence, storm surge, dam failure, and water-borne disease. Taking the example of floods, it has often been said, in news accounts and insurance policies, that flood events are “Acts of God.” However, geographer Gilbert F. White (1945) transformed the field of hazards management by documenting how flood losses are “acts of man.” Human beings have a long history of occupying floodplains inundated by river channels for purposes of water transport, fisheries, land development, and other benefits. Investment in flood protection through dams and levees can induce further floodplain settlement, and thus greater exposure to less frequent but
more damaging events. White also showed how nonstructural measures of flood risk reduction, such as warning, evacuation, insurance, and preparedness, can reduce losses. Subsequent research has shown how social groups marginalized in terms of race, class, or ethnicity have been pressured to live in vulnerable floodplain locations (Mustafa 2013). Hazards mitigation policies strive to rectify such injustices, reduce exposure to extreme events and losses of life and property, and increase resilience (i.e., the capacity to recover from disaster).

Water resource problems and hazards generate conflicts, and they can be aggravated by conflicts over other issues. Ancient Mesopotamian, Roman, and Asian water laws record conflicts over scarce water supplies for irrigation, fishing, and domestic water use. They stipulate the obligations of one water user to another and the penalties and remedies for various types of damage. The development of modern nation-states from the seventeenth century onwards has led to formal transboundary conflicts between countries and among the subnational states within countries. Water conflicts range from formal declarations of war to lesser uses of force and legal disputes. Although water wars as such have been extremely rare in history, lesser conflicts are frequent and intense (Gleick et al. 2014). Conflict resolution at all scales is thus a central function of water governance.

No discussion of water conflict would be complete without some reference to the role of social power relations and politics, and to historian Karl Wittfogel’s (1981/1957) controversial hypotheses about the role of water in the origin of cities and states. Wittfogel argued that despotic empires arose through forced construction of large irrigation projects in arid regions, while more democratic societies were associated with decentralized water systems and private property. These arguments were proven to be false, but they drew attention to the importance of social and political dimensions of water management. Unequal power relations contribute to the impoverishment of irrigators at the tail end of canals, place heavy burdens on women to fetch water and cope with water-borne disease in the home, and increase exposure of low-status water users to water pollution and flooding (Mustafa 2013). Wittfogel and his critics helped usher in a comparative global perspective on water resources (Wescoat 2000).

### Estimating the world’s water supplies

Aside from very small losses and gains in the outer atmosphere, the Earth has a finite amount of water. It circulates in dynamic ways while sustaining a balance at the global scale. Early global estimates of how much water there is on Earth were made in the late-nineteenth century and were revised in the mid-twentieth century by Soviet geographers, who also estimated runoff for each of the continents, in a book titled *World Water Resources and Their Future* (L’vovich, 1979).

These estimates were further refined by Russian hydrologist Igor Shiklomanov, who increased the proportion of groundwater to ice and glaciers, and added the category of biological water (Table 1). The largest volume of water in the world is in the oceans (93.5%). In terms of fresh water, the main volume is held in ice caps, glaciers, and permafrost (69%), followed by groundwater (30%). Surface waters in soils, rivers, and lakes constitute less than 1% of global fresh water. And biological water, including that which constitutes over 60% of the human body, is a mere 0.003% of the fresh water total.

However, these static figures are misleading because some water bodies cycle much faster...
than others. Their renewal periods (i.e., length of time required to discharge and replace all of the water in that condition) vary from hours to thousands of years. The annual flux shown in the far righthand column is the amount of each type of water renewed over the course of one year. Those quantities underscore the significance of rapidly circulating atmospheric and ocean water, followed by soil moisture and comparable volumes of water circulating through ice, lake, and river forms. Particularly interesting is the massive circulation of biological water (1647.1 × 10³ km³/year), which is almost three times the annual circulation of the atmosphere. This large volume of biological water movement gives support to the emerging subdiscipline of ecohydrology, which strives to bridge the ecological and hydrologic sciences.

Remote sensing and world data centers for water supplies

These gross estimates of global water stocks and flows are changing as new hydrologic data are produced by remote sensing satellite technologies. The entire suite of water resources measurement technologies and computational methods is evolving dramatically (National Research Council 2012). For example, new satellite sensors are planned to transmit near real-time data on soil moisture and evapotranspiration. Global synthesis of these measurement and modeling efforts has come in part through international scientific projects such as the Global Energy and Water Experiment (GEWEX). Initiated in 1990, GEWEX has gone through three cycles of program development focusing on global data, hydroclimatology, and land atmosphere interaction modeling. In contrast with earlier world water balance estimates, based on

Source: Modified from Shiklomanov and Rodda 2003, 13, 17.
periodic ground measurements, remote sensing provides more information on spatial and year-to-year variation, interactions, and trends (e.g., Trenberth et al. 2007). In addition to GEWEX, international scientific organizations have created world data centers that may be consulted for records on various components of the hydrological cycle, such as the following.

- Global Precipitation Climatology Project (GPCP),
- National Snow and Ice Data Center (NSIDC),
- Global High-Resolution Soil-Water Balance (Consortium of International Agricultural Research Centers – Consortium for Spatial Information, CGIAR-CSI),
- Global Runoff Database (GRDB),
- National Climate Data Center’s (NCDC) global climate databases.

Rapid advances in data storage, data mining, and modeling will also transform twentieth-century approaches to global hydrology and water resources.

**Local water balance analysis**

Similar water balance methods, also known as water budgets, have practical applications at local scales. For example, climatic water balance analysis compares two key variables – precipitation (snow and rainfall in millimeters) and potential evapotranspiration (the maximum depth of water in millimeters that would be evaporated or transpired by vegetation when there is unlimited water available). These variables are plotted over time (Figure 2). When precipitation (P) is greater than potential evapotranspiration (PET), soil moisture is recharged and surplus water begins to run off (dark blue). When PET exceeds P, soil moisture is drawn down (yellow), there is a deficit, and plants undergo stress (orange). Annual water balance studies have been used for local irrigation, forestry, and water supply planning. Multi-year water balance analysis with shorter time steps are used to assess water supply variability and drought hazards.

Although water balance analysis appears simple, estimating the evapotranspiration term is challenging. The earliest models tried to use only air temperature data, but that neglected key processes of energy and water transfer at the Earth’s surface. The Penman–Monteith equation is the most widely used equation today: in addition to temperature it includes measures of solar radiation, humidity, and heat transfer in the ground and atmosphere. Its widespread use for agricultural purposes has led to the creation of public databases such as the United Nations Food and Agriculture Organization’s CLIMWAT and CROPWAT webdata and software.

**Figure 2** Climatic water budget diagram for 0.5 degree grid that includes Cambridge, MA, USA. Hydrological measurement and management

Each component of the water balance poses resource opportunities and hazards that need to be measured and managed, and it is useful to examine each one of them.

Precipitation

Often the first process considered in the hydrologic cycle is precipitation in the form of rainfall. Although there are examples of ancient rain gauges, the modern instrumental record for most areas of the globe only dates back to the start of the twentieth century. Precipitation records are complicated by weather station histories that change location, land-use context, measurement technology, or recording methods (e.g., human observation, automatic recording, or telemetric data transmission). Various techniques are used to convert these measurements at a point in space into areal and volumetric data, for example, interpolating observations between stations, constructing representative polygons (Thiessen polygons) on flat terrain, or mapping equal rainfall lines (isohyets) on more varied terrain. Enormous effort has been devoted to designing rain gauges that dampen wind effects and other sources of measurement bias. As noted above, measurement is being revolutionized by remote sensing analysis of storms for both weather forecasting and climatology. Remote sensing is especially valuable for estimating the spatial and temporal distribution of intense storm cells and low-frequency storms in arid regions.

Precipitation management remains difficult. Various experiments with cloud seeding using silver iodide and other precipitation nuclei have been attempted since the mid-twentieth century with little in the way of controlled results. More widespread are attempts to estimate probable maximum precipitation to plan for floods based on estimates of maximum storm intensity and the time of concentration for rainfall to reach the stream. Record precipitation measurements range from 38 mm per minute and 1870 mm per day in Cilaos, Reunion, in the Indian Ocean to 26461 mm per year at Cherrapunji, India.

Precipitation management in the early twenty-first century is focusing on rainwater harvesting and climate change. In the field of climate change, precipitation variability remains among the great uncertainties, in terms both of shifts in precipitation means, and of changes in rainfall variability and extreme events (IPCC 2012). Rainwater harvesting, by comparison, is an ancient method of rooftop and surface runoff collection and storage, which is being rediscovered and adapted for new contexts and uses. India is a leader in the field, but there are centers of innovation in all regions of the world (Agarwal and Narain 1997). In addition to rainfall quantity, water harvesting is affected by changes in precipitation quality and the dry deposition of particulates which require diversion of the first flush of runoff, sedimentation, filtration, and storage. The interception of precipitation varies by different tree species, vegetation structure, and building facades in urban environments – all of which can cause a 10–40% change in the amount of rainfall that reaches the soil and the pathways by which it does so.

Snow and ice

Snow and ice hydrology are crucial for river and reservoir forecasting in high latitudes and high-altitude headwaters, but they are even more challenging to measure. Issues range from the complexity of snow physics and snowpack dynamics to snow water chemistry and alpine water quality. The geographic distribution of snow is concentrated in landscapes above 40’N
and on the windward face of high elevation ridges (e.g., the Hindu Kush-Karakorum-Himalayan mountain ranges). The percentage of precipitation that falls as snow tends to increase linearly with altitude. The liquid water contained in snowpack is a function of its density (e.g., fresh powdery snow may have a density of 10% in which 10 cm of snowfall would contain 1 cm of liquid water). Melting depends upon energy and heat transfer through the snowpack. Snow management includes meltwater forecasting using temperature and energy budget models, as well as physical structures such as snow fences. Redistribution of snow through windblown drifts and avalanching complicate snowmelt runoff modeling.

Avalanche management has developed methods for prediction, warning, controlled triggering of dangerous accumulations, and construction of snow retention structures and bridges. At the other end of the spectrum, low snowfall years have given rise to snowmaking technologies to support skiing and winter sports industries. Cooperative management of snowmelt processes has been documented among villages in the Karakorum region of northern Pakistan (Kreutzmann 2000). Concern is escalating worldwide over glacial retreat associated with climate change in most regions of the world, from the small disappearing glaciers of the Andes to large gliated regions of the eastern and central Himalayas, the Greenland ice sheet, and arctic and Antarctic sea ice, which are closely tracked to assess the implications of sea level rise.

**Infiltration and soil moisture**

In nonurbanized gentle grasslands and forest landscapes, most precipitation infiltrates into the soil. The maximum rate of infiltration depends upon soil texture, grain size, crusting, crumb structure, grading, and organic matter. On relatively flat vegetated loamy soils, rainfall infiltrates up to the moisture-holding capacity of the soil, when all of its pores are filled, after which water ponds on the surface and begins to run off or evaporate. Soils with high sodium content in arid regions (sodic soils), or iron content in the humid tropics (laterites), may have surface soil structures that repel water, especially when compacted by grazing or human activities. Once infiltration occurs, percolation of moisture downward through the soil by gravity continues until it reaches an unconfined water table, recharging groundwater aquifers and causing the water table to rise until the soil is saturated. Percolation is accelerated by plant root holes, fauna tunnels, rock fracturing, and lenses of porous soil; it is obstructed by rock layers and dense hardpan layers in a soil that may be broken up or compacted by different cropland cultivation methods. Infiltrated water may also drain laterally through the upper layers of a soil in a process known as interflow, emerging in springs or stream discharge.

When drainage ceases, the soil is said to be at field capacity, which retains moisture available to plant roots. Managing the soil moisture used by plants is a primary determinant of agricultural food and fiber production. It is also important for managing slope stability, erosion, sedimentation, and landslides affected by the additional weight and lubricating effect of soil moisture.

Saturated soils and ponded water in flat areas create wetlands whose boundaries are subtle and dynamic. Throughout history, enormous human effort has been devoted to soil drainage and filling for land development, cultivation, and health reasons. Drainage of wet (hydric) soils may involve cutting open channels or installing porous drain pipes at regular intervals; protecting low-lying lands by earthworks known as polders, levees, or bunds; and pumping drainage waters
over those barriers. These drainage practices accelerate the subsidence of soil surfaces, especially in soils with high organic content that decomposes when drained, leading some landscapes to subside below sea level and become vulnerable to coastal storm surge as well as terrestrial flooding. In agricultural regions, drainage water may be laden with chemical leachates. In addition to their effects on pollution, algal blooms, and reduction of oxygen (eutrophication) in local water bodies, agricultural chemicals can accumulate in regional food chains and contribute to large-scale oxygen reduction (hypoxia) in coastal waters.

An estimated half of the world’s presettlement wetlands have been lost through drainage and filling for agricultural and urban land development. Wetlands are defined by the presence of water, hydric soils, and aquatic vegetation—all of which fluctuate seasonally and from year to year in what is termed the “hydroperiod” of the wetland. Wetlands have been deemed unhealthy from antiquity, due in part to the habitat they provide for insects but also to erroneous theories of poisonous vapors (miasma). However, the late twentieth century witnessed a dramatic reversal of attitudes toward wetlands, brought about in part by scientific understanding of their rich ecological productivity and economic value (e.g., for fisheries, waterfowl, flood protection, and stormwater treatment). Wetland protection efforts have increased at every level, from local advocacy to the international Ramsar Convention on Wetlands of International Importance in 1971. Despite increasing recognition of wetland values, delineating them for protection and regulating land development remain highly contested processes. Conservation of degraded wetlands has had some success, while attempts to create new wetlands are more difficult and less productive in terms of ecological values and services.

**Evapotranspiration**

Soil moisture is subject to evaporation and transpiration through plants. Evaporation from open water surfaces such as lakes, ponds, and reservoirs has important effects on microclimate and storage. Evaporation from oceans is the principal source of atmospheric water vapor (approximately 85%). Evaporation from terrestrial water bodies is smaller but significant for water supply planning. Efforts to reduce evaporative water losses through shading are successful in small-scale cisterns and covered water reservoirs. Floating objects and films designed to reduce evaporation on medium-sized water bodies are often blown to the edge of the water body. Evaporation from upper soil horizons occurs through capillary action and heating. It is particularly significant on bare cultivated soils at the start of the growing season. It can be reduced by mulching, reduced tilling, and composting, which have been practiced from prehistoric times to the present.

Transpiration from natural vegetation and irrigated plants represents the highest consumptive use of water worldwide. Transpiration rates vary greatly by species, climate, cropping practices, and atmospheric heat stress. Plant water uptake is also influenced by rooting patterns, microbial transport, and soil porosity. When plant water stress is initiated, a host of chemical and physical signals operate to conserve water and reduce plant stress. Wilting and defoliation can be followed by plant mortality due to hydraulic failure in the root, stem, or leaf zones, carbon starvation, or stress-induced disease.

In light of food security implications, a great deal of agronomic research has focused on managing plant water requirements. The Green Revolution in the late twentieth century developed hybrid plants that have greater yields but also greater water and nutrient requirements. Subsequently, plant breeding has focused on
drought tolerance as well as yields and disease resistance. A cultivation method known as the System of Rice Intensification (SRI) is producing higher yields with fewer, more carefully tended plants that have lower total water requirements. Efforts are being made to test intensification techniques for other crops such as wheat as well.

Evapotranspiration from phreatophytes (deeply rooted floodplain plants) such as *Tamarix* can be a major source of water losses along river corridors, especially on impounded rivers favored by invasive plants. This problem has led to eradication methods that further disrupt riparian ecology, and to watershed experiments that aim to increase water yield by changing tree to grass cover, a method that at best increases short-term yields while also aggravating erosion and wildlife habitat disturbance.

By far the greatest potential for managing evapotranspiration involves irrigation management. Every irrigation variable from scheduling to water delivery, application methods, and drainage water reuse can help increase water use efficiency. For example, precision land leveling ensures more uniform application rates, water-course lining reduces seepage losses, and drip irrigation delivers water directly to the root zone. Evapotranspiration-based irrigation scheduling uses automated controllers with on-site weather station data, soil moisture sensors, and dynamic crop coefficients to deliver the right amount of water for each stage of plant growth. Excess irrigation runoff reuse reduces agricultural chemical runoff. However, care must be taken that conservation does not increase salinity concentrations or impact downstream users.

**Groundwater**

Water that percolates below the root zone continues to drain through the soil until it reaches either an unconfined water table lying on top of an impervious soil layer, a limestone (karst) flow channel, or an aquifer confined between two impervious layers. Depending upon aquifer slope and saturation conditions, percolation may be lateral as well as downward. Groundwater ultimately discharges into springs, streams, or coastal waters. Most soil and rock strata are complex in materials as well as stratigraphy, which complicates the measurement and modeling of groundwater quantity and quality. Aquifer drainage may or may not follow surface drainage patterns. In addition, the timescales of aquifer flows are much longer than those of surface waters, which makes groundwater supplies difficult to calculate through simple water balance methods.

Most ancient societies relied upon shallow hand-dug groundwater wells. Expansion of large-scale canal irrigation in the nineteenth and twentieth centuries led to dramatic changes in shallow groundwater conditions, including waterlogging and salinity in some irrigated regions of the world. Diffusion of pumping technologies in the mid-twentieth century reduced waterlogging in some areas, but greatly depleted streams, traditional irrigation systems, and groundwater levels in others. The rate of groundwater depletion accelerates when energy and pumping costs are subsidized (Birkenholtz 2009), and it is so dramatic in some regions that it has been inferred from satellite measurement of variations in the Earth’s gravity in some regions.

Depletion is by no means the only challenge. Saline groundwater caused by natural geological deposits and leaching of salts by irrigation has diminished soil fertility from the Colorado to the Amu Darya basins. In the latter basin, the Aral Sea has receded so far that it has left salt and agricultural chemical residues along the former sea margin. These deposits are transported by wind erosion, causing various respiratory and internal diseases. Careless lining of oil and water
pump shafts has also led to mixing of saline and freshwater aquifers. Groundwater contamination by industrial wastes raises enormous concerns due to the technical difficulty of cleanup, and the long renewal times of most aquifer waters, which range from hundreds to tens of thousands of years. Leaching of contaminants from surface wastes is one concern. Injection of drilling fluids for oil, gas, and hydraulic fracturing is another. The latter is extremely controversial as careless drilling can easily contaminate shallow aquifers in this underregulated industry. Modeling the flow, transport, and fate of groundwater contaminants is technically difficult, and the consequences of groundwater’s misuse are likely to be as serious as those of its overuse.

Runoff into springs, streams, and rivers

Excess stormwater runs off into streams and rivers, generating high flows and sometimes floods. Soil moisture and groundwater maintain the base flow of springs and streams, long after precipitation storm events have occurred. Springs were deemed sacred in ancient Greece and Rome, as the sites of nymphs and magical grottoes. At the same time they were pragmatically tapped by venators (Latin for “hunters”) who opened their flows into aqueducts that served major cities and landscapes.

The smallest tributaries emerge from springs and join other streams to form perennial rivers in all but the most arid regions. Arid and dry mountainous regions, by contrast, have intermittent channels (called arroyos, torrents, or wadis in different cultures), which carry occasional thunderstorms with high velocity and erosive power. River channel planning on large perennial rivers such as the Danube and Rhine Rivers in Europe has centuries-long records of engineering, development, and pollution. Many rivers were channelized and impounded by dams. While the removal of small dams is increasing in some regions, such as the United States, construction of large dams is accelerating in China, the Himalayas, and the Andes. Efforts to restore streams to fishable, swimmable, and ecologically productive systems is now a specialized professional field with impressive examples but limited in regional-scale implementation. While the transportation of hazardous substances was addressed early in European water treaties, that did not prevent continuing processes of urban and industrial contamination from occurring.

Streams are the most accessible water bodies and are thus the best known components of the water budget. Even so, they present complex challenges for scientific management of multiple uses, flood hazards, and water quality. Channel networks vary by terrain, from the most common dendritic (branching like a tree) patterns on alluvial soils to rectangular patterns in geologically block-faulted terrain and streams that radiate from volcanic mountains.

In each case, stream flows respond to precipitation storm events through peak flows that rise during the initial time of concentration in the watershed, and wane as surface water runoff declines. Stream discharge is influenced by watershed size, shape, steepness, land cover, soil depth, and channel configuration. Channel cross-sections and alignments are affected in turn by slope, suspended sediment load, bed load, and riverbank materials, which produce characteristically meandering, braided, or rock channel sections. Some channel morphologies exhibit the self-similarity of fractal systems. Each channel type and configuration has a floodplain shaped by former river channels, deposits, terraces, and natural levees that reflect its history of flood events.

Human activities also shape complex river systems in the following ways:
WATER RESOURCES AND HYDROLOGICAL MANAGEMENT

- changes in land use that accelerate runoff, erosion, sedimentation, and river pollution;
- floodplain use for farming, settlement, and waterfront development;
- river crossings by bridges, fords, and ferries;
- stream channel use for domestic drinking, fishing, and boating purposes;
- channel engineering (straightening, widening, armoring) for drainage, flood control, navigation, and commercial shipping;
- dam construction for multiple purposes of flood control, water supply, and hydropower;
- withdrawals of river water for irrigation, municipal, and industrial use;
- wastewater disposal from all human activities, from agricultural runoff to urban sewer discharge, industrial releases, and accidents; and
- planned and accidental introduction of exotic and invasive aquatic species.

These river modifications must be examined within a comprehensive approach to floodplain management. While the regulation of land uses adjacent to stream channels has proven politically difficult to implement, nonstructural measures such as warning, evacuation, and flood proofing are now diffusing widely.

Deltaic, estuarine, and coastal waters

As rivers approach the sea, they shift from tributary to distributary systems. The distributary channels have reduced slopes and velocities that discharge coarse sediments on the levees that guide them and fine sediments in the low-lying swamps and marshes between them. They meet tidal processes that redistribute those sediments and mix the salt and fresh waters in brackish zones that extend miles inland. These brackish mixing zones (estuaries) tend to be some of the most ecologically productive waters in the world for plankton, shellfish, and fish spawning. Management of estuaries is made challenging by their complex flows, biogeochemistry, and mixing processes. Human actions compound these difficulties by the construction of roads and infrastructure that block freshwater flows and sediment transport. River engineering confines channels within artificial levees that reduce the overbank flooding and sediment deposition that sustain delta growth. This leads to accelerated coastal subsidence and erosion of all but the main delta channels. These channels often have major ports that discharge partially treated wastes from municipal and industrial facilities. The Rhine delta has gone through a long succession of flood control and management regimes, the most recent of which strives to “make room for the river.” Other deltaic regions in North America, Asia, and Africa are studying the Rhine’s example closely for lessons that may be adapted to other regions (National Research Council 2013).

Water resource management at different scales

In everyday life, water management begins at the personal and household levels of early morning excretion, bathing, and drinking. It continues through the day in manifold uses of water to support different forms of livelihoods, waste disposal, and reuse. Each of the hydrologic processes discussed above is involved and affected. For thousands of years communities have developed diverse ways of managing water resources, hazards, and water conflict. They are shaped by water management practices at larger regional, national, and increasingly international scales, which interact with one another in complex ways. In recent decades, specialized water planning has developed at each of these scales, from the global to the local.
Global and international water management

International river problems date back at least to the mid-seventeenth century with the advent of modern nation-states. Early water conflicts among nations dealt primarily with issues of navigation on major rivers. By the eighteenth century, international river organizations were organized to address physical, economic, and political conflicts over shipping. By the nineteenth century, water scientists and planners in Europe and elsewhere began to realize shared interests in knowledge about water resource management and water-related hazards. They formed international nongovernmental organizations (INGOs), such as the International Meteorological Organization in 1879 and the International Institute of Agriculture in 1905, both of which became United Nations (UN) agencies in the mid-twentieth century. As international concerns grew over water quality, environmental impacts of large water projects, and safe drinking water and sanitation for all, new UN agencies and NGOs were created to address them.

The early twenty-first century is witnessing growing concerns about global water problems, including global climate change (Gleick et al. 2014). As populations grow, gross per capita water supplies are declining relative to the water scarcity threshold of 1000 m³ per capita per annum, especially in arid regions of the world, though the significance of these gross estimates is challenged by those who underscore the greater problem of unequal access to water by different social groups. The United Nations Millennium Development Goals sought to reduce the estimated 1 billion persons without adequate access to safe drinking water by half by 2015, and this goal was reportedly met ahead of schedule (WHO/UNICEF 2014). Far less progress has been made in assisting the estimated 2 billion persons worldwide who lack access to safe sanitation. Deaths from flooding are declining, albeit with spikes during extreme events, but the economic losses of flooding worldwide continue to rise due to increasing floodplain development. Child mortality due to water-related diseases is declining as a result of oral rehydration therapy and antibiotics, though the frequency of those diseases and their related malnutrition effects remain high. These positive trends in water management reflect the purposeful efforts of millions of people working in the water sector.

Water is arguably the major natural resource concern associated with global climate change, along with its connections to energy and food security. Although there is a scientific consensus about climate warming trends, there is much greater uncertainty regarding trends in precipitation and extreme water hazards. Fears of international water wars are often repeated, notwithstanding research on the historical rarity of large-scale military conflicts over water. Most agree, however, that there is a high frequency of social conflict over water uses that sometimes becomes violent. Conventionally, modern water planning worldwide has distinguished four major categories, or subsectors, of water withdrawal and use:

- agricultural water use – for irrigation, livestock, and aquaculture;
- industrial water use – for thermoelectric power production, mining, and commercial purposes;
- municipal water use – for domestic and related urban purposes; and
- in-stream water uses – for recreation, fisheries, and navigation.

However, the practice of water planning requires that they be addressed jointly, in part due to competition and conflict between subsectors and in part due to recycling and reuse...
of wastewater. It is encouraging that total water demand forecasts in the late twentieth century exceeded actual withdrawals in the year 2000. However, forecasts in the first decade of the twenty-first century project a 50% increase in withdrawals by 2025 in some studies and by 2050 in others (UN Water 2014).

The UN Food and Agriculture Organization compiles the most comprehensive country data on water use in its AQUASTAT database. It relies on self-reported country data, which are variable in quality and often estimated rather than measured. AQUASTAT includes five main categories of data:

1. geography and population – baseline areas and populations for normalizing water use data per hectare and per capita;
2. water resources – estimates of country’s supplies from precipitation, renewable domestic and transboundary surface and groundwater quantities;
3. water withdrawals – categorized by type of use (agriculture, municipal, and industrial); and source (fresh water, groundwater);
4. irrigation and drainage – areas under irrigation, by source of water, technology, and type of drainage; and
5. environment and health – limited in this database to waterlogging, salinity, nutrition, and water-borne disease.

Worldwide, agriculture is by far the largest water use in terms of withdrawal from natural water sources (70%), though regions such as Europe withdraw far more water for municipal and industrial purposes (79%). As urbanization increases worldwide, there is pressure to increase agricultural water productivity (“more crop per drop”) and to transfer water from agriculture to urban use. Urban populations are also demanding increased regulation of agricultural water pollution.

The UN also publishes a World Water Development Report periodically on a wide range of indicators (Table 2), which are broader in social and environmental scope than assessments focused on water use alone.

The Global Water Partnership (GWP) is an important international NGO that seeks to integrate international water programs. It was created following the Dublin Conference on Water and Environment in 1991 and the UN Conference on Environment and Development at Rio de Janeiro in 1992. Those conferences propounded four guiding principles for world water management: (i) water is a finite and vulnerable resource; (ii) water is an economic good; (iii) water management should occur with public participation at the lowest possible administrative level; and (iv) women play a central role in water management. GWP has subsequently advocated an approach known as Integrated Water Resources Management (IWRM), which strives to more closely link water development with improved environmental, economic, and governance approaches. It holds triennial conferences on major issues and themes. In 2014, the main thematic foci were as follows.

WATER RESOURCES AND HYDROLOGICAL MANAGEMENT

- Climate resilience and water security.
- Transboundary water security.
- Food and water security.
- Urbanization and water security.
- Energy and water security.
- Ecosystems and water security.

GWP meetings and the IWRM approach have been increasingly challenged by social and environmental activists who regard it as a neo-liberal approach to economic growth, trade, top-down planning, large infrastructure finance, and commodification of scarce water supplies and services.

Every six years, the Intergovernmental Panel on Climate Change (IPCC) provides a perspective on global freshwater impacts, adaptation, and vulnerability. Its Working Group II report on the impacts of climate change in 2014 underscored concerns in which there was “high confidence” scientifically that glaciers, permafrost, and ice-caps are melting (IPCC 2014). A special report on water-related disasters and extreme events reported more variable levels of scientific confidence about the effects of climate change on floods and droughts (IPCC 2012).

Global databases on floods, droughts, and other hydrologic disasters have been compiled by organizations such as the Centre for Research on the Epidemiology of Disasters (CRED). The trends in Figures 3 and 4 reflect increased reporting, but they also indicate increased floodplain encroachment and investment, and may indicate more extreme storm events as well. However, the most severe impacts associated with water hazards occur where governance has broken down in areas of war, civil strife, and involuntary population displacement.

Such crises have contributed to international movements to recognize a universal human right to water and sanitation (Sultana and Loftus 2012). In 2010, the UN passed Resolution 64/292 on the Human Right to Water and Sanitation, according to which each person must have access to water that is sufficient (50–100 liters per capita per day), safe (World Health Organization water quality standards), acceptable (for domestic use), accessible (within 1 km of the home), and affordable (no more than 3% of household income). The resolution was supported by 122 countries.

![Figure 3](image)

![Figure 4](image)
Some larger international regions have formulated integrative water policies. One of the most advanced of these is the European Union’s Water Framework Directive adopted in 2003 (European Commission 2007). The Water Framework Directive calls for common monitoring programs by 2008, river basin planning by 2009, and good water status in all rivers, lakes, coastal waters, and groundwater by 2015. However, an interim progress report indicated that most countries of the European Union still report that a majority of their surface water bodies are “at risk” or have “inadequate data.”

Transboundary water conflict resolution

Some transboundary water disputes go to international tribunals and courts. These include conflicts over upstream water development (e.g., dams, industrial discharge, increased runoff) that adversely affect downstream water availability and environmental quality, or downstream development that forecloses upstream navigation and future water uses.

Three major breakthroughs occurred in the late twentieth century that addressed transboundary water disputes. The UN Convention on the Law of Non-Navigational Uses of International Watercourses was completed in 1997, after more than 20 years of negotiation (McCaffrey 2007). By formulating the concept of “international watercourse systems,” this agreement struck a balance between river basin planning, which was rejected as too broad in scope by some riparian nations, and river channel planning, which was seen as too narrow. It developed the concept of an “international watercourse system” to encompass a network of surface water bodies and associated aquifers that cross or run along an international boundary. The Convention calls for a balance between the principles of “equitable and reasonable utilization,” and “no significant harm.” It requires prior notification of development plans to neighboring states. Although only 36 states were parties to the Convention as of 2016, that was sufficient for it to enter into force as the current legal perspective of the UN.

The Transboundary Freshwater Dispute Database (TFDD) at Oregon State University was a major academic development. This web database is searchable by country, river basin, water issue, and other variables. It provides the full text of historical water treaties online. It also includes an international water events database for 1950–2008, which compiled accounts of international water news, and ranked them from major conflict (−7, war) to major cooperation (+7, voluntary territorial unification). Interestingly, most events fell on the positive side of the scale, indicating that cooperation has been more common than conflict (Wolf 2007). Some scholars disagree, arguing that a lack of extreme events in the database does not necessarily signify the absence of severe conflict, especially in regions of power imbalance. The TFDD database includes transboundary agreements between states within a country, which can be just as intense and protracted as international conflicts.

UNESCO (the United Nations Educational, Scientific and Cultural Organization) has established an international Centre for Water Law, Policy, and Science in Dundee, Scotland, which emphasizes international water law research with students from around the world. As indicated by its title, it seeks to link legal research with policy analysis. Similarly, UNESCO also supports an International Hydrology Education (IHE) program based in Delft, The Netherlands, which addresses issues of water management as well as scientific hydrology. International education at such centers plays an important role in advancing the theory and practice of international water research and conflict management.
National water resources management

Most countries have national agencies that deal with water resources, although these are often fragmented across separate agencies responsible for navigation, flood control, irrigation, fisheries, drinking water, pollution control, and so on. Smaller countries with strong central governments are sometimes able to concentrate water knowledge and authority at the national level (e.g., The Netherlands, Singapore). The Netherlands has had a combination of local water boards with national coordination for almost a millennium. Although a relatively new nation, Singapore faces reductions in water supplies from Malaysia and is therefore establishing strong programs for water development and management, ranging from potable water reuse to ecological stream restoration, wetland treatment, and coastal water impoundment for water supply.

Some countries have developed integrated water programs because of major historical events. For example, after the dismantling of South Africa’s apartheid regime, representatives of the country traveled the world studying national water law and policy approaches. Beginning in the 1990s, it adopted policies for both cost recovery and access to basic water services by the poor. Another exceptional case occurred in Australia where a lengthy drought followed by floods led to national intervention for water rights reform in 2010–2012. Brazil stands out for its comparative international studies of national drought policy alternatives that have been undertaken to inform its own policy. While these innovations face continuing challenges, they constitute advances in national water policy.

The situation is more complex in federal systems of government where constitutional authority for water matters rests primarily at the subnational state level, even when financial and technical resources may be concentrated at the national level. The United States, for example, has failed to adopt a coherent national water policy since the 1970s (Christian-Smith and Gleick 2012). Notwithstanding the strong water research and management capabilities of the US Geological Survey, National Oceanic and Atmospheric Administration, Environmental Protection Agency, US Army Corps of Engineers, and other agencies, these capabilities remain fragmented at the national level and only partially coordinated with counterparts at the state level.

India also has a federal system of government with water responsibilities divided between the state and national levels. The government of India adopted a new National Water Policy in 2012 which has stimulated vibrant debates in state, national, and civil society forums. After surveying the array of water problems that India faces, the policy calls for a new water framework law and outlines policies for adaptation to climate change, enhancing water supply, demand management and water-use efficiency, water pricing, environmental protection, floods and droughts, project planning, transboundary rivers, database development, and so on. Implementation committees are now devising ways to achieve this broader scope of national water policy.

In the face of increasing water demand, some nations are pushing ahead with large dam construction, notwithstanding domestic and international opposition based on environmental costs, seismic risks, and large-scale human displacement. Examples include China’s Three Gorges Project, India’s Sardar Sarovar dam on the Narmada River, and Turkey’s Southeastern Anatolia Project (GAP, Guneydogu Anadolu Projesi). Some of these emerging economies have the internal financial resources to build their own dams, while countries in weaker financial positions continue to rely upon international
development banks and bilateral aid to finance large dam projects.

Watershed and river basin planning

The field of scientific hydrology began with local experiments in the seventeenth century which showed that rainfall over a watershed was sufficient to produce springs and streams, as opposed to ancient arguments by Aristotle and others that springs originated from deep groundwater sources. The French geographer Philippe Buache (d. 1773) mapped physiographic basins of the continents and oceans. Mapping river basins was important in processes of exploration and settlement, for example, by Joseph Nicollet (d. 1843) and John Wesley Powell (d. 1902) in the American West, and English geographer James Rennell (d. 1830) in British India.

The concepts of watershed and river basin are closely related. Both refer to a drainage area delimited by a ridge (e.g., a mountain ridge) that directs and discharges runoff to a common outlet. Although sometimes used interchangeably, the term “watershed” tends to mean a relatively smaller drainage used for agriculture and forestry, while the term “river basin” refers to a larger-scale drainage area managed for multiple purposes of hydropower, navigation, and water storage for urban and industrial uses. Watershed management has been associated with movements to decentralize water management while river basin planning has accompanied large-scale public infrastructure development. Both approaches strive to link water management with related land resources. A common challenge that they face is defining the “navigable waters” of the basin, as that has been a criterion for determining the scope of public rights of water access and environmental regulation since Roman times. Some jurisdictions follow a strict definition of waters that are navigable in fact, while others include creeks and wetlands. During the late twentieth century, watershed and river basin planning have both given increasing emphasis to water quality and ecosystem health.

Smaller-scale watershed management is practiced in uncounted areas around the world. Early European watershed planning was linked with scientific forestry and hill torrent control. The United States has witnessed the formation of thousands of watershed organizations dedicated to local environmental planning and water quality improvement since the late twentieth century. India’s participatory watershed management program has focused on upland resource protection for erosion control, which in some regions has pitted forest hill tribes and pastoralists against lowland farmers. Watershed management is especially effective at reducing erosion, runoff, and flooding from regularly recurring storm events.

At the larger scale, the iconic example of integrated river basin development is the Tennessee Valley Authority (TVA) in the United States. The TVA began with the conversion of a dam and munitions factory constructed in World War I to peacetime use, and it ultimately encompassed a broad range of innovative programs for rural electrification, agricultural development, and hydropower generation to alleviate rural poverty. The hydropower options were initially assessed in basin-wide surveys carried out by the US Army Corps of Engineers. However, to address the broader range of river basin development issues the federal government created a new type of river basin “authority,” which is a federal corporation dedicated to comprehensive natural resources planning and economic development.

The TVA model was partially successful, but it was never replicated in the United States.
for political reasons. Critics called it “grass-roots bureaucracy” and “creeping socialism,” dismissing its contributions toward more integrated water resources planning. Over time, its water and agriculture programs declined, and it devolved into a regional power utility with coal and nuclear as well as hydropower generation. However, the TVA has been emulated by river basin authorities in other countries, for example, the Damodar Valley Corporation in India.

One of the largest examples of river basin development outside the United States involves the Indus River basin in South Asia. TVA director David Lilienthal wrote an early article proposing a collaborative approach to river basin development between India and Pakistan. Eight years of negotiation led to an Indus Waters Treaty in 1960 based on the opposite principle, namely the partition of three tributary rivers to India and three to Pakistan. However, these negotiations also contributed to the establishment of a Water and Power Development Authority (WAPDA) in Pakistan, which is like a TVA on a national scale. WAPDA led the development of large-scale water storage and canal infrastructure to mitigate the effects of partition and develop the agro-economic base of the country. To support those planning efforts, the World Bank created a series of sophisticated Indus basin optimization models to evaluate water investment alternatives. The Indus basin models have more recently been used for climate impact assessment and adaptation.

The Rhine, Danube, Yellow, Nile, and Colorado Rivers have been laboratories for water development on their respective continents. Some experiments have failed. The Colorado River Compact of 1928 was based on flawed estimates of average basin discharge that used a short instrumental record that coincided with the wettest period in centuries. Other Colorado River experiments have had mixed effects. The shift from single-purpose single-means dams to multipurpose multiple-means reservoirs, such as the Hoover and Glen Canyon Dams, constituted an engineering advance, on the one hand, that proved damaging to environmental, social, and cultural resources on the other. Integrated river basin development came to mean a chain of jointly operated reservoirs and infrastructure rather than a process for progressive social and environmental management (Wescoat and White 2003). Over the course of decades, the Colorado acquired a complex “law of the river” that is fascinating in its institutional complexity, but insufficiently responsive to changing social values and climatic extremes.

Several river basin experiments are trying to address these constraints. For example, adaptive environmental management is an innovative method for transforming acrimonious battles over dam operations, fish and wildlife protection, indigenous water rights, and other issues. In large regulated water systems, adaptive management focuses on clarifying stakeholder objectives and supporting stakeholder design of restoration experiments to enhance multiple purpose management. It argues for learning by doing, citizen science, and a jointly scientific and political approach to water and environmental management. It has been attempted in the Columbia River, the California Bay Delta, Glen Canyon Dam, the Florida Everglades, the Danube River basin, and scores of other projects. After two decades of investment and experimentation, the institutional results are encouraging as they have helped shift water management from conflict toward collaboration, but the long-term ecological benefits remain to be established.

As noted above, Europe has emphasized transboundary basin planning in its Water Framework Directive. While most European countries have complied in principle and on paper, progress on the ground varies enormously. On the Mekong
River, the lower basin riparian countries of Thailand, Laos, Cambodia, and Vietnam established a Mekong Commission to pursue joint interests in river basin management. Although international conflict in the third quarter of the twentieth century constrained this vision of joint development, the Commission was able to sustain a basic level of cooperation even during war, particularly in the field of flood forecasting (Sneddon and Fox 2007). What was less anticipated was the acceleration of upper Mekong dam development by China.

