The Uruguay grasslands contain both C3 and C4 grasses. Trees are rare. The genera with most species are Paspalum, Axonopus, Setaria, Digitaria, Andropogon, Bothriochloa, and Schizachyrium (all C4, NADP-ME species except Panicum, which contains a few C3 species); the genera Eragrostis, Distichlis, and Chloris, Eleusine, and Bouteloua (all C4, NAD–ME species). C3 genera include Calamagrostis, Agrostis, with only a few species present.

The Pampas in Argentina is dominated by C4 grasses at low elevations. Andropogon lateralis is the most common species, with some grasslands dominated by Sorghastrum agrostoides, Paspalum quadrifarium, and P. intermedium. All are C4, NADP-ME species.

Pampas deer, armadillo, guanaco, and rhea are the primary native grazers of the Pampas and capybara in the Llanos.

The steppes of Russia and Mongolia

The vast grasslands Inner Asia and Central Asia lie between taiga forests to the north and desert
to the south. The grass cover is dominated by *Stipa* spp., *Festuca* spp., *Elymus chinensis*, *Agropyron* spp., and *Koeleria macrantha*. All are C3 grasses and these genera are common throughout the Northern Hemisphere (Figure 2). *Koeleria macrantha* is also native to North America. A minor grass species that is native to both Eurasia and North America is *Hierochloe odorata*. In Eurasia it is known as bison grass and is used in some vodka as a flavoring. In North America it is known as sweetgrass and is used in Native American rituals.

The major grazers are or have been horses and asses, camel, antelope, and gazelles. Steppe polecat, black-footed ferret, gray wolf, and Siberian tiger represent some of the carnivores that once roamed in the steppes in greater number.

**Africa**

The grasslands of Africa are diverse, with many hundreds of grass species represented. Most are C4 grasses, with genera of *Andropogon*, *Setaria*, *Panicum*, *Aristida*, *Chloris*, *Digitaria*, *Eragrostis*, *Paspalum*, *Schizachyrium*, and *Sporobolus*, all represented by numerous species. *Festuca*, a C3 genus, is also present and other C3 grass species are numerous near the Mediterranean where winter rainfall supports them (Figure 2). There are also numerous C3 species in South Africa.

Elephant, antelopes, kudu, ostrich, giraffe, wildebeest, gnu, and zebra are but a few of the large mammals of African grasslands, which are richer in large animal species than any other grasslands. Lion, cheetah, leopard, wild dogs, and hyena are major predators of the grazers.

**Australian grasslands**

All photosynthetic types occur in Australia, with C3 grasses dominating south of 30° south latitude (Figure 4). NADP–ME grass species are the most abundant of the C4 grasses, but they are rare south of 30° south latitude. Xerophytic tussock grasses, dominated by Mitchell grass (*Astrebla* spp., C4 NAD–ME biochemical type), are widespread (40 million ha) on clay plains of inland Queensland.

Prior to settlement by humans, the major Australian grazers were wallabies, kangaroos, wombats, emus, rat–kangaroos, and lizards. Lacking were the hoofed animals universal in the grasslands of the other continents, but excluded from Australia by a deep ocean barrier. Europeans introduced cattle, sheep, goats, horses, and rabbits as today’s major grazers.

The basic principles of green capitalism

Green capitalism is a form of environmentalism that emphasizes the economic value of ecosystems and biological diversity and attempts to reduce human environmental impacts by ensuring that the importance of environmental services is reflected in the way that markets operate. It starts from the recognition that ecosystems perform a wide range of services that societies depend on. This includes provisioning services (e.g., the supply of water, food, and energy), regulating services (e.g., carbon sequestration and water purification), and also cultural services (e.g., recreational services such as ecotourism and outdoor sports). Green capitalism extends the economic concept of capital (assets used to produce goods and services) to include “natural capital.” The United Nations Natural Capital Declaration (UNEP 2012, 3) defines natural capital as “the stock of ecosystems that yields a renewable flow of goods and services that underpin the economy and provide inputs and direct and indirect benefits to businesses and society.”

Proponents of green capitalism see pollution, loss of biodiversity, and the unsustainable use of natural resources as a form of “market failure.” In other words, environmental degradation is the result of the failure of capitalist systems to account for the financial value of environmental services:

Capitalism, as practiced, is a financially profitable, nonsustainable aberration in human development. What might be called “industrial capitalism” does not fully conform to its accounting principles. It liquidates its capital and calls it income. It neglects to assign any value to the largest stocks of capital it employs – the natural resources and living systems, as well as the social and cultural systems that are the basis of human capital (Hawken, Lovins, and Lovins 1999, 5).

As a result of the inability to value natural capital, the profit motive at the heart of capitalist societies tends to drive environmental degradation, since it is cheaper to pollute than to control emissions and more profitable to use resources now than to save them for the future.

The solution from a green capitalist perspective is to factor the value of nature into the way markets operate to encourage producers to become more efficient and innovative in the way they use natural resources. Rather than relying on state or international regulation (so called “command and control” strategies) or demanding radical cultural, political, and economic changes, green capitalism is based on the premise that private property, entrepreneurial business, and economic growth can be good for the environment (Beckerman 1974). Green capitalism is also referred to as “natural capitalism” (Hawken, Lovins, and Lovins 1999), “free-market environmentalism” (Anderson and Leal 1991), “blue-green environmentalism,” or “eco-capitalism.”
Green capitalism’s roots

Belief in the power of markets to solve socioenvironmental issues is grounded in the ideas of classical and neoclassical economics where, in a world of finite resources and infinite human wants, markets are seen as the most efficient way of allocating scarce resources. According to free-market thinking, individuals and firms will rationally pursue their own wealth. Competition in a free market will therefore stimulate an entrepreneurial spirit of hard work, innovation, and efficiency. This produces more and better goods and services for everyone. Furthermore, resources are allocated to those who need them most (measured by the willingness to pay).

Green capitalism takes the idea of the “invisible hand” (i.e., the idea that markets are inherently self-regulating systems that should not be interfered with, especially by governments) and extends it to the environment.