Urban and community water management

The largest body of water management experience occurs at the local level, from households to communities and cities. Roman water law and waterworks provide some of the best documented ancient water systems, though there are ancient water texts and archaeological waterworks in many regions of the world (Mithen 2012).

Modern cities adopted different approaches to water management. For example, eighteenth-century Philadelphia created a public water department, while New York City granted a charter to a private company to provide water to its residents (Gandy 2002). The latter approach failed to provide a safe, reliable service when the company diverted its revenues to more lucrative nonwater investments, which led to a public utility approach in much of the United States. Interestingly, the late twentieth century witnessed a new wave of private water utility arrangements in European and UK cities that with strong public regulatory oversight of pricing, quality, and disconnection of low-income residents provide high levels of service (Bakker 2010). In England and Wales, the Water Services Regulation Authority (Ofwat) has undertaken this role since 1989. However, movements to privatize urban water systems in developing countries, often with the involvement of Western water companies, have generated greater controversies due to weak regulation and inequitable service, pricing, and provisions for low-income access to water for basic needs (Swyngedouw 2004).

Cities affect regional water quality and stormwater runoff in ways that were not initially taken up by water planners, but became major water management issues in the late twentieth century. Linkages between urban planning, conservation, and ecological approaches to stormwater and floodplain management are being widely adopted and becoming specialized fields of water research and professional practice.

While a majority of the world’s population now live in cities, greater water challenges continue to face those living in rural areas. Access to safe water and sanitation in rural areas consistently lags behind access in urban areas (WHO/UNICEF 2014). Even when they have adequate water supplies, rural communities rarely have the resources to regularly test water quality or treat water effectively at the source and at home.

While considerable progress has been made in community-based water management, communities are not inherently cooperative or equitable. For example, rural domestic water and sanitation challenges are highly gendered, with women responsible for most of the fetching, carrying, and managing of household water supplies at great physical, time, and economic cost. Inadequate local supplies can reduce hand washing and bathing, and thus aggravate the incidence of sanitation-related diseases, which women also manage (Harris 2009). These burdens are accentuated by male migration to cities for wage labor, which can shift the irrigation work formerly undertaken by men to women as well.
Groups who are marginal in economic or social status may be excluded from community water sources and decision-making processes that affect them. They may also be concentrated in areas subject to greater water hazards, for example, floodplains, hillslopes, open drains, and the tail end of canals that receive less reliable water (Mustafa 2013).

These unequal power relations at the household and community levels have parallels at each of the larger levels of governance discussed above. Cities are able to outbid and annex rural areas to obtain a larger regional share of scarce regional water supplies. Hydropower development generates more financial revenues than other river basin uses and garners a larger share of investment. Nationally and internationally funded river basin development historically prevailed over community-based watershed management, though that has been effectively challenged in places with strong water users associations. Upstream users have an inherent advantage over weaker downstream neighbors, though a powerful downstream riparian country such as Egypt can threaten to block development in a weaker upstream country such as Ethiopia. Negotiations to mitigate and adapt to the effects of climate change require an understanding of water management alternatives that connect these different levels of analysis, from the local to the global.

Future water resources

As in previous eras, new water resources are being discovered, developed, and managed in the twenty-first century. Water balance analysis has been extended from individual sites and watersheds to whole industries (e.g., bottled drinks) and their supply chains of growers, processors, and transporters. Some of these studies involve “water footprint” analysis which strives to optimize the amounts of blue water (surface supplies), green water (soil and plant water), and gray water (recycled wastewater) that are used (Hoekstra et al. 2011).

Tracking the flows of goods and services that have consumed water, known as “virtual water,” is a growing field of analysis. Virtual water trade was pioneered by geographer Tony Allan (2011). From early estimates of water used in imports and exports, virtual water research is incorporating increasingly detailed modeling of water use in value chains affected by climatic processes, product inputs and substitutions, prices, and regulatory policies (Konar et al. 2011). To better understand the linkages between hydrologic and social processes, a new subfield of socio-hydrology is developing. Like the field of ecohydrology, which bridges hydrologic and ecological sciences, socio-hydrology strives to link the social sciences, hydrologic sciences, and management (Sivapalan et al. 2014).

The turn of the current century may also be remembered for its discovery of new terrestrial and extraterrestrial waters. There have been recent freshwater discoveries on Earth, including those of the upper mantle and submerged coastal continental shelf. The quantity of water in the hydrous mantle (410–660 km below the surface) is disputed, though a recent study identifies the water-holding capacity of the hydrous mantle transition zone as approximately 1% by weight (Pearson et al. 2014). Water in the upper mantle has been associated with the lubrication of continental plates. Another recent discovery of fresh water has been found buried beneath the coastal continental shelves (Post et al. 2013). These deposits of meteoric groundwater could be substantial but are likely to be nonrenewable except where they continue to receive continental recharge. Should they be tapped, they could face problems of salinity ingress. All of these sources contribute to the Earth’s water budget, from
atmospheric humidity to precipitation, freezing, melting, infiltration, evapotranspiration, recharge, and runoff, each of which is challenging to measure and monitor at a global scale.

The origins of water on Earth is a related question. Although it is often stated, not quite correctly, that no new quantities of water are created on or lost from Earth, such processes take place on such long geological timescales as to have little bearing on water management. The origins of Earth’s water include early cooling of Earth’s mass 4 billion years ago, which created a gaseous atmosphere that held water in a vapor phase. Some of Earth’s water came from numerous water-bearing comet and meteoric collisions, some from Earth’s hydrous mantle, and some from early forms of photosynthesis. Some water input from space continues at an estimated rate of 0.01 km³ per year (Shiklomanov and Rodda 2003). Conversely, the Earth loses small amounts of water vapor through evaporation beyond its atmosphere (ranging from 0.03 to 0.27 km³/year, or approximately 0.1 km³/year). More water is lost than gained, and as the sun becomes hotter, the Earth’s liquid water supply is expected eventually to evaporate.

The search for extraterrestrial water, especially liquid water, is driven by intense curiosity about life beyond Earth. The results to date include identification of frozen water on some planets such as Mars, in the atmospheres of suns such as CW Leonis, in the brilliant tails of comets, and on diverse moons. These studies tap a range of evidence, from landform analysis to absorption spectroscopy for detecting water vapor and theories of habitable zones, which bear comparison with early geographic thought on the ecumene of Earth. Water vapor is believed to be present in most planetary and solar atmospheres. However, inferences about liquid water and oceans on other planets and moons remain tenuous to date. The utility of such knowledge for hydrologic management on Earth is also tenuous, but that is not to downplay the potential power of the imagination in adapting these astronomical sensing and visualization tools and ideas for water resource management on Earth.

Water rights

Olen Paul Matthews
University of New Mexico, USA

Property rights are defined by relationships, and with water rights the relationships are particularly geographic. A water right defines the ways a water right holder can use water (human–environmental relationships) and the relationships within the network of right holders who have an interest in the same water. As a water molecule moves through the hydrologic cycle, it is subject to a sequence of rights that are geographically interconnected. The use of water at one place and one point in time can impact the quality and quantity of water available to other down-cycle right holders. Thus, water rights define not only the uses allowed, but the obligations to other users. Water rights allow users to transform landscapes by developing irrigated agriculture, supplying municipal and industrial water users, and generating hydro-electric power. Water rights allow uses that can dramatically change the hydrologic cycle’s integrity (quality and quantity). Some uses can cause environmental degradation while other water rights preserve in-stream flows and prevent harm to the cycle’s integrity. Understanding water rights is fundamental to understanding a region’s geographic patterns, especially where water is in short supply.

The nature of water rights

Water rights are complex and easily misunderstood primarily because water, unlike most other property, is naturally mobile. This mobility leads to two interrelated but fundamental misconceptions – all water rights are privately owned (it’s my water) and all rights are exclusive (I can do what I want with it). When most people think of a property right, they envision private ownership of land (their suburban home) or personal property (their car or computer). But water rights are not always private, at least not in the way other property can be, and water is not owned in the traditional way that term is used. Private property ownership has specific attributes (a bundle of rights) that generally include a right of exclusive possession, a right to use, a right to sell or transfer, and other items depending on the particular property conceptualization. Even when landownership is as complete as possible (the greatest number of sticks in the bundle of rights) the owner still has obligations to other property owners and is subject to government controls such as zoning, subdivision, and building regulations. Rights associated with water use are even more constrained. Water is mobile and therefore inherently shared, precluding a similar bundle of rights. Water is not subject to exclusive possession and may or may not be subject to sale or transfer. The closest water comes to being private property occurs when a consumer purchases a bottle of drinking water. All the attributes of private property apply to that bottle of water until a short time after it is consumed. Because exclusive possession is missing from the water rights bundle, a water right is usually defined as a usufructory right (a use right) rather than an ownership right. In addition, private water rights can be either attached to the ownership of land as in the riparian rights doctrine found in the eastern United States or
WATER RIGHTS

completely detached from landownership as in the appropriation doctrine found in the western United States.

Water rights can also be public and common property (a private right shared in common with others). Common property rights are a form of private right held by a limited number of interests. Landowners surrounding a lake or along a river may have a property right in the water body. This limited pool of users must in some way share in the use of water. Riparian property owners in the eastern United States and acequias (traditional irrigation districts in New Mexico) are examples.

Public rights can take three forms – the commons, regulatory rights, and government rights. With the commons everyone has free and open access. The commons is not the same as common property, which has a limited pool of users with access. Overuse of the commons can lead to private property rights, regulatory rights, or a combination of both. Regulatory rights are based on command and control laws and permits. Government rights in water are distinctive in that they generally serve some public purpose but are held in the name of the government. They can have substantial impact on other rights, as with the federal navigation servitude (protecting the navigable capacity of the nation’s waters) or federal reserved rights (providing water on federal reserved lands). To make things more complicated, a single molecule of water passing sequentially through the hydrologic cycle could conceivably have all these different property rights connected to it at different points in time.

When the commons is overused one solution is a system of private property rights allocating the resource. Theoretically the system of private rights will reduce conflict and prevent overuse. A private rights approach to water is complicated by its mobility and the strong interest the public has in water use. Any system of private water rights must define the relationships between competing users to prevent conflicts. But defining relationships requires a full understanding of the interconnections within the hydrologic cycle. At the time the common law system developed in England and the United States, the linkages between the elements of the hydrologic cycle were unclear. Private rights were based on landownership and the water adjacent to or under the land. As hydrologic science evolved, the connectivity between the cycle’s elements forced a redefinition of the relationships between users and a modification in the water rights structure.

Some parts of the hydrologic cycle fit easily within a private property regime but not all. For example, it would be difficult to create a private water right in soil moisture that is separated from landownership. Creating a private property right to atmospheric moisture would be difficult unless the water can be captured. Many private water rights allow uses that modify the integrity of the hydrologic cycle. The integrity of the hydrologic cycle includes physical (temperature, volume, movement/speed, etc.), chemical, biologic, and radiologic elements. It also includes social, cultural, religious, and political elements. Property rights associated with protecting the integrity of the hydrologic cycle are generally, but not always, public rights. Historically, many of these public rights were unregulated, leading to pollution and other overuse. Balancing these public and private interests is complex, and the complexities increase as the value of ecosystem services becomes better understood.

Different property rights regimes produce different outcomes in balancing the complexities found within water management systems. This gives policymakers choices. Unfortunately, most water right systems were established when hydrologic science was in its infancy; in addition, a different set of norms and values were associated with water use at that time. For that reason,
existing property systems are often unresponsive to current policy needs. The result has been a regulatory overlay modifying existing water rights.

Water use is controlled by a combination of property rights and regulations. Regardless of the system, certain fundamental elements must be present. Water rights are generally defined within a specific portion of the hydrologic cycle, but they need to recognize the interconnections within the cycle. The right should specify who can use the water and who can enforce the right. The public’s interest in water use must be balanced with any private rights. Rules for establishing a right and rules for using water (uses allowed, location of use, quantity, time period, etc.) are required. Terms of the entitlement need to be established. Is it permanent, temporary (for a period of years), or subject to termination under specific circumstances? Rules for selling, modifying, or transferring water are needed and must examine the potential impacts on third parties and the public. Rules are needed to allocate water between competing uses when shortages occur. Many of these water right elements are interrelated and complex. An understanding of water rights begins with the ways different water uses and users change the integrity of the hydrologic cycle. This provides a framework for understanding property relationships.

Water use and the integrity of the hydrologic cycle

Water uses differ in their impact on the hydrologic cycle’s integrity. Volumetric consumption, controlling flowing water (speed, direction, etc.), and using water for waste disposal can substantially alter the cycle. Consumptive uses include irrigation, municipal and domestic uses, and industry. Rights to consume water have a long history and are extremely important in arid areas. When most people think of water rights they generally envision a consumptive use. Irrigation is by far the largest, with 80% of the consumptive use in the western United States being attributed to it. In the West these consumptive water rights are private rights which can be sold under specific rules. Not all consumptive uses are allocated under a system of private rights.

Controlling water flow also changes the integrity of the cycle, but the issues that result are different. Flow can be controlled to capture the energy created by flowing water (water mills and hydroelectric power), for flood control (dams and levees), to store water for later consumption (municipal, industrial, and irrigation uses), for navigation improvement (dredging, channelization, and canals), and to drain wetlands. Some of these uses are subject to private rights but others require communal or governmental approaches. Two examples illustrate different property rights approaches. The energy from flowing water has long been used in milling operations. By 1800 Britain’s available mill sites were almost completely occupied. Mill dams backed up flowing water, interfering with the upstream mills, and diverted water deprived downstream mills of flow. Litigation was common and expensive (Getzler 2004). The result was a property rights system designed to protect flowing water to the mills. All riparian landowners shared a common property right to use the flow. Since the right was associated with landownership, it was considered a private right attached to the land. Flood control is the second example. Property owners along the lower Mississippi River built individual levees to prevent flooding. Inconsistent levee heights between adjacent land, or no levee at all, required a different scale of response to flooding. Local flood control districts were formed, but even these were inadequate for major floods.
WATER RIGHTS

State and federal projects were eventually implemented, but remnants of older systems are still in place. Flood control does not lend itself to a private rights approach.

Waste disposal, historically, was looked on as a public right open to all. Rivers were frequently used to dispose of industrial and mining wastes as well as untreated urban effluent. Downstream property owners frequently objected, especially as scientific knowledge increased, proving that public health dangers resulted from traditional disposal practices. In order to protect the public’s interest (right) in clean water, regulations placed limitations on disposal practices. Some regulations were absolute prohibitions and others allowed disposal through permit systems. These permits grant regulatory rights which in some circumstances could be considered private regulatory rights. Markets for these private rights can be created if policymakers so chose.

Other human uses have less dramatic impacts on the hydrologic cycle’s integrity. Navigation and recreation will be used to illustrate this point. Historically, free navigation has been an important public right, especially on waters where commercial navigation is possible. Interference with the right is often protected by government actions. For example, the Magna Charta (1225) prohibited the construction of fish weirs that interfered with navigation. In the United States the federal navigation servitude protects the public’s right of navigation. This federal constitutional power, exercised for the benefit of the public, requires permits before any actions that interfere with the navigable capacity of a water body. On the other hand, the eastern US riparian rights doctrine gives riparian landowners a private right to “warf out” (build a dock). This private right may not always be exercised since federal permission is required on waters subject to the navigation servitude. Recreational uses (fishing, swimming, boating, etc.) are considered public for many waters, but not always. For example, in Britain public fishing is only allowed in waters affected by the ebb and flow of the tide. Fishing in other waters requires the consent of the landowner. In the United States public access for recreational purpose varies by state. Some states have expansive public rights, but not all. Overuse can lead to the imposition of permit systems such as a fishing license or rafting permit. In some circumstances these may become marketable property rights.

Other uses (nonuses) have virtually no direct impact on the integrity of the hydrologic cycle. Humans enjoy/use water for scenic, aesthetic, and spiritual purposes. Historically, water rights systems did not address these uses, leaving them as part of the unregulated commons. Increasingly, some kind of public interest is being asserted. Indirectly, these uses are protected by establishing in-stream water rights or by establishing minimum stream flows. These rights may be public or private depending on circumstances, but most derive from some form of legislation. The federal Wild and Scenic Rivers Act and the Endangered Species Act are examples. Water left in-stream can provide valuable ecosystem services. Establishing rights to ecosystem services is an evolving theoretical topic.

**Legal relationship between water and the user**

The relationship between water and the user depends on the subset of the hydrologic cycle subject to the right, the nature/security of the legal entitlement, the rules for establishing a right, and the operational rules for using water. Different kinds of property rights may be associated with water in different parts of the hydrologic cycle. These rights may ignore the interrelationships that exist. Water rights do not
follow a single drop of water moving through
the hydrologic cycle. Water in a stream may
have one set of rules and groundwater another.
Atmospheric water may have no rules at all.
To illustrate, a single drop of water is followed
through the hydrologic cycle. As atmospheric
moisture, the water drop is an unregulated
commons, at least as far as water quantity is
concerned. Cloud seeding may require a permit
or a license for cloud seeders, but rights are
not granted to the water produced. Proving the
causal connection between the cloud seeder’s
actions and a specific molecule of water is dif-
ficult, as is proving harm from cloud-seeding
operations. From a water quality perspective,
the water drop is subject to regulatory rights.
Statutory permit systems are designed to prevent
acid rain and other atmospheric pollution that
may impact the integrity of the hydrologic cycle.
Once the raindrop hits the surface some of it
will infiltrate, becoming soil moisture, and some
may run across the surface, eventually reaching
a watercourse. Soil moisture is a land right and
from a practical viewpoint is really usable only
by the landowner. If the water drop infiltrates
reaching an aquifer, water rights can be estab-
lished because the water can be extracted and
separated from the land. Once the water reaches
a stream it may also be captured, and private
water rights can be established. Diffused surface
water or runoff may be treated as a land right,
but it is possible to separate the water right from
the land right. Generally, private water rights
are limited to groundwater aquifers and surface
water in streams, lakes, and rivers. Potential
conflicts exist between these two kinds of rights
when established on an interconnected source.

Entitlement refers to the right’s legal status
/license, permit, title, permanent, temporary,
etc.). Security of entitlement refers to the potential
for losing a right. Security of entitlement is
not the same as actually receiving water for
use (security of delivery). Ownership of land may
be the basis of a permanent entitlement, for
example, when the federal government has a
water right on reserved land. If a water shortage
occurs, then any right established prior to the
federal act of reservation will have a preference
for delivery. Thus, the federal right is still in
place, but water may not be delivered until the
shortage is alleviated. Ownership of riparian land
in the eastern United States contains a similar
permanent entitlement, but the rules for sharing
do not guarantee a specific volume of water. The
riparian landowner has an entitlement (right)
equal to all other riparian landowners. In the
western United States the entitlement is based
not on landownership but on the acts of appro-
priation. In times of shortage prior rights have
a preference over those established subsequently,
meaning that delivery is not guaranteed. Title
still exists and delivery will occur after all prior
rights have been satisfied.

In the West a water permit or license may grant
a right to use water, but this permission does not
necessarily mean the title is secure. Water rights
must be adjudicated through a judicial or admin-
istrative process. The adjudication process exam-
ines all the use claims in a watershed to determine
their validity and establish their relative prior-
ity. Many western states are still completing the
adjudication process. This process can invalidate
rights with existing permits.

Although some entitlements are permanent,
others are limited by time or are conditioned in
some way. For example, many regulatory rights
have permits that must be renewed after a period
of years. Renewal may be based on meeting spec-
ified conditions that take into account changing
circumstances. Other rights can be lost because of
actions by the right holder. In the western United
States a water right may be lost for nonuse. “Use
it or lose it” is the common saying. Also, the use
must be beneficial, meaning that wasteful uses
WATER RIGHTS

will not qualify. In riparian rights states, title can be lost if a lot that was once riparian (adjacent to water) is subdivided and sold. Any portion that no longer touches the water body loses the riparian right. Public rights exercised in an unregulated commons can also be lost. Recreational access, for example, can also be lost through overuse. Too many rafters could lead to a permit system with a limited number of permits available.

The rules for establishing a water right depend in part on the kind of right involved. Some rights are an attribute of owning riparian land and require only ownership of the land (eastern United States riparian right). Federal reserved rights require the federal government to reserve federal land for a specific purpose. This act of reservation creates a water right sufficient to accomplish the purposes of the federal reservation. Unregulated public rights (the commons) exist without a process for establishing rights. For this reason overuse is possible. When the commons is regulated, rights are established by rules derived from the regulations. Some of these regulated rights can take on attributes of private property. A good example of this is the appropriation doctrine in the western United States.

Under the appropriation doctrine a water right is established by intentionally diverting water from a stream and applying it to a beneficial use. The earliest versions of this doctrine resolved conflicts between users by creating common law property rules. These rules separated the water right from the ownership of land. Miners during the California gold rush did not own the land and, prior to the passage of federal mining laws, were trespassers. The miners also wanted to move water from one watershed to another. The common law riparian rights doctrine was inadequate for the miner’s needs. The result was a new set of common law rules – the appropriation doctrine. The basic principles of these rules were incorporated into the early water codes. By the time the Reclamation Act (1902) passed, many states also required permits. Water still had to be diverted from a stream and applied to a beneficial use. Permits could be denied if another water right would be harmed or if it was in the public interest. Public interest in 1900 does not mean the same today, but at that time included uses that were economically beneficial.

The operational rules are the primary element of any water right system. They define the uses allowed, quantity, location, time, cost, and conditions. Some water rights have very specific and narrow uses such as a right to navigation (federal navigation servitude). Others uses are based on vague standards. Federal reserved rights are based on the purpose of the reservation, which for national forests includes timber harvest and watershed protection. This vague description makes it difficult to quantify the volume associated with the right. In riparian rights states, the use must be reasonable, and in appropriation doctrine states the use must be beneficial. Determining reasonableness requires a balancing process between competing riparian rights. Beneficial uses were traditionally limited to economic (profit-oriented) uses, but many states have expanded definitions to include in-stream uses that are environmentally beneficial or that provide recreation and aesthetic benefits. If the right is based on a permit, it may specify in detail the uses allowed. The other operational rules may be very general or they may be clearly specified in a permit. A federal Indian reserved right has a volume of water associated with it that is sufficient to irrigate all the practicably irrigable acreage on the specified reservation. This standard was established by the Supreme Court in 1964, requiring an agricultural survey of each reservation to reach a specific volume.

Problems can also occur in defining the operational rules. Quantity could be based on a diversionary entitlement (amount taken from
the stream) or a consumptive use (the volume consumed). Location includes place of use and point of diversion. If the quantity is measured at the place of use rather than the point of diversion, incentives for efficient delivery systems may be missing. Changes in place of use, point of diversion, point of return flow, time of use, or any other element of the operational rules can impact other water rights. These third-party effects need to be considered before making any change in the operational rules for a particular right (Gould 1988). Operational rules also include any costs assessed to the water use. Generally, users only pay for the cost of delivery and not for the value of the water. Often the cost of delivery is subsidized, especially for irrigation. Operational rules can be conditioned to meet efficiency standards or to conserve water.

When people think about a water right it is often the relationship between the user and the water that first comes to mind. This brief discussion gives the flavor of that relationship. More complex are the interrelationships within the network of users.

Defining relationships between users

The interconnected system of water rights requires a system of rules to resolve conflicts. Conflicts occur for many reasons. Water shortages, controlling water flow, and waste disposal will illustrate the range of rules used in defining relationships.

Water shortages

A drought can cause a water shortage that interferes with a water right. The security of the user’s delivery is a critical element in determining the value of the right. If a right holder has a low security of delivery in an area prone to drought, they should not plant an orchard requiring regular water deliveries. Property rights systems use three basic approaches for allocation water in times of shortage – preferences, flexible criteria, or proportionality. A fourth approach, absolute ownership or rule of capture, allows the right holder to do what they want with water; the consequences to others are not considered. Although this type of right has been claimed in international disputes and in disputes between US states, it is not the current law. The doctrine still has some remnants when applied to groundwater. Nominally, several US states claim that if a landowner pumps groundwater they can use it as they please.

Preferences can be based on use, time, or region (spatial). With a use preference the specified use receives water first in time of shortage. This is the type of preference most people think of when the term “preference” is used. If water is in short supply, then some uses should get water before other uses. Use preferences frequently recognize the importance of domestic uses such as drinking water. Other preferences can be based on important economic needs. For example, Idaho grants mining a preference over other uses in organized mining districts. In New Mexico’s traditional acequias, orchards have a customary preference over annual crops. Preference systems allow policymakers to rank the uses that will receive water in time of shortage. Almost all systems have some kind of preferences. An international human right to water will create a preference for drinking water and sanitation.

In appropriation doctrine states, a temporal preference, based on the date the water right was established, sets the order in which users will receive water in times of shortage. “First in time, first in right” is the mantra. An early priority (right established before others) thus has a high security of delivery, making the right more valuable than one with a recent priority.
Strict interpretation of the doctrine would treat all beneficial uses the same, whether the use was for a hospital or an irrigated pasture. The results can be inequitable and economically inefficient. To overcome this problem, water can be rotated between users so that all get a share at different points in time. This has always been a common practice in irrigation districts. Additionally, some western states have limited use preferences. For example, municipal or domestic uses may be granted a temporary statutory preference if a shortage occurs, but compensation may be required. Accommodation and augmentation plans, as well as contracts, have been used to avoid a strict application of priorities.

Spatial preferences limit the place water may be used. These preferences are often stated as area-of-origin or local public interest preferences. Some of these preferences prevent water exports from the preferred area. The protected spatial unit can be a watershed, a county or other political unit, or an undefined local place. For example, if a local economy develops around irrigated agriculture and the water is transferred to another location, substantial harm can occur. Farms will no longer be viable, businesses will be closed, the tax base will erode, and depopulation will occur. The Owens Valley in California illustrates this problem. Water once used for irrigation now goes to Los Angeles. In response, California statutes place area-of-origin limitations on water movement.

In the United States some states have tried to limit water exports to protect their own economies. These antiexport statutes have constitutional problems. The commerce clause creates a level playing field for the movement of goods and services between states. Because water is considered an article of commerce, spatial restrictions must pass the legal tests developed under the commerce clause. Local public interest and area-of-origin statutes are also designed to protect economic interests which bring them into direct conflict with the commerce clause.

Flexible systems for resolving disputes require balancing multiple factors. Balancing can create a degree of uncertainty when looking at security of delivery, because balancing is done on a case-by-case basis. Balancing requires looking at other users and uses within the system. A good example is the riparian rights doctrine based on reasonable use, as found in some eastern states and the reasonable use doctrine applied to groundwater. Flexible doctrines have also been used in disputes at different scales as seen with equitable apportionment (disputes between US states) and equitable utilization (international disputes). The riparian rights doctrine requires a more detailed examination because of the misconceptions describing it in the literature.

The riparian rights doctrine grants an equal right to all riparian landowners contiguous to the water body. This equal right refers to the entitlement each landowner has but not to the quantity of water delivered to them. An equal right does not mean an equal or proportionate share of water. A riparian right (entitlement) grants adjacent riparian landowners a right of access to water, a right to build a wharf, a right to use water without transforming it (the hydrologic cycle’s integrity is maintained), a right to consume water, the right to accretions, and ownership of the bed of non-navigable waters. Many of these rights are nonconsumptive, and some early court decisions implied the doctrine was designed to protect nonconsumptive uses under the natural flow doctrine. The natural flow required water to be left in the stream in its natural condition. This doctrine prevented consumptive uses and was modified to allow consumptive uses that are reasonable (the reasonable use doctrine). Reasonableness is an open-ended list of social, economic, environmental, religious, and cultural uses that benefit
WATER RIGHTS

the adjacent land. If insufficient water is available for all coequal riparian landowners, a balancing test is used where the harms and benefits of each use are evaluated. If some scheme for sharing the resource is possible, the water will be shared between users. If sharing is impossible, one user could obtain the entire available supply. If the use is socially desirable, is economically beneficial, and benefits a large number of people, that use may be preferred over another that does not fit this degree of desirability. A new use on a stream may be preferred over an older use. In addition, values change over time. What was considered the most valuable use in 1900 may not be today.

Where reasonable use is the legal test, security of delivery changes with the circumstances. This applies to both surface waters subject to riparian rights and groundwater where the reasonable use doctrine applies.

When the delivery of water is based on flexible standards, the results can be equitable but unpredictable. What one person thinks is fair may be inequitable from another perspective. In addition, equity, fairness, or reasonableness can change with time.

Proportionality is the last method discussed under security of delivery. Proportionality means that water is divided based on specific criteria. The criteria could be based on population, amount of land owned, number of shares in an irrigation district, or a percentage of flowing water. This applies to both surface waters subject to riparian rights and groundwater where the reasonable use doctrine applies.

US water rights controlling flow have roots in both common law and constitutional/statutory law. Many of the common law rights developed as a result of conflicts between water users. The constitutional and more recent statutes generally protect some public right. Rights associated with flowing water occur in two parts of the hydrologic cycle – streams/rivers (watercourses) and diffused surface water.

Diffused surface water (runoff) is legally different from the same water molecule once it reaches a stream. In western appropriation doctrine, water can be captured by the landowner without obtaining a water right. Once the water reaches a watercourse, defined by having a bed, banks, and reasonably regular flow, the appropriation doctrine applies. Check dams, contouring the landscape, and planting vegetation to inhibit runoff are considered to be rights associated with landownership. Western
WATER RIGHTS

states are beginning to connect surface water rights with groundwater rights, but diffused surface water is excluded. Colorado is an exception and has recently extended the connectivity within the hydrologic to include harvesting rainwater from rooftops. Diffused surface water also creates drainage issues. The problem here is too much water.

Three different common law doctrines developed in drainage cases. The common enemy rule allows landowners to take whatever measures necessary (speeding up flow, erecting barriers) to prevent harm to their land. This absolutist form of property right ignored potential harm to neighboring property. The natural servitude rule is the opposite approach. Changes in a drainage pattern that harm another’s property, upslope or downslope, violate the doctrine. Both doctrines create inequities so the trend today is a reasonable use rule. This flexible doctrine allows a balancing of harms and benefits between competing property interests.

Flow conflicts within a water course can create tension between public and private rights. The appropriation doctrine allows a river to be completely consumed, leaving the river bed dry. But, if the water is subject to the federal navigation servitude, the public’s right to navigation can be protected. Public rights to navigation and the protection of ecosystem services are designed to keep water in-stream and to protect the integrity of the hydrologic cycle. The navigation servitude is based on a federal constitutional power and has been extended to the tributaries of navigable waters. Consuming or diverting a tributary’s water can be prohibited if the action affects the river’s navigable capacity. This federal power has been used to stop irrigation projects and can impact a water right established under state law. In addition, dredging and filling navigable waters requires a permit and can be prohibited if navigation will be harmed. More recently, statutes have been designed to put more water in-stream for a variety of purposes. Some western states have modified the diversion requirement of the appropriation doctrine to allow in-stream appropriations. In other instances minimum stream flows are created that keep a specific volume in-stream. This is done either through reserving a minimum flow or by rules for dam management. Many of these minimum flow requirements stem from the Endangered Species Act. Competing uses may be curtailed in order to provide water needed for species survival.

Waste disposal

Water quality disputes have a long common law history. Doctrines of nuisance, negligence, and trespass have all been used by individual property owners to protect their property from harm. Public interests have also been protected through a public nuisance doctrine. The riparian rights doctrine of reasonable use includes water quality. Reasonable use and nuisance, public or private, require a balancing of the harms and benefits of the various interest holders. Thus, a property owner who wanted an injunction to stop a pulp mill had to show that the harm to their property was greater than the benefits of the mill. Historically, courts did not favor the individual very often. The best bet for the property owner was to prove a trespass where damages might be possible.

Common law solutions did not work very well because individuals had to bring a law suit. In addition, as the harm to public health and the environment was better understood, pressure increased to change the approach. The result is a regulatory structure. Point source pollution is controlled through a permit system while nonpoint sources are controlled through land-use planning.
Responding to challenges in water management

Although property rights define relationships, conflicts are inevitable. Conflicts occur for many reasons and some are difficult to resolve. This is especially true because of the fragmentation within the system and enforcement problems. In addition, property rights systems do not always have good mechanisms for responding to change.

Enforcement

The first step in enforcing a water right is to determine the source of the right. Not all water rights are equal. When right holders compete for the same water, they may win or lose depending on the source of the right. The federal navigation servitude trumps state water rights. Water is considered an article of commerce under the US Constitution, giving the federal government regulatory powers over water. That power was exercised with the Clean Water Act and many other federal environmental statutes. Under the Supremacy Clause, the exercise of a federal constitutional power is supreme over conflicting state laws. At the same time, states have created property rights in water. These rights are constitutionally protected, requiring compensation to be paid if the property is taken. The question of federal regulations taking water rights is unresolved.

Enforcement also requires the identification of the user or beneficiary of a right, the right's title holder, and the party that can enforce the right. These are not always the same. For example, the title to the federal navigation servitude is in the federal government, and the public is the beneficiary. The federal government can enforce the servitude and in some circumstances users may have legal standing to bring a lawsuit. If individual right holders must take action to enforce a right, enforcement may never occur. Inertia must be overcome before action is taken. If court action is required for enforcement, it could be expensive and beyond the financial ability of the right holder. Public rights are problematic because of the difficulty of identifying parties that can act in the public's name. In some instances individuals or public interest groups have standing, which is a legal concept that will allow them to bring a lawsuit. Even if a group or individual has standing, inertia must still be overcome and costs can be high. Government agencies are generally given power to enforce public regulatory rights. At times statutes may give standing to individuals or public interest groups to compel government action if they fail in their enforcement obligation. The Clean Water Act is an example. In some instances enforcement may be impossible because of insufficient budget or lack of legal clarity.

Fragmentation

Fragmentation occurs because the system of water rights does not integrate the hydrologic cycle, water rights are subservient to land rights, and water quantity is not integrated with water quality. The appropriation doctrine is a good example of an unintegrated approach to the hydrologic cycle. In the early 1900s most appropriation doctrine states had a system for establishing water rights for water in a watercourse. Groundwater rights came much later, with separate codes for establishing rights even though the basis was still the appropriation doctrine. Different priority systems were in place, which was fine as long as surface water and groundwater were disconnected. As the interconnections became better known, courts were asked to enforce priorities for the interconnected rights. Colorado and New Mexico were the first
WATER RIGHTS

states to do so. Except in Colorado, where rainwater catchment is included, the rest of the hydrologic cycle is ignored.

In addition, water in many parts of the hydrologic cycle is controlled by land rights. These land rights are dominant over water rights and are exercised without regard to them. Diffused surface water can be captured in appropriation states without obtaining a water right. Land surfaces can be modified to prevent soil erosion, while at the same time increasing infiltration. No water right is required even though water flow may be decreased in an adjacent stream. Orchards can be planted which stick their roots into an aquifer without obtaining a water right. The trees can consume water that would otherwise move downgradient to a well with an existing right. The water right holder would have no recourse because the orchard does not require a water right. The dominance of land rights over water rights makes water planning difficult. Land-use planning and water planning are generally done at different scales and by different planning bodies. Integrating the two planning processes is difficult.

Managing water quality and water quantity is also fragmented. The Clean Water Act is federal, while state law establishes water rights controlling water quantity. Even when states administer the Clean Water Act, it is usually a different agency than the one administering water rights. Fragmentation makes conflicts between water right holders inevitable.

Responding to change

New demands for water and changing preferences for water use require a water rights system capable of reallocating water from one use to another. Two reallocation methods can be used – markets and regulation. As seen from the discussion, regulatory rights have been used to prevent harm to the public’s interest in water. Once in place, these regulatory rights may not have sufficient flexibility to respond rapidly to new challenges. Regulatory rights are generally a response to a particular water problem such as pollution. As seen earlier, the regulation may ignore the integrated nature of interlocking rights while solving the specified problem. Piecemeal problem-solving, although typical, need not be the only regulatory approach. Integrated response to change requires a long-range planning process.

Markets are another way of reallocating water in response to changing circumstances. Markets exist for appropriation doctrine rights in the West and could be developed for regulatory rights with permits. Because of the high degree of connectivity between water uses, a free market in water would be inappropriate. Western water rights cannot be sold if other water rights will be harmed or if there is injury to the public’s interest in water. Both these factors have been in place since the codification of water rights 100 years ago. Even so, for most of this time the evaluation of the public’s interest has been perfunctory. As can be seen by the broad nature of the public’s interest, a thorough evaluation should occur. Protecting the public interest requires more market rules than are in place in most water rights systems. Markets without rules will not work because of the substantial number of interrelationships that exist within water rights systems. The rules should be designed to achieve specific policy goals. Identifying such goals requires a planning process.

Water security

Mark Giordano
Georgetown University, USA

Water security as a concept emerged in the early twenty-first century as a new rallying cry of the epistemic water community and quickly found its way into water policy and practice. In contrast to almost no mention of it before 1990, there are now (at the time of writing) over 400 peer-reviewed journal articles from across the social, natural, and medical sciences using the term (Cook and Bakker 2012), with the majority published since 2010. The concept is now so ubiquitous among water scientists and practitioners that it regularly forms the basis of major conferences (e.g., Water Security, Risk and Society Conference, Oxford, 2012; Securitization of Water Discourse Conference, Jerusalem, 2013; Stockholm Water Week, 2013; World Water Week, 2015) as well as of books and journal special issues, all of which examine what water security means and whether it can be achieved.

The concept of water security has made an equally rapid rise in policy and practice, with multiple organizations now using it as a basis for awareness raising, project design, and bureaucratic structuring. The United Nations increasingly links its programs, such as those related to climate change, with water security, and has framed the Global Environmental Facility’s water strategies around the idea. National governments have taken similar approaches. In the United States, for example, the Environmental Protection Agency now has a Water Security Division; the US intelligence community organized its 2012 assessment around water security; and the Agency for International Development’s 2013–2018 water strategy has set the achievement of water security as its primary goal. Nongovernmental organizations (NGOs) are following similar paths, with the Nature Conservancy, for example, highlighting water security as a key challenge and Harvard University establishing a Water Security Initiative.

While there is widely shared interest in water security as a concept within organizations ranging from grassroots NGOs to the world’s largest military and the United Nations, there is not always a shared understanding of its meaning. One end of the spectrum thinks of it in terms of existential threats to nation-states, the other in terms of individual welfare. What led to the emergence of water security as a concept? What are the purposes to which it is put? How is it defined? This entry examines these questions and summarizes the current thinking on water security.

Origins of water security

Until the early 1990s, reference to water security was limited to narrow questions related to legal allocation entitlements (e.g., “Is my water right secure?”). Since then the concept has extended in two distinct directions that reflect two separate sets of changes in conditions and understanding. The first is related to climate change, with water security, and has framed the Global Environmental Facility’s water strategies around the idea. National governments have taken similar approaches. In the United States, for example, the Environmental Protection Agency now has a Water Security Division; the US intelligence community organized its 2012 assessment around water security; and the Agency for International Development’s 2013–2018 water strategy has set the achievement of water security as its primary goal. Nongovernmental organizations (NGOs) are following similar paths, with the Nature Conservancy, for example, highlighting water security as a key challenge and Harvard University establishing a Water Security Initiative.

The securitization of water

Since at least the early 1990s, there have been growing fears in the popular and academic press that disputes over waters shared by two or more countries could lead to conflict and even “water wars.” The increasing emphasis on water and international conflict fit within a broader change already occurring in international relations on the conception of national security. National security had traditionally been viewed as safety from external military threats, but by the 1980s the idea began to take hold that national security could be endangered not only by foreign military power but also by internal disruptions, including natural disasters, a degrading environment, and resource scarcity. This new line of thinking “securitized” the environment, and its proponents highlighted the potential interconnection between resources, social turmoil, and intra- and international conflict. In fact, water is perhaps second only to oil as the resource most associated with conflict and most often “securitized.”