Although green capitalism is a relatively recent form of environmentalism, it draws on a long history of Western environmental ideas. Its emphasis on the rational use of natural resources is reminiscent of early twentieth-century “wise use” environmental philosophies in the United States of America. These ideas emerged from the development of scientific forestry and the principle that forests could be managed and optimized to satisfy human needs. Foresters such as Gifford Pinchot rejected the romantic and preservationist views of nature promoted by early conservationists such as John Muir and Henry Thoreau. Instead, the wise use movement argued for efficiency, waste reduction, and the management of forest resources for multiple activities (e.g., logging, recreation, and wildlife conservation).

One of the most important ideas at the heart of green capitalism is that nature provides financial benefits to societies and that any damage to ecosystem function has an economic cost. The problem is that these costs are not factored into market exchanges. In other words, the price of goods and services does not reflect their environmental impacts. Environmental economists describe these as negative externalities. In *The Economics of Welfare* (1920) Arthur Pigou defined an externality as an economic activity whose cost or benefit affects someone who did not choose to incur it. For example, a factory produces consumer goods that are mostly consumed by people far away from the factory. The company owning the factory gets the financial benefit of selling the goods, while consumers get the benefit of purchasing and using the goods. However, the factory also emits pollution that has numerous economic costs. Industrial wastewater released into a river impacts on other river users (for example, recreational fishers) and also other businesses (such as fish farms). Atmospheric pollution can affect the health of nearby residents. These third parties gain none of the benefits of production (unless they buy the goods produced or are employed by the factory) and suffer all the costs of pollution.

A possible solution to the problem of negative externalities is to impose a tax on polluting activities to “internalize” the cost of pollution. These Pigovian taxes make polluting a costly activity. There is thus a strong incentive for companies to reduce pollution in order to reduce costs and stay competitive. This in turn changes consumer behavior, since they rationally seek to purchase the cheapest (and therefore less environmentally damaging) products.

As well as Pigovian taxes there are also Pigovian subsidies. These are designed to stimulate positive externalities. Examples include government subsidies for installing solar panels and feed-in tariffs for energy generated from renewable sources. Such measures are designed to encourage investment in green technologies.
GREEN CAPITALISM

that might not otherwise happen due to the high start-up costs.

The imposition of Pigovian taxes and subsidies faces a number of challenges. The biggest challenge is calculating the correct level of taxation necessary to counterbalance negative externalities. For example, carbon taxes have often been too low to stimulate changes in production and consumption. This is compounded by the fact that economic sectors that generate sizable externalities (the fossil fuel energy sector, for example) have often lobbied governments to keep environmental taxes low or block proposals for new taxes. Environmental taxes are also regressive, since poorer households spend a large proportion of their income on acquiring basic resources such as water and energy, and are thus disproportionately affected. Free-market environmentalists also argue that subsidies do not necessarily support the best or cheapest environmental solutions and are thus economically inefficient.

Alternative solutions have been proposed based on the belief that market-based solutions are more efficient ways to reduce externalities than regulation or taxes (Anderson and Leal 1991). The economist Ronald Coase (1960) argued that as long as there were clear property rights over natural resources and transaction costs were sufficiently low, negative externalities could be dealt with through negotiations between those creating the externalities and those affected by them. Returning to the example of a factory releasing pollutants into a river that affect a fish farm, the Coasian solution would be to assign property rights to the river. If the fish farm owns the rights to the river, the factory will have to compensate it for any impacts, thereby creating a strong incentive to reduce pollution. Conversely, if it is the factory that owns the property rights, it may accept payments from the fish farm in return for a reduction in pollution. These payments would compensate it for the opportunity for costs of reduced production or the costs of developing solutions to deal with the pollution. From a Coasian perspective, this delivers the most economically efficient solution without the need for expensive regulation or monitoring. Coase’s basic idea has since been expanded on and interpreted in various ways, including mathematical models of the most efficient and therefore “socially optimum” level of pollution and its correct price.

Examples of free-market environmental policies influenced by Coasian theory include pollution permits and emissions trading. In a “cap and trade” system, a central authority sets an overall limit on the amount of emissions of a particular pollutant. The total cap is then divided into individual units and either allocated or sold to polluters. This gives the polluter the right to emit a given quantity of pollutants. Surplus pollution permits can be sold. The advantage of this system is that polluters who can find quick, easy, and cheap ways to reduce pollution are rewarded by being able to sell surplus permits to those sectors and industries that find it more difficult. The ability to sell surplus permits creates a continual incentive to reduce emissions. Coasian policies move away from traditional “command and control” models where states and international organizations simply set regulatory limits on pollution at the point of emission (for example, vehicle exhaust emission standards for pollutants such as nitrogen dioxide and sulfur dioxide). While “command and control” solutions have the advantage of simplicity, once minimum pollution standards are met there are no incentives to go any further.

Although the various ideas underpinning green capitalism have a long history, it is only since the emergence of the concept of sustainable development in the 1980s that they have
GREEN CAPITALISM

become mainstream. This represents a significant shift away from the “limits to growth” and “zero growth” environmentalism of the 1960s and 1970s, which argued for radical political, economic, and cultural changes to drastically cut production and consumption. Green capitalism also fits well with neoliberal economic thinking, which places an emphasis on individual liberty, minimal involvement of the state, and free markets as the most efficient way to coordinate the diverse needs of people.

Emerging forms of green capitalism

Accounting for nature and paying for ecosystem services

There have been growing efforts to include the value of natural capital into business activities and government policy. These depend on (i) being able to calculate the value of various ecosystem services and (ii) creating mechanisms whereby those who benefit from ecosystem services pay those who maintain those services. Calculating the economic value of ecosystem services remains technically challenging. With regard to creating financial flows to pay for natural capital, the most advanced attempts to establish such schemes have been under the banner of Payments for Ecosystem Services (PES). These are defined as voluntary transactions that involve the purchase of a well-defined ecosystem service from a service provider, who is paid if (and only if) the provision of that ecosystem service is secured (Wunder 2005). From a green capitalist perspective the advantage of PES is that they conform to Coase’s view that environmental issues are best left to negotiations between individuals or groups with clear ownership rights over natural resources.

A green industrial revolution: harnessing the competitive and innovative aspects of market forces to improve manufacturing processes

Internalizing the value of natural capital into the operation of markets is the first step toward green capitalism. Once pollution has a cost and natural capital has financial value it is expected that the logic of capitalism will drive innovation and efficiency to reduce costs and maximize income. In the same way that the first industrial revolution harnessed machinery and new forms of fossil fuel energy to dramatically increase productivity, a green industrial revolution would harness technology to deliver radical improvements in efficiency.

Hawken, Lovins, and Lovins (1999) propose a range of ways that a green industrial revolution might occur. First, radical improvements in productivity and efficiency could allow societies to produce more from fewer resources. Looking at the automobile industry, for example, ultra-light “hypercars” with fuel-efficient engines could dramatically reduce fuel consumption. In order to generate radical leaps in productivity, Hawken, Lovins, and Lovins (1999) advocate biomimicry, a design principle that imitates biological processes and structures in order to improve manufacturing and create new materials. For example, the physical properties of spider silk could be mimicked to make ultra-strong and ultra-light materials.

The concept of biomimicry can also be extended to industrial processes through “cradle to cradle” manufacturing, which models processes on ecosystem nutrient flows and metabolic pathways. Cradle to cradle manufacturing involves two types of materials: (i) synthetic technical materials, which must be non-toxic and able to be used continuously in production cycles without losing their integrity (i.e., there is no “downcycling” to lower quality products);
and (ii) biological materials, which can be put back into ecosystems and nutrient cycles. There is also the closely related concept of closed-loop manufacturing, which involves planning manufacturing processes around the life cycle of materials so that they are reused with minimum waste.

Green consumerism and ecolabeling

As well as changes in the production of consumer goods, green capitalism also needs to be able to change consumer behavior. Green consumerism emphasizes the ability of “consumer power” to deliver more sustainable patterns of resource use. It is part of a broader trend of “ethical consumption.” This is based on the belief that consumer choices are driven by more than just price and are often based on the moral attributes of goods and services. “Eco” labeling works on the assumption that consumers can be provided with information about the conditions of production through the use of labels. This enables them to make informed decisions to reduce the environmental impacts of their consumptive patterns. The expectation is that producers will then react to changing demands in the marketplace by changing production to reduce environmental impacts.

In addition to changes in the types of goods purchased, green consumerism also needs to deliver changes in the amount of goods purchased, owned, and consumed. Green capitalists envisage a move away from economies based on the ownership of goods to “service and flow” economies where resource goods are primarily rented (Hawken, Lovins, and Lovins 1999).

Critiques of green capitalism

Green capitalism is based on the premise that market forces and profit motives can drive more sustainable resource use patterns. While green capitalist thinking has had considerable influence on environmental policy-making, it has given rise to a large body of critical work. The strongest critiques of green capitalism have emerged from a broadly Marxian perspective. Ultimately, these critiques argue that any attempts to reduce environmental impacts will need radical economic and cultural changes that are not possible within a capitalist framework.

Capitalism and the metabolic rift between societies and the ecosystems that support them

According to Green Marxist theory, the underlying drivers of environmental degradation in capitalist systems are: (i) capitalism’s logic of competition, economic growth, and a relentless increase in the productive and consumptive capacities of society; combined with (ii) capitalism’s social relations, which are based on an unequal distribution of wealth, property, and power. Capitalism thereby allows the resources that everyone depends on to be owned and exploited for profit by a wealthy elite. This results in a “metabolic rift” whereby people are increasingly separated – both spatially and socially – from the ecosystems that support them.

For example, in eighteenth- and nineteenth-century Britain, wealthy elites claimed that peasant agricultural practices were backward and unproductive and argued that land could be put to more profitable use. As a result, parliamentary land enclosures moved large areas of land from communal management into the private sphere. Peasants lost their rights to carry out subsistence activities such as grazing animals and collecting firewood. The process was often violent with peasants forcibly evicted. By seizing control over the means of agricultural production and subsistence, land enclosure forced peasants to seek
work in order to support themselves. However, given the changes in agricultural production and increased mechanization during the eighteenth and nineteenth centuries, work was increasingly unlikely to be found in rural areas. Workers were forced to move to growing industrial towns to seek employment in factories.

The changes brought about by land enclosure and urbanization not only led to social upheaval but also had serious environmental consequences. While industrialization led to obvious environmental impacts such as air and water pollution from factories, Foster (2000) argues that there were more profound changes in human–environment relations through disruptions in the exchanges of nutrients between society and the environment. The nineteenth-century chemist Justus von Liebig was the first to point out that urbanization led to a physical separation of food production and consumption. In agrarian societies, food production and consumption are carried out in close proximity and nutrient cycles can easily be maintained by returning organic waste (and therefore nutrients) to the land. However, with urbanization, food is produced in rural areas and moved to cities to be consumed. Waste, rather than being returned to the soil as fertilizer, is disposed of as sewage and the nutrient cycle broken. Marx drew on this idea to argue that capitalism not only robbed people of control over their livelihoods but also robbed the soil of its nutrients. So for Marx, the exploitation of natural resources and the exploitation of people were two sides of the same coin.

The concept of metabolic rifting has since been expanded spatially and ecologically by Marxist scholars, most notably by Foster (2000). They argue that processes such as agro-industrialization, industrial fishing, and aquaculture have focused on modifying biological processes to maximize yields and generate economies of scale at the expense of biological diversity and ecosystem function. Together with the globalization of food systems they have created vast commodity chains. For example, prawn farms in Asia not only clear mangroves to create their ponds, but often use wild-caught species as feedstock, leading to problems of over-fishing. Their produce is then shipped halfway across the world, using fossil fuels for refrigeration and transport, to be consumed by affluent Western consumers. Industrial food systems and global commodity chains mean that consumers have very little knowledge or interest in the environmental impacts of their consumptive actions. The metabolic rift is therefore not just spatial and physical but also social and cultural.

The treadmill of production and the continuous expansion of capital

Schnaiberg’s (1980) concept of the “treadmill of production” combines insights from environmental sociology and technology studies to understand how and why capitalism tends to push production and innovation down certain paths. According to the treadmill of production, the competitive logic of capitalism means individuals and firms must always invest, innovate, and grow or risk being outcompeted. In other words, they must always be running to stay in the same place.