The water securitization discourse now takes at least three distinct forms. Fischhendler (2015) describes two, which he terms strategic and tactical. Strategic securitization relates to internationally shared waters and the environmental, economic, and political interdependencies they create, which are associated with direct conflict between states and the classic idea of water wars. Tactical securitization relates to the connection of low-politics aspects of internationally shared waters (e.g., data sharing) between states and other, high-politics issues. Tactical interconnection is not portrayed as leading to interstate conflict but as a possible exacerbating factor in existing interstate conflicts or a new avenue for international cooperation.

A third form of securitization discourse relates to the secondary or spillover impacts of intranational water outcomes on the relations between states. If natural disasters, including droughts and floods, increase the risk of violent internal conflicts, those conflicts may spill over to neighboring states. This logic has been applied to the crisis in the Darfur region of Sudan, where drought has been linked to civil war, and then to fighting with neighboring Chad. Others believe the relationship between natural disasters and civil unrest is less clear and may in fact run in the opposite direction. In Pakistan, for example, while the large-scale floods of 2010–2011 and slow government response have been linked to a weakening of the government and a rise of fundamentalism, other evidence actually suggests that the floods brought increased credibility to the state. Given Pakistan’s geopolitical context, there are direct implications for regional stability (e.g., “security”) whichever view is correct.

Pushing this view to its logical extreme, if water impacts a state’s internal security, and the security of that state is held to be of strategic importance to a second state, wherever its location, then water issues anywhere in the world can be considered as security threats in any other part of the world. Aid or other resource transfers and interventions are then justified. As the US Agency for International Development’s 2013–2018 water strategy puts it, “Ensuring the availability of safe water to sustain natural systems and human life is integral to the success of the development objectives, foreign policy goals, and national security interests of the United States” (USAID 2013, 1).

Water security as human security

While one epistemic and policy community has focused on water security in terms of international relations, another has, separately but in parallel, considered it as a part of a more broadly defined human security. In 1994 the United Nations Development Program published a landmark report that de-emphasized
both traditional military security as well as gross national product as measures of welfare. The resulting “freedom from fear” and “freedom from want” approach incorporated food, health, environmental, and other “securities” within an overarching framework of human security.

In the initial conception, water was subsumed under other securities, most notably through the placement of potable water access under the environmental security rubric. The role of water within the human security discourse grew over time, though, in particular with increased understanding of the global challenge of ensuring sufficient freshwater supplies to meet growing agricultural needs, by far the largest consumer of water. The 1997 Congress of the International Water Resources Association, for example, focused on water scarcity as a critical issue in food security. While for some water scarcity continued to be viewed as a factor in ensuring human security through food supplies, for others it morphed into water security and became an end in itself. For example, the “Ministerial Declaration of The Hague on Water Security in the 21st Century,” presented at the 2000 World Economic Forum, recognized the role of water in basic needs, the food supply, and ecosystem maintenance, but made water security its goal. As stated in the document “together we have one common goal: to provide water security in the 21st century” (World Water Council 2000, para. 1). The Food and Agriculture Organization of the United Nations similarly declared that water security should be the main goal inspiring the international agenda for the twenty-first century (FAO 2000).

As water security became an end rather than a means, it took on different meanings for different authors and practitioners with differing backgrounds and goals. Cook and Bakker’s (2012) review identifies water availability (focused on drinking water and sanitation), human vulnerability to hazards (e.g., flooding and possibly drought), human needs (focused on food production and availability), and sustainability as four key water security themes that have emerged in recent years. A review by Clement (2013) also found substantial variation in how the term “water security” has been defined and utilized.

Water security has also found its way into another new discourse, that of the water, food, and energy nexus. Allouche (2011) described water and food as two separate “securities” but also described how they have been interconnected, and others have highlighted an even broader web of securities and how water security is a function not only of local and international water policies but also of policies outside the sector. Recent high-level conferences in Bonn (2011) and a follow-on in Chapel Hill (2014) have further promoted and put forward ideas on the interconnections between water, food, energy, and other “securities.”

Usage: synonyms, instruments, and agendas

As the concepts of water security have grown and evolved, so too have the uses to which the term is put. This section describes three usage themes that can be discerned from the literature and as applied in the organizations that use the term.

Water (in)security as a synonym for water scarcity

Despite the substantial discussion of water security, in practice the term is often used primarily as a synonym for water scarcity or other water problems. In other words, “water security” is simply employed to signal that a paper or an organization is going to address issues, but it is not pursued further as an idea in itself. An illustrative textual example is the 100-page FAO
WATER SECURITY

publication, *New Dimensions in Water Security* (2000). The document uses the term “water security” only three times. It is used in the title and once to refer to crops having enough water in the growing season. The third use occurs where one chapter mistakenly refers to another as being titled “The Turn of the Screw – Social Adaptation to Water Security” when the actual title is “The Turn of the Screw – Social Adaptation to Water Scarcity.” This small mistake suggests a perceived interchangeability between the terms “scarcity” and “security” in common usage. An institutional example of how the term “water security” is used to signal a focus on water problems is provided by the United States Agency for International Development’s Water and Development Strategy 2013–2018 (USAID 2013). The opening paragraphs of both its introduction and conclusion highlight water security as the strategy’s key goal. However, the body of the document does not use the term even once. Instead it focuses on the range of water problems USAID hopes to address.

Water security as a new agenda?

A number of authors have already questioned whether the water security concept reflects an evolution in thinking about water problems or a paradigm shift, or is simply a new buzzword to replace old concepts. For example, Clement (2013) showed how the water for food discourse has shifted away from the earlier ideas of water productivity and toward water security. However, while the shift expanded the water productivity debate, she argues that its water security manifestation still focuses on technical issues and still fails to take into account the power and politics that are the key to water outcomes. A perhaps more common discussion is whether water security is simply a rebranding of integrated water resources management (IWRM). The chief institutional proponent of IWRM, the Global Water Partnership, was actually an early advocate of the water security label (GWP 2000) and continued to promote it as a way to achieve cross-sectoral cooperation in water management, a goal normally associated with IWRM itself.

How these changes are reflected in practice can be seen in the reframing over time of the International Water Management Institute’s (IWMI) recent strategic planning documents. As a member of the Consultative Group on International Agricultural Research, IWMI’s main work relates to water as a means of agricultural development and poverty reduction. This is consistent with the organization’s official vision of “Water for a Food-Secure World,” as articulated in its 2004–2008 strategic plan (IWMI 2004), which highlights IWMI’s contribution to the food security agenda through the promotion of two paradigm shifts in water management: increasing water productivity at the basin level and focusing on integrated natural resources management. To support the change, a new research theme was established which emphasized water productivity improvement, basin-scale approaches, and cross-sectoral (i.e., integrated) thinking on water management. While the plan mentions food and environmental security multiple times, water (in)security is mentioned only once, and then as a synonym for water scarcity (“water poverty or water insecurity”).

In the follow-up 2009–2013 plan, the vision of water for a food-secure world remains (IWMI 2009). However, the path for achieving the goal has changed, with IWRM elevated to a “guiding principle” for all work and water productivity improvement no longer having an explicit home but still highlighted throughout the document as a key goal. Food security, and water’s role in it, continue to be frequently mentioned but water security itself is mentioned only once.
in terms of security in “water access rights” for the poor. In the current 2014–2019 plan (IWMI 2014), IWMI’s official vision has been changed to “A Water-Secure World,” and thus from water as a means to achieving food security to water security as an end in itself. Water productivity is no longer mentioned, though agricultural productivity and water’s contribution to it are, and IWRM has disappeared entirely.

Water security as an instrument

Fischhendler (2015) has described how (traditional) securitization of any issue, including water, can be used as an instrument to increase public awareness and perceptions of the important issues and to create a sense of urgency to mobilize funds. Allouche (2011) has demonstrated in the case of water how scholars and policymakers have used “water security” to raise the profile of water through its linkage with violent conflict at local, national, and international scales. Similarly, Clement (2013) describes how water has been viewed in (human) security terms as an instrumental means to move it higher up the international policy and aid agendas, for example to justify development bank investment in large-scale water storage structures.

How the traditional and human security aspects of water securitization have been combined and used instrumentally can be seen in the United States’ Environmental Protection Agency (EPA). The EPA’s main purpose with respect to water is to protect its quality as required by the 1972 Clean Water Act. Its responsibilities included eliminating high releases of industrial pollutants into water, preventing additional water pollution, and ensuring that surface waters meet the standards necessary for sports and recreation. However, in a post-9/11 world, perceived sources of water quality threats expanded to include terrorism. The EPA then took on the role of the agency in charge of water and water infrastructure protection from traditional and now terrorist threats. This change raised the agency from one working primarily with domestic polluters and users of water to one working at the core of US diplomatic and military agendas. The EPA’s mandate was even expanded by Homeland Security Presidential Directive 9 to include international intelligence-gathering, since the agency must “develop robust, comprehensive, and fully coordinated surveillance and monitoring systems, including international information, for … water quality that provides early detection and awareness of disease, pest, or poisonous agents.”

Definitions, scales, and methods for assessing the state of water security

Since the concept of water security now has multiple meanings and uses, it is not surprising that it has been formally defined at different times in many different ways, as illustrated by the following quotations, which have been selected to illustrate key variations and to highlight those most commonly cited or promoted.

A condition in which there is a sufficient quantity of water, at a fair price, and at a quality necessary to meet short and long term human needs to protect their health, safety, welfare, and productive capacity at the local, regional, state, and national levels. (Kaplowitz and Witter 2002, 379)

[An overarching goal in which] every person has access to enough safe water at affordable cost to lead a clean, healthy and productive life, while ensuring the environment is protected and enhanced. (GWP 2000, 12)

[Water security] involves the availability of water in adequate quantity and quality in perpetuity
to meet domestic, agricultural, industrial and ecosystem needs. (Swaminathan 2001, 35)

[Household water security is] the reliable availability of safe water in the home for all domestic purposes. (WHO 2003)

The state of having secure access to water; the assured freedom from want of, or poverty for, water for life. (Wouters 2005)

The availability of an acceptable quantity and quality of water for health, livelihoods, ecosystems and production, coupled with an acceptable level of water-related risks to people, environments and economies. (Grey and Sadoff 2007, 545)

Availability of, and access to, water sufficient in quantity and quality to meet the livelihood needs of all households throughout the year, without prejudicing the needs of other users. (Calow et al. 2010, 248)

Sustainable access, on a watershed basis, to adequate quantities of water, of acceptable quality, to ensure human and ecosystem health. (Norman, Bakker, and Dunn 2011, 54)

Water security is a tolerable level of water-related risk to society. (Grey et al. 2013, 4)

The capacity of a population to safeguard sustainable access to adequate quantities of and acceptable quality water for sustaining livelihoods, human well-being, and socio-economic development, for ensuring protection against water-borne pollution and water-related disasters, and for preserving ecosystems in a climate of peace and political stability. (UNU 2013, vi)

Two overarching observations come from a reading of the list. First, each definition is derived from human security rather than securitization perspectives of water security, though some connection between the two is provided by the final UN definition. This is perhaps in part because there is a broader understanding in the international relations literature of what water resource securitization means, and water is just one example of many environmental and other concepts that can be securitized. It may also be in part related to the second observation, which is that none of the definitions are based on how the term “water security” is used but rather on how author(s) will use it or like it to be used. This perhaps demonstrates the perceived power of reframing water discourse and the instrumental uses to which water security discourse is put.

Looking more specifically at definition content reveals substantial variation. For example, the spatial scales used to frame or define water security range from the household (WHO 2003) to a population (UNU 2013) to society (Grey et al. 2013). In one of the earliest definitions, water security is held to exist when there is security simultaneously across scales, from the individual to the national level (Kaplowitz and Witter 2002). In at least one case, water security is linked to the favored scale of hydrology, the watershed (Norman, Bakker, and Dunn 2011), but other definitions are silent on scale (Grey and Sadoff 2007).

While a few definitions (e.g., Kaplowitz and Witter 2002) consider at least vague notions of temporal scale (e.g., “long term”), most either ignore time dimensions or invoke sustainability language (Norman, Bakker, and Dunn 2011; UNU 2013). These latter two approaches ignore possible tradeoffs between short- and long-term water security, for example the tradeoff between the use of fossil groundwater today and the option for its use in the future.

Definitions also show considerable variation in what it means for the unit of interest to be water-secure. Some define water security as the existence of physical water supplies (Kaplowitz and Witter 2002; WHO 2003; Grey and Sadoff 2007). Others define security in terms of access
to those supplies (Norman, Bakker, and Dunn 2011), while yet others define water security not in direct relation to water but as an ability to manage water-related risk (Grey et al. 2013) or, strangely, as having the capacity to be water-secure whether or not security is the chosen outcome (UNU 2013). A final point is that many definitions conceptualize water security in terms of both human and ecosystem uses. Whether the focus on water-secure ecosystems is related to the inherent (or existence) value of the ecosystems or to the ecosystems’ contributions to other aspects of human security is unclear.

There have been limited attempts to use the definitions to measure the state of water security. Most attempts have used largely biophysical approaches based on the availability of water resources and population. While this may be the only way to realistically assess and map at regional or global scales, it cannot account for the social and political factors that determine water access and therefore whether an individual or a nation is water-secure. As a result, they miss explanations of why, for example, water outcomes (water security) in Israel or Jordan may be different from those in India, why differences exist between a commercial farm in South Africa and one on a former homeland, or why there may be differences between individuals within a single city, community, or state. Calow et al. (2010) use the example of groundwater to describe how this shortcoming to examine processes at smaller scales and including human agency can skew assessments of water security across spatial and temporal scales. Physical assessments of water security based on where water is physically “produced” also ignore the impacts of globalization such as the virtual water (the water used in the production of or “embedded” within products) trade in the grain trade and the role of multinationals.

**Conclusion**

A water security discourse has grown and evolved rapidly since the mid-2000s and now has two strands of meaning, one related to security in the traditional international relations sense and the other related to the broader concept of human security. The multiple meanings have led to multiple uses of the term. In some cases water security is used as a new synonym for water scarcity or water problems in general. In others it is used to help redefine and perhaps invigorate existing water agendas. And in yet others it is used instrumentally to bring urgency and resources to water issues. As use of the term has grown, so too have definitions, which now span spatial and temporal scales and measure the nature of water security variously in terms of physical water resources, access to those resources, and risks associated with those resources.

In the securitization sense, the creation of water security, along with other environmental securities, has given legitimacy to the expansion of high politics and military affairs into what was previously a more mundane water field. In the human security sense, water security discourses have been employed to draw more attention to particular works on water, to raise awareness of water problems, and to redefine water agendas and resource flows. While in some cases this may be done to serve narrow interests, in most it is more likely a tactical adjustment in recognition of the power of alternative language. Tony Allan (2003), for example, has highlighted how his earlier concept of “embedded water” did not gain traction until it was renamed “virtual water.” Likewise, water security has more resonance and urgency than earlier terms such as “water productivity” and “integrated water resources management” (IWRM). Everyone understands the need to be water-secure, even if they are unsure of its exact meaning.
When it is combined with food, energy, and other “securities,” the power of water security may be even greater. The 2011 “Water, Food and Energy Security Nexus” conference in Bonn was successful in gathering policymakers and professionals together from far beyond traditional water circles and in ways that earlier framings around water productivity or Integrated Water Resources Management conferences could not have done. As Cook and Bakker (2012) observe, water security “thus holds promise as a new approach to water management.” Interestingly, though, the 2014 follow-up to the Bonn conference, held in Chapel Hill, North Carolina, was titled “Water, Food and Energy Nexus.” The word “security” was dropped, perhaps suggesting that another reframing has already begun.

While a water security discourse may have brought new actors and awareness to the water field, it may not have changed the content yet. Assessments and proposed solutions to water security challenges still tend to focus on the technical aspects and to be couched in terms of efficiency, continuing the assumptions that water outcomes are primarily related to physical supplies, population levels, and technology options rather than power, politics, and access. The questions of who exactly is water-insecure and what are the underlying causes of insecurity remain largely ignored.

Water has influenced the settlement and development of cities and it will determine their future vitality. The quality and availability of water have always been fundamental to settlement and population agglomeration and critical for travel, trade, industrial development, and energy production. Natural water supply is a limiting factor for urbanization, and technological developments over millennia have sought to augment local supplies. Advances in the generation and regulation of freshwater supplies include topographical modification to direct surface flows to consumers, aqueduct development to distribute water long distances, groundwater extraction, impoundments for storage, as well as other forms of mechanized water-delivery infrastructure.

Climatological patterns dictate the distribution of water seasonally and generate not only water resources, but also water hazards. Relatively regular seasonal changes in rainfall amounts and stream flow are often punctuated by unpredictable extreme conditions and are enhanced by construction of impervious surfaces (buildings and pavements) that increase runoff quantities and rates. Technological advances have changed the implications of flood and drought in cities as residents and regional authorities have sought engineering remedies for the impacts without surrendering to nature's caprice. Major projects have been undertaken to channelize and drain wetlands, to construct levees to protect settled areas, to straighten river channels to speed excess water flow through urbanized areas, and even to drill deep tunnels beneath cities to prevent flooding.

The physical availability and presence of water does not determine how it is used or treated. Historically, the management of water has ranged from unconscious and frivolous waste and maltreatment to careful use by those cognizant of its limits. Water can be used, employed in an activity, but remain unchanged in state or quality, or it can be consumed, made unavailable to users downstream by changing either its quality or its state. The former can be regarded as borrowing the work of water as it flows through a community. The latter is a depletion of the resource. How water is used or consumed by a culture can determine the long-term prospects for its cities, and is the focus of the efforts of urban water managers.

Prior to the nineteenth century, awareness of the relationship between water quality and the health of urban residents was superficial, and water was a relatively loosely managed resource. Water meets the basic needs of drinking, cooking, hygiene, cleaning, and sanitation. The rules of use and the standards for water quality have changed through the ages and are often dictated by cultural norms. Ancient Greeks and Romans built extensive water conveyance systems throughout their cities, and rudimentary devices were often developed to provide protective piping for distribution to aristocratic villas and public baths, but the water in these systems was typically gravitationally fed and often carried human waste and refuse off to rural and coastal environs. While the city of London in the United Kingdom developed an extensive water-supply infrastructure, beginning in medieval times,
water was not commonly distributed to private residents in modern cities until the middle of the nineteenth century. Prior to this time, it was typically available from neighborhood wells and drawn with buckets or by hand-operated pumps, from plaza fountains to which water was piped or physically transported, where personal containers were filled, or from barrels filled at springs or reservoirs and transported by draft animal to urban consumers.

The growth of early nineteenth-century cities, like Boston, Massachusetts, began to outstrip local water supplies. Consumption extended to the rural fringes and beyond, and eventually sites in the Connecticut River Valley in central Massachusetts were appropriated for reservoirs to meet the needs of the city. The emergence of metropolises in the United States by the 1850s established the exploitation of distant regions for water. New York City constructed reservoirs upstate and piped untreated surface water to the city. In the following decades the city promoted the establishment of Catskill Park (1885) in east central New York state and even Adirondack Park (1885) in northeastern New York state to protect critical hydrological source regions and thus its water supply. The case of San Francisco after the devastation of the earthquake and conflagration of 1906 demonstrates the political nature of urban thirst. City leaders called for a diversified water infrastructure for the city and committed to construction of reservoirs in the coastal range to the north and south of the city as well as in the Sierra Nevada far to the east. Hetch Hetchy Valley in Yosemite National Park was their prime site for a reservoir, and its eventual grant to the city water system illuminated the conflicting values of conservationists and those who held preservationist views, as well as the power held by urban boosters over rural communities and other interests.

The urban growth of the American West during the first several decades of the twentieth century was enabled by the frenzied development of hydroelectric dams and reservoirs after the Newlands Reclamation Act was passed in 1902. The dams were initially built for rural irrigation to “reclaim” land for agricultural use, but ultimately the program morphed into energy- and water-supply projects for cities like Las Vegas, Nevada, and the greater metropolitan region of Los Angeles, California. Cities like Phoenix, Arizona, relied on federally endorsed projects to extract water resources from far-off regions. Los Angeles, for instance, exploited the Owens Valley, east of the Sierra Nevada, and the Colorado River, on California’s eastern border, to promote its growth, to the detriment of the source regions. And, despite finite urban water supplies in desert regions, water was often consumed without care. Land-use practices and aesthetic preferences of western cities mimicked those of more humid eastern cities. Extensive planting of non-native vegetation demanded intensive irrigation to overcome normal precipitation deficits. As water demand increased with urbanization, the costs of water rose as well, but failed, until rather recently, to promote frugality and more indigenous landscaping. Tension grew between thirsty urban areas and water-intensive industrial-scale agricultural operations. Changes to either urban behaviors or agricultural approaches have occurred only when one’s power exceeded the other’s in state or federal governments. Pricing schemes, subsidies, and the establishment of watershed-defined ownership are tactics aimed at stopping urban–rural water conflicts during the twentieth century.

Cities, even in more humid environments, are finding it more difficult to meet the demands of their populations. States that encompass the Great Lakes region of the United States and
Canada have denied requests to allow the transfer of water beyond the boundaries of the lakes’ contributing watershed despite the volume of water in the watershed. Interbasin water-transfer restrictions have emerged to reflect the stress of the growing need for water in cities that have surpassed their local and regional supplies. Even the city of Waukesha, Wisconsin, a mere 20 miles from Lake Michigan, has not been allowed to transfer lake water across the divide 15 miles west of the lakeside city of Milwaukee to surmount its limitations. Milwaukee and the Great Lakes Compact states are concerned about setting a legal precedent.

Urban densities intensified during the twentieth century with industrialization and the construction of transportation infrastructure to fuel economic growth. Segregation by wealth and ethnicity was fostered by investment in streetcar, rail, subway, and eventually highways and improved surface roads. This uneven development was also reinforced by the extension of public services. Water and sewerage piping were quickly retrofitted in established upper-income parts and more slowly in working-class sections of cities, and increasingly presaged the sale and development of residential and commercial sections of growing cities. Modernization included bringing privies indoors, and expecting stronger piped-water pressure and higher-quality and better-tasting water. Until the 1890s, water consumed in cities was untreated and was often contaminated by sewage. Sanitary sewers to carry off human waste and storm runoff were designed and built in Chicago, Illinois, and Brooklyn, New York, in the 1850s, but few other cities built them until germ theory revolutionized understanding of the sewage–health nexus. Unfortunately, the sanitary sewers of most cities often incorporated industrial wastes into the mix and simply discharged the aggregate into adjacent rivers, lakes, or the ocean in the belief that, once diluted, the sewage would be harmless.

In 1948 the US government enacted the Federal Water Pollution Control Act to provide financial support to facilitate the construction of wastewater treatment facilities for communities of all sizes. Urban areas required greater financial backing than states typically could provide, so federal loans and grants established plants to provide primary and secondary treatment of residential wastewater. Integrated plumbing and safer piping became standard in American homes. However, the push to completely remove lead piping from waterworks and the treatment of industrial effluent did not occur until the 1980s in the United States.

According to the World Health Organization (WHO) and United Nations Children’s Fund (UNICEF), as of 2011, 96% of the world’s urban population has access to improved water sources (WHO 2015). Access for the US urban population nears 100%, as for urban areas of most of the rest of the industrialized countries. The trends in access have been rather steady for the Global North, and significant improvements have been made in less industrialized countries of Africa and Asia, some increasing urban access by more than 70% (e.g., in Afghanistan) since the 1990s. In former Eastern Bloc countries, however, access diminished with the collapse of the Soviet Union in the early 1990s. Most have not rehabilitated their water systems fully.

Aging infrastructure, increasing costs of water provision, and generally difficult economic conditions around the world have hastened the push for nongovernmental organizations and international aid agencies to step in to build infrastructure, as well as the privatization of water services in some regions and countries. The need for fresh water continues to grow with population and economic development. The
production of sewage has similarly continued apace. The WHO reports that only 82% of the world’s urban population had access to improved sanitation facilities in 2015 and the greatest need today remains throughout Africa and in some small island states where only 15% to 50% have access (WHO 2015).

Both water and sanitation have required more investment to increase supply, build infrastructure and desalination plants, construct more treatment facilities, and increase regulatory enforcement. Emerging megacities and metropolitan urban agglomerations have also revealed the artificiality of political boundaries for natural resource management. Governments may be challenged to negotiate their own needs within the contexts of other urban neighbors’ needs and rural water demands. As water and sewer systems grow in size, they grow in complexity and require increasingly complicated approaches. But funding has fallen behind. Alternative mechanisms have emerged to meet water supply and water quality demands in economical and more efficient ways.

Besides repair to extant systems, late twentieth- and early twenty-first-century approaches to water use include conservation, recycling, gray-water use, rainwater harvesting, and environmentally appropriate landscaping and development. Water conservation and hazard-mitigation projects have often sought to undo what had been done in the past. For instance, the majority of flood management in the United States throughout the twentieth century dictated the engineering of rivers to hasten the movement of water past urban areas, but today’s urban floodplain managers are working to re-establish more natural river environments and to enhance the absorption and water-holding capacity of urban stream networks. Rooftop gardens are being constructed on tall buildings to reduce runoff, to exploit available rainfall, to reduce solar energy absorbed by modern architecture, and even to recreate habitat for urban wildlife. In many Sun Belt cities of the United States, municipal governments have mandated that xeriscaping replace water-intensive lawns and gardens and that outdoor water use for landscaping be reduced significantly.

Recently, many urban areas around the world have sought sustainability of their water use in a quest for consumption practices that fit within a region’s natural supply to ensure a long-term renewable and permanent supply of water. But a major complication that is yet to fully manifest itself is climate change. Cities will experience a diverse set of trends influenced by many variables: extremes of temperature or precipitation may increase or decrease in frequency or intensity, and regular patterns may shift throughout the hydrological year; durations of hot, cold, wet, or dry periods may expand or contract; snowfall may diminish or snow may fall instead as rain and reduce the amount of mountain-stored moisture available to urban streams; the timing of seasonal weather patterns may change or persist. All of these factors will influence the amounts and qualities of water supplies throughout the year. The generally dependable long-term record of water availability is no longer assured, and planning and management of urban water now involves new uncertainties and unknowns.

Further reading

A watershed is a land surface area encompassing all points from which streamflow at a given location is derived. Watersheds are fundamental natural, hydrological, and ecological subdivisions of the Earth’s surface with system attributes and functions having great relevance to human existence. The term “watershed” is often used synonymously with “drainage basin,” particularly in the United States, and also with the term “catchment,” although the latter is frequently used to emphasize land surface conditions rather than the combined surface and subsurface hydrological system. The word “watershed” has been traced to Germany (wasserschiede; water divide), where it was in use by about 1400 CE. It was in widespread English usage by 1800 CE. However, the concept of a collecting area for waters contributing to river flow is probably much older. Watersheds have been described as fundamental geomorphic units (Chorley 1969) for several reasons. They are fully contiguous and space filling; all points on the land surface fall within some watershed. They are convenient units of system organization, with divides representing the natural and easily established positions of open system boundaries. Within-system fluxes of materials are easily conceptualized, if not always easily quantified within watersheds. Furthermore, water is the single most important of all resources for human existence, and a watershed-based system of land area organization is considered to provide the least ambiguous and most sustainable land parcel arrangement for resource assessment, development, and conservation.

Watershed extent and delineation

The spatial extent of a watershed is defined by its point of outflow on a stream. In practical application, the point of outflow, and thus watershed size, is usually determined by specific data needs. For example, the point may be a location from which water will be removed for various uses (municipal supply, irrigation, power plant cooling, etc.), or a location of flood hazard. More generically, stream junctions may be used as delineation points; thus, when speaking of a river’s watershed, all points upstream of its confluence with another water body (river, lake, or ocean) will be included.

The line delimiting the spatial boundaries of a watershed defines the drainage divide, and usually corresponds with the crests of topographic ridges (Figure 1). Locating the boundaries of watersheds, the procedure known as watershed delineation, can be accomplished by hand-tracing on a topographic map, or by using flow directions derived from computer-based geospatial analyses of digital elevation models. On a topographic map, tracing begins at the designated point of outflow, from which lines are drawn immediately upslope and perpendicular to contours, and then extended around the catchment limits until they join, encircling all upstream tributaries. These topographic divides may not always precisely correspond with the groundwater (phreatic) divides beneath the land surface, in which case their placement will be an approximation. This is particularly relevant...
where geological conditions produce unpredictable directions for groundwater movement, such as in karst environments.

Although the upper limit of watershed size is ultimately constrained by the size of a continental land mass (Table 1), there is no objectively defined lower limit. Every watershed can be subdivided into smaller subwatersheds, which can be further subdivided ad infinitum. Thus, the minimum size of a watershed is technically unlimited. More practically, however, the lower limit of watershed size is set by the sorts of problems requiring a watershed-scale analysis. For example, small-plot soil loss studies may require delineations of hillslope areas measurable in units of several square meters. But other lower limits might be proposed, such as the smallest contributing area required for the existence of a perennial stream channel.

Physical characteristics

Watersheds are composed of land surface areas and their underlying regolith and bedrock, in addition to stream channels connected to form the channel network. The land areas may be further subdivided into sloping uplands (hillslopes of variable size and shape), and flat bottomlands consisting of river floodplains and terraces. More detailed geomorphological parsings are also possible. A number of useful descriptors for watersheds have been proposed, many since the appearance of Robert Horton’s classic (1945) “Erosional Development of Streams and their Drainage Basins: Hydrophysical Approach to Quantitative Morphology,” a broadly recognized and influential publication focusing on the quantitative process geomorphology of watersheds. Among Horton’s groundbreaking contributions are the infiltration-excess mechanism of overland flow generation, a theory of drainage network development, and empirical laws of drainage network composition, relating the numbers and mean lengths of streams in a watershed to stream order.

Stream order, a widely used index of stream size, is found by assigning the smallest headwater streams an order of one (“first-order”). Progressing downstream, order is incremented by one only after two streams of equal order join (Figure 2). Later, Ronald Shreve proposed stream magnitude as an alternative to stream order to account for the substantial water inputs of excess streams (those whose additions do not increase stream order). Headwater streams are assigned a magnitude of one, then the magnitudes add progressively downstream at each junction such that the magnitude of any stream segment equals the total number of magnitude-one streams that are upstream (Figure 2). Horton also introduced the concept of drainage density, the total length of streams in a watershed divided by watershed area, which is a measure of stream frequency that is of fundamental significance in explanations of watershed material fluxes. Many other descriptors, including shape indices (circularity, elongation), relief characteristics, and topological properties of stream networks, are also frequently used in watershed analyses.

Watershed hydrology

The continuity equation \( I - O = \Delta S \) (input minus output equals change in storage) is a basic expression useful in water and sediment budgeting at both watershed and channel-reach scales. In watershed-scale water budgeting, input is via precipitation, outputs are via stream discharge (the rate of water volume outflow, or runoff) and evapotranspiration, and change in storage is via deep groundwater recharge and soil moisture storage. In dryland environments, both precipitation amounts and the infiltration of precipitation into bare, crusted soils are low, and little water is available for deep percolation on hillslopes. In such cases most streams will be influent, with groundwater primarily being recharged by streamflow infiltrating the channel bed. In contrast, much of the large
amounts of precipitation in humid environments will infiltrate hillslope regolith, subsequently following both deep and shallow subsurface pathways towards stream channels (Figure 3). Thus, the variable potential for water infiltration into the ground, known as the *infiltration capacity*, is a critical measure for understanding the rainfall–runoff response of watersheds during storms. Infiltration capacity can be expressed as a volume, or more commonly as a depth of applied water that moves into the soil per unit time.

The infiltration process is influenced by three interdependent subprocesses: (i) the movement of water across the plane separating the ground surface from air, (ii) soil moisture storage, and (iii) the continued transmission of water below ground (percolation). The boundary between air and regolith is diffuse because air extends downward into porous materials when pore spaces are not occupied by pre-existing (antecedent) moisture. However, the ground surface plane is important because kinetic energy transferred from raindrop impact can produce surface sealing only in a shallow (between 1 mm and 1 cm thick) zone below the regolith surface. Surface sealing occurs when smaller soil particles are splashed into large pore spaces on the soil surface, obstructing downward movement of water, and reducing infiltration capacity. For cases in which the precipitation rate (expressed in the same units as infiltration) is greater than the infiltration capacity of soil, the difference in the two rates will accumulate on the ground surface, first filling small depressions (depression storage), which, if the process is continued, may
spill over to produce a thin sheet or series of shallow rivulets constituting overland flow. This model for the generation of surface runoff was first proposed by Horton (1945), and is referred to as the infiltration-excess overland flow mechanism, or in honor of Horton, Hortonian overland flow.

Precipitation that infiltrates into soil may percolate downward to recharge the water table, or it may begin to flow laterally downslope through the soil as throughflow. The reemergence of underground water-flows onto the surface, known as return flow, often takes place near slope bases where ground may already be near saturation due to continual receipts from upslope drainage. Overland flow produced in these saturated zones is referred to as saturation overland flow, which combines both return flow and direct precipitation onto saturated ground. The spatial extents of these zones expand and contract through time, changing the effective storm runoff contributing area of the watershed. This is known as the variable source area model of overland flow generation, which was introduced by Hewlett and Hibbert (1967) to explain why streams can rapidly flood in humid regions even when most or all of storm precipitation infiltrates in upland areas.

Changes in stream discharge through time are depicted in hydrographs (Figure 4). The characteristics of hydrographs, including peak discharge, the delay between rainfall and the discharge peak (known as the lag time or lag-to-peak), and the duration of flows elevated by storm precipitation (known as the time base of stormflow), are controlled by the intensity and duration of the rainfall event, factors such as slope and soil cover, which affect infiltration capacity and general hillslope hydrology, watershed size and shape, and properties of the stream network such as streamflow travel distances (and associated times) and the geometric arrangement of streams. Hydrograph properties change as a flood wave moves downstream. Water storage effects are often critical, with two extremes possible (Figure 4c). Translation of the flood wave under conditions of minimal storage results in a hydrograph shape that changes little as the flood wave moves downstream, an outcome most likely to be important in fully confined stream channels with no floodplains, and steep valley walls. Where channels are unconfined, sinuous, and bordered by large floodplains, floodwaters, storage potential is higher, leading to lower peak discharge and longer time base, a process paralleling storage of floodwaters in reservoirs behind dams. Along rivers too, this in-channel and overbank storage and slow release process is known as the reservoir effect. Although either effect may be dominant at a given site, most rivers display behaviors intermediate between the two.

**Watershed erosion**

Water-flows throughout watersheds are capable of doing work by eroding and transporting sediment. Sediment can be in either particulate or dissolved (ionic) form and is derived from both surficial (or near-surface) erosion of hillslopes and erosion of stream channel bed and banks, and from both ground-level and subsurface areas via chemical weathering. Sediment transport occurs in one of three fundamental forms: bedload (particulates transported in constant or intermittent contact with the channel bed), suspended or wash load (particulates transported in suspension in the moving, turbulent water column), or dissolved load (fully dissolved ionic materials).

The amount of sediment transported during a particular flood event depends on many factors, but the most fundamental are the size of flood...
WATERSHEDS

and the nature of sediment sources. The removal of weathered and eroded sediment mass from upland areas resulting in ground surface lowering is known as denudation. Hillslope erosion may be accomplished by both mass wasting (gravitational movement of rock or regolith) and overland flow (sheet and rill erosion). Mass wasting is controlled by dynamic changes determining the ratio of driving forces (the downslope component of gravitation acting on Earth materials) to forces resisting motion (friction and cohesion). Sheet and rill erosion by overland flow is controlled by the relative rates of precipitation and infiltration capacity and hillslope position, or in the case of saturation overland flow, by throughflow mechanisms resolving near the bases of hillslopes.

Surficial erosion by water on hillslopes is a two-stage process: (i) detachment of particles from the ground surface, and (ii) transportation of those particles in overland flow. Detachment can be produced via the application of shear stress by overland flow, or by the transfer of kinetic energy possessed by falling raindrops upon impact with the ground. The magnitude of stresses imposed by overland flow is tied to the depth of flow, which is often limited on upland surfaces, particularly near the crests of ridges where cumulative flow additions from successive upslope positions is not great. Horton referred to this topslope zone as a belt of no erosion, only downslope of which sufficient depths of water could occur to initiate sheetwash erosion and incision of small channels (rills). However, in some regions, overland flow rarely reaches depths capable of producing effective detachment. In all types of areas, raindrop impact, sometimes referred to as rainsplash, can be an effective detachment mechanism, although it is severely limited in areas with dense ground cover. The combination of rainsplash detachment penetrating through shallow overland flow and the subsequent removal of detached particles in that flow is particularly effective and has been referred to as rainflow or rainwash erosion (Morgan 1986).

The far-reaching onsite and offsite consequences of surficial erosion, including soil fertility losses and excessive sedimentation in streams (siltation), have prompted many decades of soil erosion research leading to several methods for its prediction. The most commonly used models for soil loss prediction are the Universal Soil Loss Equation (USLE; Wischmeier and Smith 1965) and its global variants. The USLE-type model integrates the effects of rainfall and soil characteristics, topography, vegetation

Figure 4 (a) Components of a hydrograph; (b) hypothetical stormflow hydrograph from an urban watershed, showing decreased lag time and time base, and high peak discharge; (c) hypothetical hydrographs for translation and reservoir effects. Original artwork by author.
cover, and erosion control practices in a simple multiplicative structure created from large amounts of empirical erosion data. Although these empirical models do not directly simulate the physical processes of erosion, their spatially distributed implementation at the watershed scale using geographic information systems is straightforward and potentially a powerful tool for watershed management in both agricultural and even urban settings, if properly refined.

Upland erosion is often of overriding importance to watershed-scale erosion, given the areal dominance of uplands in the watershed, and the concentration of land use in these areas. However, fluvial processes leading to stream channel bank and bed erosion are also usually substantial in magnitude, and potentially of primary importance in landscapes with stable (or stabilized) uplands. Like erosion by overland flow, erosion of the stream channel boundary is contingent on the shear stresses applied to the bed by flowing water, which are proportional to the depth of flow and gradient (longitudinal slope) of the channel. These constantly changing stresses may be compared at any given time to the critical shear stress required to move sediment particles of sizes represented in the channel boundary to determine the likelihood of erosion. The initiation of particle movement into streamflow is known as entrainment, which is a stream channel precursor to transportation. Stream bank erosion differs from bed erosion in that banks are subjected to alternating inundation and aeration during and between floods and, when inundated, covered by lesser water depths. Furthermore, banks are often composed of finer and more texturally varied or stratified sediment than channel beds, and may be stabilized by vegetation. Banks may be exposed to rainsplash when above water, and given the relative steepness of banks and the resulting increase in downslope splash distance, rainflow erosion is capable of contributing some sediment to sediment loads when banks are less than 90 degrees. However, much greater stream bank erosion is typically produced by mass wasting of banks undercut by streamflow.

Watershed sedimentation

The continuity equation is also useful for thinking about watershed sediment budgets. A sediment budget is a structure which seeks to quantitatively define what happens to sediments generated by watershed erosion, and is an important tool for understanding short- and long-term geomorphological dynamics of watersheds. This knowledge is critical for understanding past, present, and future environmental impacts of land use, and making decisions regarding the rehabilitation of degraded streams and general watershed management. The US Environmental Protection Agency lists excess sediment as the single most common contributor to stream degradation nationwide.

Inputs in fluvial sediment budgets include all forms of erosionally produced sediments. Output of sediment is known as sediment yield, which is defined as the mass of sediment exported from a watershed per unit time (metric tons per year). To enable comparisons between watersheds of different size, the sediment yield per unit drainage area, known as the specific sediment yield, is used. Determining sediment yield values from different watersheds has been an important research focus over many decades because of the need to link excessive sediment loads and the problems they can cause to land-use practices. Erosive land uses such as row-crop agriculture almost always result in increased sediment input into streams, which manifests in the form of higher sediment yields at watershed outlets. However, strong direct relationships between
WATERSHEDS

the quantities of erosion in the uplands and contemporaneous sediment yield may not occur. Particulate erosion and sediment transportation in watersheds are highly intermittent, with travel distances during storm events ranging in magnitude from meters (or less) for coarse fractions on hillslopes, to many kilometers for finer sediments suspended in streamflow. Temporary shifts from sediment in transport to storage ($\Delta S$) may occur at many different landscape positions, and stored sediment may be remobilized over widely varying timescales. Potential storage locations include on and at the base of hillslopes, on terrace and floodplain surfaces, and in sediment benches and bars within stream channels, each having its own remobilization period.

In one of the best known illustrations of the importance of sediment storage, Trimble (1999) found that sediment yield rates from the Coon Creek watershed in Wisconsin (United States) remained virtually unchanged over almost 150 years, despite major changes in sediment inputs from upland erosion and tributaries. The modification of the relation between erosion and sediment yield, mediated by storage dynamics, is often expressed as the dimensionless sediment delivery ratio (SDR), as shown in equation 1.

$$SDR = \frac{\text{Watershed sediment yield}}{\text{gross watershed erosion}}$$

Thus the term sediment delivery refers to the proportion of gross catchment erosion that manifests as sediment yield in some period of interest. This should not be interpreted necessarily to mean that the actual sediment particulates being measured at the watershed stream outlet are the same particulates that were eroded during the period of monitoring. It is possible that all eroded materials in a given storm or other period of observation are stored for periods longer than that of observation. As long as the denominator is defined to include all locations of erosion (stream channel erosion as well as upland erosion), the sediment delivery ratio must vary between 0 and 1 (0–100%). Although sediment delivery ratios may be calculated over any time interval, individual storm periods are probably too short to give a representative value, and temporal averaging in proportion to catchment size has been advocated (Richards 1993).

Sediment yields and SDR values commonly decline downstream as watershed area grows. Explanations for these trends focus on declines in the numerator of SDR (sediment yield), and two competing explanations have been offered (Richards 1993). One explanation is that the sizes of storage compartments and opportunities for sediment storage increase with distance from more steeply sloping headwater areas. Downstream increases in floodplain width allow for greater overbank sediment storage as well as hydrograph-attenuating storage of floodwaters which, due to shallower depths, have reduced velocity, promoting deposition. The toeslopes of valley walls adjoin the flatter floodplain rather than the streambank, and the abrupt gradient decrease promotes deposition of colluvium (mass wasting sediment). Furthermore, the valley walls become more distant on average from channels due to intervening floodplain areas, and their sediments are less likely to reach rivers traveling over these gentle intervening floodplain surfaces.

The second explanation is that steeper headwater areas are often the dominant sediment sources, and thus sediment production (via erosion) per unit area of watershed decreases downstream due to decline in average land surface slope. However, the evidence in support of this hypothesis is relatively weak and explanations invoking increasing sediment storage opportunities are more widely accepted.

SDR is a black-box concept, meaning that erosion and sediment yield are the only data required for its determination. A detailed knowledge of
intervening sediment storage dynamics is not necessary. Yet, detailed spatially explicit information on all aspects of sediment delivery is critical for understanding the impacts of watershed processes on landscape change, water quality, land resources, and riparian ecosystems. Inasmuch as sediment storage indicates a disconnection, however temporary, in sediment flows through a watershed, SDRs index connective properties of watersheds which are a vital concern for current analyses of sediment cascades. Watershed connectivity can be viewed in terms of both hydrologic and sedimentological connections between adjacent land surface forms. Connectivity in watersheds depends on climatic characteristics, hillslope runoff potential, topographic positional attributes affecting energy and slope continuity, and flow-path distance. Thus, connectivity variables are similar to those important in explaining sediment yields.

The origins of watersheds

Prior to the twentieth century, few comprehensive explanations of watershed origin had been offered. The geographical cycle of W.M. Davis and similar theories of landscape evolution remained influential in the early 1900s. With increased emphasis on quantitative process geomorphology beginning around 1940 came new ideas on how drainage networks, and by necessity their contributing (watershed) areas originate. Robert Horton, in his seminal (1945) paper, was one of the first to compose a comprehensive theory of drainage network development to go along with his ideas on overland flow and the belt of no erosion. According to Horton, once overland flow becomes deep and fast enough (i.e., downslope of the belt of no erosion), rills are formed. Because of minor differences in hillslope or divide shape, one of the initial rills is likely to become larger than adjacent rills and begin capturing their flow. Horton referred to this process as cross-grading, and depicted it as a hierarchical process in which captured rills become tributaries and undergo the same differential enlargement process, progressively dividing up the former slope until drainage areas are no longer sufficient to support rilling. Captured tributary flow progressively enlarges the trunk rill to gully size, and eventually to a size necessary to be regarded as a stream.

Horton’s model may accurately describe the origins of some smaller drainage networks in dryland environments, and poorly vegetated and thin-soiled areas such as shale badlands, where infiltration excess (Hortonian) overland flow is the dominant runoff mechanism. Stream networks in humid, soil-mantled, and well-vegetated landscapes where infiltration excess overland flow is uncommon do not fit the Horton model. In these environments networks are more likely to originate in association with zones of saturation overland flow near slope base. Headward growth of stream channels often occurs along subsurface drainage lines by processes like gully wall sapping that are strongly influenced by groundwater. Larger networks may develop in more complicated ways, and multiple mechanisms of drainage network initiation and growth may be operative in a single watershed.

The long-term evolution of watershed morphology includes not only initiation and growth of stream networks, but also their contraction. Glock (1931) used topographic map data and ergodic reasoning (space-for-time substitution) to infer that drainage network evolution has distinct morphological stages, including: (i) an initiation phase in which the first poorly integrated channels are created on sloping land, (ii) an extension phase characterized by rapid elongation (headward growth) and elaboration (addition of
small tributaries), (iii) the attainment of maximum extension, and (iv) a final period of integration characterized by the loss of stream length (and reduction of drainage density) driven by relief reduction, slope decrease, and the increasing influence of hillslope processes that close out channels. Despite decades of research involving field studies, scale (hardware) models, and other approaches, a comprehensive understanding of drainage development remains elusive, and increasingly, sophisticated computer-based modeling is required to fruitfully explore the issue.

**Land-use impacts on watersheds**

Land-use practices such as timber harvesting, row-crop agriculture, and urban development impact watershed functions in distinctive ways. Forest clearance for timber sale or conversion of land to agricultural or urban uses decreases evapotranspiration losses in the short term, resulting in increased streamflows. Depending on the method of timber extraction, the land surface may undergo variable changes in ground stability leading to surfcial erosion, or more commonly of greater impact along logging roads, large hillslope mass failures. Row-cropping requires prior removal of all vegetation, and the loss of ground cover and destruction of natural soil structure by tillage exacerbate surface sealing by rainsplash, ultimately increasing overland flow and surfcial erosion rates. Urbanization involves large increases in watershed surface covered by pavement or other materials that are impervious to rainfall, greatly reducing average infiltration capacities. As a result, a large proportion of rainfall in urban areas is converted to overland flow, then carried rapidly through a partially buried stream network made up of stormwater pipes, before emptying into nearby streams. Hydrographs in urban streams are characterized by short lag times and time bases, and high peak discharges (Figure 4b), which in most cases lead to erosional enlargement of channel cross-sections. High peak discharges also represent a significant flood hazard for neighborhoods proximal to valley bottoms within urbanized areas.

Wolman (1967) tracked changes in watershed sediment yields encompassing the sequential transition from forested, to agricultural, and finally to urbanized conditions as these occurred in the Maryland Piedmont (United States) over the last two centuries. He found that sediment yields during peak agriculture were at least 20 times greater than under the prior forested conditions. Peak sediment yields began declining with reductions in cultivated area and the advent of soil erosion control practices between 1925 and 1960. Urbanization brought sediment yields at least 80 times larger than under forested conditions due to erosion on urban lands severely disturbed by construction activities. Elevated sediment yields were quickly reduced following construction due to land surface stabilization under pavement. Recent studies of urban sediment yields point to renewed channel erosion as the dominant source of sediment following the achievement of a stable impervious surface density. Other studies have noted that urban land disturbance is not steady state, because areas may undergo periodic redevelopment indefinitely through time. In many places, large quantities of sediment from historical anthropogenic erosion phases are stored in channels, on floodplains and behind small dams, and later remobilized. Withdrawal of this “legacy sediment” from storage after erosive land uses have diminished can maintain elevated watershed sediment yields for decades to centuries.

In watersheds, water quantity is inseparable from water quality, and land-use-driven hydrologic and sedimentation changes are usually paralleled by negative impacts on water
chemistry. Pollutants derived from sources distributed across watershed surfaces are known as non-point-source pollutants (NPS). In addition to excessive sediment, these include fertilizers, pesticides, and bacteria in agricultural watersheds, and fertilizers, petroleum hydrocarbons, bacteria, and heavy metals in urban watersheds. NPS pollution is now the largest cause of water quality impairment in US streams. A number of structural and nonstructural solutions to NPS problems exist, although legislation focusing on NPS pollution, such as Section 319 of the Clean Water Act in the United States (1987), is of relatively recent origin.

Watershed-based planning

Land and water resource planning applied at the scale of entire watersheds is a relatively recent occurrence in natural resource history. The famous nineteenth-century explorer, naturalist, and geographer John Wesley Powell was a strong advocate of watershed-based planning and settlement in the dry-climate western United States. Despite Powell’s efforts, watershed-based planning was not widely implemented in the United States during his lifetime, although an increased focus on integrated watershed planning was to emerge shortly after his death in 1902. One of the first major examples of comprehensive large watershed planning is the creation of the federally funded Tennessee Valley Authority (TVA) in 1933. The TVA’s multiple purpose mandate was to build dams to control flooding on the Tennessee River, enable navigation, generate hydroelectric power, and promote economic development. Modern watershed management at a smaller scale may also have a number of aims, including flood hazard mitigation, provision of water supply, and reduction of environmental hazards posed by agricultural and urban water pollution. Water resource and ecological problems caused by poor land-use practices have primarily been approached through activities focused on particular points on stream reaches where problems are acute or interfere with other needs. Although it has long been recognized that watershed-scale conditions are responsible for many environmental, natural hazard, and water resource problems, it has proven more difficult to proactively solve the complex issues of land-use regulation and change throughout a watershed than it is to attempt remediation of point manifestations of these problems as they arise.

Despite the now common recognition that watersheds are ideal spatial units for considering resource decisions, the physical integrity of their boundaries is often compromised by interbasin water transfers. Large-scale water diversions over vast distances supply water for dryland irrigation and cities such as Los Angeles, California; yet similar interbasin transfers of shorter distance have become more common in humid environments as well, sometimes resulting in water wars like those in dryland areas.

Weather affects all facets of life on Earth. Atmospheric elements such as precipitation, temperature, and wind are ordinarily considered resources supporting habitats and rudiments necessary for animal and plant survival and well-being. However, when a particular weather element deviates from a normal band of tolerance for life, it transitions from a resource into a hazard. These extremes combine with human and environmental sensitivities to create negative consequences and, in some cases, disasters.

Weather extremes are typically referred to as “storms,” which are atmospheric disturbances driven, in large part, by the foundations of our Earth-atmospheric system including: differential heating of the surface of the Earth by the sun, the heating of the lower atmosphere by energy transfer from the Earth’s surface, and Earth’s rotation and varied topography. Storms are important in redistributing excesses in energy found in the Earth-atmospheric system; however, in trying to seek an insatiable energy balance, these storms generate weather elements such as pressure extremes, high winds, intense precipitation rates, and other hazards that can be detriments to society.

Large-scale storms typically arise as regions of low pressure that are characterized by winds rotating cyclonically (hence, their meteorological name, “cyclones”). These cyclones derive their classification – extratropical or tropical – depending on their meteorological and geographic origins. Smaller, or mesoscale, disturbances can create localized hazards that are often driven by deep, moist convection in the troposphere, or thunderstorms. However, in the absence of these atmospheric disturbances, sustained quiescent weather conditions can, somewhat paradoxically, lead to climatological extremes such as drought or heat waves.

Extratropical cyclones

Extratropical cyclones are the primary genitor of weather extremes in the mid-latitudes (30°–70°). Studies as far back as the late nineteenth century recognized the important effects these cyclones have on the day-to-day variability and hazard-sapes in extratropical regions. Extratropical cyclones are large swirling areas of low pressure that are characterized by air mass fronts and are generated dynamically by the Earth’s rotation in combination with the instability caused by the uneven heating of the Earth’s surface. Storm initiation, or cyclogenesis, is provoked by upper-level disturbances, or troughs, embedded in regions of enhanced winds within the jetstream, or jetstreaks, that create diverging air currents near the tropopause. Cyclogenesis is climatologically focused where extreme gradients in orography (leeside of a mountain range) or low-level atmosphere temperatures (warm ocean current with nearby cold landmass) exist. Intense extratropical cyclones occur most frequently in the Southern Hemisphere near New Zealand, east of South America, and in the southern
WEATHER, EXTREME

Indian Ocean and in the Northern Hemisphere near east-central North America, the northern Atlantic, Europe, Far East and northwest Pacific, and south-central Asia.

In the high latitudes, cyclones with similar spiraling structures to their mid-latitude counterparts, but smaller in spatial (≈100 km in diameter) scale, are known as polar lows or, colloquially, arctic hurricanes. These events are particularly dangerous to mariners due to their forecast difficulty and rapid onset of extreme winds and snow. In the Northern Hemisphere, these severe events most commonly form and affect the areas near the Davis Strait and Labrador Sea, Baltic Sea, and Gulf of Alaska and Bering Sea.

Extratropical cyclones have the propensity to rapidly develop and intensify after their inception, lasting from a few days to over a couple weeks; the lengthier lifetimes occur when a cyclone becomes “cut-off” from the jet stream and gradually dissipates. Climatologically, cyclones tend to dominate the cool and transition seasons in each hemisphere, promoting a wide spectrum of hazards, from blizzards and ice storms on the cool side of the cyclone to tornado outbreaks, lightning, hail, severe nontornadic winds, and flooding in the cyclone’s warm sector. Cyclones cover extensive geographies, with each storm encompassing from one to three thousand kilometers at maturity and traversing wide expanses of their hemisphere. Not all extratropical cyclones produce the spectrum of weather extremes, but due to their great size, regularity, and strong dynamics, they are more responsible for weather hazards than any other storm phenomenon. In particular, events that undergo explosive cyclogenesis, or exceptionally rapid deepening of a storm’s center of low pressure, are disproportionately more likely to produce hazards due to their intense dynamics. These events are classified by meteorologists as “bombs” and, in the Northern Hemisphere, are most frequent during the cool and transition seasons along the Canada and US east coast, northern Atlantic and northwest Europe, as well as the north-central and far northwestern Pacific.

Extratropical cyclones and their affiliated fronts can promote extensive changes in sensible weather over short periods of time. Severe winter weather most frequently manifests on the poleward side of cold and warm fronts in extratropical cyclones. If an extratropical cyclone draws in a polar air mass that is sufficiently deep and cold, it can be branded a “winter storm” containing life-threatening cold temperatures, high winds, heavy snow, ice pellets, and/or freezing rain. Winter weather hazards are capable of negatively impacting public safety and human systems, with high-end events damaging infrastructure and utilities, halting transportation systems, restricting socioeconomic activities, and harming or killing livestock and cultivated plants. In particular, blizzards and ice storms can paralyze regions, impacting millions of people and causing billions of dollars in agricultural, property, utility, and productivity losses, as well as casualties (e.g., frostbite, hypothermia, or injuries sustained in weather-related vehicle crashes). Extreme cold air outbreaks into the middle and lower latitudes occasionally follow strong extratropical cyclone passages in the cool season. These cold waves can result in billions of dollars in economic loss (primarily in the agricultural sector) and can cause thousands of fatalities in exceptionally vulnerable regions.

The term blizzard is loosely applied to any heavy snowstorm; though, few snowstorms exceed official blizzard criteria employed by government forecast agencies. For example, the US National Weather Service (NWS) defines a blizzard as an event that has snow and/or blowing snow reducing visibility less than four tenths of a kilometer and sustained winds of 15.6 m s$^{-1}$ for at least 3 hours. A global blizzard
climatology does not exist, but these events are most commonly experienced poleward of the climatological track of intense, cool season extratropical cyclones, with formation occurring on the leeside of mountain ranges and within or adjacent to arctic air mass source regions. For example, in North America, blizzards most commonly affect the interior portion of the continent including large expanses of the north-central United States and central Canada prairies. On average, one to two blizzards per year can be expected in these regions.

Though less frequent than their interior continental counterparts, blizzards can be generated by powerful low-pressure systems fostered by dramatic low-level temperature gradients that predominate where warm coastal waters border cool landmasses. In North America, these coastal lows develop near the northern Gulf Coast or Cape Hatteras and intensify as they move to the northeast United States and Atlantic Canada. These coastal extratropical cyclones, called nor’easters, are particularly noteworthy due to their litany of hazardous effects – from blizzard conditions, hurricane-force winds, precipitation type variability and extreme rates, to coastal flooding and erosion. On average, approximately 12 of these coastal cyclones occur per cool season, with two or three producing significant impacts on the amplified population and infrastructure found along the east coast. Similar extratropical cyclones occur regularly during the cool season across northern Japan and northwestern Europe.

Drizzle and rain falling into air near the surface at or below the freezing point can promote ice accumulations that may have significant influences on energy and transportations systems. While minor ice accumulations, or glazes, can lead to vehicle crashes and pedestrian accidents, significant accumulations (≥6.35 mm) produced by ice storms can cause incredible damage to power distribution systems, as well as commercial and personal property due to felled trees. In North America, climatologies reveal that freezing rain and drizzle occur in about a quarter of all winter events, and are most frequent during the cool season (December–March) across central and eastern portions of the United States and Canada, Alaska, and the northern shores of Canada. Freezing precipitation events and ice storms have a propensity to develop poleward of fronts or within cold air damming or trapping patterns. In the instances of damming or trapping patterns, the cold air becomes entrenched in the low levels of the atmosphere due to airflow blockage caused by terrain barriers such as mountains. This unique effect occurs on the east side of orographic barriers in central (Rockies) and eastern (Appalachian) North America, Europe (Alps), South America (Andes), and the Far East.

Severe local storms

Smaller scale, but equally impressive, weather phenomena occur as a result of the formation of deep, moist convection. When atmospheric conditions are favorable, specifically in regards to the vertical variation in temperature and wind, thunderstorms can form that are capable of producing frequent lightning, large hailstones, copious rainfall, damaging winds, and even tornadoes. In the United States, the NWS defines these severe thunderstorm events as hail with a diameter of ≥2.5 cm, wind gusts of ≥26 ms⁻¹, and/or a tornado. Commonly, these events are found within the warm sector of extratropical cyclones. However, during the warm season, severe thunderstorms are often independent of extratropical cyclones, developing wherever the basic ingredients required for their formation juxtapose.
Three ingredients are necessary for the formation of a thunderstorm, including a moist layer of sufficient depth in the low or mid-troposphere, an unstable atmosphere, and a lifting mechanism. Essentially, thunderstorms form as theoretical volumes of air accelerate upwards due to differences in density when compared to surrounding air. This process is efficient at relieving the accumulation of potential energy caused by differential heating of Earth’s surface. While thunderstorms are most common in tropical regions, these storms are often short-lived and rarely meet severe weather criteria. In order to obtain more organized thunderstorms capable of producing severe hazards, an additional ingredient must be added – wind shear. This shear, which is a change in wind speed and/or direction with atmospheric height, promotes a separation in the thunderstorm’s updraft and downdraft region, as well as the development of distinctive internal dynamical processes. The addition of wind shear increases the strength and longevity of thunderstorms, often engendering so-called supercell thunderstorms, which are the strongest thunderstorms on Earth. These relatively rare thunderstorms are characterized by their powerful rotating updrafts, or mesocyclones, and ability to produce Earth’s most violent weather. In fact, most strong tornadoes and severe hailstones originate from supercell thunderstorms.

Large clusters of thunderstorms that undergo a mode of self-organization are known as mesoscale convective systems. Found in many tropical and subtropical areas around the world, these complexes are very beneficial to regions dominated by rain-fed agriculture. However, these thunderstorms systems can cause floods, extreme lightning rates, and extensive severe nontornadic wind events known as derechos.

The central United States is home to the world’s highest frequency of severe thunderstorms. The relatively flat topography of the Great Plains allows for little obstruction between warm, humid air positioned over the Gulf of Mexico and its interaction with hot, dry air from the high terrain of the Chihuahuan Desert and cool, dry air originating from the Canadian Prairies. If sufficient wind shear overlaps these intersecting air masses, severe thunderstorms can result. Statistically, this is most likely to happen in the United States during the period April through June when over half of all annual severe weather reports occur. Tornadoes, which are arguably the least understood of all hazards, are also most common in this region and exhibit a relatively predictable annual cycle of occurrence. Throughout the cool season, tornadoes, while climatologically rare during this time of the year, are most frequent in the extreme southern portions of the United States due to that region’s proximity to warm, moist air from the Gulf of Mexico. During early spring, tornadoes surge in frequency and tend to be most common in the southern Great Plains before migrating to the northern Great Plains and Canadian Prairies during summer. This occurs as solar declination shifts toward the Tropic of Cancer, forcing wind shear and lifting mechanisms affiliated with the polar jet stream and its disturbances toward higher latitudes.

Globally, other locations (e.g., Argentina, Australia) also exhibit similar seasonal cycles of tornado occurrence. However, since severe weather reports are biased to areas of population, climatologists favor analyzing data related to the aforementioned ingredients necessary for their formation. Global climatologies of severe weather ingredients reveal local maxima concentrated in equatorial and southern Africa, southern Europe, the central United States, southern Brazil, northern Argentina, eastern Australia, and adjacent to the Himalayas. Such environments are most common in transition seasons, when
low-level temperature gradients are maximized and extratropical cyclones are abundant.

Severe weather can have large socioeconomic consequences, especially during so-called outbreak events of significant magnitude, frequency, and spatial coverage. For example, severe thunderstorms in the southeast United States during April–May 2011 spawned tornadoes responsible for US$17.3 billion in damages and at least 350 fatalities across 20 states. Extremely devastating tornadoes such as these may rank as EF4 or EF5 on the enhanced Fujita tornado intensity scale. While only 2% of all recorded US tornadoes are rated EF4 or EF5, they are responsible for nearly 68% of all tornado fatalities. In extremely vulnerable countries, the death toll from tornadoes can be enormous; for instance, in April 1989 nearly 1300 people were killed in Bangladesh in a single event. The recent increasing trend of economic losses from severe thunderstorms and tornadoes can be attributed to societal changes rather than any detectable increase in event frequency. However, recent research has indicated that the potential exists for an increase in severe thunderstorm environments under future anthropogenically driven climate change scenarios.

**Hydrologic extremes**

Floods are one of the costliest and deadliest hazards due to their relatively high rate of occurrence and the extensive human habitation of river floodplains and coastlines. Nearly 10% of the global population lives in flood-prone areas. According to the International Disaster Database, non-geophysical floods were responsible for nearly 4000 disasters from 1979 to 2013, affecting approximately 3.3 billion people and killing 230,000. An estimated US$600 billion in damages were blamed on floods during this period. Historically, floods have been immense killers, particularly in parts of Asia. The deadliest natural disaster (excluding pandemics and famines) in the history of the world occurred in central China along the Yangtze and Huai Rivers in 1931, when between 1 million and 4 million people were killed.

Floods are classified based on their geography, sources, and rapidity. The deadliest events are associated with quick-onset coastal storm surges accompanying tropical and strong extratropical cyclones (geophysical events such as earthquakes and sub-marine landslides can cause surges, or tsunamis, as well) and flash floods, which are localized, short-duration events often produced by flood control structure failure and/or high rainfall rates in thunderstorms. Due to their swiftness and localized nature, surge and flash flood location and magnitudes are difficult to forecast. Widespread floods are more predictable and can transpire over days, weeks, or even months when excessive rain and/or snow melt occurs in river basins. The intensity, extent, and frequency of precipitation events are important flood determinants, but other contributing factors such as watershed orientation in relation to the precipitation footprint, orography and slope, infiltration rates and saturation of soils, vegetation, land use (e.g., urbanization, deforestation, fallow fields), snow melt and ice jams, and flood control structures (e.g., levees, dams) can influence the occurrence and degree of flood.

Tropical cyclones produce exceptional rates of rainfall, leading to flash and widespread floods not only at landfall locations, but inland areas affected by decaying and remnant systems. Climatologically, rainfall contribution from tropical cyclones is most pronounced over southeast North America, Central America, the Caribbean, countries abutting the Bay of Bengal, far southeast and eastern Asia, northern Australia, and Madagascar. Floods can also be
triggered by monsoons, which are seasonal reversals in regional wind circulations and precipitation produced by stark contrasts in surface heating over continents and nearby oceans. The monsoon is most prominent in south Asia, but weaker (and sometimes, incomplete) seasonal reversals in wind and precipitation occur in west and sub-Saharan Africa, the Mojave and Sonoran deserts of North America, northern Australia, and parts of Indo-China into Japan. In the last case, a front between poleward cool, dry air and equatorward warm, moist air can become quasi-stationary during the warm season. This front, known as the Mei-Yu, can trigger the continual development and training of large thunderstorm complexes, exacerbating rainfall totals. The front has a tendency to align itself along the Yangtze River basin, which can result in enormous and deadly floods. In this region, seven flood events were responsible for over 100 000 deaths each during the twentieth century.

Though tropical cyclones and monsoons are important genitors of floods, most damaging and casualty-producing flood events are caused by localized heavy rains produced by thunderstorms. Climatologies of floods caused by these intense rain events are difficult to assess due to data inconsistencies, lack of reporting, and overrepresentation of cases in some countries. However, reported floods caused by torrential rainfalls are most frequent in East and Southeast Asia, the Indian subcontinent, eastern Africa, Central America, eastern United States, and Europe.

Conversely, extended periods of precipitation deficiency can lead to drought. Drought is a particularly difficult concept to recognize and comprehend due to its slow onset, multifaceted effects on and interactions with human-environmental systems, complexity in identification due to the lack of a universal causative source, and its relativity to each locale’s hydroclimatology. In vulnerable regions, drought can prompt disasters with immense death due to famine and prolonged military conflict that, ultimately, has resulted in some of the world’s greatest human tragedies. Like floods, droughts can occur in almost every region of the globe, but the most devastating human calamities instigated by drought in the past century have occurred in the sub-Saharan Sahel and China. Similar to droughts, heat waves are weather extremes that occur absent storms. These events are particularly deceptive due to their high human mortality without visceral images of damage.

Tropical cyclones

Tropical cyclones, which include hurricanes (Atlantic and eastern Pacific Ocean basins), typhoons (western Pacific), and severe cyclones (Indian), are the most destructive storms on Earth. When these spiraling storms interact with developed landscapes, significant losses to economies and life can occur. For instance, the deadliest weather disaster in the past half century was Cyclone Bhola, which devastated the northern Bay of Bengal coastline in 1970. The costliest weather disaster in history was Hurricane Katrina, which ravaged the central Gulf Coast of the United States in 2005.

Tropical cyclones develop from clusters of thunderstorms that persist over tropical ocean waters in an environment with little or no vertical wind shear. The Coriolis force (due to the rotating Earth) causes the incipient thunderstorm complex to rotate; this force becomes negligible at latitudes less than 5° and, for this reason, tropical cyclones do not form near the equator. Tropical cyclones obtain energy for formation and sustenance from warm seas through sensible and, most importantly, latent heat transfer. Warm oceans readily evaporate water and, through this process,
heat is extracted from the sea surface. This heat is reserved, or held latent, until it is re-released into developing tropical thunderstorms when water vapor condenses in storm updrafts. The tremendous rates of condensation that occur in a tropical cyclone promote a warm-core system, indicating that temperatures in the center of the cyclone are warmer than the areas at the same altitude surrounding the core; this is counter to extratropical cyclones, which feature cold cores.

A tropical cyclone structure includes a tight center of descending air that forms a small area absent of convection known as the eye. Surrounding the calm eye is a ring of deep convective torrents called the eyewall. It is within this relatively narrow region where the storm's most significant hazards, including wind and surge, transpire. Outside of the eyewall, spiraling rainbands encircle and converge toward the center of the storm. These bands include squalls of wind and intense precipitation and, in some land-falling cases, tornadoes. Mature tropical cyclones are characterized by deep low pressures at their core, promoting concentrated pressure gradients and, in turn, low-level winds that can cause extreme damage and encourage the formation of deadly storm surges.

On average, there are approximately 86 named tropical storms (greater than $17 \text{ m s}^{-1}$ sustained winds) per year globally. Of those 86, 47 reach the minimal threshold (greater than $33 \text{ m s}^{-1}$ sustained wind) to be considered a hurricane, typhoon, or tropical cyclone. Two thirds of all tropical cyclone activity occurs in the Northern Hemisphere, with the northwest Pacific basin the most active (mean of 26 named storms per year), followed by the northeast Pacific (17), Atlantic (12), southwest Pacific (10), and southwest Indian (9) ocean basins. Interannual variability in the number of events per basin is significant and is dependent on the seasonal character of sea surface temperatures, the strength of the wind flow in the troposphere, and ambient humidity in development regions.

The northwest Pacific is the only basin that experiences year-round tropical cyclones. Tropical cyclone activity in other basins is most common after a seasonal maximum in the solar declination. For instance, in the Atlantic and eastern Pacific basins, hurricane activity extends from late May or early June to the end of November, with peak activity typically in August and September. The north Indian (south Indian and southwest Pacific) basin typically experiences cyclones from April to December (October to May). Most tropical cyclones are characterized by westward motion during their formative and mature stages due to their usual position equatorward of semipermanent, oceanic subtropical ridges and embedment in the easterly trade winds. Thereafter, some events may curve poleward around the western flank of subtropical ridges, interact with the mid-latitude westerlies, and even transition into powerful, cold-core extratropical cyclones.

Tropical cyclone strength is most often classified based on the Saffir-Simpson scale, which ranks tropical cyclones from category 1 (at least $33 \text{ m s}^{-1}$) to 5 (exceeding $70 \text{ m s}^{-1}$) based on sustained wind speed. While all tropical cyclones have the potential to cause disasters, more intense landfalling events are commonly characterized by devastating winds, storm surges, and flooding rains. Indeed, a disproportionate amount of damage and loss of life is caused by “major” hurricanes (category 3 or greater on the Saffir-Simpson scale) and “super” typhoons (equivalent of category 4 or 5). Increases in coastal population, built environment, and vulnerabilities have led to amplifying impacts, especially as measured in people affected and economic loss.

Weathering processes and landforms

Tyler J. Thompson  
Ronald I. Dorn  
Arizona State University, USA

This entry relates the appearance of bare-rock landforms to the processes of rock decay. (The term “rock decay” is used rather than “weathering” throughout this entry, because “weathering” no longer functions as a useful scientific term (Hall, Thorn, and Sumner 2012), even though it is still widely used.) This entry introduces the topic by presenting a few classic examples connecting form to process. This is followed by an explanation of why bare-rock landforms occur. Then, case studies illustrate how the appearance of bare-rock landforms relates to rock decay. The last section details the importance of scale in rock decay.

Figure 1 compiles a few classic landforms often taught in introductory physical geography. In these classes, tafoni (1a) are typically linked with salt precipitation. Pressure release shells – sometimes incorrectly called exfoliation – form when enough overlying rock material erodes away to result in the formation of meter-thick shells (1b). Wildfire suddenly heats the water in the outer shell of a rock enough to spall scales off boulders (1c). Erosion of grussified granite exposes core stones that pile into tors (1d). Accumulation of silica, manganese, and iron inside of weathering rinds results in case hardening (1e). Root growth exerts sufficient pressure to open pre-existing fractures (1f). All of these examples occur in sites where soil does not cover bare rock.

The fundamental difference between landforms of mostly bare rock (Figure 1) – the focus of this entry – and landforms covered with soil and regolith derives from an imbalance between the rate at which rock decay produces rock fragments \((P_r)\) and the rate of transport of these rock fragments \((T_r)\). Bare-rock slopes occur in deserts where \(T_r > P_r\) – stripping the rock of its cover of particles. In contrast, soil- and regolith-covered slopes occur in wetter areas where \(T_r < P_r\) – and plants play a key role of holding produced particles in place. A key determinant in whether landscapes are soil-covered or consist of a lot of bare rock is the rate at which rocks decay and soil is produced to cover the bare rock. This entry focuses on locations where soil production has not outpaced mass wasting, resulting in the exposure of rock.

Case study 1: petroglyphs and rock decay

Petroglyph rock art panels display a wide range of forms linked to rock decay (Dorn et al. 2008). Figure 2 illustrates seven of these forms generated by different decay processes: (a) the splintering form of subparallel millimeter-scale cracks (Dorn et al. 2013); (b) spalling of centimeter-thick scales; (c) tafoni growth; (d) block separation along opening joints; (e) lithobiont-enhanced decay (Viles 1995); (f) weaknesses along bedding planes; and (g) salt precipitation resulting in the flaking of a petroglyph panel face.
Figure 1  Classic forms associated with rock decay: (a) tafoni in sandstone at Timna, Negev Desert; (b) pressure release shells in granodiorite, British Columbia; (c) scaling of diorite from a wildfire, Arizona; (d) tor of granite, Sonoran Desert in Arizona; (e) case hardening of sandstone at Petrified Forest National Park in Arizona; (f) root pressure widening fractures in gneiss, Sonoran Desert, Arizona. Image widths approximately 3 m, 12 m, 2 m, 8 m, 0.5 m, 0.2 m for a–f, respectively.
Figure 2  A variety of different processes degrade rock surfaces, illustrated here for sites with petroglyphs: (a) the splintering process on silicified dolomite, South Australia; (b) spalling of joints in sandstone, Utah; (c) tafoni formation through dissolution of grain-cementing agents in sandstone, Arizona; (d) spalling of joints opened by dirt cracking and calcrete wedging, Utah; (e) lithobiont-related crumbly disintegration of sandstone, Utah; (f) enhanced granular disintegration associated with joints that align with bedding planes in sandstone, Arizona; and (g) salt precipitation enhancing flaking of sandstone, Wyoming.

Microclimatic control and mineral assemblage permit communities of various epilithic lichens (Figure 2e) and micro-organisms to inhabit the area between the surface and weathering front of the rock (Viles 1995). The acids generated by bacteria include citric, oxalic, nitric, sulfuric, and others. These acids accelerate dissolution rates of minerals. Where these micro-organisms live within the substrate (whether on the surface or in rock fractures, tunnels, or pores) may impact the resultant decay. For example, ivy overhanging historic buildings can cause deterioration through exploiting fractures (root wedging), but may also moderate the microclimate of the wall reducing thermal stresses. Lichens also moderate the thermal stresses on blocks by storing moisture in their thallus and protecting the surface from temperature changes. Contrasting with these instances of bioprotection, chemical decay rates on olivine were shown to be greater underneath lichens due the combined effects of
higher moisture retention and the secretion of organic acids (Brady et al. 1999).

Figure 3 illustrates the complexity of decay processes that can result in the flaking of a sandstone surface. First, a joint fracture opens slightly, allowing water movement and accumulation of silica glaze along the joint walls. Second, the overlying block erodes the joint face and exposes it to the accumulation of rock varnish and iron film rock coatings. Third, the silica, iron, and manganese in these coatings dissolve and remobilize into the underlying sandstone. This case hardens the outer shell of the sandstone, but it also inhibits water from flowing out of the rock; the case hardening thus acts as a “dam” that allows capillary accumulate underneath the case hardening. Eventually, enough decay takes place underneath the case hardening to reach the point where the surface flakes away.

Case study 2: limestone in different environments

Limestone dissolution typically proceeds along the lines of the chemical reaction: \( \text{CaCO}_3 + \text{CO}_2 + \text{H}_2\text{O} \rightarrow \text{Ca}^{2+} + 2\text{HCO}_3^- \), leading to the basic karst landforms of sinkholes, caves, and karren (White 1990) that occur in a wide variety of terrestrial environments. Consider the small-sized features such as flutes (Figure 4a), runnels (Figures 4c and 4d), slabs called clints separated by deep fissures called grike (Figure 4b). Karren occurs on bare surfaces in virtually all climatic settings. Substantial differences, however, do occur in the larger karst landforms found in drylands and the wet tropics. Stone forests (Figure 4d) and tower karst (Figure 4e) are forms that develop in the wet tropics, even if climatic changes can sometimes shift them into other environments. In contrast,
Figure 4  Limestone karst dissolution landforms in different environmental settings: (a) flutes in semiarid Trans-Pecos Texas; (b) clints and grikes in semiarid northern Israel; (c) large flute associated with rare fluvial discharge in arid drainage basin, eastern California; (d) stone forest in China; (e) tower karst in China; (f) cuesta face, northern Arizona; (g) anticline, Iran.
Arid and semiarid regions tend to have only minimal development of relief associated with dissolution (e.g., deep sinkholes, deep valleys between towers, and forest pinnacles). Arid and semiarid limestone tends to stand out as higher relief relatively resistant to erosion, such as the cliff-forming Kaibab limestone of Arizona (Figure 4f) and anticlines in Iran (Figure 4g). The reason for the tendency of dryland limestone to be more resistant to dissolution clearly relates to the abundance of moisture and biotic acids that enhance dissolution rates.

Scale cannot be ignored in the study of rock decay. Understanding forms at different scales – from individual grains to the scale of outcrops – is of critical importance in diagnosing the current susceptibility of rock-face features to erosion and therefore near-term stability. The system of the rock art stability index (RASI) (Dorn et al. 2008) illustrates the concurrent decay and erosion across the range of visible scales. For example, in Figures 2g and 3, varnished rock surfaces display scaling (erosion of centimeter-scale clasts) along the fringes of the varnish, while the weathering rind erodes granularly beneath the case-hardened surface. Additionally, detached blocks are subject to undercutting through block orientation in rockfalls (Figure 2d). The idea of RASI rests in analyzing current processes and evidence of past processes that influence the threat of erosion to rocks, allowing field scientists to contribute to rock art conservation.

However, connecting processes at the finest scales to the forms seen in the field is both difficult and rarely considered. Consider form of splintering (Figure 2a). The splintering form resembles the pages of a book that went through a cycle of wetting and drying. At the hand-sample scale (Figure 5a), splintering appears to correspond with the development of aligned micron-scale fractures that carry capillary

Figure 5 The weathering form of splintering of a silicified dolomite, South Australia: (a) at the hand-sample scale; (b) a micron-scale backscattered electron microscope image; (c) a nanoscale transmission electron microscope image.
WEATHERING PROCESSES AND LANDFORMS

Micron-scale quartz silt formation

Nanoscale silica spheroid deposition

Varnish at the surface

Case hardening by Fe film

Weathering rind (weakness)

Figure 6  Visualization of nanoscale decay placed within broader spatial scales of rock decay phenomena. Examples presented from nano to landscape scales are: (a) nanoscale silica spheroids a few tens of nanometers across from silica glaze in Tibet (high-resolution transmission electron microscopy (HRTEM) image); (b) micron-scale silt formation from quartz weathering in Arizona (back-scattered electron (BSE) image); millimeter- to centimeter-scale rock coatings and weathering rinds illustrated from (c) Wyoming (BSE image) and (d) Death Valley (case hardened rock shelter); meter-scale forms of (e) a mushroom rock, Arizona, and (f) limestone karst stone forest, Kunming, China; and kilometer-scale landscapes of (g) a salt-encrusted marine terrace, Peru, and (h) varnish-coated alluvial fan, western China. Reproduced courtesy of NASA.
water. Then, at the micron scale (Figure 5b) the fractures transporting capillary water align with nanoscale (Figure 5c) fractures. When these fractures do not align all the way down to the nanoscale, the splintering form does not occur (Dorn et al. 2013).

Landforms generated through rock decay processes are not restricted to any particular scale (Figure 6), but the scale at which a process operates is very important. The new frontier in rock decay studies rests at the nanoscale, where research has been slow to link across scales (Dorn et al. 2013). Nanoscale formation of rock coatings, such as silica glaze (Figure 6a), influences weathering rind and case hardening formation at the micron scale (Figure 6c). At micron scales, for example, weathering processes may dissolve (Figure 6f) and weaken the boundaries between mineral grains (Figure 6b). The cumulative effect of these minute processes may lead to patterns of granular disintegration on the stone (Figures 6d and 2e), the coating of slopes with salt (Figure 6g), and the production of materials that generate alluvial fans (Figure 6h). The environment, be it the microclimate under a boulder, the soil accumulation within a rock fracture, landscape geochemistry, or broad-area precipitation patterns, sets the bounds of rock decay and erosive interaction for the landform.