Capitalism’s competitive logic has major implications for the way firms and individuals behave, especially with regards to what they do with profits and gains in productivity. In theory, profits can be used in a variety of ways. For example, they might be used to raise worker wages and improve working conditions. The productive gains provided by innovation also open up various possibilities, including the option of producing the same amount of goods with fewer resources. The latter is the basis of the
green capitalist model for a “green” industrial revolution.

Treadmill theory argues that in reality, capitalism’s competitive logic means that profits will always be reinvested back into increasing production. Any productive gains provided by innovation will be used to produce more with the same resources rather than producing the same with fewer resources. This has important environmental implications, since every “turn” of the treadmill involves the extraction of resources and the addition of pollutants. Furthermore, the treadmill of production in turn fuels a treadmill of consumption. By stimulating competition between firms, capitalism drives ever-increasing efforts to sell us goods and services through branding and advertising. This inevitably creates mass consumption societies where more and more goods are manufactured, purchased, and disposed. The cultural values of mass consumer societies, where individuals define themselves primarily by the goods that they purchase and own, creates a significant barrier for the implementation of a “service and flow” economy in which individuals mostly rent goods.

“Green grabbing” and the neoliberalization of environmentalism

Green capitalism’s emphasis on natural capital involves commodifying material substances and processes that have never previously been commodities, for example, carbon dioxide and carbon sequestration. This leads some critics to consider green capitalism as just one part of a much broader neoliberal encroachment of market relations into various spheres of human life. Critics argue that green capitalism is leading to fundamental changes in environmentalism. This is especially the case with international environmental nongovernmental organizations (NGOs), which play a key role in green capitalism by providing expert knowledge about the functioning and value of ecosystem services. They have thereby gone from being at the margins of global capitalism (and often critiquing the practices of trans-national corporations) to acting as facilitators in the expansion of capitalism.

There are concerns that attempts to commodify natural capital will lead to individuals and groups being dispossessed of their land by more powerful state and corporate actors. This is because market-based environmental solutions are based on establishing property rights over the environment. Any scheme that seeks to create payments for environmental services must be based on a clear agreement of the precise ecosystem service being purchased, as well as who will be paid for delivering it. However, many ecosystems have multiple, complex, and often contested values as well as ownership rights. For example, many forests in sub-Saharan Africa are in theory owned by the state but in practice managed by rural communities according to customary rules. There are worries that the financial value suddenly created from ecosystem services will lead to strong incentives for powerful interests to take control of these ecosystems. Market-based schemes could see rural communities dispossessed of their rights to land so that ecosystem services can be secured. Critics argue that much like the “land grabs” that occur through the enclosure of agricultural land, green capitalism will lead to “green grabs,” where land is acquired to benefit from the revenue streams created by payments for environmental services (Fairhead, Leach, and Scoones 2012).

Ecolabeling and the fetishization of commodities

Green capitalism’s emphasis on consumer power has also come under considerable criticism. Scholars have drawn on the concept of
commodity fetishism to argue that green consumerism will only ever be a niche activity and may also act as a barrier to meaningful changes in consumption. In the common usage of the word, the term “fetish” is used to describe a strong and also unusual desire for an object or activity. It is also used in anthropology to describe objects believed to have magical powers, for example, religious idols. According to Marxist theory, capitalism encourages both forms of fetishism with regard to commodities. This occurs because commodities are primarily produced for the purpose of making profit. This means that their exchange values are prioritized over their use values or the value of the labor that went into creating them. Furthermore, individuals in mass consumer societies tend to define themselves through conspicuous consumption, so that consumer goods are purchased less for the functions they perform and more for their status-enhancing properties.

Capitalism is particularly good at fetishizing objects because of its social relations, which separate workers from the objects that they produce and separate consumers from workers. This means that consumers do not know where the goods they consume are produced, by whom, and under which social and environmental conditions. In theory, solutions such as ecolabeling help to defetishize commodities by providing consumers with information about the environmental conditions of production. However, Green Marxists argue that by reducing complex socioecological problems to simple labels and brands, ecolabeling in fact fetishizes commodities in new ways by selling the idea to consumers that they are “saving the environment” simply through their consumptive choices. Critics argue that green consumerism’s emphasis on consumer power in fact hides the need for more radical changes, especially in terms of how much individuals consume.

References

Green infrastructure is increasingly used as a way of bundling a host of components of the natural environment into a single heading or category. The term refers to a wide range of things, including parks, rivers, street trees, natural floodways, nutrient recycling schemes, and protected habitats such as forests and moorland. The term is mobilized in policy documents to assert the value of natural environmental processes and materials in enhancing healthy living, maintaining urban environments, addressing sustainability questions from local to planetary scales, even addressing threats to property values in a context of industrial decline. Thus, high levels of quality green infrastructure are argued for in order to combat anthropogenic climate change, manage storm events and flooding, moderate urban heat and coldness events, enrich agricultural assets including in urban areas, and enhance the quantity and quality of sub-surface water quality through better absorption processes.

These sorts of arguments have made green infrastructure a popular policy term in development and planning policies in both advanced and developing nations. But there are implications of such use, especially in terms of how the natural environment and nonhuman species are valued.

**Definition**

Because it is a pragmatic term, it is difficult to nominate a single correct use of the term “green infrastructure.” In many ways the term has emerged as a way of tidying up the growing number of ways that the natural environment is referred to in planning and policy documents. A handy article explaining the evolution and, at times, contested meanings for the term is Wright (2011). Because it is a term in common use, however, it is handy to have a working definition for it. Hence, for here at least, green infrastructure refers to those components of the natural environment that are assembled or mobilized to underpin human settlement. This underpinning includes the provision of the basic elements of life and then the supply of environmental services and materials in ways that enhance human productivity and the quality of human existence.

Underpinning the idea of green infrastructure is the assertion that the environment is more than a passive bystander or context in the day-to-day operations of cities and regions. Drawing on the meaning of the word “infrastructure” – and thereby a universal acceptance that society has to build and operate a wide range of infrastructure assets in order for its members to live successfully, especially in urban conglomerations – the idea of green infrastructure asserts that human settlement draws by necessity on things like green spaces, resources-rich ecosystems, and cohabiting nonhuman life. Most importantly, by attaching the simple adjective “green” to the
powerful economic word “infrastructure” the phrase implants an inseparable economic logic to the presence and acceptance of a cared-for natural environment in and around human settlement. This appropriation parallels the successful development of the idea of “social infrastructure” in the 1960s when social development theorists and advocates argued successfully that state expenditure on education, health, and social welfare was vital to enduring economic growth and prosperity (Rankin 2009). Likewise, the idea of green infrastructure is very much an opportunistic and politically pragmatic view of the natural world.