The ever-changing balance between rock decay processes and erosion generates the great variety of landscapes seen on Earth’s surface. The forms seen in bare-rock landscapes reflect most closely rock decay, since erosion rates far exceed decay rates in these settings. Forms seen in the field result when decay proceeds far enough to result in detachment. Thus, in some settings, geological processes can control mineral compositions and textures that in turn help define chemical decay rates. In other settings, tectonic histories and material properties govern joint density and orientations, thus providing avenues for solution processes between joint walls and planes of future mass wasting failure. Organisms can play both protective and accelerative roles. Rock decay across scales ultimately sculpts landforms by generating points, planes, or zones of relative physical strength or weakness that are then exploited by agents of detachment and then transport.

Web-mapping services

Michael P. Peterson
University of Nebraska at Omaha, USA

Cartography has evolved through the years to incorporate new tools and methods of data acquisition, map analysis, and presentation. The discipline can trace its origins to Greek scholars over 2000 years ago, with a history marked by a number of intellectual accomplishments that have furthered understanding of the world and its representation. Beginning in the early 1960s, the computer started to be used to make maps. Initially, paper maps were “digitized,” literally converted to numbers. Eventually, these digitized maps would be distributed between computers through the Internet. Along the way, new and related areas of study developed including remote sensing – the use and analysis of imagery taken by aircraft and satellites – and geographic information systems (GIS) – the input, manipulation, and analysis of geographic information by computer. Today, cartography and these new areas of study are put under the umbrella of “geospatial technology.” A central activity in all areas of geospatial technology is the making of maps (Peterson 2014).

The Internet is a global computer network linking computers in different continents that are thousands of miles apart. Its development was revolutionary for maps, similar to the invention of printing. Maps were not duplicated in mass until the mid-1400s. Before this, they were reproduced by hand and very few existed. As a result of printing, more people had access to maps and, thus, had a better understanding of the world. Like printing, the Internet increased the availability of maps, but the Internet went further and combined the printing and distribution in a single step. One of the major benefits of this new age of mapping is that maps could be made available to the user in a fraction of the time required to distribute maps on paper.

Interaction through the Internet is made possible through an interface that allows the user’s client computer to interact with a program running on a server. Access to the resources of a remote computer is the basis of the Internet. Every time that we use the Internet, we are interacting with a distant computer – increasingly located in massive data centers.

Introduced in 1991, the World Wide Web (WWW) is a particular protocol of the Internet conceived at the European Particle Physics Laboratory (CERN) located near Geneva, Switzerland. It was intended to assist researchers in high-energy physics by linking related documents. The developers wanted to create a seamless network in which textual information on high-energy physics from any source could be accessed in a simple and consistent way. Sir Tim Berners-Lee, director of the World Wide Web Consortium (W3C), played a major role in designing the system.

As originally conceived and implemented by CERN, the World Wide Web consisted only of text. Two university students in the United States, Mark Andreesen and Eric Bina, working at a supercomputer laboratory at the University of Illinois at Urbana-Champaign, recognized that the web would have limited acceptance as a text-only system. They added the display of graphics, sound, and video with the Mosaic web browser introduced in March 1993.
WEB-MAPPING SERVICES

As conceived by Andreesen and Bina, the WWW fostered a series of developments for the delivery of maps. Web mapping services is sometimes narrowly defined as a set of protocols that assist in the delivery of maps and the underlying information. A somewhat broader interpretation is taken here to include any web-based technology that assists with the generalization, manipulation, analysis, and representation of a map. It is perhaps best to begin with a chronological development of these services.

Development of web mapping

The online map is a product of the web. Although maps were distributed through the Internet before the introduction of the graphical World Wide Web, it was the graphical web that made it possible for large numbers of people to access both static and interactive maps. By the end of the 1990s, it was estimated that 200 million user-defined maps were distributed within webpages on a daily basis.

Client/server

The client/server architecture is the major distributed computing model (Figure 1). In this system, clients request services that are provided by servers. The server may be viewed as a dominant computer that is connected to many client computers with fewer resources. In this system, the user’s client computer communicates with a server through a specific protocol. Most often, the server resides in a data center that houses a cluster of computers that respond to user requests. A client computer requests these services using the Internet as the medium of communication.

The distributed model provides an open and flexible environment in which a wide variety of client applications can be distributed and used by large numbers of computing devices, including mobile phones. Client/server computing has already reshaped the way computers are used and is affecting nearly every facet of our lives. Some predict that all computer applications in the future will be “in the cloud” on a system of distributed computers. An example is Google’s G Docs, a series of online applications for the creation and distribution of word processing, spreadsheet, and presentation documents. Amazon Web Services (AWS) provides a platform for bringing applications to the cloud.

Google’s Chrome operating system is an example of a cloud-based appliance. Installed on a basic, sub-$200 computer with a small amount of memory and disk space, the computer is merely an interface to the resources of the cloud. The user accesses programs in the cloud and the files that are created are stored there as well. The Chrome operating system, distinct from the Chrome browser, is an example of a client with very few resources. Most people access the cloud with a Windows or Macintosh computer that has much more computing resources than needed.

Figure 1 The client/server model. The client/server architecture is an example of a centralized architecture where the whole network depends on a central server to provide services.
WEB-MAPPING SERVICES

Servers reside in data centers that contain a large number of computers and are housed in specialized buildings, usually without windows. They require uninterrupted power and diesel generators provide emergency backup in case of a power failure. A lead–acid battery backup system is also in place to temporarily power the computers. It has been reported that, in the case of a natural disaster such as an earthquake, Google data centers in California have contingencies to acquire diesel fuel by helicopter to continue operations. It would be difficult for any individual to implement these types of backup contingencies to maintain the operation of a server.

The main program for serving web content is Apache. Begun in 1995 as a series of “patches” (thus, the name “Apache”) to a hypertext transfer protocol (HTTP) server running at the National Center for Supercomputer Applications (NCSA) at the University of Illinois. Apache is now open source software maintained by the Apache Software Foundation (http://www.apache.org/). The program is available on multiple platforms, including Windows, Unix/Linux, and Mac OS X. In 2013, approximately 60% of all web servers were using the Apache web server, with most of the remaining 40% using a combination of commercial software from Microsoft and Google, and Nginx – the latter also a free and open source project (Netcraft 2013). The Microsoft server has made major gains since 2013 with the growth of Microsoft Azure, a cloud-based server environment. In cloud computing, multiple servers can be implemented on a single computer.

Interactive online maps

On-demand web maps began appearing soon after the introduction of the Mosaic browser in 1993. An early online mapping system was developed by Steve Putz (1994) at the Xerox Palo Alto Research Center (PARC). His Map Viewer program allowed the user’s client computer to create maps from a geographic database. Each interaction with Map Viewer would request a map from a server that was zoomed in on a specific point (Figure 2). The server would respond with a new map that was embedded into a new webpage.

A new era in online mapping was introduced with MapQuest’s user-defined street maps in 1996. Using a standard client/server technology, the user’s client computer would make a request for a specific map, then MapQuest servers would respond to the request by drawing the map from a database of points and lines, converting this to a grid-based raster format and delivering the resultant map within a webpage. Each request for an additional map, at a different zoom level or centered at another point, would

**Figure 2** Xerox Parc Map Viewer was an early example of an interactive web map. The user interacted with a program on a server through the common gateway interface (CGI). The user was able to generate a map of the world at different scales. The resultant map was converted into a graphic file and inserted into a webpage.
WEB-MAPPING SERVICES

Figure 3 A 2001 version of the MapQuest webpage. Dominated by advertisements, the map constitutes only a small part of the webpage. The maps of southern Florida are at three different zoom levels. A total of ten zoom levels were available. Reproduced from MapQuest © 2001 MapQuest – Portions.

result in another server request that would produce another map that would be embedded in another webpage that would update the page on the user’s computer (Figure 3).

Although the entire MapQuest mapping process was fairly fast, there was always a wait for the server to respond. Any zoom or pan required waiting for the server to produce another map that was inserted into another webpage. Response times would also be subject to Internet traffic so a request for a map might take considerably longer when traffic was heavy. Maps would be produced very quickly during the overnight hours but the service would be slow at peak times during the day. This variability in response times was found to be more annoying by users than the generally slow response.

MapQuest quickly became the largest publisher of maps on the Internet. By 1999, MapQuest was responding to 20 million daily map requests (Peterson 2001). Developed by a map publishing company, GeoSystems, MapQuest was a major business success and was soon purchased by the Internet giant AOL in 1999 for $1.1 billion dollars (Rohde 2000, 64). MapQuest held the distinction of having the greatest market share among mapping sites until 2009, when it was replaced by Google Maps.
MapQuest competed effectively against corresponding mapping services from Yahoo!, and Microsoft (Bing). The phrase “I’ll MapQuest it” was used to describe how to find a location, even if using a site other than MapQuest.

**Tile-based mapping**

Google Maps, introduced in 2005, revolutionized the online mapping landscape. Known for its search engine, Google effectively added a map-based search through Google Maps. By not including advertisements around the map, like MapQuest, they left more room for the map on the computer screen. More importantly, from a map user’s perspective, Google Maps streamlined how maps were interacted with.

The delivery of a Google map is based on two major ideas: (i) asynchronous JavaScript and XML (Ajax); and (ii) image tiling. Ajax was the culmination of many years of effort to re-shape how clients communicate with the server. Essentially, AJAX maintains a continuous connection with the server – exchanging small messages in the background even when the user has not made a specific request. This leads to faster server responses. AJAX might be thought of as an application that works in the background of a browser page to anticipate what the user might want, ready to communicate with the server to respond to a request. Operations in Google Maps that are particularly assisted by AJAX include zooming and panning, the most common form of interaction with maps.

Image tiling had been used since the early days of the World Wide Web. In comparison to text, images require more storage and, therefore, take longer to download. A solution is to divide the image into smaller segments, or tiles, and send each tile individually through the Internet. These smaller files often travel faster because each can take a different route to the destination computer (Sample and Ioup 2010). On the receiving end, the tiles are reassembled in their proper location on the webpage. With a moderately fast Internet connection, all of this occurs so quickly that the user rarely notices that the image is actually composed of square pieces. With slower connections, the individual tiles are clearly evident. In a dramatic transformation, all of the other major online map providers – MapQuest, Yahoo, Microsoft (Bing) – converted from the standard client/server interface – popularized by MapQuest – to the AJAX, tile-based method of map delivery within a short time after Google Maps was introduced in 2005. The projection used by all of these online map providers is a slight variation of the Mercator projection, termed the Web Mercator.

Many tiles are needed to implement tile-based mapping. Each is 256 × 256 pixels and requires about 15 KB to store in the PNG format. Table 1 shows the number of tiles that are used for 20 levels of detail (LOD), or zoom levels, and the associated storage requirements and storage costs. With 20 LODs, approximately one trillion tiles are needed for the world. At an average of 15 KB per tile, the total amount of memory required is 20 petabytes, or 20,480 terabytes. No single computer currently has this much storage capacity.

Storing tiles is expensive. If the cost of data storage is estimated at about US $100 per terabyte, storing the entire one trillion tiles on disk drives would be about US $2 million (Table 1). In order to achieve faster response times, there is strong indication that data centers use faster random-access memory (RAM) to cache the map tiles. At $30 per gigabyte, storing all of these tiles in RAM would cost more than US $629 million. Data centers likely use a combination of disk drives and RAM. This would result in a cost of map storage at each data center somewhere between approximately US $2 million and US $629 million. A still faster storage option...

</table>
would be to use a graphical processing unit (GPU). These devices are specifically designed to store and manipulate images and transfer image data much faster than computer memory. Map storage on GPUs would be at least twice as expensive as on RAM, or nearly US $1.3 billion for the whole world.

These data storage requirements and costs are only for the map. The satellite view, with tiles in the JPEG format, requires approximately the same amount of storage space. Google also stores multiple versions of the satellite image from different dates. Each Google data center would likely have a copy of the map and satellite images, and any other map that is provided – such as the terrain view (offered at only 15 levels of detail). Combining all of these data storage costs provides some indication of the importance placed on maps by Google and other companies.

In 2010, Google switched from raster to vector tiles for some types of map delivery. One impetus for the change was the increased use of maps on mobile devices. Limited by a monthly data plan, mobile users noticed that any application involving maps quickly consumed this monthly allocation. A less data-intensive method was needed to distribute maps to these devices. While the satellite and terrain views are still sent as raster tiles, Google adopted a vector approach for its map layer. Rather than sending tiles as pre-rendered PNG files, the map is sent as a series of lines and shapes. While the primary benefit of this vector approach is a reduction in the amount of data to create a map, it also facilitated changing the style of the map by specifying different colors for features like roads.

Map mash-ups

Probably the most important development in mapping during the first decade of the twenty-first century was the introduction of online mapping tools in the form of the application programmer interface (API). APIs are specialized libraries of computer code that are accessible through the Internet. Soon after the introduction of Google Maps, the company made a library of routines available that would allow for the creation of custom online maps. Users could map their own points, lines, and areas on a Google Map and make these maps freely available to others. The data used for mapping often came from other websites, thus the term “mash-up” to indicate the melding of data and mapping tools to create new presentations of information.

An early application was the mapping of apartment listings from Craigslist, a free service for selling goods and services. New businesses were born simply by combining free data from one site and free mapping software in the form of a mapping API and mashing them together. Websites like MapsKrieg and HousingMaps are examples of this type of combination (search: MapKrieg, HousingMaps). Mash-ups have made it possible to map data that had never been mapped before.

Map mash-ups have had a major influence on how spatial information is presented. One particular advantage of using an API from a major online mapping site is that the maps represent a standard and immediately recognizable representation of the world. Overlaying features on top of these maps provides a familiar and comfortable frame of reference for the map user. This has created a different way of making thematic maps. In the past, thematic maps limited the display of reference information such as cities and transportation networks – partly for simplicity and to emphasize the distribution being mapped. In doing so, the cartographer may have left out critical information to help the user understand the locational aspects of the spatial pattern. It should be noted, however, that adding locational information may also detract from the spatial pattern that is trying to be communicated.
WEB-MAPPING SERVICES

Google Maps API

Introduced soon after Google Maps in 2005, the Google Maps API is by far the most commonly used of any currently available API, whether for mapping or otherwise. The API consists of a series of functions that control the appearance of the map, including its scale and location, and any added information in the form of points, lines or areas and associated descriptions.

The use of the Google Maps API is essentially free, provided the site does not charge for access. Google places a limitation on the number of maps that can be served. A site cannot generate more than 25 000 map loads a day for 90 consecutive days. A map load is one map displayed with the Google Maps API. Once loaded, the degree to which a user interacts with a map has no impact on the map load number.

It would be extremely difficult for the average user of the Google Maps API to reach 25 000 map loads. Even if a site were to go “viral” with a topic that generates considerable interest, it would need to sustain 25 000 map loads per day for 90 consecutive days before the limit would be reached. Usage limits can be placed on a site so that it does not exceed that number. If the site consistently exceeds 25 000 maps a day, Google charges US $0.50 for each 1000 map views beyond this limit. Serving 100 000 Google maps a day would cost $37.50 (75 000/1000*0.5) a month.

Specialized Google Maps API web services have additional usage limits, including:

- directions – provides directions in text form – limited to 2500 a day;
- distance matrix – returns travel distance and time – limited to 100 elements per query and 2500 a day;
- elevation – elevation at points – limited to 2500 requests per day where each request returns up to 512 elevations for a total of 1 280 000;
- geocoding – converts a street address to latitude and longitude – limited to 2500 a day;
- places – returns business establishments and other points of interest around a point – requires an API key and limited to 1000 requests a day.

A Google Maps API key is a numeric code that registers your site with Google. It is not needed for normal applications and would only be required if the usage limits are exceeded, or the Places web service is used. A $10 000 a year pay service, Google Maps API for Business, provides an unlimited number of map downloads and no limits on these specialized services. Over 99% of Google Map API users pay nothing for the use of the service.

The example in Figure 4 shows the JavaScript code and API calls for displaying a simple map that is centered at a specific location. The zoom level, which can range from 0 to 21, is set to 15 under “myOptions.” The center is defined with a specific latitude and longitude value, and the ROADMAP option is selected to define the map style. All of the API calls are made in the “initialize” function. This function is called with “onload” within the body of the HTML file.

There are four basic types of maps that can be displayed:

- MapTypeId.ROADMAP displays the default road map view;
- MapTypeId.SATELLITE displays Google Earth satellite images;
- MapTypeId.HYBRID displays a mixture of normal and satellite views;
- MapTypeId.TERRAIN displays a physical map based on terrain information.

The example in Figure 5 places the basic Google upside-down teardrop marker at the center of the map. The initial zoom level is 15.
The event.addlistener option sets the zoom level to 17 when the marker is clicked. The title text, “Hello World,” is displayed when the mouse is hovered over the marker.

**Overlays**

Overlays are map layers that are placed over a map, satellite, terrain, or digital globe view to provide some type of additional information.
Overlays can be done in two different ways. The first is as a series of points or flags that are placed on top of the map. Google, for example, uses the upside-down teardrop as a standard point symbol to indicate a location.

The second type of overlay is a series of tiles that have the same size and dimension as the base tiles, but these overlay tiles are made transparent so that you can see the tile underneath. Whatever part of the tile is opaque becomes superimposed on the underlying map (Figure 6). Overlaying transparent tiles in this way is faster than overlaying individual points or lines. Most views are transparent tile overlays with a particular theme such as traffic, webcams, or photos.

Another major advantage of vector tiles is that they allow text to be separated from the underlying map as its own overlay. Previously,
the cities in China and Japan were written with local characters. It was not possible to change the text to a western script because the text was “burned-into” each raster tile. By separating the text, it is now possible to switch between western and local scripts (Figure 7).

Online GIS

The growth of geographic information systems (GIS) has been phenomenal since the 1980s. These systems essentially combine a database with query and mapping capabilities. By the late 1990s, web interfaces began to be developed for these systems. Online GIS systems initially only implemented a subset of the overall GIS system functionality.

In online GIS, the user is presented with a webpage that allows a query to be made of a database. The resultant map is then displayed within a webpage and further controls are provided to perform another query. Response times are typically slower than with online mapping systems because the map is usually drawn in the background and then converted to a raster image using the older client/server approach.

The user interface in online GIS is generally not very intuitive and it can sometimes take considerable effort to navigate. Panning and zooming are not as cleanly implemented and this, among other things, makes the experience less than satisfactory. Although often frustrated, a motivated user is usually willing to accept a poor user interface and slow response times in order to get a specific piece of information.

Free and open source software (FOSS) has also become available for online GIS. The most commonly used is MapServer, originally developed at the University of Minnesota. It has been implemented around the world for a variety of online mapping applications. Continual development of MapServer is accomplished through a loose association between developers from various parts of the world.

As with other online GIS implementations, including commercial versions, the person who installs MapServer creates the specific user interface. Many poor decisions that detract from the usability of the program are made during this process. In addition, like most older client/server forms of online map delivery, MapServer sites
tend to be slow. While it is possible to implement a tile-based, AJAX approach, a large number of MapServer sites still use the older client/server method. With minimal server resources, these sites will likely never achieve the map display speed or general user-satisfaction of commercial online mapping systems that have larger data centers, more resources, and are based on the tile-based method of map distribution.

Open standards and open source

A considerable amount of geographic information has been placed into GIS databases since these systems came into widespread use in the 1980s. In order for this information to be useful to more people, standard methods were needed for both “pulling” and disseminating the information from GIS databases. In 1999, the Open Geospatial Consortium (OGC) defined a set of standards for distributing geographic data.

The OGC is an international consortium of more than 420 companies, government agencies, research organizations, and universities established to create a publicly available geospatial interface and format standards. OGC standards provide developers with a way to make geospatial information and services accessible and useful. The Open Source Geospatial Foundation, or OSGeo, is a not-for-profit organization whose mission is to support, promote, and endorse the collaborative development of open source geospatial technologies and data. The foundation provides organizational, legal, and financial support to the broader open source geospatial community. It also serves as an independent legal entity to which community members can contribute code, funding, and other resources. The code and other contributions are maintained for public benefit. OSGeo also serves as an outreach and advocacy organization for the open source geospatial community, and provides a common forum and shared infrastructure for
improving cross-project collaboration. The foundation’s projects are freely available and usable under an open source license (OGC 2014).

The development of standards is a central activity of the OGC. Standards are intended for a common system of communication. The OGC defines open standards in the following way:

- freely and publicly available – they are available free of charge and unencumbered by patents and other intellectual property;
- nondiscriminatory – they are available to anyone, any organization, anytime, anywhere with no restrictions;
- no license fees – there are no charges at any time for their use;
- vendor neutral – they are vendor neutral in terms of their content and implementation concept and do not favor any vendor over another;
- data neutral – the standards are independent of any data storage model or format;
- defined, documented, and approved by a formal, member driven consensus process – the consensus group remains in charge of changes and no single entity controls the standard.

The OGC’s open standards specify interfaces and encodings that enable interoperability between geoprocessing systems from different developers, whether proprietary, application developers or active in open source projects (OGC 2014).

Open standards contrast with open source in that the latter involves some type of code. As defined by opensource.org, the distribution terms of open source software must comply with certain criteria.

- Free redistribution. The license shall not restrict any party from selling or giving away the software as a component of an aggregate software distribution containing programs from several different sources. The license shall not require a royalty or other fee for such sale.
- Source code. The program must include source code, and must allow distribution in source code as well as compiled form. Where some form of a product is not distributed with source code, there must be a well publicized means of obtaining the source code for no more than a reasonable reproduction cost preferably, downloading via the Internet without charge. The source code must be the preferred form in which a programmer would modify the program. Deliberately obfuscated source code is not allowed. Intermediate forms such as the output of a preprocessor or translator are not allowed.
- Derived works. The license must allow modifications and derived works, and must allow them to be distributed under the same terms as the license of the original software.
- Integrity of the author’s source code. The license may restrict source code from being distributed in modified form only if the license allows the distribution of “patch files” with the source code for the purpose of modifying the program at build time. The license must explicitly permit distribution of software built from modified source code. The license may require derived works to carry a different name or version number from the original software.
- No discrimination against persons or groups. The license must not discriminate against any person or group of persons.
- No discrimination against fields of endeavor. The license must not restrict anyone from making use of the program in a specific field of endeavor. For example, it may not restrict the program from being used in a business, or from being used for genetic research.
- Distribution of license. The rights attached to the program must apply to all to whom the
program is redistributed without the need for execution of an additional license by those parties.

- License must not be specific to a product. The rights attached to the program must not depend on the program’s being part of a particular software distribution. If the program is extracted from that distribution and used or distributed within the terms of the program’s license, all parties to whom the program is redistributed should have the same rights as those that are granted in conjunction with the original software distribution.

- License must not restrict other software. The license must not place restrictions on other software that is distributed along with the licensed software. For example, the license must not insist that all other programs distributed on the same medium must be open source software.

- License must be technology-neutral. No provision of the license may be predicated on any individual technology or style of interface.

Web services

The basic purpose of the OGC standards was to both facilitate the distribution of data and make layers of information more accessible. A series of standardized services were defined for supplying geodata universally across any platform. With standardization, map data services are able to interact with and display maps through an Internet-based interface.

Prior to standards being established, extracting information from a GIS database required interacting with a variety of large and complicated databases. The OGC streamlined this process by placing the burden for the extraction of data on the server. As defined by OGC, the web mapping service consists of two functions: (i) GetCapabilities that defines the capabilities of a server such as defining the supported file formats, the available map layers, and the method of display; and (ii) GetMap that tells the database what is needed. The database reads a request and creates the map-based data from the requirements that have been defined by GetCapabilities. The requested data package is then sent to the web mapping service.

In addition to the two primary functions just discussed, most web mapping services support a handful of other functions as well. For example, GetFeatureInfo sends specific information about locations on the map, such as the name of a road or the altitude at a location. Another function, GetLegendGraphic, provides information about symbols used on the map.

The OGC standard has led to the development of a variety of services, including:

- Web map service (WMS) – georeferenced map images typically in the form of raster tiles (PNG, GIF, or JPG). The tiles can also be delivered in a vector format. Requests are made using a standard web URL address.

- Web coverage service (WCS) – a geographical area that can be overlaid upon a map but cannot be edited or analyzed. WCS is used to transfer coverages that consist of objects such as data points, pixels, or paths defined with vectors.

- Web feature service (WFS) – allows requests for geographical features, essentially providing the information behind the map. WFS allows features to be queried, updated, created, or deleted by the client. This data is usually provided in an XML format like GML.

GeoServer

As the reference implementation of the web feature service standard, GeoServer also implements
the web map service, web coverage service, and web processing service specifications using open standards set forth by the OGC. Written in Java, GeoServer allows users to share, process, and edit geospatial data and allows for great flexibility in map creation and data sharing. Built on Geotools, an open source Java GIS toolkit, GeoServer has become standard method of connecting existing information to web-based maps.

The main advantage of GeoServer is that it permits the actual sharing and editing of the data that is used to generate the maps. Others can incorporate this data into their applications, freeing data and permitting greater transparency. GeoServer can display data on any of the popular mapping applications such as Google Maps, Google Earth, Yahoo Maps, and Microsoft Virtual Earth. In addition, GeoServer can connect with traditional GIS architectures such as Esri ArcGIS.

GeoServer reads geographic data in a variety of database and nondatabase formats, including:

- **PostGIS** – an open source software program that adds support for geographic objects to the PostgreSQL object-relational database.
- **Oracle Spatial** – a separately licensed option component of the commercial Oracle database. The spatial features in Oracle Spatial manages geographic and location-data in a native type within an Oracle database.
- **ArcSDE** (spatial database engine) – is a server–software subsystem that is marketed by Esri and enables the usage of relational database management systems for spatial data. The spatial data may then be used as part of a geodatabase, a database that is optimized to store and query data that represents objects defined in a geometric space.
- **DB2** – a family of database server products developed by IBM. These products all support the relational model but in recent years some products have been extended to support object-relational features and nonrelational structures, in particular XML.
- **MySQL** – is the world’s most widely used open source relational database management system (RDBMS) for the administration of websites.
- **Shapefile** – a popular geospatial vector data format for geographic information system software developed and administered by Esri as a mostly open specification for data interoperability among GIS software products.
- **GeoTIFF** – a public domain metadata standard that allows georeferencing information to be embedded within a TIFF file, a computer file format for storing raster graphics images.
- **GTOPO30** – is a digital elevation model for the world, developed by the United States Geological Survey (USGS). It has a 30-arc second resolution of approximately 1 km/pixel, and is split into 33 tiles stored in the USGS DEM file format.
- **ECW** – (enhanced compression wavelet) is a proprietary wavelet compression image format optimized for aerial and satellite imagery.
- **MrSID** – a multiresolution seamless image database developed and patented by Lizard Tech for encoding of georeferenced raster graphics, such as orthophotos.
- **JPEG2000** – an image compression standard and coding system created by the Joint Photographic Experts Group committee in 2000 with the intention of superseding the original discrete cosine transform-based JPEG standard (created in 1992) with a newly designed and more efficient, wavelet-based method.

### Databases

Everything on the Internet relies on a database. Defined as an organized body of information that is arranged for ease and speed of access, databases
WEB-MAPPING SERVICES

are simply the way information is stored and retrieved. In most cases, before anything is put onto a webpage, some type of information for that page has been extracted from a relational database.

Although many different ways of storing data have been proposed, the two most common in general usage are the flat file and the relational database. Spreadsheet programs like Microsoft Excel™ are based on the flat file concept. All records in a flat file are stored in the same number of fields in a table format. A flat file is very good for summing columns of data, or sorting data with a certain theme, but complex queries are difficult to perform. In contrast, a relational database may be viewed as multiple tables of data that are tied together by a key field or fields. The relational database results in less duplication of data and, more importantly, the ability to easily query the data.

Relational databases are the most common and the basis of almost all information presented through the web. All relational databases use SQL, often referred to as structured query language, a computer language designed to input, manipulate, query, and extract data. Development of relational databases began in 1970 by IBM, eventually resulting in a product called SEQUEL. The associated language to manipulate the data became known as SQL and was standardized by the American National Standards Institute (ANSI) in 1986. The latest standard defines a language called XQuery to query data in XML documents. SQL is essentially a set of statements that result in certain actions on data stored in relational tables. SQL is what makes a relational database work.

New features have been added to SQL to incorporate object-oriented functionality and extensions to handle spatial data. In 1997, the OGC published the OpenGIS® Simple Features Specifications For SQL, a document that proposed several conceptual ways for extending SQL to support spatial data. With version 5.0.16, MySQL supports a subset of spatial extensions to enable the generation, storage, and analysis of geographic features.

Spatial extensions refer to a SQL language that has been augmented with a set of commands that code geometry types such as points, lines, and areas. The specification describes a set of SQL geometry types, as well as functions on those types, to create and analyze geometry values. The initial spatial extensions implemented by MySQL were only a subset of those proposed by OGC. More recent versions of MySQL incorporate more of these spatial extensions.

A geographic feature in SQL is anything in the world that can be specified by location. The following are all examples of geographic features:

- an entity, such as a mountain, a pond, a city;
- a space, for example, a town district or the tropics;
- a definable location, such as a crossroads where two streets intersect;
- a location associated with a spatial reference system, which describes the coordinate space in which the object is defined.

The GEOMETRY spatial extension supports any type of point, line or area feature. Other single-value types include POINT, LINESTRING, and POLYGON that restrict their values to a particular geometry type. Still other data types hold collections of values, including MULTIPOLYGON, MULTILINESTRING, MULTIPOLYGON, and GEOMETRYCOLLECTION. GEOMETRYCOLLECTION can store a collection of objects of any type. The remaining collection types (MULTIPOINT, MULTILINESTRING, MULTIPOLYGON) restrict collection members to those having a particular geometry type.
With the spatial extension, latitude and longitude are no longer input as separate fields but as a single entity.

Database programs

The most commonly used relational database software for webpages is MySQL. Pronounced “my sequel” or “my ess cue el,” MySQL is an open source relational database management system (RDBMS). It is used for all types of database applications including e-commerce, airline reservation systems, and online social networks. MySQL is known for its performance, reliability, and ease of use. It can handle large databases with billions of entries. MySQL continues to be adopted by organizations as they discover that it can handle their database needs at a fraction of the cost of commercial software. Any http address that ends with PHP has likely consulted a MySQL database before constructing the webpage.

MySQL is free and open source software (FOSS). FOSS presents a major challenge for commercial software companies because it makes similar software available for free that companies sell for a great amount of money. While no one company is responsible for open source software, there may be many thousands of installations and millions of users. In considering the long-term viability of any software, it is always best to stay with those that have the greatest number of users, whether commercial or open source.

While still free, MySQL is technically no longer open source because it is now owned and supported by Oracle, the largest database company in the world. While the company has stated that it will keep MySQL open and free, many open source developers are switching to another database package called PostgreSQL (PostgreSQL Global Development Group 2010). In many ways, the two databases are very similar – both being based on SQL. At one time, MySQL was considered to be faster but with fewer features while PostgreSQL was seen as slower but with more features. With improvements in both databases, these characterizations are no longer accurate. MySQL has added functions, such as spatial queries, and PostgreSQL has dramatically improved its speed. PostgreSQL with the PostGIS extension is more SQL compliant while MySQL has greater support by Internet service providers. The most important consideration for many is that while PostgreSQL has many sponsors and developers, it is not controlled by any one company – especially one as influential as Oracle.

PostGIS adds support for geographic objects to PostgreSQL (PostGIS 2011). In effect, PostGIS “spatially enables” the PostgreSQL server, allowing it to be used as a backend spatial database for geographic information systems (GIS). PostGIS follows the OpenGIS Simple Features Specification for SQL and has been certified as compliant with the “Types and Functions” profile (PostGIS 2011). As a more specialized service, PostGIS is not commonly offered by web hosting sites, especially those offering minimal services at no cost.

Preprocessors

PHP, or PHP Hypertext Preprocessor, is a server-side scripting language that works with a database. It constructs dynamic webpages on the fly by combining html with information derived from a database. It is the most popular language to create websites competing against other commercial and open source languages like ASP.NET, Java, ColdFusion, Perl, Ruby, and Python. As of 2014, 82% of all web servers use PHP as a server-side programming language (W3Techs 2013).

As an interpreted language, PHP does need to be compiled into executable code. PHP code cannot execute locally on a client computer. This means
WEB-MAPPING SERVICES

that PHP code is not viewable by choosing the source code option for a webpage. The webpage has itself been written by PHP and what is seen by viewing the source code is only the output. Because of this, it is less transparent than JavaScript code. The advantage for programmers is that they can hide their code on the server so nobody else can see it. In that sense, it becomes like any compiled computer language, like C++.

While PHP is the most popular preprocessor, its use varies considerably in different parts of the world. Over 90% of all server-side applications in Europe use PHP but that rate is only 40% in China. Microsoft servers are much more common in China, prompting greater use of Microsoft's ASP.NET (W3Techs 2013).

Web services and the cloud

The cloud will have major influence on the future development of web mapping services. Wikipedia defines cloud computing broadly as: “Cloud computing is web-based processing, whereby shared resources, software, and information are provided to computers and other devices (such as smartphones) on demand over the Internet.” As there was confusion over the terms, the National Institute of Standards and Technology (NIST) was asked to develop a common definition for cloud computing:

Cloud computing is a model for enabling convenient, on-demand network access to a shared pool of configurable computing resources (e.g., networks, servers, storage, applications, and services) that can be rapidly provisioned and released with minimal management effort or service provider interaction. This cloud model promotes availability and is composed of five essential characteristics.

1 On-demand self-service. A consumer can unilaterally provision computing capabilities without requiring human interaction with each service’s provider.
2 Broad network access. Capabilities are available over the network and accessed through standard mechanisms that promote use by heterogeneous thin or thick client platforms (e.g., mobile phones, laptops, and PDAs).
3 Resource pooling. Computing resources are pooled to serve multiple consumers with resources dynamically assigned and reassigned according to consumer demand. The customer generally has no control or knowledge over the exact location of the provided resources.
4 Rapid elasticity. Capabilities can be rapidly and elastically provisioned.
5 Measured Service. Cloud systems automatically control and optimize resource use by leveraging a metering capability at some level of abstraction appropriate to the type of service.

Key aspects of cloud computing are pooling and elasticity. These two characteristics are especially relevant to web mapping services.

Summary

Web mapping services are continually evolving. The major work since 2007 has been to decrease the amount of map related data transmission to adapt to limitations of mobile devices. Open source offerings have also improved while commercial entities have struggled to innovate and differentiate their offerings to provide added value for the paying customer.

The new technology has fundamentally changed the processing and distribution of maps. It has also changed the way maps are used. Multiscale pannable (MSP) maps are now the norm and will forever dictate how maps are presented and used. Mobile devices are adding
ubiquitous blue dot to show the user’s current position, creating a MOMM (Me on My Map) representation.

Maps are a major part of the Internet. Determining location, and navigating, are firmly tied to the Internet. Most people would now be lost with a paper map. Web mapping services is the basis of our new relationship with spatial information.

Welfare geography

Andrew Kirby
Arizona State University, USA

Welfare economics emerged after World War II with the goal of determining individual and collective utility. Welfare geography began to develop as a related but distinct subfield in the 1970s, with an emphasis upon collective outcomes manifested in, and measured across, spatial units.

The fundamental logic of Anglo-American geography after 1945 was the examination of spatial difference. Embracing physical and social phenomena its concerns were not social outcomes, but rather differentiation and its measurement – the essence of regional geography. With an increased focus on social science research after 1945, however, geographers began to develop normative principles and empirical techniques. Theories of settlement and industrial location, allied with increased computing power, generated a burgeoning field committed to identifying “what and where.”

A fundamental tension existed within what was increasingly labeled as human (rather than regional) geography. Political sophistication, driven by the civil rights movement and the Vietnam War, caused an increasing number of academics to modify the disciplinary focus to “what, where, and so what?” (or “who gets what, where”). Here, then, we find the basic but essential foundation of welfare geography.

The 1970s was a period in which spatial difference was analyzed in varied ways. Social segregation was documented at different spatial scales, ranging from broad analyses, between and within nations, through to the smallest units for which data were available, namely census tracts in cities. In large measure these were data-driven exercises: the empirical analysis was shaped by the computing packages available, the data that had been collected from public sources, and the scales at which the information was tabulated. Scale was neither a concept nor a construction but a taxonomic device defined by those collecting the secondary data. It is worth noting that what was typically identified as the “quantitative revolution” produced a predisposition toward technique at the expense of a preference for fieldwork (which had tended to migrate to physical geography). Bunge’s Detroit Expedition and Institute, which sought to collect primary data on social difference in the incendiary years 1968–1971, was perhaps a unique example.

Around the time that the Vietnam War ended in 1975, there were, then, several disparate strands of research investigating sociospatial difference. Some was focused upon heavy secondary data manipulation, using social and housing statistics for census tracts in cities, known as the factorial ecology approach. The intention of this research was to identify commonalities in social space, which was connected to abstract principles of social area analysis. In contrast were approaches that marked the emergence of the social indicators movement, which looked explicitly at the manner in which spatial units displayed variations in income and ethnicity, and outcomes such as mortality. In addition, there was a growing questioning of the mechanisms that drove such differentiation: an early instance of this was Harvey’s research on redlining and the manner in which financial institutions shaped the housing market and reproduced racial constructs in urban space (Harvey and Chatterjee 1974).
This research began to diverge in dramatically different ways. The work that was increasingly identified as “positivist” by its detractors pursued technical sophistication, and ultimately contributed to an instrumentalist focus on social and spatial outcomes. The more radical approaches—grounded in the extremes of urban politics in the American city—began to move toward a sophisticated understanding of economic inequalities, expressed via Marxian analysis. And a third way also emerged, that ultimately claimed for itself the explicit term “welfare geography.” This research was most closely associated with David M. Smith who, after stints in South Africa and Florida, was long based at Queen Mary College, London.

Smith published an influential paper in Geography, asking “who gets what, where and why?” (Smith 1974). This work connected the empirical interests of those mapping difference to specific mechanisms, including the operation of the market but also, importantly, the activities of the state apparatus. In this early paper, and then in detail in his later work, Smith laid out a series of propositions. These had been summarized in his first book: “As geographers we have a special role—a truly creative and revolutionary one—that of helping to reveal the spatial malfunctionings and injustices, and contributing to the design of a spatial order of society in which people can be really free to fulfill themselves in a secure social setting where the rights of all are respected” (Smith 1973, 121).

Fears of the imminent collapse of the Western economies, marked by inflation and high unemployment, and political dislocation extending to urban terror, emphasized the pressing need for theories of the state, its local components, and the mechanics of state expenditure. Some of this research had explicit spatial components, such as the UK Inner City initiatives that were very influential in the late 1970s and early 1980s. Other research sought correlations between expenditures and social outcomes, but there was a general sense that much of this work was asking the wrong questions. Increasingly, research sought to position spending and social outcomes in much broader modes of understanding, and this was also true of political science and sociology, where a European neo-Weberianism was especially influential. Some of this research was presented in a summary of a joint NSF–SSRC initiative that occurred between 1981 and 1983 (Kirby, Knox, and Pinch 1984). While this work was innovative, its multidisciplinary nature inevitably placed it at the margins of all the subjects involved, while its political nature gave it a politicized taint. Smith’s work was, for example, seen as both “radical” and rather marginal. Those who actually engaged with welfare geography found its ambitions to be outstripping its abilities.

Welfare geography was ineluctably of its time, caught up with assessments of inputs and outcomes, out of step with the tenor of practical politics, expressed most visibly in the Reagan–Thatcher alliance but most damagingly in the emergence of neoliberal austerity budgets and a roll back in public expenditures. Clearly, empirical work on budgets and outcomes, and theoretical work on state formations might have constituted a valuable counter-weight to this trend. This was also the moment, however, when the postmodern turn began to manifest.

The devastation wrought by postmodernism can only now be assessed across the disciplines. Its impact upon geography did not occur in isolation from other influences, but collectively the result was an emphasis upon critical theory and a concomitant retreat from social and political theory on the one hand, and from empirical work on the other. Postmodernist urbanism (expressed, for instance, in the Los Angeles school) generated an infatuation with text, identity, and design at the expense of more
WELFARE GEOGRAPHY

grounded empirics. Bibliometric research shows few geographic contributions to the study of welfare published after the close of the twentieth century, and equally few citations.

Welfare geography has not left a lasting contribution, either to the broader study of welfare or to the narrower context of geography. As shown in Krugman’s work, economics has demonstrated little interest in geography’s extant body of research. Within the latter, the shift toward identity and emotion has marked a move away from collective outcomes and the manner in which they can be achieved. Subjective assessments of life quality now appear to be much more important than objective measures.

Perhaps the one lasting residual is at the international scale, where comparison between the have and the have-nots is a constant reminder of the issues that link global development and human progress. Smith himself has continued to emphasize the importance of justice in this context.

Wetland biogeography

Joe R. Melton
*Climate Research Division, Environment and Climate Change Canada*

Wetlands are regions that are frequently inundated or saturated for extended periods of time such that they are a distinct ecosystem—separate from the upland and deep-water water systems that they connect. As wetlands form an ecotone between terrestrial and aquatic systems, they provide unique habitats for diverse flora and fauna and many important ecosystem services including flood mitigation of rivers and streams, protection of clean water, buffering of coastlines from high energy waves (such as from typhoons or tsunamis), and habitat for a great diversity of plant and animal species. These ecosystem services have led wetlands to be termed the “kidneys of the landscape” as they receive both water and waste from upstream natural and human sources (Mitsch and Gosselink 2007). When compared to adjacent terrestrial and aquatic systems, wetlands are generally among the most productive ecosystems on the planet (though not all are highly productive, for example, peatlands and cypress swamps have low productivity). Wetlands commonly have anoxic soils which slows the decomposition of organic matter. This slow decomposition over time results in wetlands storing an immense amount of carbon in their soils. Decomposition of this carbon produces proportionately more methane, a potent greenhouse gas, during respiration than upland systems, making wetlands the largest natural source of methane.

Many different definitions of wetlands exist for scientific, legal, and management purposes but they generally share three common criteria. One, wetlands have the presence of water at the soil surface, or within the root zone, either continuously or for extended periods of time. Two, wetlands have unique soil conditions that differ from adjacent uplands, commonly containing hydric soils (soils that have anoxic conditions). Lastly, wetland vegetation and biota are adapted to wet conditions while flooding-intolerant biotas are absent.

Globally, wetlands cover about 7–10 million km² (about 5–8% of the land surface) (see Figure 1). Wetlands are found predominantly in boreal and tropical regions with lesser amounts in temperate latitudes (Figure 2). The general controls on wetland occurrence are climate and geomorphology. While many cultures evolved in concert with wetlands (e.g., the Babylonians, Egyptians, and Aztecs all delivered water via wetlands), and indeed paddies used in rice cultivation are a form of domestic wetlands, regions with high human impact have lost about 50% of their wetlands. Wetlands are generally less impacted by humans in sparsely populated areas, but have suffered up to complete removal in densely populated areas. Wetland destruction has occurred for a variety of purposes—some examples include filling-in for residential or industrial developments; peat mining; drainage for agriculture, mosquito control, or forestry; and indirect effects through the construction of dams.

Wetlands are often divided into three main categories: (i) coastal wetlands, which include salt marshes, tidal freshwater marshes, and mangrove swamps; (ii) peatlands; and (iii) freshwater
swamps and marshes. As the physical and biotic characteristics of these classifications grade between each other, characterizing a wetland in practice can be somewhat arbitrary with the same term used for different systems in different regions.

Coastal wetlands constitute a relatively small fraction of total global wetlands (ca. 5–10%). Salt marshes occur primarily in high latitudes while mangrove swamps become dominant in tropical latitudes. Some characteristic salt marshes occur in the Mediterranean Sea, a famous example being the Camarague in the Rhone River delta. San Francisco Bay also has salt marshes (now over 95% destroyed). Mangrove swamps occur in the Florida Everglades and the extensive Sine Saloum Delta in Senegal. Coastal wetlands are heavily influenced by two primary factors: salinity of the water and the energy provided by tidal forces. Tidal energy influences processes such as gas exchange, sediment deposition, fluxes of mineral and organic matter, and removal of toxins while salinity creates unique habitats for organisms that are able to withstand the stress of salinity ranges from freshwater (yet still influenced by tidal forces) to approaching that of seawater. Wetland plant adaptations to saline conditions include exclusion and excretion of salt, pneumatophores, production of viviparous seedlings, and prop roots.

Peatlands, also termed moors and muskegs, are the most common wetland type globally, covering some 2.4 million to 4.1 million km², primarily in the humid northern boreal regions. Peatlands include fens and bogs as part of a succession in which fens can transition to bogs over time. Bogs commonly have low nutrient availability with no significant water source besides rainwater.
Figure 2 Predominant occurrence of wetlands. Source: Kaplan (2007) in Bergamaschi et al. (2007).

Bogs typically have peat deposits dominated by acid-loving vegetation such as mosses and can be forested or open. The Pocosins of the Carolinas is an example of an evergreen shrub bog. Fen-dominated peatlands are characterized by a flow-through water source and are covered by sedges, reeds, and grasses. There is an extensive body of research conducted on peatlands, especially in the extensive peatland complexes of the Hudson’s Bay Lowlands in Canada and the West Siberian Lowlands in Russia.

Freshwater marshes and swamps are typically differentiated based upon the dominant vegetation type such as: marshes (herbaceous plants), swamps (woody vegetation, trees, or shrubs), sedge or wet meadows (shallow marshes), and wet prairies (intermediate between a marsh and a meadow), among other subcategories. Freshwater swamps cover approximately 1.1 million km² globally and vary from almost continually inundated to only sporadically. Few tree species can exist in continually saturated soils, however, some exceptions exist such as the tupelo/gum (Nyssa spp.) and cypress (Taxodium spp.) prevalent in the swamps of the southeastern United States. The Great Dismal Swamp (southeast Virginia and northeast North Carolina, United States) is an example of a predominantly bald cypress-gum swamp. Trees are also the dominant vegetation in many riparian zones, such as floodplains, that are not continually saturated but are flooded often enough to be classified as wetlands. Freshwater marshes do not have extensive peat deposits like peatlands, but have a shallow-water regime and soft-stalked emergent aquatic plants. The Mesopotamian marshlands of southern Iraq and Iran were originally a large freshwater marsh complex but have been heavily damaged by human land use.

WETLAND BIOGEOGRAPHY

Wetland hydrology

Tim Beach
Jonathan M. Flood
University of Texas at Austin, USA

Wetlands are defined based on soil types and ecosystems and on the presence of water, meaning duration, level, and quality of water. A wetland can be perennially wet or seasonally wet, depending on multiple classifications. This entry considers the hydrologic conditions inherent in the types, functions, evolution, landscape connections, and human alterations and trends of wetlands. Hydrologic conditions play a paramount role in creating and maintaining the structure, function, and unique physiochemical conditions that define wetlands. Water level, hydropattern (or hydroperiod), water chemistry, and residence time are the primary hydrologic variables influencing most wetlands. Wetlands, like all terrestrial ecosystems, are the complex product of the Earth’s physical spheres within the wider concept of the critical zone, which is the slice of Earth from the top of the vegetation to the bedrock (Figure 1).

Water level within wetlands is principally a function of hydrologic input (i.e., precipitation, runoff, stream and groundwater inflow), hydrologic output (i.e., evapotranspiration, stream and groundwater outflow, and percolation), and geomorphology in terms of landscape position and sediment flow (Figure 2). Water content directly influences the dissolved oxygen within submerged soil matrixes, which, in turn, influences the structure and distribution of plant and animal communities within the wetland. Deeper water levels and more biological oxygen demand (BOD) generally lead to more anaerobic soil/sediment conditions. Many emergent plants cannot survive these oxygen deficiencies in their root zones. Shallow waters have a greater capacity for oxygen delivery and exchange with the submerged matrixes and generally host a greater variety of emergent plant species and other primary producers. Water level and anoxic conditions drive and maintain the creation of hydric soils; both influence the biotic community (Figure 3).

The majority of the world’s wetlands do not maintain a perfect balance between hydrologic inputs and outputs over the course of a year. Water level tends to fluctuate over time in most wetlands and, typically, mirrors larger-scale seasonal patterns in precipitation and temperature or even longer term aquifer-related fluxes. Wetland hydropattern (or hydroperiod) is a measure of temporal variability in water level. A hydrograph is the common method for plotting flux in water level as a function of time, which could be over a short- or long-term scale, depending on whether the interest is in variation over a flood cycle or an annual cycle. The constancy of the hydrologic pattern from year to year characterizes each type of wetland and represents a degree of regularity that determines the types of plant and animal communities. For example, monsoon or strongly seasonal tropical watersheds go through long flooded periods on floodplain wetlands in the Amazon Basin called Igapô and Várzea forests (Junk et al. 2011).

The hydrologic residence time is a measure of the amount of time it takes for a hydrologic input to pass through a wetland and exit the system. Hydrologic residence times may be different for different sections of a wetland.
WETLAND HYDROLOGY

Figure 1  Wetland spheres.

Figure 2  Wetland, terrestrial, and aquatic systems.
Water may run faster through the deeper, better connected sections of a wetland, while shallow systems remain still and stagnant for greater periods of time. Water level within an entire wetland may fluctuate collectively over a year but different sections with differing residence times will create dissimilar conditions. The network of biotic and abiotic processes at work in wetland systems complicates specific measurements but general hydrologic residence times are a useful metric. Residence time influences the amount of dissolved and particulate material (nutrients and toxins) entering and exiting a system. In coastal wetland systems the residence time directly impacts salinity concentrations.
Scales and classes

The scale of wetland hydrology ranges from less than a hectare vernal pool in California or Prairie Pothole in Minnesota to the nearly 20 million hectare Pantanal wetlands of South America and the seven million hectare Llanos de Moxos wetlands of Bolivia (McClain 2002), the largest protected wetlands on Earth. All wetlands have diachronic and synchronic characteristics, indicating their evolution over time and in context with surrounding environments. Wetlands are usually both evolutionary over time and ecotonal over space because the hydrology that maintains them is always changing. The US Clean Water Act (33 CFR 328.3 (b); 1984) defines wetlands as “those areas that are inundated or saturated by surface or groundwater at a frequency and duration sufficient to support, and that under normal circumstances do support, a prevalence of vegetation typically adapted for life in saturated soil conditions.” Cowardin also added soil to this definition of wetlands by including the notion that water was also a dominant element for soil development and soil ecosystems in wetlands (Cowardin et al. 1979).

In soil terms, wetlands with consistent saturation usually have Histosol (dominantly organic matter) soils with O horizons and sometimes L (limnic) horizons of open water deposition. Where water tables are seasonal, they have many other soil types often with the aquic descriptor term of reducing conditions (see Soil water). Wetland soils often have the horizon designation of “Bg” or “Cg” with “g” signifying “gleyed” or reducing conditions. In groundwater terms, wetlands reside where the phreatic zone is near the surface, though they may seasonally be in the vadose zone (Figure 3). Since saturation is a defining feature, an area with a high water table within the capillary fringe would not necessarily be a wetland, though many such areas become saturated or inundated for some part of the year.

Geography

The distribution of wetlands based on latitude shows a peak in area in the mid to high latitudes (45–70° N) in the Northern Hemisphere and a secondary peak in the equatorial zone (Figure 4). The main reason for this distribution is the vast area of formerly glaciated lowlands with deranged drainage in North America and Eurasia. No equivalent peak occurs in the Southern Hemisphere’s high to mid latitudes, ironically in the latitude of the great Pantanal wetland, due to the small area of land and deranged drainage in this hemisphere. The area of wetlands decreases in the lower latitudes of the Northern Hemisphere through the global belt of arid climate to about 10° N. Wetland area rises again in the equatorial zone with increased precipitation and runoff of this rainiest zone of the planet but also with well-developed and efficient drainage networks. Poleward of 45° S and 70° N wetlands are tiny areas because most of this zone is open water or glacial ice (Figure 4).

Types

The international Ramsar Convention classifies wetlands based on hydrology, which include 12 marine/coastal, 20 inland, and 10 human-made wetland types (www.ramsar.org). The Ramsar Convention, officially titled the Convention on Wetlands of International Importance, is an international agreement signed in Ramsar, Iran, in 1971, which now has 169 signatories. The treaty’s three pillars are to work together internationally for wise use, list and safeguard wetlands of international importance (more than 2200), and work together on transboundary wetland
Figure 4  Global distribution of wetlands.
WETLAND HYDROLOGY

systems. Ramsar has a comprehensive definition of wetlands by including marine classes and human classes of wetlands.

The geomorphic controls on wetlands include any agents that create depressions or high water tables, and most wetlands have a geomorphological cause of their high water table. The Ramsar classification describes the coastal geomorphic classes of saline (e.g., sea grass beds), brackish (e.g., intertidal marshes), or freshwater (e.g., lagoons). Ramsar also describes karst sinks and fluvial systems such as deltas, floodplains, springs, and geothermal areas. To this can be added other sinks created by landslide dams, a host of glacial depressions such as the Prairie Potholes, aeolian blowout hollows, fault lines, especially tension faults with sinking blocks, and bolide impacts.

The US Environmental Protection Agency (EPA; www.epa.gov/wetlands/) categorizes wetlands succinctly as marshes, swamps, bogs, and fens. Marshes, for example, can be tidal and nontidal and are usually covered by pH neutral water. They feature soft stemmed, emergent plants anchored in saturated soils. Examples include both deeply and perennially inundated lands like the Everglades to more seasonally inundated (after spring snowmelt) Prairie Potholes. Tidal marshes include the lower, strongly tidal zone and the upper marsh.

Swamps have woody plants and have seasonal water tables ranging from occasional flooding to a saturated soil surface. These may be dominated by maple trees (Acer spp.) in the higher latitudes of the United States and Canada or Bald Cypress, White Cedar, and Tupelo trees in subtropical areas of the United States. An iconic type is the nearly year-round Bottomland hardwood swamps with buttressed Bald Cypress trees and oak and sweet gum trees, as with the Mississippi River valley. These swamps usually have alluvial and organic, nutrient-rich soils. Another globally important type is Mangrove swamps, which act as barriers to coasts but are endangered by hydrology from sea level rise and freshwater abstraction and rampant development.

Bogs usually are precipitation dependent, have mosses, especially sphagnum moss, and develop peat layers. They may form either as lakes fill in from the sides or as wet upland develops a sphagnum moss surface that traps moisture, termed paludification. The formation of such blanket bogs occurs naturally or as deforestation removes the heavy transpiring trees, leaving wetter conditions pioneered by water retaining sphagnum moss. The vegetation is often acidic, which imparts a low pH to these wetlands, and has low levels of decomposition, which makes them hotspots of carbon sequestration. These occur both in poleward latitudes and in more subtropical conditions as with the pocosins of the southeastern United States, which are on uplands with shallow water tables and evergreen shrubs and trees.

Fens are groundwater- and runoff-fed, peat-forming wetlands that are less acidic and more nutrient rich. They are more biodiverse with woody or herbaceous vegetation and, like bogs, often occur in higher elevations and latitudes. These may become bogs if the peat growth separates them from runoff, and they grow to form in just the acidic mossy vegetation.

Wetland hydrology functions

Wetland environments support, generate, and interact with a large web of biotic and abiotic processes that influence distant components of the biosphere, atmosphere, and hydrosphere (Figure 1). Wetlands provide many ecosystem services as a result of their dynamic hydrology: storing water and delivering the water downstream and/or allowing aquifer recharge through infiltration and percolation; serving to decrease
the impacts of flooding and storms by storing water and moderating storm energy; acting as sediment sink to remove sediment loads from streams; providing habitats for many species; and serving as nurseries for numerous fish, insect, reptile, bird, arthropod, and amphibian species. Wetland bodies and hydrologic corridors serve as transportation networks for species and economic activities. Wetlands are important for plant domestications and paddy rice agriculture and have an ancient and worldwide history of human uses.

**Human interactions with wetland hydrology**

Humans have a long history of both positive and negative interactions with the hydrology of wetlands of many types (Beach and Luzzadder-Beach 2013). Cultures around the world have actively and complacently used perennial wetlands for numerous resources, including hunting, fishing, gathering, and transportation. Humans have also developed intensive agricultural systems in wetlands around the world. Intensive systems include active manipulation of wetlands to maintain their water levels, and to drain water, associated with “miasma” or disease, to make dry, healthier farmlands (Larson and Kusler 1979).

The Ramsar list of internationally important wetlands has both significant natural wetlands like the Ria Celestun, Yucatan, Mexico, where groundwater interfingeres with saltwater in an estuarine channel on the northwest coast of Yucatan, and human-made ones like Xochimilco in Mexico City, where Aztec farmers built chinampas fields between canals into a lake. These two examples show the importance of hydrology on wetlands in many ways. First, lowered water-flow in the Ria Celestun results in salt-water intrusion inland and a rearrangement of habitats and reduced foraging for charismatic species like flamingos. Second, ancient Aztec farmers dammed out water of lower quality and maintained water heights to grow a wide diversity of crops, which farmers have carried on to the present. Beyond Ramsar, UNESCO lists several cultural wetlands as world heritage sites, including the Subak system of rice terraces of Bali and the rice terraces of the Philippines.

To build wetland field systems means the maintenance of hydrology, and they represent widespread global success because they range from 45°N to 40°S and sea level to nearly 4000 m. Mainly the hydrology is to water crops but it is also for moderating temperatures in places like the Highlands of Mexico and Bolivia. In the tropical lowlands of Mesoamerica and South America were vast wetland field systems that may have persisted until European conquest or declined with the varied fates of civilizations, such as those as the Maya civilization a millennium ago (Beach *et al.* 2015).

The iconic chinampas of Xochimilco and other wetland field systems around the world relied on maintaining field plots between canals and using the canals for maintaining soil water through irrigation and capillarity from high water tables (Beach and Luzzadder-Beach 2013).

In contrast, paddy rice wetlands in Asia generally relied on growing rice in wet paddies with the monsoon water up to a phase in their phenology. Rice can transport oxygen from the air to roots but even rice has limits to the flooding and needs to dry out for the final maturation of the seed to harvest. Other cereal crops need better drainage, and the indigenous wetlands of the Americas required raising beds above the water table or lowering the water table for drainage for their maize, beans, squash, and other crops. The latter implies alteration of hydrology through canals, subsurface drains or tiling either horizontally or vertically, and diversions.
Another important human impact on wetlands is from deforestation, because grasslands and croplands have about one-third less evapotranspiration than do forests (Woodward et al. 2014; Zhang, Dawes, and Walker 2001). In many environments, 9–12% of global wetlands, deforestation leads to the water equivalent of 10–15% more precipitation annually. Moreover, if these areas stay deforested, they should stay wetter (Woodward et al. 2014). Countering this increased water in environments, especially in tropical forests, is decreased precipitation over time linked to the decreased transpiration into the atmosphere, seen in large-scale empirical and model studies (5–10% for Congo basin simulations in Akkermens, Thiery, and Van Lipzig 2014; Lawrence and Vandecar 2015).

All types of wetlands have declined around the world (https://www.fws.gov/wetlands/), often due to hydrological changes such as groundwater table drawdown, tiling and other forms of drainage, and vegetation changes. Ramsar states 87% of world wetlands has been lost since 1700 CE and wetland losses have accelerated in the twentieth and twenty-first centuries, with a meta-study concluding a 64–71% wetland loss since 1900 CE. Since the 1980s, these rates have slowed in the United States, Canada, and Europe but continue unabated in Asia (Davidson 2014). The ecosystem services from wetlands have also declined by almost 10 trillion dollars (in 2011 dollars) from 1997 to 2011, caused by declines in area (Costanza et al. 2014).

Many wetlands will be vulnerable to climate change from greater water abstraction, higher evapotranspiration, and sea level rise (Zedler and Kercher 2005). In permafrost regions, climate warming is especially severe (IPCC 2013), which is leading to loss of permafrost and new types of wetland or to losses in wetlands in some places, depending on their changing water table levels and water balance inputs. Permafrost is likely to decline further, 30–70% by 2100 (Schuur et al. 2013).

The interaction between sea level and wetlands takes many forms. Wetland drainage leads to higher sea levels, likely rising too fast for wetlands to maintain their equilibrium by growing upward with peat accumulation. Moreover, many wetlands will not be able to migrate inland in response to sea level rise because of competing land uses like urban infrastructure and even future seawall construction.

Many regions are also changing in the face of accelerated sea level rise, such as the Chesapeake Bay region. Other land-use changes, such as deforestation and reforestation and the removal and reintroduction of beavers, have changed wetland hydrology (Pollock, Heim, and Werner 2003). Future sea level rise may occur at too rapid a rate for wetlands to adapt to new states, and many wetlands may suffer further erosion of their functions, but wetlands have a proven ability to counter coastal erosion (Spalding et al. 2014; Barbier et al. 2013). There are many wetland enhancement programs to help meet these changes and mitigate the impacts of storms on coastlines in developing countries, but not in undeveloped ones (Denny 1997).

Human impacts are also in the form of wetland restoration and mitigation, which always requires restoration of hydrology to restore some part of the function of a wetland. Wetland restoration efforts include passive measures designed to halt damaging actions and active measures that primarily focus on the restoration of the hydrology in order for biological recovery to occur (Kauffman et al. 1997). Several iconic wetland restoration sites, such as the Kissimmee River in the United States and the “Garden of Eden” (Iraqi marshes), successfully re-engineered hydrologic inputs to increase wetland areas, but the loss of wetlands to hydrologic changes far
WETLAND HYDROLOGY

outweighs these successes worldwide. Unfortunately, the databases are lacking for wetland losses for much of the developing world and there is, thus, a strong need for understanding trends in this most important part of global environment.

The future of wetland hydrology

Multiple factors are likely to influence the hydrology of wetlands over the next decades. One factor is likely climate change, especially in the high latitudes of the Northern Hemisphere, where so many wetlands occur in the zone with the highest rates of warming. Here, more permafrost will melt but increased evapotranspiration without equal precipitation increases will reduce wetland area. Further wetland drainage and land-use conversion will likely continue, with the net effect of lowering water tables, although the initial response to deforestation is often raised water tables. In many tropical areas, deforestation will also likely decrease rainfall, which may transform some wetlands to drylands. Drainage of wetlands continues in many forms, from channel stabilization to tiling and canalization. Sea level rise will inundate many wetlands; in some places, new wetlands will form inland but with reduced ecosystem functions (IPCC 2014). In other places, new sea walls will counter wetland formation to maintain private and public property. Some coastal wetlands can keep up with lower rates of sea level rise but sea level rise in the next decades may be too fast.

Whiteness

Alastair Bonnett
Newcastle University, UK

White and whiteness are terms used to describe the skin color of people of European heritage and, hence, to depict them physically as a race. From the late eighteenth century this identification became tied to the development of ideas of racial difference and hierarchy in which the possession of whiteness was used as: (i) evidence of natural, innate, superiority; and (ii) the norm and standard of racial identity against which others (the “nonwhites”) are measured.

Once it had been established as the central symbol of European racial power, whiteness began to take on an important function in the organization of colonial societies. Three basic roles may be discerned, the importance and practice of each varying considerably between different countries and regions and none of which should be taken to imply that “whites” can be approached as a homogeneous group. The first is ideological: whiteness was used as a justification for the power and prestige of European heritage peoples, as well as constituting a site of solidarity and identity for this group. In this way a racial bond was established, a bond which ensured that white people had a cultural and economic stake in aligning themselves with other whites. Second, whiteness became a mechanism for the organization of society. This function is particularly apparent in the logic of colonial economies, where access to different occupations and labor organizations; familial, cultural, and social affiliations; and economic leverage (i.e., what one’s labor was worth) was often determined by one’s position vis-à-vis whiteness (either by way of a white/nonwhite binary split or through a gradual loss of socioeconomic power the further away from whiteness one was imagined to be). Third, whiteness developed a psychological dimension: the formation of personality through the construction of self and other became bound up with a racialized set of fears and desires concerning the nature of whiteness (especially in respect to notions of purity and defilement) and its loss or acquisition; however, it is worth reiterating that these processes were all complicated by established and, sometimes, entirely distinct dynamics of ethnic separation that meant that whiteness was cross-cut with religious distinctions (such as between Catholic, Protestant, and Jew) and ethno-national differences. These distinctions and differences suggest that polemical generalizations about the behavior or status of “white people” rarely sustain detailed historical and geographical analysis.

Nevertheless, not only has discussion of “whiteness” been dominated by political and campaigning voices, but many of these interventions have been highly perceptive. One of the first critical investigators of whiteness as a social and historical phenomenon, the African American writer and activist W.E.B. Du Bois, writing in the early 1930s about the 1860s and 1870s, noted of “the white group of laborers” in the United States, that,

while they received a low wage, were compensated in part by a sort of public and psychological wage. They were given public deference and titles of courtesy because they were white. They were admitted freely with all classes of white people to public functions, public parks, and the best schools … The newspapers specialized on
WHITENESS

news that flattered the poor whites and almost utterly ignored the Negro except in crime and ridicule. (Du Bois 1992, 700–701)

Du Bois also exemplifies another of the ironies of whiteness: that whiteness is often more visible to people who feel whiteness acting against them than to white people themselves.

Whiteness is not, however, a static phenomenon. Its changing cultural and economic role across the world shows it to be a persistent but flexible current. Much antiracist discussion of whiteness over the past 30 years has been dominated by a concern to show that whiteness is still relevant and that the hierarchies and inequality associated with it remain important. The defensive quality of these assertions is the result of widespread yet diverse arguments and processes that suggests that white racism is not the force it once was; that distinctions of culture and religion have become more pressing than “old-fashioned” ideas of color, and/or that, in a multipolar world, ideas about the origin of race and racism need to be diversified beyond a sole focus on the West and its global impact.

The shifting nature of whiteness is also apparent from a study of its history and its changing deployment in the discipline of geography. The imperial geographies of the late nineteenth and early twentieth centuries constantly strove to map out the limits and possibilities of white settlement and colonial control. However, it would be a mistake to read these applications of racial environmental determinism as indicative of a confident and unchallenged white supremacism. Rather, they formed part of a larger debate on a perceived crisis of white authority and colonial legitimacy. The focus within this body of geographical research was, after all, on the limits of white rule. From 1880 to 1930 a considerable literature arose on the “perils” and problems of whiteness, its vulnerability to a myriad of challenges. Common sites of crisis identified were internal racial strife (the “fratricidal” nature of World War I emerged as the prime illustration), the rising power of the nonwhite world (the outcome of the 1904–1905 Russo-Japanese war quickly became the principal example), the racial treason of Bolshevism, and the rise of the “underman” (i.e., the white proletariat).

From the late 1930s onward, the idea of openly celebrating whiteness – of talking about it as a positive identity, as something to be proud of – was gradually dropped within British public discourse and, increasingly if unevenly, across Europe and North America. At the same time, the idea of “the West” and “Western” (terms that had been developing contemporaneously with the crisis of whiteness literature) began to come to the fore. The same pattern can be witnessed within academic geography. White attitudes became things to be studied, and eventually “whiteness” became a term to be problematized (indeed, it can sometimes appear to be the sole object of antiracist scrutiny). But “the West” and “Western” emerged as categories to be deployed in a taken-for-granted fashion, understood not as constructs but as coherent and meaningful expressions.

Despite its declining status within public discourse, white identity continues to be significant, within both everyday and popular culture (including among Western antiracists) and in coded or euphemistic forms within government discourse. The function of whiteness in symbolizing or producing “normal” space in the West rests on the social fact that nonwhite people are far more likely to be visible, to be considered to be “out of place” than whites. Ingrid Pollard’s photographic meditation on her (black British) presence in the English countryside provides a straightforward illustration. Her images work by producing an immediate but uncomfortable thought: that black Britons’ place is in the city. John Urry (1995, 27)
asserts that there is a “racialisation” of the phe-
nomenology of the urban; and this works partly in
England through the contrasting high valuation
which is placed upon the English countryside,
which is taken to be predominately white.”

Yet, even within the “cosmopolitan” and
“multicultural” city, whiteness has its territories
and spatial limits. Recent studies affirm that it
is only when “white places” and “non-white
places” come into contact that the former
become visible, the reality of white space
becoming legible against a darker background.
Thus, for example, Wendy Shaw’s ethnographic
research on Sydney suggests that,

Away from the stark black/white racialised
boundary near The Block [i.e., the Aboriginal
identified area of Redfern], where the space of
whiteness absorbs other ethnicities, whiteness
appears to fade into ethnic neutrality. Away from
the Aboriginal “other,” whiteness is not so visible
... whiteness strengthens and consolidates against
the presence of The Block. (2001, 8)

The geography of Britain, the United States,
and Australia is also racialized at other spatial
levels, such as the street (McGuinness 2000), the
shopping center (Jackson 1998), the suburb (Watt
1998), and the town. The role of the town as a
kind of haven of the white urban, defined against
the menacing presence of the “cosmopolitan”
city, appears to be particularly important in
parts of the United States (Kobayashi and Peake
2000). Anoop Nayak (2003) has researched the
intersections of globalization, youth culture,
and whiteness in both city and suburban loca-
tions. A methodological literature that challenges
researchers to reflexively identify the influence of
whiteness on research assumptions and practice
within the discipline of geography has also begun
to emerge.

It is one of the ironies of both contem-
porary ethnic and racial studies and cultural
geography in the West that these two scholarly
traditions – which might be assumed to offer a
resolutely antiparochial frame of reference – have
tended to restrict the focus of their inquiries
to Western countries. The shift in the latter
half of the twentieth century, away from the
racist assumptions of colonial era geography
and anthropology and toward a scholarship of
self-doubt and self-questioning, may help to
explain this reticence to “explain” other soci-
eties. However, although it remains limited in
scope, study of the role of whiteness outside the
West has attracted a growing interdisciplinary
literature. One of the foci of this work is on the
interplay of neoliberalism and whiteness. This
interest has developed, in part, because it has
been noted that, despite the almost universal
abandonment of explicit doctrines of white
supremacy, and the adoption of antiracist rhetoric
as the lexicon of legitimacy by institutions the
world over, “cultural whiteness” continues to
be globally influential. The patterns and paths
of resistance to this process are diverse, yet if any
one attribute of the white racial norm stands
out from the last century it is its capacity for
adaptation. Today it appears that the durability
of whiteness is a function of its changing rela-
tionship with modernity. It is pertinent to note
that a biologically identified view of “the white
race” as the physical carrier of modernity was
central to its early development. This association
was most starkly apparent within the successive
campaigns of governments throughout South
America in the late nineteenth and early twenti-
eth centuries to modernize both their economies
and their social structure by “pouring in white
blood” through assisted immigration schemes
for Europeans. In the latter half of the twentieth
century this phase declined in significance and
a new point of emphasis within the relationship
between whiteness and modernity was forged. In
contemporary South America the white ideal is
“enforced,” not necessarily through the physical
WHITENESS

presence or even the agency of white people, but rather through a close association between the aspirational lifestyle of consumer capitalism and the actual lifestyle and culture of the white West. The white ideal is not limited to South America. However, to date, Latin Americanists have provided the most thoroughly researched explications of this process. In 1997 the Peruvian activist Patricia Oliart identified an association of the internationalization of economic and media interests with the reinvention of the white European as the symbol of modernity, as the corporeal marker of social progress and physical attractiveness.

What is happening now is that racism is coming back stronger ... Money counts again now and the way you look, we have lots of gyms, that we never had before, all classes doing aerobics and dying their hair, like a blond hair ... it doesn't matter if you're not white, you can look white, you can become white, you can wear nice shoes, you can dye your hair, you can get a great body, and if you don't do that, you have a ponytail, wear ethnic skirts or whatever, then that's your problem. (Oliart 1997, quoted in Bonnett 2002, 355)

Oliart’s observations indicate that whiteness is being connoted as a lifestyle, symbolically tied to the pleasures of a consumption-led identity (pleasures such as “freedom” and “choice”). A further implication of this process is that, far from being an archaic ideology from a discredited past, the white ideal is being reimagined and appropriated. In its new guise, this racial and cultural archetype is less identifiable as the foreign belief system of white supremacists. It is offered instead as part and parcel of a widely disseminated aspirational agenda – a process that entails its availability to local reinterpretation, mutation, and transgression as well as emulation.

Wicked problems

Steve Rayner
University of Oxford, UK

Origins

Horst Rittel and Melvin Webber (1973) first identified wicked problems in the late 1960s. Professors in the planning department at the University of California, Berkeley, they contrasted the relatively straightforward challenges of the late nineteenth and early twentieth centuries, such as public health and basic sanitation, with the more difficult challenges facing planners in the latter half of the twentieth century, such as the redevelopment of entire neighborhoods.

Rittel and Webber (1973) contrasted complex problems of social policy with more straightforward puzzle-solving kinds of activities typical of mathematics and the natural sciences. They also recognized the value conflicts arising from the increasing heterogeneity of contemporary communities and emerging popular protest against expert formulations of policies being imposed on populations without their consent. Wicked problems have also been described as messy problems (Ackoff 1974).

Characteristics

Different authors list different characteristics of wicked problems, but the main ones can be summarized as follows. First, wicked problems are often symptomatic of deeper problems and often display circularity, as in explaining educational problems by poverty, poverty by social class, and social class by educational achievement. Second, wicked problems offer little room for trial-and-error learning: once a neighborhood has been demolished, it can never be restored. Third, they don’t present clearly defined alternative solutions; indeed available solutions are often used to define the problem, as in the idea of monetizing ecosystem services to address “market failure” in environmental protection. Fourth, they are characterized by contradictory certitudes, in that there are many different diagnoses of the problem and many different prescriptions for solving it, often ones that are incompatible; for example, the recent banking crisis has been blamed on both too much and too little regulation. Fifth, wicked problems tend to have redistributive implications for entrenched interests, such as those of the fossil fuel industry in relation to greenhouse gas mitigation.

Responses

Nancy Roberts (2000) proposes three strategies for “taming” wicked problems: (i) simplify the issues and apply routines; (ii) use expertise to control resources; (iii) open the problem up to stakeholders. Each strategy offers an ideal solution from the respective standpoints of hierarchical, competitive, and egalitarian forms of social organization. However, they represent contradictory strategies, so any chosen strategy can only succeed by overriding the interests and values of those advocating either of the others.

In contrast, cultural theorists in the tradition of Mary Douglas advocate “clumsy solutions”
or hybrid strategies in which all of the voices – hierarchical, competitive, and egalitarian – are heard and responded to (e.g., Verweij and Thompson 2011). As such, clumsy solutions are likely to emerge from negotiation or conflict rather than be planned from the outset.

In the final analysis, wicked problems have no definitive solutions. They can only be managed more or less well through “settlements” (Peck and 6 2006) that endure for a while before the problem reasserts itself in a new form that requires renegotiation.

**Women explorers**

Sarah L. Evans  
*University of the West of England, UK*

A lady explorer? A traveller in skirts?  
The notion’s just a trifle seraphic  
Let them stay and mind the babies, or hem our ragged shirts  
But they mustn’t, can’t and shan’t be geographic.  
*(Punch 1893, quoted in Maddrell 2009, 32)*

These lines, which appeared in the popular journal *Punch* in June 1893, satirized a debate then central to contemporary UK geography. In 1892, after years of debate, the Council of the Royal Geographical Society (RGS) decided for the first time to admit women as fellows, electing a total of 22 women to their fellowship between 1892 and 1893, including the traveler and explorer Isabella Bird. This brought the RGS into line with the policies of many of the United Kingdom’s regional geographical societies, including the Royal Scottish Geographical Society, and with other national geographical societies such as the American Geographical Society and the Paris and Vienna geographical societies (see Maddrell 2009).

The decision to admit women to the RGS prompted a backlash among its more conservative fellows, however, whose subsequent campaign resulted in fellowship being once again closed to women in 1893, a situation which lasted until 1913 (Bell and McEwan 1996). Despite British women’s involvement in the United Kingdom’s regional geographical societies, and in geographical teaching associations, their exclusion from the leading UK geographical society restricted the opportunities available to them for exploration and geographical fieldwork. Similarly, although the Association of American Geographers (AAG) admitted women from its foundation in 1904, they were few in number, with many female applicants rejected and excluded in accordance with the contemporary gendered standards for geographical practice. As the satirical ditty cited earlier states, at the heart of this issue was the notion of a “lady explorer,” and the question of whether a woman could – or should – be “geographic.”

Exploration, as a particular form of geographical knowledge production, has played a key role in the history of geographical thought and practice, shaping the development of geography as an academic discipline and leaving its marks on the modern world. In this context it refers to European exploration of other parts of the world from the fifteenth century onward, a key and central part of the geographical tradition. Exploration therefore encompasses a diverse set of concepts and practices, which nonetheless share some common themes, as have been identified by numerous historical, feminist, and postcolonial geographers in recent years. These could include a sense of novelty, of being somehow a pioneer and the first to reach the area being explored or to make a particular discovery; a sense of risk, danger, and endurance; and a sense of making a contribution to knowledge or of conducting scientific research, broadly defined. These elements of exploration were often closely linked with European imperial dominance and colonization of the places being explored. As the work of feminist researchers has shown, these tropes and practices have also often been strongly

gendered as male: the element of discovery was often expressed in terms of the male domination of landscapes cast and depicted as female; the element of risk and danger was tied to the performance of heroic masculinity, while the element of scientific achievement was linked to norms of manly objectivity (Rose 1993). As a result, women have had a complex and at times uneasy relationship with the exploration tradition.

Although exploration is only one particular, and contested, aspect of geographical thought and practice, it continues to capture the contemporary popular imagination. The figure of the explorer continues to dominate popular understandings of geography past and present, as well as to trouble the contemporary academic discipline with imperial and colonial legacies. Who counts – who is allowed to count – as an explorer is a question that is still central to many of the debates on this topic, and particularly those around gender and exploration. In the popular imagination, the figure of the explorer is still often gendered male; one has only to think of the many books, films, and anniversaries of iconic expeditions led by heroic figures such as David Livingstone, Ernest Shackleton, and Edmund Hillary, who together make up a veritable – and decidedly male – pantheon of exploration.

Although the popular figure of the explorer is gendered male, there has also been a long-running tradition of interest in apparently “plucky” or intrepid female travelers and explorers, beginning with popular press interest in their exploits and continuing to the present day. Approaches to these women have varied considerably over time. Earlier work tended to position them as oddities, or somehow eccentric, while early feminist research in the 1970s and 1980s sought to recover these perceived lost heroines and pioneers, an example of a somewhat naive feminist empiricist approach that took a largely uncritical stance on these women and their complexities, as well as leaving existing understandings of exploration and geography unchallenged. More recent work in feminist historical geography and related fields has sought instead both to situate these women in their own contexts, and to interrogate the underlying assumptions that govern and shape exploration as a form of geographical knowledge production. It also seeks to avoid the construction of a female canon of exploration, and to go beyond simply adding women explorers to the history of geographical thought and practice. This approach draws on a number of literatures, including the feminist epistemology of situated knowledges and positionality, and the development of a contextual approach within the history of geographical thought and practice, which is now very well established.

This research has revealed women’s varied and diverse participation in the exploratory tradition, and the ways in which they engaged with diverse forms of exploratory thought and practice, from exploratory travel of the kind undertaken by the British women Gertrude Bell, Isabella Bird, and Freya Stark in the late nineteenth and early twentieth centuries, to the more scientific, systematic work undertaken by British women such as Gertrude Caton-Thompson, Evelyn Cheesman, and Stella Worthington in the early to mid-twentieth century. As shown by these examples, much of the existing research focuses on white Western women explorers, and particularly British and American women, and there is considerable scope for expanding this research further to include women from other countries and traditions.