As an infrastructure asset, green infrastructure can be seen to take on various characteristics of infrastructure assets in general (O’Neill 2013). These characteristics are fourfold: that infrastructure mobilizes factors of production, expands markets, enhances the productivity of both labor and capital, and supplies essential services not capable of being supplied by private capital on a for-profit basis or without unfair monopolization practices. Talking about the environment in infrastructure terms, then, says that the environment is a key supplier of factors of production, particularly resources, such that the protection and nourishment of ecological systems are as vital to running a successful economy and a prosperous society as are the provision of reliable energy, water, and transport systems. Second, this conceptualization consciously removes the divide between urban life and the natural environment and between the economy and the natural environment by accepting the vital role of the environment in not just generating the essential conditions of life (air, water, sunlight, food) but also maintaining the stocks and flows of energy and materials essential for the formation of both the means of production and the final consumption goods and services. Green infrastructure, then, can be seen to be a prime determinant of market growth and innovation in capitalist economies. Third, the idea of there being “green” infrastructure says that both capital and labor will be more productive in the presence of quality green assets. Better quality natural environments in cities, cleaner work environments, and superior natural materials enhance the work process, generate higher incomes, and fund better employment conditions. Likewise, plant and equipment (capital) operate more efficiently with lower maintenance costs and fewer delays (e.g., due to congested supply chains) when their host cities are pollution-free with environmentally sensitive transport and energy systems, and so on. Fourth, inherent to the idea of green infrastructure is the assumption that the components of green infrastructure are best treated as societal “commons,” meaning their operation would be distorted by commercialization and marketization, and by their control and supply by for-profit private producers. In this sense, green infrastructure assets are seen as natural monopolies with essential public goods characteristics. Therefore, like public health and education systems, for example, the supply of green infrastructure assets is best organized by some sort of public delivery mechanism, or through private delivery under a regime of heavy public regulation or contractual conditions.

Major dimensions of green infrastructure

A useful discussion of the components and dimension of green infrastructure can be found in Tzoulas et al. (2007). Drawing on this work, a number of dimensions of green infrastructure can be nominated: its green space role; its ecosystem services role; its complementary contribution to human health; its functioning as an economic resource; and its place in human thought and planning. These are dealt with in turn here.
Green spaces

Green infrastructures evolution as an integral part of a city or a region can be traced to the creation of large city parks during Victorian times, places that went beyond carefully cultivated display gardens or civic gathering spaces. Large parks like Central Park in New York and Hyde Park in London included parts which purposely mimicked natural forests and woodlands. There were multiple motivations for such extensions to the view of what was acceptable inside a city. Some were scientific, others were recreational, aesthetic, and spiritual, and there were fledgling arguments that natural spaces enhanced city living, hence such parks carried descriptors such as the “lungs of a city.” By the twentieth century, green spaces were accorded their own land-use classifications, and then became tools for planners to curb, guide, and shape the growth of urban areas. Green spaces as urban planning tools were thus manifest in greenways, greenbelts, garden cities, and new towns (Wright 2011). This evolution from a relatively idle urban space into a purposeful planning action was important in enlisting green spaces as mainstream components of cities, and establishing an argument for their preservation and maintenance, not to be obliterated by economic or residential functions as the opportunity presented.

Ecosystems and their health

Beyond green spaces as land-use zonings and buffers, and protected habitats and conservation zones, green infrastructure also refers to the presence of regenerating, operative ecosystems as active participants in cities and regions. Sometimes these aspects of green infrastructure are referred to collectively as “ecosystem services.” Thus, green infrastructure can be seen as capable of addressing obstinate environmental concerns, such as air pollution and smog events, generated by the capture of mass automotive and industrial pollution within inverted layers of the atmosphere; and urban heat islands where the heat output of urban buildings, especially high-rise office buildings, is exacerbated by direct heat reflection and absorption by common road, pavement and building materials, and urban surfaces, especially concrete and asphalt.

At one level this means an accepted presence in highly populated areas of things like habitat trails and corridors, acknowledging the rights of nonhuman species to have formally constituted transport and breeding spaces, and thus accepting nonhuman species as normal occupants of a city or region. At another level, there is the utilitarian notion that cities and regions that are host to thriving ecosystems generate better economic and social conditions for human life. This could involve, on one hand, the active preservation of pre-existing thriving natural ecosystems or, on the other hand, a conscious program of detoxification, rehabilitation, and species regeneration on lands degraded by, say, decades of industrialization, land clearing, waterway channeling, and straight-out neglect. It might also involve reconsideration of hard infrastructure items, such as water collection and discharge systems, and their reincorporation into water catchment and wetland rehabilitation schemes in ways that allow high levels of natural ecosystem functioning (Faucette 2012; Benedict and McMahon 2006).

At a regional scale, a green infrastructure approach might involve the integration of urban areas with natural environmental zones and sympathetic agricultural land uses in ways that are beneficial for all users. Such integration offers prospects for efficiencies across multiple economic sectors as well as in civil and other infrastructure investments, notably flood mitigation systems. This integrated provision is highlighted in the European Commission’s 2013 report into green infrastructure, a document...
GREEN INFRASTRUCTURE

which mandates green infrastructure as a core concern in urban and regional planning.

For human health

Green infrastructure is seen as a major contributor to the conditions for good human health, especially in urban settings. Urban forests, woodlands, and wetlands are seen to improve local air quality, moderate temperature extremes, and contribute to better groundwater quality, all of which have positive human health implications. Greenspaces are also important spaces for formal and informal recreation and sporting activity, as well as being desirable spaces for meditation, reflection, and intimate human exchanges.

For aggregated urban and economic resources

Green infrastructure is increasingly seen as a prime economic resource for a number of reasons. Properly designed and managed green spaces enhance other urban infrastructure assets. The ways that green spaces can be deployed as relatively inexpensive assets in storm water and flood management have already been discussed. Properly managed, large belts of green space are also useful as passageways and thoroughfares for the operation of other infrastructure assets, including roads, electricity wires, gas and water pipes, telecommunications cables and towers, and so on. Green infrastructure also gives rise to improved productivity of natural resources. Water, soils, timber supply, even breeding conditions for domesticated animals for food are all enhanced by well-functioning ecosystems.