While there are distinctions between the explorer and other, closely related categories such as traveler, geographer, field scientist, climber, and aviator, the boundaries between these terms are blurred and expansive – not clear borders but frontier zones. There are also several examples of women engaging in all these forms
of exploration-related geographical practice, beginning in the early eighteenth century with women such as Lady Mary Wortley Montagu. Posted to Turkey with her ambassador husband, Montagu wrote letters home that provide a fascinating account of her travels in the region. In anthologies of Western female travel writers, Montagu is often positioned as launching the genre of women’s travel writing, and as a pioneer of women’s participation in exploration. As well as holding this pioneering status, some of her experiences would find echoes in the experiences of other later female explorers, allowing us to explore some key themes within the broader topics of female explorers.

The first of these parallels is the fact that, like Montagu, many of the Western women involved in exploration were from upper and upper middle-class backgrounds until well into the twentieth century. They had sufficient available resources and the leisure time to undertake extensive travel, as well as to participate in the social networks that enabled and supported their exploratory travel. By the late nineteenth century, many of these women explorers had also participated in higher education, enabled by their elite status. Examples include Gertrude Bell and Katherine Routledge, both educated at the University of Oxford in the late 1880s (although, in line with gendered restrictions then in operation, both were not permitted to graduate), and Freya Stark, educated at Bedford College in the 1920s.

Gender shaped the experiences of many of these women. Montagu’s gender played a key role in enabling the particularly novel elements of her account, by allowing her access to the women’s quarters or harem in places that she visited, spaces from which male European travelers and explorers were barred. Gertrude Bell and Freya Stark reported similar experiences during their exploratory travels in the Middle East in the early twentieth century. In many other cases, their gender served to limit and constrain women’s ability to participate in exploration or to be recognized as explorers producing geographical knowledge. Women were barred from many professional opportunities, such as fellowship of the RGS, or full access to higher education, until the end of the nineteenth century.

Even when such professional barriers fell, gendered roles and expectations continued to limit women’s access to opportunities. This limitation can be seen, interestingly, in women’s engagement with tropes around risk, danger, and exploration, particularly in their subsequent publications about their travels, which have given rise to the popular image of the “plucky” lady explorer. For example, in her books about her 1890s expeditions in West Africa, Mary Kingsley both describes the thrilling dangers she encounters, and downplays her own courage in facing them. A similar strategy is deployed by Evelyn Cheesman in her books about her 1930s expeditions in the southwest Pacific, positioning herself as simultaneously brave yet appropriately ladylike. These women had to tread carefully between adhering to gendered expectations of appropriate conduct for a woman while also meeting reader expectations of excitement, danger, and adventure, to demonstrate their status as explorers and not merely travelers. Other examples include the British desert explorer Rosita Forbes, and the French Alexandra David-Neel, who traveled through Tibet in the 1920s when it was still closed to foreigners.

Another important aspect of the positionality of many of these women was that they were not only women explorers, but white women explorers, who need to be considered within their appropriate colonial or postcolonial contexts. Montagu’s text expresses many Orientalist tropes (although, in depicting the
active agency of the Eastern women that she meets, she also subverts them), as does the work of a nineteenth-century travel writer, Harriet Martineau. Many women explorers were active participants in colonizing projects, acting to achieve colonial, imperial, and nationalist aims. For example, a number of women, including Stella Worthington, Kate Ricardo, and Janet Owen participated in a series of British expeditions in the 1920s and 1930s to East Africa, which sought to survey the Great Lakes geographically and ecologically, with a view to using their fish stocks to feed a growing colonial workforce. These women gained status from their raced position as white women, where their gender might otherwise have constrained them.

Another parallel between Montagu’s experiences and those of other women explorers is the fact that she was traveling alongside her husband. Although interest has often focused on the women who traveled without (European) male companions – such as Mary Kingsley, Freya Stark, and Gertrude Bell – many others traveled with male partners, relatives, and colleagues – such as Florence Baker, Katherine Routledge; and Louise Arner Boyd, an American polar explorer who organized and funded a number of expeditions to the Arctic in the 1930s. Whether female explorers were accompanied by male Europeans or not, exploration and expeditionary work were fundamentally collaborative in nature, drawing on the expertise and labor of local people in addition to the European expeditionary team. Boyd’s work suggests another important dimension of women’s involvement in exploration, that of helping to fund and support such endeavors, without directly participating in the work “in the field.” A good example is that of Lady Jane Franklin, the first woman to receive the Royal Geographical Society’s Gold Medal, in 1860, in recognition of her extensive efforts in organizing and funding a series of expeditions in search of her husband, Sir John Franklin, who disappeared alongside the rest of his crew and expeditionary team while in search of the Northwest Passage in 1845.

Women in geography

Linda J. Peake
York University, Canada

Although women’s presence in the discipline of geography and engagement in geographical research may appear to be firmly entrenched, they are unevenly and often precariously positioned within the discipline. In the Anglo-American world there are substantive differences between women along the lines of geographical location, language, subfield within the discipline, age, racialization, and level of job security. Even for those most privileged – white, middle-class, and able-bodied women in the Anglo-American world in tenure and permanent positions – there are often marked disparities vis-à-vis their relation to male colleagues. Studies have shown that both subtle and structural barriers (many of which emulate those in other disciplines) to equality exist for women, especially women marked by race and disability; sexism, racism, able-bodiedism, and a general “discomfort with difference” (Falconer Al-Hindi 2000, 699) still permeate the discipline.

Notwithstanding this gloomy scenario, women have a long and somewhat hidden historical presence in geography. Although geography as a field of study has a history going back to the time of the ancient Greeks, women did not appear in it as individuals until the nineteenth century. And prominent women geographers who existed outside of the formal institutions and societies of geography that started to emerge in the nineteenth century have a fragile existence in accounts of the emergence of geography as a discipline. In the preprofessional phase of the discipline, prior to the emergence of geographical associations, women’s engagement in geography was primarily undertaken by women travelers and explorers, most of whom were European and North American (Maddrell 2009). Their involvement in geographical practices of travel and exploration, however, did not lead to an acceptance of their ability to produce legitimate geographical knowledge, and they were commonly denied entrance into professional geographical associations. The Royal Geographical Society (RGS) finally admitted women as fellows in 1892; in the following year it admitted a further 22 women before closing its membership to women until 1913 (see Women explorers). Other national geographical societies in Europe and the American Geographical Society in the United States also admitted women in the late nineteenth century. Perhaps the best-known female academic geographer of this period was Ellen Churchill Semple, a founding member of the Association of American Geographers (AAG) and its president in 1921. She studied anthropogeography with Ratzel and was involved in the environmental determinism debates in the late nineteenth and early twentieth centuries. Well into the twentieth century, gendered roles and expectations limited women’s ability to contribute to “professional” geographical knowledge production. The AAG had women members from its inauguration in 1904, albeit very few until its merger in 1948 with the short-lived American Society for Professional Geographers (ASPG) (Miller 1950) and the disbanding of the AAG’s “elitist and exclusionary membership policies [which] until the late 1940s required a record of original research,
nomination by two sponsors, and affirmation by
90 percent of voting members” (Monk 2004, 5).
The work of the feminist geographer Jan Monk
(2004) has revealed, however, that AAG policies
did not prevent women’s entry into the discipline
in the United States, and that there have been
hundreds of women geographers since the late
nineteenth century, though most have heard
of few of them beyond the aforementioned
Ellen Churchill Semple. Many of these women
worked as professionals – as teachers, librarians,
administrators in government departments, and
editors – although employment in universities
was far less easy to break into. As Monk (2004, 1)
has pointed out in relation to geography in the
United States: “Histories of American geogra-
phy have tended to concentrate on geographic
thought and on the men who have been seen
as major figures in research.” By choosing to
focus instead on the professional practices of
American geography in the nineteenth and
twentieth centuries she has unearthed a wealth
of long-forgotten women geographers, some
of whom have been trailblazers of radical social
change, including, among others, Thelma Glass
(1916–2012), the African American civil rights
activist who was active in the Women’s Politici-
Cal Council in Montgomery, Alabama, which
sparked the 1955 Montgomery bus boycott and
the significant ruling a year later that segregated
buses were unconstitutional (Monk and George
2004). Yet Thelma Glass, who helped initiate the
geography program at Alabama State University,
where she taught for over 30 years until her death
in 2012, was unknown within the discipline of
geography except to a relatively small number of
geographers.

Women started to trickle into the (overwhelm-
ingly white and male-dominated) discipline of
geography at the university level after the 1960s
and 1970s. In Europe the 1968 student revolts
marked a demand for left-wing reform. In
North America, engaging in social and political
movements advocating for black and gay civil
rights and an end to imperialism in the Global
South, including the Vietnam War, but also in
the Peace Corps and second wave feminism,
marked a changing context for women (Monk
2004). There are now over four decades of data,
from both quantitative and qualitative studies,
including personal accounts, documenting the
position of women and gender imbalances in the
discipline. The most comprehensive overviews
come from surveys from the United States, the
United Kingdom, Canada, and more recently
Japan, South Korea, Germany, Norway, Israel,
and Australia (Johnson 2009).

From the early 1970s there has been an interest
in recording and questioning the underrepre-
sentation of women in geography (particularly
at the level of the professoriat) (Zelinsky 1973;
McDowell 1979; Monk and George 2004). In
1973, for example, women accounted for
only 3.4% of the faculty in US and Canadian
graduate geography departments, with only one
female full professor, which Zelinsky (1973)
attributed to wider patterns of sexism as well
as particular institutional rules, traditions, and
biases. In the United Kingdom in 1978 a survey
of its departments of geography (with an 83%
response rate) found that women comprised
only 7% of all teaching staff, only three women
were full professors, and 43% of departments had
no women staff at all (McDowell 1979). This sit-
uation was to improve in the late 1970s and early
1980s, which were a period of consolidation for
white women in Anglo-American geography;
however, the later 1980s and 1990s cannot be
characterized as a glowing affirmation of the
relentless rise of women in geography. Common
barriers of gender-based discrimination were
(and still are) encountered during the academic
job search and in the hiring and the promo-
tion and tenure processes, as evidenced by the
increasingly smaller numbers of women the
further one proceeds up institutional hierarchies
(Falconer Al-Hindi 2000).

In the late 1980s the institutional picture
remained virtually as dismal as in the preceding
two decades in many respects. It was proving
very difficult to diversify the academic profession
in North America. Although there had been an
increase in the number of women gaining faculty
positions, they were still significantly underrep-
comprised only 10.6% of faculty, and there was
still only one female full professor (Mackenzie
1989). The numbers of women in permanent
academic ranks in US geography departments
still constituted only 8% of geography faculty
members. Women comprised a quarter of the
new doctorates and low-ranking professors but
only 10% of associate and 3% of full professors,
in both large and small departments (Lee 1990).
A 1987 survey of geography departments in
North America also found that just over 5%
of academic geographers were people of color
(African Americans, Hispanics, Native Ameri-
cans, and Asians) (Shrestha and Davis 1988), and
a more recent survey of black geographers in
the United States put the number of female and
male practitioners at just over 60 (Darden and
Terra 2003).

Although white women in the Anglo-
American heartland of geography have made
increasing forays into the discipline in significant
numbers, women of color still find geography
institutionally racist and not only a space that has
proven difficult to enter but also one that some
of those who found a way in have subsequently
decided to leave. A survey of AAG members in
2004 found that

The shares of black and Hispanic members in the
AAG have risen since 1980, but are still minis-
cule, at 1.2 and 1.3 percent respectively in 2001.
The number of members identifying as Asian,
however, has grown rapidly over this period: in
2002, it accounted for approximately 5.5 percent
of the total membership. (Pandit 2004, 15)

Over a decade later, there is nothing to indicate
that these figures are significantly differ-
ent. Not only are women of color missing
from Anglo-American geography, but women
geographers of color outside of Anglo-American
geography are also being marginalized. While
multilingual, including English-speaking, women
of color in previously colonized countries – India,
South Africa, Singapore – are accorded some
visibility in geography, those in “Europe, Asia,
South and Central America, and Africa, are truly
on the edge of feminist as well as geographical
discursive spaces – a power geometry of knowl-
edge circulation that necessarily renders invisible
much work” (Johnson 2009, 54). These issues
concerning the composition of women in the
discipline are indicative of the consideration of
women’s representation being replaced by those
of the absence of women of color (Kobayashi
2006; Pulido 2002) and the hegemony of the
English language (Garcia Ramon, Simonsen, and
Vaiou 2006).

This is not to dismiss the invaluable contribu-
tions to the discipline that a number of individual
key white women geographers have made, pro-
viding intellectual leadership through teaching
and publishing, ensuring the appointment and
promotion of women, mentoring, networking,
supervision, and promoting the production of
(feminist) geographical knowledge, not least
through feminist journals: since 1994, Gender,
Place & Culture: A Journal of Feminist Geography,
and, since 2010, the Revista Latino-Americana
de Geografia e Gênero (Latin American Review
of Geography and Gender). Johnson (2009)
points out that the key women who entered
geography affected by the tumultuous times of
the 1960s, the 1970s, and early 1980s (before the
cultural turn), and who have remained figures
of influence, are now retiring or entering senior management positions. Their successors, she observes, “are coming of academic age in a very different political and theoretical era, one where gender is no longer fundamental … What is now emerging is therefore a very different feminist geography, and … such changes have seen the evacuation of the category by many” (Johnson 2009, 54). These changes are echoed in the organizations that women in geography occupy.

Women’s organizations in geography

The institutional framing that would allow women to address professional issues and for feminist approaches to prosper was first established at the national level in the early 1970s, notwithstanding that women constituted only a very small percentage of faculty members in that period. These bodies can be loosely differentiated as serving two functions, with many serving both. The first group consists of those that represent the professional interests of all women in the discipline and that typically engage in issues of affirmative action/equal opportunities to increase the representation of women and promote data collection to aid such efforts (some of it reported earlier in the entry). Second, there are organizations that promote research undertaken by women/feminist geographers. They either embrace all women geographers – including physical geographers – regardless of whether they engage in feminist research and are also open to male members, or tend to be run by feminist scholars and attract only women and men engaged in feminist research. It should be stressed, however, that, while a few sympathetic male geographers may join these groups, their numbers are extremely small, just as it is often still rare to see male geographers at conference sessions organized by feminist geographers. Active groups representing these two functions can be found in the United States, Canada, the United Kingdom, Japan, and a range of Western European countries, including the Netherlands, Spain, Germany, Austria, and Switzerland. Women/feminist geographers in Australia, New Zealand, India, Israel, Southeast Asia, Eastern Europe, Scandinavia, Africa, and South and Central America, among other places, tend to work together outside of any official women’s organizations (Morin 2009).

Nationally, the first body to be inaugurated was the Committee on the Status of Women in Geography (CSWG) of the AAG in 1971, although this happened more by accident than by design (Monk, personal communication; Monk 2004). In 1979 the AAG Specialty Group on research on women and gender, Geographic Perspectives on Women (GPOW), was launched, and the AAG also adopted a bylaw on affirmative action. A similar thing happened in Canada a few years later, not least because a number of Canadian feminist scholars who were to play important roles were outside Canada (mostly in the United Kingdom and United States) pursuing PhDs and did not return until the early 1980s, when the Canadian Women and Geography Study Group (CWAG) of the Canadian Association of Geographers (CAG) was formed in 1982. In the United Kingdom, the (then named) Women and Geography Study Group (WGSG) of the Institute of British Geographers (IBG) was also formed in 1982, preceded by the formation in 1980 of the Women and Geography Working Party (Bowlby and Tivers 2009). Strong transnational linkages existed between a number of feminist geographers in Canada, the United States, and the United Kingdom. Indeed, the establishment of the WGSG was predominantly due to the presence in the United Kingdom of a Canadian feminist
geographer, Suzanne Mackenzie. Suzanne was a charismatic presence whose warmth, wit, and expansive nature influenced a whole generation of women geographers to embrace feminism. All three of these organizations – GPOW, CWAG, and the WGSG, now renamed the British Gender and Feminist Geographies Research Group (GFGRG) – remain very active, publishing geographical research from feminist perspectives, bestowing awards, funding named lectures, maintaining a feminist geography bibliography, and facilitating the exchange of information and ideas through websites, newsletters, conference sessions, workshops, reading groups, and listservs (geogfem@lsv.uky.edu has a largely North American and international audience and gfgrg@jiscmail.ac.uk has a UK audience). Similar groups exist in a few other countries, such as the German-speaking Specialty Group of Gender and Geography, which mostly represents women in Germany, Switzerland, and Austria (www.ak-geographie-geschlecht.org/), and the small but vibrant Study Group on Gender and Space/Place in the Association of Japanese Geographers. The Australian equivalent of these groups – the Gender and Geography Study Group within the Institute of Australian Geographers – closed down in 2004, a potential sign of the inability of such groups to be self-sustaining in countries where the number of younger feminist geographers in the discipline is insufficient.

A number of loosely affiliated groups further support women in geography in the United States (Morin 2009). The Washington-based Society of Women Geographers (SWG) is a professional and social organization established in 1925 by women who were accomplished explorers. Its membership now also includes academics from the AAG and the American Geographical Society (AGS), and it bestows a number of awards on women who have made distinguished contributions to knowledge about the world (Monk 2004). The National Council for Geographic Education (NCGE) has a women’s special interest group that provides awards for research in geography education by women graduate students. Other professional networks to which women geographers belong include the Association for Women Geoscientists (www.awg.org), the Earth Science Women’s Network (http://eswnonline.org), and the GIS Lounge–Women in GIS (www.gislounge.com/women-in-gis).

Subnational organizations are not a common format adopted by women geographers, but one such well-established body is the Association of Pacific Coast Geographers Women’s Network (http://apcgweb.org/womens-network), which offers scholarships and mentoring opportunities to its members.

The Commission on Gender and Geography of the International Geographical Union (IGU) (http://igugender.socsci.uva.nl) is the only women’s geography group whose mission and purpose is international in scope. The IGU was formally initiated in 1922 (although it has met since 1871; Morin 2009), and the commission was established with study group status in 1988, then granted standing as a commission in 1992. It is now one of the most active groups in the IGU; in 2014 it was recognized by the IGU as its “best” commission (Monk, personal communication). The commission was the initiative of Jan Monk, an Australian feminist geographer who conducted her career in the United States and has been a stalwart supporter of feminist geography and mentor to many feminist geographers globally. The geographical unevenness of organizations for women within institutions of geography has partially been offset by the work of the IGU, which has been of particular importance for women geographers in countries where there is no strong heritage of feminist work, such as Taiwan, for example, where feminist geographers are present but few
WOMEN IN GEOGRAPHY

in number, and Africa, where no organizations for women in geography exist and where the commission has held meetings in the anglophone countries of Ghana and South Africa. The IGU Commission has also been important in Southeast Asia, where the regional geography association (SEAGA) does not support a distinct geography group related to women, although in East Asia the Association of Japanese Geographers Study Group on Gender and Space/Place has strong links to the IGU Commission. The IGU is also increasing its presence in Latin America, where women’s groups in geography also do not exist, although there are vibrant networks of women geographers (see Peake (1989) and Garcia Ramon and Monk (2007) for global overviews of women in geography).

In its role of bringing together feminist geographers from many countries, the IGU Commission now has 670 members from over 50 countries. While it has done much to counteract the Anglo-American hegemony of the field, the majority of its members are from countries already well appointed with women’s organizations – the United States, United Kingdom, Canada, and Spain – and women from India are also well represented (although there is no women’s group in the National Association of Geographers of India). The context where institutional groups supporting women in geography are lacking, such as in India and other countries in the Global South, is one where geography as a discipline has not always been prominent in university curricula, is still largely descriptive in focus, and is valued primarily as a subject for training teachers or policymakers (Morin 2009). In such instances there is little political space for women’s organizations or for feminist work in geography to flourish. The countries of Australia and New Zealand; Brazil, Argentina, and Mexico in Latin America; France, Germany, Italy, and Switzerland in Western Europe; the Scandinavian countries of Sweden, Norway, and Finland; Israel in the Middle East; Japan in East Asia; Singapore in Southeast Asia; and South Africa are also moderately well represented in the IGU Commission. Membership is lowest in Eastern Europe (including Russia), East Asia (except Japan), Southeast Asia (other than Singapore), and Africa (except South Africa). The commission organizes several meetings each year and maintains its intellectual network through its website, working papers, and an excellent newsletter (igugender@list.arizona.edu), compiled by Jan Monk and published in English, French, and Spanish.

In addition to national and international bodies, there are also formal and informal cross-national networks of feminist geographers. For example, the Erasmus Network for graduate teaching existed within the European Union for nine years between 1990 and 1998, consisting of individual feminist geographers from six universities in five countries (United Kingdom, Spain, Denmark, the Netherlands, and Greece). Coordinated by Joos Droogleever Fortuijn, an active IGU Commission member, the network organized courses on gender and geography each year. More recently, the Great Lakes Feminist Geography Collective (Fem-geog-network@listserv.uoguelph.ca) has been formed, a group of nearly 30 feminist geographers from universities surrounding the Great Lakes in North America, which in a 2013 meeting brought together for the first time feminist geographers working in Canada and the United States. It has already been extremely productive, serving to energize a number of its members.

There are also, of course, informal academic groups that exist outside of the formal institutions that represent geography. Perhaps the best known are the Supporting Women in Geography (SWIG) groups in the United States
(and present but less prominent in Canada), which have been set up in various departments of geography, and at which professors, postdocs, and graduate students meet informally to engage in various activities that support the intellectual, professional, and personal participation of women in the discipline and provide mentoring opportunities for women who are pursuing academic and professional careers in geography (there is a list of SWIG groups at http://www.aag.org/diversity/gender). SWIGs have now spawned parallel professional groups built on the same ideas and philosophies. In 2007, Supporting Women in Geography Geographical Information Systems (SWIGGIS) (http://swiggis-austin.org) was formed in Austin, Texas. This is the first group of its kind in the professional realm. Its members are trained women geographers who work in the field of geographical information systems (GIS) in private businesses, public institutions, and local and state agencies.

Finally, informal professional and friend-based feminist networks operate globally. These networks do much to explain the development of particular research foci and, with technological developments, do not always require face-to-face meetings to flourish. These informal networks may also represent a more common future mode of organization that is no longer underpinned by the notion, which arose out of second wave feminism, of women as a unified group intent on a (reformist) politics of inclusion via separate organizations for women (Johnson 2009).

Whither forward?

Although there has been a more or less constant expansion of formal and informal organizations run by women geographers since the 1970s, they create geographically uneven networks – they are particularly thick on the ground in Western Europe and North America – often serving to better link in those who are already well linked. They have been successful in highlighting the low numbers of women in the discipline, in aiding the development of feminist work, in contributing to ways in which geographical knowledge is produced and disseminated, and in some cases in highlighting the Anglo-American hegemony of geography. What the range of women’s organizations and networks reflects, moreover, is the diversity of politics, practices, types of knowledge production, and modes of organizing in various countries (which may or may not speak to the status of women in the discipline in those countries). It is hardly surprising then that, despite the encompassing work of the IGU Commission, political divides between feminist geographers, across nationality and race in particular, have prevented the development of any robust transnational feminist praxis via these organizations. Indeed, whether existing groups can maintain their presence in some countries is in doubt. Women of color in white-dominant countries are less inclined to join what are often, in effect, white women’s organizations. And younger women, both white and of color, are often more attracted to more encompassing groups that work with different others across issues or to different political and theoretical projects of poststructuralism, post-colonialism, antiracism, and queer organizing in which gender is no longer the fundamental organizing category. The latter point is currently evidenced in the name changes being considered by some of these organizations from the ubiquitous but singular and knowable category of “woman” to encompass gender, with a nod to being more inclusive of trans women and of men.

While some may see the demise of women’s organizations as detrimental to women’s progression in the discipline, others see these
organizations as only serving to benefit white women and as speaking to the past, and therefore do not regret their dissolution. Peake has argued that the influx of women and second wave feminism into geography have left its racialized composition virtually undisturbed:

Notwithstanding feminist geography’s call to difference and inclusion, our failure to leave our own history uninvestigated subjugates the role that women of colour have played in it. It also speaks to a complacency in the failure to tackle the current racialized composition of our practitioners’ body as well as to investigate our interests in avoiding the truth about such an injustice, for it verges on institutional apartheid. Affirmative action is needed to address the whiteness of our field[;] without it we will only be able to reproduce ourselves in our own image and our role as an epistemic community will be far less rich and credible. (Peake 2015, 265)

Pulido (2002), among others, has also argued that a lack of diversity has deleterious effects on the breadth of geography’s intellectual production. Structural change along the lines of affirmative action is needed, including, for example, interventions into job descriptions, strategies of recruitment, and mentoring of women of color. Pulido (2002) states, however, that in addition there needs to be a fundamental change in the disciplinary culture to make geography more open and welcoming to all groups. Achieving this culture requires women in geography to remain engaged in viewing the composition of their discipline as an inherently political project that speaks to broader challenges to inequality.

Work–life balance

Diane Perrons
London School of Economics and Political Science, UK

Work–life balance, as a problem, entered the academic and policy arenas as the scale of women’s participation in the paid economy increased. While gratuitous attention was given to gender justice, reflecting long-standing feminist campaigns, policy discussion centered on how resolving the tension between paid work and caring would increase firm competitiveness and economic growth. The Organisation for Economic Co-operation and Development (2002, 5), whose mission is to “achieve the highest level of sustainable growth,” argued that “family friendly policies are a goal in themselves” but “getting the right policy in place will promote other societal goals … they will allow aggregate labour supply and employment to be increased.” Likewise the World Bank promoted gender equality as “smart economics” and recognized the importance of childcare to support women’s increased involvement in the economy.

Neither of these organizations contemplated a lateral redivision of domestic labor between women and men in line with Nancy Fraser’s (1997) ideal Universal Carer Model. More explicitly, Gøsta Esping-Andersen (2009, 169) considered “sufficient change in male behavior to substitute effectively for the decline in female domestic work unlikely.” More progressively, he argued that state support for carework would increase social efficiency by enabling low- as well as high-income women to enter the workforce and prevent gender equality in employment from being a middle-class privilege.

Apart from some of the Nordic countries, however, state childcare provision remains low in the Global North and Global South, leaving households to find their own resolution to work–life balance, which they do in class-differentiated ways. These resolutions sustain social inequalities within countries as high-income households can afford private care to facilitate the dual-earner model while lower-income households opt for a one-and-a-half-earner model, to the detriment of women’s careers and long-term incomes.

As caring and domestic work are highly labor-intensive and considered a natural talent of women, they are characterized by low pay and as such increasingly depend on a socially disadvantaged workforce, ethnic minorities, and migrant labor, a practice which sustains inequalities between people and places. In the Global North and Global South, maids and nannies from lower-income households, regions, and countries provide an important source of labor, as discussed in the global care chain literature. Such migration represents an individual solution to structural inequalities and exacts an emotional cost as migrants provide care while jeopardizing their ability to care for their own children.

While seemingly a small matter of decision-making within households, work–life balance raises a whole range of issues relating to economic and social relations between people and places and with respect to deep-seated gendered and racialized norms regarding the value of and suitability for different forms of work. Securing work–life balance requires resolving tensions between...
competing work-life scenarios of the free competitive disembodied worker presumed within economic policy and required by firms and the embodied worker for whom permissive work–life policies, parental leaves, and working time regulations are advocated in social and equality policies. Research in the information technology sector (James 2014) shows that resolving these tensions can be a win-win scenario for firms and workers alike, though realizing these potential gains more broadly remains elusive, leaving households to revolve their own problems with the associated gender, social, and geographical inequalities that this implies.

World cities

Kathy Pain
University of Reading, UK

World cities are generally understood to be leading global centers of economic and political power. Widely seen as internationally competitive urban concentrations of business, with specialized expertise, knowledge, and finance, they are undoubtedly a major manifestation of global resources and capital.

The world cities phenomenon has captured the imagination of scholars and policymakers, especially after Peter Hall’s book *The World Cities*, published in 1966, brought this powerful concept to widespread international attention. Fifty years earlier, Patrick Geddes’s *Cities in Evolution* (1915) had depicted world cities as a manifestation of the competitive international economy and, prophetically, as the generators of competitive regions. Roderick McKenzie went on to describe them in 1927 as world “centers of gravity” within a new form of global urban organization characterized by relations of dominance and subordination. It is this foundational conceptual framing of world cities as both an outcome and a generator of competitive spatial relations that has sustained discourse about this evolving expression of modern global capitalism for almost a century. Unsurprisingly, contemporary global economic integration has acted as a spur to intense world city competition, yet, at the same time, the ethics of the spatial centralities and power geometries which manifest the global system of world cities remains subject to contestation and vigorous debate.

In the globalizing world economy that has been emerging since the 1970s, the processes by which economically competitive world cities and their regions are generated and sustained have become increasingly complex. Facilitated by advances in information and communications technologies (ICT), the pace of change has accelerated to a once unimaginable speed. Fast forwarding to the twenty-first century, in comparison with the world metropolises described in the early world cities literature, contemporary cities are interconnected by a veritable blizzard of digitized information and financial flows. Developments in both communications and transportation have given specialized financial and linked business and professional services – first referred to as prominent in world cities by Hall and then, in 1986, by John Friedmann – an even more critical role in determining the way the present-day global system of cities functions. However, the specific link between the global dispersion and concentration dynamics of “new economy” finance, insurance, accountancy, law, management consultancy, and advertising “advanced producer services,” and the world cities phenomenon, was only made in the latter years of the twentieth century. The theory that, as offices servicing global capital extend worldwide, leading world cities gain a new role as strategic sites in economic globalization was not advanced until 1991 when Saskia Sassen’s *The Global City: New York, London, Tokyo* was first published.

Drawing on Manuel Castells’s (1996) theorization of the role played by advanced producer services in the contemporary network society, Peter Taylor and coresearchers in the Globalization and World Cities (GaWC) Research Network have empirically specified the global...
system of cities as a “world city network.” They have revealed a major reshaping of world city power geometries during the first decade of the twenty-first century in the form of a shift from localized and even national political control of cities to new de facto controls exercised by world money and information flows. This chimes with the prophetic vision of McKenzie who in 1927 pointed to coming changes in global urban organization “at variance with the existing political structure” as a consequence of increasing connectivity.

Alongside these global changes, a linked contemporary dynamic has been emerging at a more localized scale. Evidence for the global integration of extensive city regions in the new economy since the turn of the twenty-first century has sparked parallel empirical research into global centralities. This is not only focusing on the highly clustered business quarters of major world cities but also encompasses the proximate urban landscapes of nearby towns and cities. Interlinked by multimodal transportation infrastructures as well as virtual communications, these polycentric global regions such as the London “South East England mega-city region” integrate multiple surrounding urban centers of diverse size (Hall and Pain 2006). Theorists had already noted a similar process in the nineteenth-century “megalopolis” along the northeast coast of the United States and in the so-called “blue banana” in northwestern Europe. However, recent investigations of both of these extended urban regions have identified a further very high level of intraregional connectivity in global advanced producer services networks.

These multinodal global formations are sites for major flows of international skilled labor, knowledge, and finance that increase, as opposed to diminishing, economic returns and have a positive impact on GDP. This new scale of global activity has been described as creating the new engines of the world economy that threaten to overturn the primacy of nation-states. However, as is the case for the global system of world cities, new divisions of labor and polarizations are emerging at a local scale. The new foci for global centralities are generating spatially differentiated effects. These are illustrated by Doreen Massey’s 2007 analysis of the globalized spatial relations and political dilemmas facing contemporary London in World City.

This brief commentary on a topic that has been extensively explored in a large literature has necessarily been highly selective. Precedence has been given to a small selection of the key theoretical and empirical developments that provide an overview of the transformative processes and main lines of argument that have underpinned recent debates.

Origins of the world city concept

For Hall, who first brought the concept of the world cities to international attention, these complexes were “great cities, in which a quite disproportionate part of the world’s most important business is conducted” (1966, 7). A concentration of professional expertise, specialized knowledge, and finance was enabled by superb transportation and communications infrastructures. As centers for advanced business and professional activities, knowledge, and learning, as well as governmental organizations, the power of world cities extended far beyond national borders. Hall identified not only major metropolises such as London, New York, Tokyo, Paris, and Moscow as world cities, but also multinodal urban regions such as the Randstad (Netherlands) and Rhine-Ruhr (Germany). He recognized early on the potential
world competitiveness of extensive polycen-
tric urban regions, an idea elaborated 40
years later by Hall and Pain in The Polycentric
Metropolis (2006).

Drawing on the pioneering regional perspec-
tive developed by Geddes, Hall’s world cities
analysis identified the significance of the coming
shift from early capitalism to “finance capitalism”
for a dramatically changing regional landscape.
In particular, he drew attention to the physi-

cal spreading out of globally competitive city
growth and its consumption patterns, includ-
ing individual travel by car. These city-region
developments, and the challenges they present
for governance and planning, have become even
more apposite worldwide today.

By way of contrast, and drawing on theories of
a new international division of labor (NIDL) in a
world economy where people and finance capital
flow into and out of the city, in his World City
Hypothesis, Friedmann (1986) focused on the
global economic system as a whole and the city
distinctions it gives rise to. In prioritizing world
economic development as the key explanatory
factor in urban analysis, he emphasized the
importance of rapidly expanding financial and
“high-level” business services in creating “global
financial articulations” such as London, New
York, and Tokyo that were the world “basing
points” for global capitalism. Different localities
were identified as having varying global and
subglobal roles in the “spatial organisation and
articulation of production and markets,” result-
ing in a complex spatial “hierarchy of world
cities.” Certain “primary” centers for major
capital accumulation in “core” countries, such
as New York, were distinguished as carrying out
“all of these functions simultaneously,” whereas
other cities had multinational or national func-
tions and roles. Importantly, the cities in this
global hierarchy were, for Friedmann, all part of
a network.

Compared with the world-systems framework
in which relations between core and periph-
ery were conceived as process— as opposed to
place-specific, Friedmann’s world city hierarchy
was unequivocally spatial, with North American,
Asian, Southeast Asian, and Western European
subsystems, the latter including Hall’s exten-
sive Randstad and Rhine-Ruhr world cities.
Referring to research such as the early study of
New York by Sassen (2001/1991), he also drew
attention to consequent crises inflicted on the
state by the social and fiscal impacts of interna-
tional capital in primary core and semiperipheral
world city locations. The insights provided by
Friedmann have influenced the thinking of many
subsequent writers.

The world city as process versus place

Building on Friedmann’s analysis, the 1991
edition of Sassen’s The Global City was a seminal
contribution to the world cities literature. The
timely attention by Sassen to the process by
which prominent financial centers such as New
York, London, and Tokyo acquire distinctive
roles as agglomerations of command functions in
specialized business services also had a distinctly
spatial focus (Sassen 2001/1991). Her analysis of
the simultaneous dispersion and concentration
dynamics of specialized businesses servicing
multinational corporations worldwide informed
a wave of subsequent empirical studies into
the spatialities of global business organization
and practices, and their societal impacts. The
insights provided into the drivers behind the
centralization of the global command and con-
trol functions of advanced producer services and
the implications for the management of the new
space economy have had an ongoing influence
on urban research to the present day.
But a new way of understanding the production of global city space was introduced by Castells in 1996. In his *Information Age* trilogy, Castells advanced the seminal theory of the emergence of a new “network society.” The city network concept had previously been alluded to by other writers but Castells added a distinctive perspective in the shape of the rising influence of new economy producer services as key generators of increasing network relations between cities. In the context of late twentieth-century developments in ICT, he saw such services as active agents in a global space of flows that was superseding the mosaic space of places appropriated by states. The importance of this theoretical leap is illustrated by John Allen in a less well-known contribution to the world cities debate in 1999, “Cities of Power and Influence.” This analysis went against the grain of previous (and prevalent ongoing) interpretations of city power relations, hypothesizing that, in the network society, power can no longer be understood as “fixed” in space or as belonging to any one city, but must instead be seen as distributed through intercity networks. Allen’s challenge to competing world city narratives that present power as deeply embedded in place has, unfortunately, been somewhat overlooked in subsequent debate.

For example, in *World City*, Massey (2007) observes London predominantly through the geographer’s lens of a “global sense of place,” focusing on the concentration of wealth and resources there and the associated local and global polarizations. Her deliberately accessible writing style leads to an inference that London, the city, is the agent actively shaping globalization and generating its uneven economic and power geometries. Allen’s interpretation of world city power as distributed through networks of economic actors, and flows within and between cities, is less in evidence. Massey’s plea to London’s government leaders to adopt a deterritorialized politics that recognizes the city’s moral responsibilities perhaps overestimates the capacity of the bordered state to reshape power relations that are mobile in intercity networks. This critical question for world city policy will be returned to shortly.

### A world network of cities

Taylor deduced that cities can only be understood through their worldwide network relations. According to network theory, cities are “not a place but a process”; therefore, according to Taylor, writing in 2004, they must be studied by quantifying their interlinkages and connectivity as nodes in a world city network that services global capital. This theoretically inspired empirical departure marked a late twentieth-century turning point in world cities analysis in two ways. First, the analysis recognized cities as shaped by or as the outcome of a social process, as postulated by earlier pioneer urban sociologists, in which city relations and connectivity are constructed by business networks that straddle and use them to conduct global business. Second, empirical network analysis allowed the dynamic distribution of connectivity across the global system of cities to be measured robustly for the first time. Furthermore, the numerous quantitative network analyses initiated by GaWC and others have been supplemented by qualitative studies that shed light on the relations and practices of the advanced producer services that generate city network connectivity and the consequent functional interlinkages and flows between cities.

What can be learned from the results of this research is that the power of contemporary world cities cannot be assessed simply on the basis of place-based city attributes but must take into account intercity relations in dynamic global
networks. This new way of thinking about city relations is acknowledged by Sassen in her 2001 edition of *The Global City* and in subsequent publications which credit the partial deterriorialization of spaces of centrality in digital networks. But Sassen’s view that spatiality that “pivots on” global networks remains interdependent with a major territorial concentration of resources illustrates an important spatial contradiction that has underpinned ongoing controversy about the ethics of world cities.

To put the city network thesis into context, Castells too is acutely aware of the differential spatial impacts that globalization encompasses. Albeit modern society is increasingly networked, as in previous eras, it remains an expression of deeply territorialized political relations with unequal impacts. Castells’s dystopic world vision presented in the final 1998 volume of his *Information Age* trilogy engages with the deeply divisive inequalities prevailing within, as well as between cities worldwide. Spaces of fragmentation and political contestation have not disappeared, even in the world’s richest cities. Therefore a major challenge, it would seem, is the need for the politics of cities to engage with the networked space of contemporary intercity relations and flows, which are now more volatile than ever before.

**Cities of towers**

In the complex networked world economy, the concentration of value-adding functions has been ongoing and has become intertwined with new modes of “grounding” finance capital in the physical structure of cities.

In his 2009 book *Towers of Capital*, Colin Lizieri demonstrates how, in major world international financial centers where real estate interacts with other globalized economic activities, advanced producer services and office property markets are critically interlinked in the production of the evolving world city network. World cities are the sites for increasing major international financial investment, encouraged by the financial innovations introduced by their specialist transnational labor that have modified the relationship between office property development and its commercial funding. As the creation of new investment vehicles, such as private real estate funds or real estate investment trusts (REITs), has spread the risk on high-value property developments, the financialization of city real estate has accelerated. In this way, the capital that flows through financial and business services networks is stored in the physical city infrastructure such as the office buildings that they occupy.

Meanwhile, high-revenue streams associated with city “signature” or “starchitect”-designed landmark office space, literally build the evolving vernacular of competitive global capitalism. The integration of global finance and city real estate in world cities therefore facilitates the circulation of mobile international capital and also fixes it in specific city locations. Put simply, the workspace of the contemporary service economy is molding the politics of the world’s cityscapes.