For thinking and planning

Given the dimensions of green infrastructure explored above, it is not surprising to find that green infrastructure is accepted increasingly as a legitimate budget item for urban and regional development spending in both advanced and developing nations. This progression is now actively encouraged by international agencies such as the World Bank (Baietti and Shlyakhtenko 2012). At the same time, thinking about the nature and desirability of coexistence with functioning ecosystems gives rise to non-instrumentalist ways of valuing green assets. On the one hand this involves respect for the presence of nature for its own sake; and, then, the understanding that the presence of wild things in and around us is mutually beneficial, for example, in major questions like solving urban social issues and addressing climate change challenges.

Elevating green spaces and natural things to having a legitimate copresence in cities and regions also raises the question of the priority status of green infrastructure assets. Is green infrastructure necessarily accorded the status of a “commons” in property terms; or, like any other infrastructure asset, can it be held in a variety of property forms, ranging from discrete private property units through to publicly owned and operated commons title? Beyond ownership, there is also the question of the governance of green infrastructure, including the extent to which the green infrastructure assets of a city, be they in public or private ownership, can be regulated in ways that control their use, performance, and ongoing availability. These questions are more readily resolved with traditional environmental assets such as waterways and parklands, but require complex negotiation when green assets are held in private hands – such as a pristine natural habitat on a private estate – while delivering considerable public benefit.
Future directions in research, theory, and methodology

Although never mentioning the phrase directly, Jennifer Wolch (2007) provides an important exposition of the options for deployment of green infrastructure in creating cities that hold more promise for the future, especially regarding better social and ecological justice outcomes. Wolch notes that it has become common, even in rich cities, for urban residents to be forced to tolerate toxic soils, airborne pollutants, poor water quality, and species eradication. A source of the problem, says Wolch, were twentieth-century ideas that constructed dualisms between city and wilderness and between nature and culture. It has already been seen how green spaces were enlisted in early twentieth-century planning not as spaces for integrated, sustainable human use but as separation or buffer zones to human activity, as refuges for escape from the intense nature of urban activity, or as some sort of environmental recharge device to deal with urban excesses, especially in regard to air and water but also for material waste, such as landfill. As Wolch notes, it was rare for urban scholars in the twentieth century to think about “rivers, or oak trees or red-legged frogs,” and beyond issues of economic growth, class, gender and racial equality, human behavior (voting, commuting, shopping, parenting), and political movements and processes (Wolch 2007, 373). But global and local awareness of environmental devastation and unsustainability have dramatically changed the ways our urban world is seen, with growing cognizance of the inseparability of human and nonhuman worlds and of the need for significant and urgent responses. Nature and urbanism, says Wolch, are increasingly spoken of as integrated parts of a new approach to environmentalism.

Wolch illustrates her arguments with a case study of the Los Angeles River – and it is here that Wolch presents an agenda for interpretation and analysis, and for policy change, that can be easily tagged as belonging to a contemporary green infrastructure approach to urban and regional management. The Los Angeles River runs through Los Angeles from the outer affluent suburbs at the foot of the San Gabriel Mountains, through the movie-making center of San Fernando, through downtown LA and its adjoining industrial districts and poor inner neighborhoods, and then across a vast military industrial complex to the river mouth at Long Beach, with much of its urban journey steered by concrete channels and pipes.

Concrete passageways and diversions were built into the Los Angeles River from the 1930s as a way of controlling its waywardness during flooding events. The river needed to be tamed in order for urban activity to proceed. A by-product of flood engineering, however, was the destruction of major riparian habitats, the loss of infiltration and groundwater replenishment systems, and the removal of fish breeding spaces. The river as a key asset in the Californian water cycle was broken. It had ceased functioning, if you like, as a core piece of the city’s green infrastructure.

Replenishing and fixing the Los Angeles River required major engineering, political, and behavioral elements, which Wolch documents. These are encapsulated in the state strategy “Green Visions Plan for 21st-Century Southern California.” This strategy operates at a number of levels. Importantly, it builds a regional vision that integrates the river into urban life by promoting its restoration as essential to watershed health, habitat conservation, and recreational open space. Then the plan assembles parcels of data and analysis tools to assess, monitor, and guide changes to the way the river exists as an urban entity. The document argues for a better understanding of what will happen as water flows are changed in speed and direction, as
GREEN INFRASTRUCTURE

Local flooding events are accepted as normal, and as nonhuman species are invited back into the valley to live.

Beyond a direct focus on the river itself, Wolch shows how the emergence of a planning approach that values and nurtures green infrastructure requires also a reappraisal of the human behaviors that lead to stress on local water flows. These include consumption behaviors responsible for the waste that requires landfill, energy systems whose waste products end up in parts of the water cycle, and the worrisome ownership and investment practices that impede not-for-profit uses of riparian lands, including sustainable small-scale agriculture and wetland regeneration schemes. Central to a new planning approach, says Wolch, is the development of new types of “urban ecological citizenship” (Wolch 2007, 380) capable of devising or insisting on the governance processes necessary to power-up the claims for a renewed Los Angeles River environment. In this sense, the claim is for the river to eventually need no justification for riparian and water health other than for being a river. Perhaps this is why Wolch avoids the term “green infrastructure”; perhaps she sees green infrastructure as creating a view of nature as being a servant of human occupancy of the planet, with its worth measured by the contribution it can make in terms of services to human life. Perhaps she sees the river as having its own integrity and rights.

Ground-based LiDAR

Ruisheng Wang  
*University of Calgary, Canada*

Ground-based LiDAR (light detection and ranging), also called terrestrial laser scanning, is an active imaging system that uses LiDAR measurement technology at ground level. Each LiDAR measurement contains range and intensity values. The range values combined with the LiDAR sensor’s position and orientation produce X, Y, Z values; the intensity values are determined by the laser property and reflectivity of the surface. Ground-based LiDAR is used for close-range applications, such as heritage documentation, façade modeling, mapping and monitoring of road infrastructure, and precision forestry. In comparison with aerial LiDAR data, which are normally sparse with low laser ranging accuracy, the point clouds from ground-based LiDAR are relatively dense and have higher accuracy.

Ground-based LiDAR systems can be mounted on a stationary platform, such as a tripod, or on a moving platform, such as a vehicle, trolley, or boat. A lightweight LiDAR scanner can be portable and used for a handheld 3-D mapping system (CSIRO 2016). The choice of the platforms depends on the application. For instance, a tripod platform is suited for detailed documentation of cultural heritage, while the use of a moving vehicular platform is suitable for large-scale corridor mapping tasks. A hand-held device may be fit for indoor mapping applications. In general, ground-based LiDAR systems are often used for producing detailed 3-D models of buildings, trees, bridges, and other artificially constructed or natural objects.

Airborne platforms are frequently used for topographic mapping and digital terrain model (DTM) generation applications.

The laser scanner is an essential component of ground-based LiDAR systems. A laser scanner can be composed of three subcomponents: the optomechanical scanner, the ranging unit, and the control processing unit (Yang et al. 2015). The optomechanical scanner generates a laser pulse that is fed to the ranging unit. These pulses are reflected to the target via a rotating mirror within the ranging unit. There is also an electro-optical receiver within the ranging unit that records the total laser transmission and reception travel time. This value is passed to the control processing unit to further calculate the distance between the laser scanner and the target. This process occurs at a rate of 100,000–200,000 times per second (Yang et al. 2015); this timing accuracy is an important factor in determining the accuracy of LiDAR systems.

Unlike aerial LiDAR, which is normally georeferenced via GPS (global positioning system)/IMU (inertial measurement unit), terrestrial laser scanning on stationary platform georeferenced data cannot be provided by the laser scanner itself. The coordinates of the resultant point clouds are only related to arbitrary local coordinate systems. When multiple scanning at different locations is required to produce a consistent dataset for a complete scene, registration among these scanning data is needed. Using iterative closest point algorithms (Besl and McKay 1992) is a common practice to align multiple scanning data into a consistent point cloud. To relate point clouds to geodetic data, either GCPs (ground control points) or a direct
A georeferencing component is required. A GCP can be defined as a point on the surface of the Earth with known geographic location that is used to georeference data collected from sensors, such as remotely sensed images or point clouds. A direct georeferencing system relates data collected to the Earth by measuring the geographic position and orientation of the sensor, rather than using GCPs.

Ground-based LiDAR on a stationary platform provides point clouds with good accuracy due to its stable scanning. However, this scanning mode is not suitable for large-scale applications, such as scanning an entire city or mapping long distance corridors.

Ground-based LiDAR mounted on a moving platform, also known as mobile LiDAR, is a newly emerging technology for large-scale mapping applications. A mobile LiDAR system is defined as an integrated platform consisting of one or more short-range laser scanners (e.g., 100–200 m range), a high-precision positional system, and, optionally, one or more electro-optical cameras (Graham 2010).

In comparison with an airborne platform, mobile LiDAR systems are often operated at street level in cities, where GPS signals can be intermittently lost or affected by induced errors due to tall buildings. It is known that the IMU aids GPS positioning when the satellite signals are intermittently lost for short periods. However, over longer periods of GPS outage, the positioning information will start to degrade due to the problem of IMU drift. To overcome this problem, mobile LiDAR systems employ additional motion-detecting sensors, DMIs (distance measurement indicators), to provide corrections to GPS/IMU solutions. Since the data have been georeferenced to geodetic data, the resultant point clouds compose a scene without the need of registration.

Mobile LiDAR systems collect 3-D and visual data while vehicles drive at a posted speed; it is an extremely efficient data acquisition technology. In corridor mapping applications, such as railway or highway corridor mapping, mobile LiDAR systems are becoming a major technique for direct 3-D data collection (Graham 2010). In particular, companies such as Microsoft and NAVTEQ have adopted this technology and jointly deployed more than 40 mobile LiDAR mapping vehicles for their mapping applications. Google also introduced a significant number of mobile mapping vehicles for their street view data collection.

There are two types of mobile LiDAR systems in terms of the data accuracy provided: survey grade and geographic information system (GIS) grade. Survey-grade mobile LiDAR systems are designed to collect engineering/survey grade LiDAR data. The data resolution can be as good as 1 cm and the absolute accuracy can be 1–5 cm. Such accuracy is suitable for certain engineering applications where accuracy is an important factor, such as road crack detection and compliance certification. GIS-grade mobile LiDAR systems provide quality data that requires lower accuracy than design engineering projects, which suits applications where accuracy is not primarily concerned, such as visualization and animation.

Ground-based LiDAR has found wide applications in many disciplines. Terrestrial laser scanning can be used to determine parameters of trees, such as height or crown width in forestry, and can also be used to render detailed tree structure in computer graphics. In geomatics, it is often used for documenting heritage or pipelines and so on. Obviously, the scales of these applications are limited.

Mobile LiDAR is becoming an important tool for road infrastructure mapping and modeling. It has been used to obtain the geometry of roads.
and road attributes such as curbs, lane markings, traffic signs, and poles. Furthermore, it is also being used for detecting road cracks for roadway asset management. Research has indicated that the accuracy of crack detection and width measurement as well as the accuracy and repeatability of rut depth measurement can be improved using LiDAR technology. A mobile LiDAR system is a promising and cost-effective solution to assess pavement surface conditions, such as rutting and cracking, and for detecting potholes. Besides road pavement assessment, mobile LiDAR systems can be utilized for detecting and assessing conditions for traffic signs.

Mobile LiDAR can be also used for detailed modeling of building façades. Building models produced from airborne LiDAR lack detailed building façade information and are not suitable for applications where street-level representation of cities is required. Mobile LiDAR systems can produce accurate georeferenced 3-D points with sufficient detail in a short time and provide great potential for the generation of detailed 3-D models. However, due to the line-of-sight problems of any ground-based data acquisition system, it is difficult to always obtain complete and sufficient data from all the building surfaces, such as rooftops. The combination of mobile and aerial LiDAR will contain information from both a top-down perspective and a street-level view and will, therefore, be a valuable data source for large-scale photorealistic urban modeling.