Lizieri’s account is particularly pertinent to recent debate about the exposure of world cities to global financial risk. Counterintuitively for some commentators, London’s office market has proved resilient to the post-2008 global financial crisis. But a stream of qualitative world cities research suggests that this actually resonates with Lewis Mumford’s view that “the nature of the city is not to be found simply in its economic base: the city is primarily a social emergent” (1938, 6). Mumford complained that “people treat pragmatic abstractions such as money, credit, political sovereignty, as if they were concrete realities that had an existence independent of human conventions” (1938, 7).
WORLD CITIES

As already noted by Hall in the 1960s, world cities are used by a “significant proportion of the richest members of the community” (1966, 8). They are the places where highly paid labor with specialized skills congregate, tacit knowledge is exchanged, relationships are developed, global deals are brokered, and foreign direct investment is concentrated. London’s transnational constitution generates global work. A major high-value financial transaction taking place in the City of London can involve participants in, say, New York, Tokyo, or Shanghai. And it is the globalizing strategies of London’s transnational capitalist city users that have, for more than a decade, helped to sustain its supreme world city network connectivity, also creating investment confidence in its real estate markets. Together with its time zone and other place-related advantages, a politics of openness to foreign labor and firms since the 1980s, has undoubtedly been instrumental in sustaining London’s high-value office real estate market.

In the context of increasingly agile transnational capital investments, neoliberal strategies to attract inward investment through entrepreneurial development projects have also more directly promoted the commodification of city real estate. A progressive literature has drawn attention to the active role now played by the state in the mobilization of city space for the operation of global capitalism and its elite consumption practices. These developments highlight the huge resources that are necessary for globalized capital accumulation in world cities, endorsing Sassen’s (2001/1991) view that, in the parts of the city where major structures of the world economy are located, a “strategic new spatiality” is constructed. They also demonstrate that the wording of cities is at least partially cogenerated by political interventions. So, although Massey underemphasizes the role of London’s network relations, her call for a more progressive politics of space which looks “both within and beyond the city and [holding] the two things in tension” is pertinent (2007, 191).

The mobile world city

Nevertheless, world urbanization, increasing market liberalization, and economic integration ensure major transformative world city realignments and, as foreseen by McKenzie in 1927, “new centers of dominance are arising.” Twenty-first-century world city geographies are being reshaped in two important ways.

First, new strategies adopted by global advanced producer services are increasing the connectivity of many places in the world city network, leading to a dramatic global repositioning of some cities. Rapidly globalizing cities in emerging economies now accommodate a large number of strategic functions and are catching up with the “big three” global cities of the late twentieth century: London, New York, and Tokyo.

Second, as these rising world cities are gaining important global roles and economic status, a new landscape of functionally interlinked world city-regions is emerging. The “great urban regions” first described by Hall as world cities are subject to diverse development processes with morphologically “monocentric” regions, such as London, developing extensive globally connected mega-city regions that feature functional complementarities and polycentricity, as described by Hall and Pain in 2006. Meanwhile, in regions long regarded as polycentric, such as the Randstad and the Rhine-Ruhr, cities such as Amsterdam and Dusseldorf have become global nodes surrounded by urban centers exhibiting sectoral specialization and lower levels of global connectivity. Thus, new geometries of global agglomeration are arising.

In the meantime, on the other side of the world and half a century ago, Shanghai was only a minor player on the world cities economic stage when the Yangtze River Delta (YRD) was first described as one of six giant world city regions. The city has since experienced a staggering rise in world city network connectivity and prominence under China’s Open Door modernization project. During just one decade, Shanghai has risen to fifth position and Beijing to eighth position in the world city network for financial services (see Box 1). In consequence, London and New York are now highly connected to China through their global financial and linked advanced producer services, forming a new prominent, cross-border geography of superconnectivity within the world city network. And the major, rapid development of Shanghai is being accompanied by sweeping functional and economic changes across the once urban industrial/agrarian YRD megacity region. Mobilized by transnational corporate and state entrepreneurial strategies in an ambivalent political economy landscape, the iconic skyscraper landscapes typical of Shanghai are also being rolled out across China as part of a vast metropolitanization project that will provide new infrastructures for global capitalism.

The system of world cities is undoubtedly in a state of flux and hybridization as the asymmetric spatial relations of urbanized global capitalism are redrawn in a network landscape (see Figure 1). Differential work and wealth creation, environmental, ecological, or food and water security geometries have yet to play out across evolving megacity region and rural/urban divides in the longue durée.

What can we take from this brief trawl through a range of key contributions to world cities scholarship? The world cities phenomenon is defined by a plurality of complex cross-cutting relational geographies and power geometries with equity implications. The contradictions it presents remain challenging to address. On the one hand, the conception of cities as constituted by a new logic of network flows generated by economic agents informs understanding of the cross-border integration of world cities but, on the other hand, states are complicit in the mobilization of world cities as focal points for the operation of global capitalism. The metaphorical power of the world city concept has undoubtedly been a driver for burgeoning contemporary territorial competition. A reflexive approach to interpretation that takes into account the temporalities of world city transformation in a dynamic geopolitical context is therefore clearly necessary.

World-systems theory

Salvatore Engel-Di Mauro
State University of New York at New Paltz, USA

Foundations of world-systems theory

Geographers, since at least the 1980s, have borrowed from, contributed to developing, and critiqued (Flint and Shelley 1997) what should be more precisely called the world-systems perspective. It is an analytical framework or paradigm encompassing diverse, sometimes conflicting, macro-social approaches premised on certain broadly unifying theoretical positions. It emerged in the early 1970s mainly in response to prevailing capitalist explanations of worldwide inequalities, among other related processes, in a context of openings and heated debates within institutional or party-line Marxism (especially over the concept of “ Asiatic mode of production” and the causes of the feudalism-capitalism transition). In fact, the critique challenged both capitalist and predominant Marxist approaches because it pointed to the inadequacy of stage-based formulations of progress (especially for non-European histories) and the national-scale emphasis (the exclusive use of internal processes to explain social change) shared by mainstream capitalist and leftist theories and politics. The alternative offered, the world-systems approach, crystallized through a paradoxical confluence of neo-Marxist perspectives, especially from within the Latin American Dependencia (Dependency) School, and the partly anti-Marxist history approaches of the French École des Annales (the Annales School).

Elaborating on the unequal exchange thesis developed within the UN Economic Commission for Latin America, neo-Marxist Dependencia proponents, during the 1960s, studied the effects of external imperial forces from the metropole (core) on prospects for economic development (in the modernizationist sense) in regions like Latin America. These regions were argued to be structurally dependent on the metropole and, thereby, forced into the periphery of the world economy (Amin 1974). Some dependentistas were also directly involved in policy formulation and implementation, privileging national state control of investments and favoring such policies as land ownership reform. Various US-backed military dictatorships cut short such reform processes, especially following the murderous 1973 military coup in Chile. Many dependentistas experienced such dictatorships directly, some even losing their lives. At least some aspects of dependency theory were thereby radicalized (e.g., the proposition of delinking from the world economy).

In contrast, French Annales historians represented an academic response to what they presumed a mainly academic endeavor, that of how to study history. The 1929 establishment of the Annales d'Histoire Économique et Sociale (Annals of Economic and Social History, eventually renamed Annales. Histoire, Sciences Sociales, or Annals. History, Social Sciences) generally marks the beginning of this approach. Expressing dissatisfaction with treating history as a series of events, where formal political aspects drew most scholarly attention, these historians drew from multiple fields of knowledge, including
the environmental possibilist regional geography of de la Blache (hence, there are some geographical roots to world-systems perspectives). The Annales School alternative was a focus on material culture and long-term processes behind quotidian activities and attitudes, within what would eventually be called a world-economy composed of different societies. However, their particular brand of materialism is expressly antithetical to Marxist perspectives and largely unconcerned with power issues, especially class relations (cf. Braudel 1977). While most of its founding proponents lived through the Nazi dictatorship and one of its main figures (Marc Bloch) was executed by Gestapo officers, the Annales School perspective has not contributed to addressing coeval power relations in any direct way, such as the relationship between France and the Algerian independence struggle.

By the early 1970s, the world-systems framework combined aspects of the above-discussed schools of thought to provide the foundations for an innovative approach that situates national within broader geographical and historical processes (e.g., the world-economy of the Annales School) and attends to the relations of power behind large-scale social inequalities (e.g., the unequal exchange, core-periphery concepts from the Dependencia School). It joined a world-scale core-periphery model of uneven development with a long-term historical view to overcome narrow understandings of social change or struggles, which are still often treated as if they unfold ahistorically within disconnected countries. Implicit from the start in this conceptualization were a geographical orientation (e.g., emphasizing interlinkages between places and scale of analysis) and the quest for the unification of knowledge production modes (social and physical sciences, humanities).

Four premises guiding world-systems analysis

What emerged out of such alchemy of contrasting approaches was a set of theoretical premises guiding a general framework called world-systems analysis. First, world-systems are the most important units of analysis and general explanatory variable for social change, especially in the long term. The hyphenation in the term “world-system” actually serves to signal this explanatory focus on spatially and temporally delimited worlds, composed of multiple elements (e.g., polities, cultures) integrated within a single system. A world-system is thus defined as an entity encompassing different state-based and stateless societies interlinked and integrated through a division of labor, which implies that any form of labor counts, including unwaged labor in a capitalist world-system. For systems predicated on stateless societies, the term mini-system is employed. A world- or mini-system cannot be treated as operating independently of its scale-producing elements, which create the world- or mini-system in the process of interaction. The analytical framework is, therefore, both systemic and relational. Accordingly, the unevenly experienced historical emergence of capitalism, still the primary focus of attention, is explained as an intrinsically expansionistic system integrating other world- and mini-systems, often by force, into its periphery. Hence, what occurs in one area cannot be assumed to be independent of processes happening elsewhere (Amin 1974; Hall 2000).

Second, and a main premise of all world-systems approaches, is that social change cannot be explained through internal dynamics alone but by understanding how societies are interconnected with others as parts of a changing whole. This means that scale (at least the social one) is not static, but made through networks of social relations.
In fact, the scale of the specifically capitalist world-economy has increased historically, unlike any other system, to cover the entire physical world. The large-scale that is often referred to as “global” has been produced through capitalist expansion. Consequently, world-systems research focuses on both the effects of such world-system dynamics on the internal processes of the societies (or subsystems) that compose it (ultimately, all the human actors within it), and the influence of change within societies (subsystems) on the overall characteristics of that world-system itself (Hall 2000).

Third, and a major theory within the world-systems paradigm, is that over long historical periods there developed, out of multiple succeeding mini-systems, world-economies, and world-empires, a capitalist world-system (with a single world-economy) that marks the first planet-encompassing world-system in human history. The rise and fall of different world- and mini-systems and related multiple-scaled social changes are the product of the mutual constitution of societies (the parts) and world-/mini-system (the whole). In this manner, the insights of the Dependencia School are refined by addressing the existence and maintenance of political economic inequalities between and within countries. Wallerstein is especially interested in the long-term emergence, development, and demise of self-contained world-systems (if state-based) and, to a much lesser degree, mini-systems (if stateless) in different parts of the world. This long-term perspective, elaborated from the works of Braudel and others from the Annales School, allowed for an understanding of the specificity of the capitalist world-system and for the elucidation of the processes whereby wealth accumulation could become concentrated in some regions at the expense of others. The main mechanism, already considered by Dependencia theorists, is unequal exchange, benefiting the core countries unevenly and largely the ruling classes of the semi-periphery and periphery (Wallerstein 2011/1974, 347–357).

Fourth, a world-system (presumably not so much mini-systems) develops structurally into zones having uneven influences over the system as a whole. These zones are called core, semi-periphery, and periphery, which are relational concepts. In a capitalist context, core, semi-periphery, and periphery are spatial categories used to describe tendencies present in the world economy and the relative world-system position of places integrated therein. Core places are those characterized by capital accumulation and attendant combinations of high economic, military, and political influence in the world-system. Peripheries are impoverished places of largely imposed economic dependence on core regions and that may have marginal status in the capitalist world-system. Semi-periphery describes an intergrade world-system position of dependence on core countries and influence over some countries in the periphery.

The enormous breadth of studies undertaken under world-systems analysis spans most fields of social science, including human geographies, and increasingly the sciences concerned with paleoenvironmental change (Babones and Chase-Dunn 2012). World-systems analysis covers a vast array of topics, from explanations of long-term historical change at different scales, including indigenous peoples’ histories and world-systems, to issues of racism, gender relations, colonialism, urbanization, and warfare. Within geography, it is especially the political subfield of human geography that has benefited most from the insights of world-systems approaches, particularly through a de-emphasis of the national scale and through such concepts as hegemony cycles and regional power differentiation (core, semi-periphery, periphery) and their application in conjunction
with economic processes. In the case of the latter, analytical categories and studies of commodity chains, cyclical phases (e.g., Kondratieff waves), and phase-dependent technological innovation, among others, also markedly influenced economic geography.

Critiques and countercritiques of world-systems analysis

World-systems approaches have been critiqued since their very introduction and from diverse theoretical perspectives. One critique is the privileging of scale to the world-system level at the expense of processes at other scales. This is especially of concern to those taking individual actors and everyday activity as the primary research entry point. Through this and other lenses, world-systems analysis seems to prioritize structural explanations or to espouse another form of structuralism, rather than enable forms of inquiry that are more context-sensitive or consider agency and/or contingency. Another is the assumption that the geographical expansion of capitalist relations is coextensive with a capitalist world-system. This is related to conflating relations of exchange with interactions among modes of production. Another is the disproportionate attention to a presumed Europe-centered capitalist world-system and the virtual absence of such oppressive processes as racism, patriarchy, heteronormativity, and arguably even class struggles in world-systems analyses. Aside from these problems, there are some underlying issues in the world-systems framework that derive from problems in the Dependencia and Annales schools out of which the framework was wrought. Namely, they are the setting of system boundaries sufficiently clear for analytical purposes (both in terms of space and time) and a tendency to reduce processes to the activity of social forces influential at the world-system level (it is not so much agency in general as to whose agency), which can lead to missing world-changing processes coming through other scales of analysis. Some of the more potent charges include functionalism (tautology) and determinism.

Critiques of world-systems analysis have been in themselves problematic (Wallerstein 2011/1974, xix–xxviii). There are issues of problem misidentification and theoretical mischaracterization. One example is Laclau’s denial of the possibility of articulation of modes of production and insistence that capitalist systems must have a largely proletarian presence, which implies that capitalism is receding as wage employment becomes increasingly a privilege even in the most industrialized countries (see a rebuttal in Wallerstein 2011/1974, 127). The charge of functionalism confuses analytical categories used in world-systems theories for explanatory statements. Core, semiperiphery, and periphery and accumulation processes are analytical categories used not to explain but to describe a world-system. The content of these analytical categories has recently been challenged for their social reductionism but they have not been abandoned. They remain useful if understood through context-specific spatio-material mechanisms (Bunker 2003, 238–239). World-systems theories attempt to explain the evolving characteristics of and rise and fall of different world-systems, requiring careful and detailed historical analysis at many scales, including microsocial (see Straussfogel in Hall 2000). This theory is also contested in that some maintain that such a global world-system emerged much earlier and/or is not as Europe-centered as once thought (Frank and Gills 1993). However, in all these perspectives, the starting unit of analysis remains at the world-system scale (a historically variable unit in terms of Earth surface area and time period covered).
The imputation of determinism is similarly misplaced. Wallerstein (2011/1974), for instance, has made it very clear from the beginning that world- and mini-systems develop and change as a result of shifts within and between their components. The characteristics described and explained in world-systems research involve the understanding of co-determination of all forms of social relations, including cultural, political, and economic aspects of ethnic, class, and gender relations (Hall 2000). World- and mini-systems are also open systems, tending to be thereby dynamic, complex, and unpredictable. Far from reducing social phenomena to macroscale processes, world-systems approaches consider and attempt to integrate potentially all possible scales and aspects of social relations, cultural, political, economic, following in the footsteps of the Annales School. The historically informed accounts of world- and mini-system processes accord with the recent understanding of scale in human geography as socially constructed, as the product of power relations. The global, for example, is a recent phenomenon brought about by capitalist development and expansionism over the past 500 years or so and the construction of the global scale has simultaneously involved multiple social processes, including non-capitalist relations and Indigenous Peoples’ agency (Hall and Fenelon 2009).

There are, nevertheless, some fundamental shortcomings in world-systems perspectives, though not necessarily in terms of the theoretical framework itself. For example, studies are still rare that treat as fundamental to world-system dynamics the processes of, for example, gender and heteronormativity. However, since the 1980s there have been ways in which, for example, household and patriarchal processes have been fruitfully analyzed in relation to resistance to neoliberal policies or to colonialism, including indigenous peoples’ struggles, to furnish more effective explanations of world-system processes (Dunaway 2001). Similarly, and despite early works on environmental degradation, most world-systems research does not address biogeophysical processes, although much work has emerged to redress this situation. In part, the problem lies not just in the framework itself, but in social science approaches generally. As Bunker (2003) pointed out, the socially-based, analytical categories of core-, semiperiphery, and periphery must be defined according to context-specific spatio-material mechanisms (e.g., the highly uneven spatial distribution of metalliferous ores and the variable material conditions for their extraction, processing, use, and transport). He therefore called for a “new historical materialism.” Work is being done to redirect world-systems research agendas towards ecological processes with human world-systems as component parts of major interest. Recent advances hold much promise in explaining the interrelations between larger-scale social and environmental dynamics and smaller-scale phenomena. For example, the combination of world-system analysis with insights from environmental sociology has been increasingly adopted to explain shifts in global to local anthropogenic environmental impacts, but the work has really just begun (for newer developments in the wide variety of world-systems analyses, see Babones and Chase-Dunn 2012).

Zoogeography

Michael N. DeMers
New Mexico State University, USA

Zoogeography is the subdiscipline of biogeography that aims to explain the distributions of animals and, through doing so, to further explain the relationships of these distributions to other geographic phenomena. The science differs from the broader biogeography in that it focuses on fauna rather than flora. This distinction is important because fauna have the capability to adapt not only by adaptation but also by migration to habitats that are more conducive to species survival. There is also a significant difference between traditional zoogeography, which focuses on the patterns of zoological phenomena and emphasizes historical as well as environmental distributional factors, and ecological zoogeography, which tends to restrict its examination to ecological factors. While the distinction is there, it is becoming more blurred with time.

The historical roots of zoogeography are inextricably linked with those of ecology and the research and musings of Ernst Haeckel, who not only introduced ecology in his general zoology text (1866) but also gave a new name and new content focus for what would eventually become zoogeography. His view was that the spatial distribution and organization of organisms should be a new discipline. He called that discipline chorology.

According to Udvardy (1969), chorology included the description of not only geographic and topographic habits and the distributional limits of species but also the elevational and bathymetric zonation of species. Interestingly, Haeckel (1866) believed that, while biogeographers of the past had studied these factors, they lacked the necessary underpinning of Darwin's evolutionary theory to explain their findings. In effect, Haeckel was emphasizing the zoogeographical method as a means of understanding biological phenomena.

Alfred Russel Wallace, a contemporary of Charles Darwin, developed his own theory of evolution independently and was the first to establish a clear distinction between the biologist and the zoologist. His Geographical Distribution of Animals (1876) identified the zoologist's work as "geographical zoology" and the geographer's as "zoological geography." For geographical zoology he advocated a classification of the distribution of the world's animals by taxonomic groups, but still made an allowance for biological interactions and historical factors (Udvardy 1969). Wallace's book was the definitive textbook on zoogeography until the mid-1950s.

Like today's zoogeographers, Wallace did not limit his work to extant species. He included evidence derived from the fossil record to discuss mass extinction, evolution, and migration which resulted in the geographic distribution of modern animal species. Wallace was well aware of the mass extinction of megafauna in the latter portion of the Pleistocene. This led him to believe that we are currently in a "zoologically impoverished world, from which all the hugest, fiercest, and strangest forms have recently disappeared" (Wallace 1876, 150). He eventually believed that the most likely cause of the rapid extinctions was not so much glaciation as the impact of humans. Such working hypotheses, and opposing hypotheses regarding species extinction, are also part of modern zoogeography.
ZOOGEOGRAPHY

Zoogeographic regions

Using the zoological geographic approach, Wallace was among the first to identify the distinct regionalization of the Earth’s fauna. This regionalization was based on very few species and partly on his famous study of the Malay Archipelago, in which he identified unique faunal assemblages in the Indonesian islands of Bali and Lombok in the south and of Borneo and Sulawesi in the north. This line separated what he defined as the Asian (Oriental) and the Australian zoogeographic regions. Later named Wallace’s Line (Figure 1), it clearly showed marked differences in fauna in islands that were a mere 20 miles apart. It is also part of the general zoogeographic regions (more accurately, realms) which, at the time, in addition to the Oriental and Australian, include the Nearctic, Palaearctic, Ethiopian, and Neotropical realms (Figure 2). The appeal of this system for geographers is that it coincides well with the limits of continents or major topographic regions. Unlike biomes, which are defined exclusively by ecological factors, zoogeographic realms are delineated by the presence or absence of particular assemblages of animals that are then explained by ecological or other factors. In a way, they are two sides of the same coin.

The general structure of the zoological regions and the methods by which they are derived have changed over the years, and many attempts have been made to make it less subjective and more quantitative. These continue to the present, and consider ancestral species relationships but seldom focus on explicit phylogenetic relationships. Phylogenetic trees are increasingly available for more and more species, which contain considerable additional information that is useful for grouping species assemblages into zoogeographical regions at a global scale. This approach clearly demonstrates that the original concept of zoogeographic regions devised by Wallace is still a focus of research. With increasingly robust datasets, including phylogenetic and phylogeographic data, zoogeographic regionalization research is likely to continue for some time to come.

Dispersal and migration

While analyzing zoogeographic regions as they exist today is one focus of the geographer’s research, the changes in distributions of individual species is also an area of research common to geographers and zoologists. Ecological zoogeographers are more likely to focus on dispersal, the spreading of individuals from their parents, siblings, or social group. Geographical zoogeographers are more likely to follow the approach of Wallace in that they look at movements of large numbers of animals from one place to another, often abandoning original environments in favor of more ecologically suitable ones. This, of course, results in different zoogeographic patterns that intrigue the geographer as they search for causal factors or, alternatively, for the impacts of these migrations on the new habitats. These pattern changes can be examined over any temporal framework, involving recent environmental changes or paleoenvironmental changes. Such studies often include a range of such changes from short-term ecological forcing functions to those involving long-term climate change and continental drift.

In examining individual dispersal or large-scale migration, some general factors play a role. Forcing functions – external factors that cause species to migrate seasonally, relocate, or become locally extinct or extirpated – and large-scale environmental changes that either displace whole faunal assemblages or cause their extinction are topics of concern to the zoogeographer. Each
species also exhibits its own level of environmental plasticity. For example, the cockroach has adapted to a symbiotic relationship with humans; ants seem to be able to survive a wide range of environmental conditions; and locusts adapt to changes in food availability and landscape patchiness by both changing their physical form and adopting a social structure for survival. Once a species is forced to relocate, it must face obstacles to relocations such as physical barriers (e.g., streams, lakes, or mountains); distance barriers, whereby the nearest compatible habitat might be thousands of kilometers away; or ecological barriers, where there simply is no compatible habitat at all. Each of these is a concern to the pure zoogeographer hoping to understand shifting patterns, and to the applied zoogeographer who uses this knowledge to plan for environmental change.

The methods by which species disperse also vary, and are often affected both by their mode of locomotion and by the physical features they encounter. Generally there is a steady movement or diffusion into adjacent areas because of proximity, or a jump dispersal may take place, often suddenly, thousands of kilometers from the original habitat. Flying species, for example the cattle egret, are best adapted to jump dispersal because of their mode of locomotion and their ability to cover large distances and overcome barriers. Dispersal can also be aided by corridors (e.g., roads, riparian areas, habitat edges), which act very much like highways for the movement of species. Closely spaced islands or habitat patches
Wallace’s map showing the zoogeographic regions of the world.
may act as stepping stones for this type of dispersal as well. Whatever the mechanism, dispersions may also be classified as invasions if the habitat is already occupied. This results in the possibility of niche overlap and conflict, which may result in the extirpation or elimination of an existing species, especially if the invading species is exotic. The devastating simplification of insect fauna as a result of the mass migration of fire ants into the east coast of the United States is one example. From just these few examples, it is clear that an understanding of zoological displacement is critical to conservation and land management efforts.

**Areography**

The importance of the environment to dispersal is part of a broader topic called areography, which examines how species interact with the geographical areas in which they reside. Interestingly, Rapoport (1982) uses the term “areography” synonymously with “chorology,” which was an early term for zoogeography itself. The primary topics of areography examine the impacts of the shapes, orientations, and dimensions of geographical features on the organisms that inhabit them; longitudinal impacts on species diversity, range compaction, and delimitation and compaction of species range areas. Beyond the identification of these geographic patterns, areography attempts to create new methodologies for their quantification and analysis.

Among the topics most relevant to zoogeography is the peninsular effect, which describes how species richness decreases as the shape of a peninsula narrows. This is the result of a reduction in the amount of habitat. Areography studies the methods of delineating and compacting species ranges to most accurately represent both location and species integrity. It evaluates geographical range and distance in relation to the number of species that are likely to occur. As suggested, the barriers to dispersion are also a topic of interest to the areographer and include examination of pest species.

Among the most well known of concepts to arise from areography is Rapoport’s rule, a hypothesis that the latitudinal range of species is smaller at lower than at higher latitudes. Among the explanations for this phenomenon is the suggestion that at very high latitudes species are restricted as a result of glaciations having wiped out species that would normally have narrow ranges and climatic variability, while areas with seasonal variability accommodate species with greater climatic tolerance and therefore a wider latitudinal range.

**Species adaptation**

Because species vary widely over the Earth’s surface, it stands to reason that they will encounter wildly different persistent environmental conditions. By extension, it stands to reason that such environmental differences result not only in different zoogeographical regions, but also in the species themselves, over time, adapting to such conditions through the evolutionary process. One ecogeographic principle associated with this, called Bergmann’s rule after the German biologist who described the pattern, holds that the body mass of birds and mammals (endotherms), and apparently other taxonomic groups as well (e.g., the ant *Leptothorax acervorum*), tend to be larger and bulkier in colder regions and smaller in warmer regions. Apparently, this is an adaptation of species as a way of conserving or of radiating body heat, depending on the climate. The degree to which Bergmann’s rule holds true is still a topic of zoogeographic research.
Animal species have also adapted in other ways to different environmental conditions. Allen’s rule, for example, indicates that body shapes and proportions in endotherms adapt to climatic temperature regimes either by minimizing exposed surfaces or by maximizing surfaces, depending on whether the adaptation is meant to minimize or maximize heat loss. Examples of this include long and thin appendages (ears, tails, limbs, snouts, etc.) in hot climates and shorter and thicker appendages in colder climates.

Other adaptations to geographic factors include the ability to store food and water in deserts, as in a camel’s hump; a massive layer of fat and thick insulating fur which allow polar bears to endure extreme cold; and the long arms of monkeys in tropical rainforests to allow them to use the dense vegetation as a means of locomotion and to avoid ground predation. Adaptations may also involve behavior rather than physiological modifications, such as the development of social structures (e.g., wolves), aestivation and hibernation during seasonal extremes, or seasonal migration to follow food sources. Species adapt to changing conditions through physical appearance (e.g., the British peppered moth) or even how they live within their environment (e.g., nest orientation to avoid harsh winds). An awareness of these adaptations not only informs the geographer about the ecology of an area, but may also explain how variations in zoogeographic regions affected by climate change can take place.

Zoogeography and evolution

Geography has an impact on the processes and patterns of evolution and speciation. The adaptations discussed in the previous section are likely a result of such evolutionary processes. It is generally understood, for example, that small populations that are geographically separated from their original parent population have a smaller composite genetic makeup. Because of the smaller genetic makeup, such founder populations frequently experience more genetic mutations, thus encouraging speciation when the mutations are advantageous in the new environment. This concept is known as the founder principle and the result is called the founder effect. Alternatively, the part of the population that remains also has a smaller genetic composition, called a bottleneck, which can also result in the increased likelihood of speciation for the same reasons.

In some cases, particularly where the splitting of continents is involved, large populations can become geographically isolated. These changes are called vicariance events, and the speciation that can result is the subject of vicariance zoogeographers. As with the founder effect, the isolation of the portions of the populations impacts the genetic composition, thus encouraging speciation. Given the much larger size of the populations, the process of speciation is likely to take a considerably longer time than those developing via the founder principle.

While the founder principle and vicariance zoogeography explain the divergence of one species into two, cases exist where speciation produces more than one new species. This process, called adaptive radiation, results when species evolve from a common ancestor to fill all environmental niches in the newly colonized region. Among the classic examples of adaptive radiation are the marsupials of Australia, which evolved to occupy niches occupied by placental mammals on other continents.

These results all suggest that the species survive through some form of genetic mutation. The alternative is that there is a loss of all individuals from taxa, a process called extinction. Extinction can be local, occurring when a species or taxon
disappears from one or more geographic locations but persists in others. Global extinctions refer to the elimination of an entire taxon throughout its range. The American bison is an example of a local extinction, while the passenger pigeon is a classic example of a global extinction in that these species no longer exist. Interestingly, both of these examples are fundamentally a result of human intervention, a factor that will play a larger role in zoogeographic research as time goes on, together with the impacts of rapidly changing climates.

Island biogeography

Perhaps one of the most well-known and among the first ever attempts at employing the experimental method in zoogeographic research was that of MacArthur and Wilson (1967), who focused on the determination of species numbers on a newly created island. Their theory was that the number of species on an undisturbed island would be a function of immigration and extinction. These processes are impacted by the distance of the source of immigrants from the target island. This distance effect suggests that the more remote the target islands are from the source areas – usually nearby continental mainlands and nearby islands – the fewer the immigrants.

The other component of island biogeography theory holds that the rate of extinction of a species that has colonized the island is related to the area of the island on which it established itself. This relationship, called the species–area curve, takes the general form illustrated in Figure 3. This is well established as a general theory; however, there are modifications to the original. For example, the isolation affects not only immigration rates but also extinction rates. Populations that are less isolated are less likely to go extinct because more individuals from the source population continue to add to the population. This is called the rescue effect. Likewise, while the size of the island affects the extinction rate, it also has an impact on immigration rate. The target effect suggests that species may actually select larger islands over smaller ones because they have more resources and available niches; or the larger islands may simply acquire more species and more individuals of each species simply because they are larger.

In addition to these modifications, there are other influencing factors, such as the degree of isolation (distance to mainland or nearest neighbor), time of isolation, and size of island where larger islands frequently result in greater species diversity. The habitat suitability of the target island also modifies the general theory, especially with regard to climate (e.g., tropical versus arctic); initial plant and animal composition if, for example, they were previously attached to a larger landmass; and the current species composition. Additional influencing factors include location relative to ocean currents that influence the availability of nutrients, fish, bird, and seed flow patterns. Serendipity – pure chance – obviously modifies the likelihood of species arriving or the interactions of other factors. Finally, humans produce often profound modifications of the original theoretical model.
ZOOGEOGRAPHY

Macroecology

Brown and Maurer (1989) coined a new term, “macroecology,” to describe what they considered a new discipline which focused on the study of the relationships between organisms and their respective environments at large spatial scales. For those who examine animals primarily and do so at large scales, this acknowledges the relationship between zoogeography and macroecology. The differences are useful for both disciplines. The focus of macroecology is on an understanding of the mechanisms underlying patterns of biodiversity at large spatial scales. The questions likely to be examined by the macroecologist include how changes in global climate impact wildlife populations and their distributions, the impacts of environmental conditions on species richness and diversity, and latitudinal gradients in species diversity. The typical research agenda of the macroecologist is surprisingly similar to that of the traditional zoogeographer but with a distinct ecological emphasis.

Conclusion

Zoogeography is the science of the distributions of the Earth’s fauna. Regardless of the name under which it is pursued, the field ultimately focuses on the distribution, movement, evolutionary impacts, and ecology of animals as they are distributed around the Earth. While the term itself is less often used today, its study continues and increases in importance, particularly with rapid changes in climate and anthropogenic influences on animal habitats throughout the Earth.

Zoogeomorphology

David R. Butler
Texas State University, USA

Biogeomorphology, a subdiscipline of the field of geomorphology, examines how geomorphic processes (e.g., glacial ice, running water) affect the distribution of plants and animals, but also studies the effects of plants and animals on the landscape. Zoogeomorphology is a subfield of biogeomorphology that specifically focuses on the study of animals as geomorphic agents. The term “zoogeomorphology” was coined and defined by Butler (1992) as the study of animals as geomorphic agents, using the impact of grizzly bears on mountain slopes in Glacier National Park, Montana, as an example (Figure 1). That paper examined two different digging processes associated with grizzly bears, food excavation and seasonal hibernacula creation, from which a minimal annual sediment budget associated with bear excavations was calculated. Three years later, the book Zoogeomorphology – Animals as Geomorphic Agents (Butler 1995) was published. That book synthesized research on the geomorphic impacts of hundreds of species of animals, both invertebrates and vertebrates, into one volume. A related concept, ecosystem engineering (Jones, Lawton, and Shachak 1994), developed contemporaneously in the ecological literature. Zoogeomorphology studies the roles of animals in landscape formation and decay, whereas in ecosystem engineering ecologists study environmental change caused by biota and the consequences for the engineer, other organisms, and ecological processes. Not all ecosystem engineering has geomorphic impacts, however; a bird’s nest constructed entirely of twigs is an example of ecosystem engineering, but without direct geomorphic impacts.

Animal impacts on the landscape

Animals geomorphologically affect the landscape in a variety of ways, including trampling, wallowing, digging for food, excavation of burrows and dens, construction of mounds, ingestion of soils (geophagy) and rocks (lithophagy), mixing of soils, and even stabilizing sediments so that they are not eroded. Naylor (2005) categorized the suite of biogeomorphological processes, including those carried out by animals, as bioerosion, biostabilization, and bioconstruction. Statzner (2012) examined the role of a variety of animals that live in streams and provided examples of both sediment stabilization and sediment destabilization and subsequent movement downstream. This work, based on many years of field and laboratory experiments, is a thorough and meticulous presentation. The geomorphic impacts of animals may be direct or indirect. Direct geomorphic impacts include the aforementioned processes of burrowing, digging, and other processes whereby animals are directly moving soil, sediments, and/or rocks on the landscape. Indirect geomorphic impacts include the effects of trampling, whereby soils are compacted and surface infiltration of water is reduced such that runoff rather than downward percolation results.
The effects of trampling by domestic animals were examined in detail by Trimble and Mendel (1995). They illustrated how trampling produces compacted soils that in turn preclude infiltration and instead produces rapid runoff and erosion. They also described direct geomorphic impacts in describing the chiseling effects that cattle hooves have along stream margins where large amounts of sediment can be carved off and introduced into, and subsequently removed by, streams. Butler (1995) described a variety of large mammal species, including bison, elk, bighorn sheep, mountain goats, elephants, rhinoceri, and hippopotami, that create distinctive trampled trails on the landscape as well as areas of sediment removal associated with mud wallowing and resting in day beds. Some areas of localized trampling and wallowing are associated with natural salt outcrops where animals come seasonally to ingest salt-rich sediments (geophagy).

Soil mixing, or biopedoturbation, typically is accompanied by some form of mound production (Richards 2009; Wilkinson, Richards, and Humphreys 2009). Butler (1995) illustrated numerous examples of biopedoturbation with associated mounding, including the work of ants and termites, crayfish, mound-building birds, and a variety of mammals, including (but not limited to) gophers, marmots, and prairie dogs. Richards (2009) discussed the astonishingly high rates of sediment bioturbation produced by a specific genus of ant. Wilkinson,
Richards, and Humphreys (2009) offered an extremely thorough review of biopedoturbation studies, covering studies from the late 1800s to the mid-2000s. Burrowing for shelter, food acquisition, and production of birthing chambers also produces bioturbation as well as extensive underground tunnel systems and surface spoil mounds at the mouths of burrow entrances (Figure 2). Such tunnel systems in turn may profoundly affect surface drainage, capturing, and localizing water runoff into underground passageways. The burrowing behavior of birds has been studied in association with colonial seabirds that employ burrows for birthing chambers as well as protection from the elements. Entire islands (Butler 1995, and references therein) have been honeycombed and undermined by such burrowing to the point where some islands virtually sink into the sea.

Geomorphic impacts of beavers

One of the most significant zoogeomorphological agents is the beaver – in North America, the Canadian beaver, *Castor canadensis*, and in Europe, the European beaver, *Castor fiber*. Many more Canadian beavers currently exist than do European beavers, but historically their influences may have been equally important. Butler (1995) presented an entire chapter devoted to the geomorphic effects of beavers that is a useful and accessible entry to the topic and the literature pre-dating the mid-1990s. Known for their unique ability to construct dams, beavers and the variety of dam types they build are the focus of a short but very useful study (Woo and Waddington 1990) that also illustrated the effects of beaver dams on water retention and evaporation rates.
Gurnell (1998) offered a valuable examination of the specific hydrogeomorphological results of beaver-dam construction, as well as a valuable literature review. Beaver dams and associated pond creation (Figure 3) entrap water and therefore drastically reduce stream velocity, which in turn induces sedimentation over years to decades within individual ponds. The creation of a pond also elevates the local water table, with attendant ecological benefits for riparian species. The reduction in stream velocity results in reduced stream erosion and entrenchment downstream of beaver dams. In a variety of locations in the American West, beavers have been reintroduced into environments where they had been historically removed by trapping in an attempt to assist in reducing stream erosion and entrenchment and to increase and enhance riparian habitat.

Beaver meadows have been described in the literature since the 1930s and were briefly summarized by Butler (1995), but the specifics of the sedimentation necessary for their construction have not been clear. Polvi and Wohl (2012) showed that beaver meadows in Colorado contain sediments laid down over thousands of years and that those meadows are comprised

Figure 3  A beaver dam, approximately 1.5 m high, in Glacier National Park, Montana, USA. The pond impounded behind the dam was approximately 1.3 m deep when examined in the field. A second, downstream, pond is visible at lower left; that pond was impounded by a second dam out of sight, approximately 50 m downstream. Both ponds drained catastrophically in 1995 after a heavy thunderstorm over the adjacent mountains.
of sediments equally derived from stream sedimentation and from sedimentation in beaver ponds.

The geomorphic effects of European beavers are increasingly examined in the literature as that species continues to expand its range. Nyssen, Pontzeele, and Billi (2011) examined the role of reintroduced European beavers in the Belgian Ardennes and illustrated how their reestablishment is altering stream hydrology throughout the area. The geomorphic effects of the European species of *Castor* are basically the same as those of the North American species, that is, dam building and pond retention with attendant effects on riparian habitat and local water tables, reduction of stream velocity and discharge downstream of dams/dam sequences, and canal and bank burrow excavation. Sedimentation rates and patterns in European beaver ponds also seem similar to those described from North America, based on a limited number of studies to date.

Beaver dams occasionally fail catastrophically during periods of intense rain and/or rapid snowmelt. The failure of one dam can lead to a cascading effect, washing out additional dams downstream, that is, causing a domino effect. In North America, several examples exist where outburst floods from beaver-dam failure have washed out highways, clogged culverts leading to additional flooding, and washed out railroad bed sediment leading to train derailments. Several fatalities have resulted from washouts and floods associated with beaver-dam failure.

**Future zoogeomorphology**

Climatic change and human impacts have profoundly altered the zoogeomorphic signatures across a variety of landscapes and will continue to do so into the foreseeable future. As climates change, animal ranges also necessarily shift. Zoogeomorphically active animals may see their range reduced or even disappear; conversely, other active zoogeomorphic agents may see a range expansion. Very little research has been carried out in assessing how climate change will affect zoogeomorphic processes in terms of distribution or severity.

Human impacts, through human-caused drastic reductions in animal populations, through reduction of animal habitat via changing land uses, or by introducing zoogeomorphically active species into habitats where they escape and expand unchecked, need further examination as well. Certainly the range and strength of the zoogeomorphic impact of North American bison have been drastically reduced by human action; similarly, prairie-dog “towns” cover only a minute fraction of the geographic range they covered prior to European contact. In Australia, the introduction of non-native species has led to dramatic shifts in zoogeomorphic impacts. The introduction of the rabbit to Australia not only resulted in drastic overharvesting of vegetation in the continent’s semiarid and arid interior, but the burrowing actions of the rabbits have had impacts on surface runoff by channeling overland flow into underground tunnel systems.