Ground-based radar

Liming Jiang

Institute of Geodesy and Geophysics, Chinese Academy of Sciences, China

Ground-based radar (RAdio Detection and Ranging) is an active instrument on board a terrestrial platform; it measures the strength and round-trip time of microwave signals that are emitted by a radar antenna and reflected off the scattering surfaces or objects. Radars have a wide variety of working forms in terms of their various applications in military and civilian fields. This entry, however, focuses on an advanced imaging radar called synthetic aperture radar (SAR), which can produce high-resolution remote sensing imagery. Specifically, ground-based SAR (GBSAR) is a relatively new imaging radar that has been developed to measure surface topography and deformation by exploiting the interferometric capability of the received microwave signal, which is based on the same principles as the well-established spaceborne SAR technique (Henderson and Lewis 1998).

Typically, it is equipped with two antennas and a radar sensor that moves along a linear rail of a certain length, usually 1–3 m (Figure 1). This configuration allows the acquisition of 2-D SAR images by synthesizing an antenna aperture electronically.

As a terrestrial radar imaging technique, GBSAR is characterized by the following unique features: (i) imaging capacity with high spatial resolution (submeters to meters) and nearly real-time sampling (10 s to minutes), independent of weather conditions and sunlight illumination; (ii) a long measurement range, up to several kilometers; (iii) high flexibility in terms of data acquisition over a specific area of interest, at the required time and with the needed viewing angle; (iv) high precision and accuracy of deformation measurements (submillimeters to millimeters); and (v) a wide applicability range, for monitoring deformation phenomena from a few millimeters per year up to meters per day. Consequently, these enhanced characteristics of the GBSAR represent a fundamental advantage with respect to airborne or spaceborne SAR systems, and also make it complementary to other remote sensing techniques (e.g., terrestrial LiDAR scanner, digital photogrammetry and topographic total station) for topography and deformation measurements.

There are two different acquisition modes to obtain GBSAR data: (i) continuous acquisition mode (C-GBSAR) and (ii) revisit acquisition model (R-GBSAR). In the continuous mode, the GBSAR is mounted on a regular ground base and acquires SAR images with high temporal sampling, for example, every a few minutes. In the revisit mode, the instrument is installed and dismounted at each campaign by revisiting a site to acquire data with a given time interval, for example, weeks, months or years, depending on the deformation kinematics of interest. The C-GBSAR allows a near-real-time monitoring of ground deformation and can be used to measure fast deformation phenomena with displacement in the order of mm day$^{-1}$ to m day$^{-1}$ (Rödelsperger 2011). The R-GBSAR, on the other hand, is appropriate for measuring slow ground deformations and can be used to monitor several survey sites of interest with the same instrument; in this case the C-GBSAR is not recommended due to either logistic or cost...

![Diagram of ground-based radar](image)

**Figure 1** Working principle of ground-based SAR.

The radar sensor transmits, step-by-step, continuous waves at discrete frequencies over a frequency range. Furthermore, GBSAR measures the in-phase and quadrature components of the received signal at each frequency and position on the rail.

**Scattering surface**

Tx is a transmitting antenna and Rx a receiving antenna. The radar sensor transmits, step-by-step, continuous waves at discrete frequencies over a frequency range. Furthermore, GBSAR measures the in-phase and quadrature components of the received signal at each frequency and position on the rail.

Reasons (Monserrat, Crosetto, and Luzi 2014).

The phase information of the GBSAR complex data can be exploited for digital elevation model (DEM) generation and deformation measurement using interferometric techniques. It is worth noting that the deformation measurement is usually performed using a zero-baseline GBSAR configuration where all images are taken from the same position, whereas a nonzero baseline configuration is needed when GBSAR measurements are aimed at DEM generation (Monserrat, Crosetto, and Luzi 2014). Generally, the working principle of ground-based interferometric SAR (GBInSAR) is similar to that of satellite SAR interferometry (Hanssen 2001), and key interferometric processing steps consist of image coregistration, interferogram generation, phase unwrapping, atmospheric effect correction, displacement calculation, and geocoding. In this entry, detailed descriptions on the InSAR basic principle are not discussed; readers are referred to the literature (Hanssen 2001; Rödelsperger 2011).

Since the first prototype GBSAR system operating with the radar sensor based on a vectorial network analyzer (VNA) technology, a number of GBSAR systems have been developed by companies and research teams from the European Commission (EC), Spain (ES), Italy (IT), Ukraine (UA), Netherlands (NL), Switzerland (SW), China (CN), Japan (JP), United Kingdom (UK), and Korea (KR). Table 1 lists the main GBSAR systems presented in the literature; they are generally classified by the two major characteristics of (i) radar type – VNA, SFCW (step frequency continuous wave), FMCW (frequency modulation continuous wave), and others, for example MIMO (multiple-input and multiple-output) – and (ii) scanning model – linear scanning and angular scanning.

GROUND-BASED RADAR

In the last decade, the GBSAR has gained increasing interest as a terrain mapping and early warning tool for use in a wide range of environmental and geological applications (Monserrat, Crosetto, and Luzi 2014). These applications of GBSAR, especially of GBInSAR, take advantage of the unique capabilities already discussed to measure surface displacement and topography. The GBSAR with a nonzero baseline configuration has been proven to be effective in generating high-resolution DEMs of restricted areas (e.g., within a ranging distance of few kilometers) with an accuracy of about 5 m. The resultant DEMs can be subsequently utilized to geocode the GBSAR data and mitigate the atmospheric influences, hence, correctly interpreting and exploiting the displacement measurements.

The main GBSAR application filed is deformation monitoring (Monserrat, Crosetto, and Luzi 2014). In recent years, monitoring of natural and artificial instable slopes related to different phenomena, such as rockslides, open pit slopes, landslides, volcanic movement, and snow covered slopes, has become the most consolidated deformation-related application of the GBInSAR technique. In fact, great developments at both radar systems and data processing levels have been achieved in the last few years, which enables this technique to be a real-time monitoring and operational early warning tool to assess the risk of rapid landslides. Another group of important applications is the displacement monitoring of human-made structures, such as urban infrastructures, historical buildings, bridges, dams, and dikes. A major advantage for urban and structural monitoring is the capability to detect remotely small displacements with high spatial resolution and deformation sensitivity. Finally, recently the GBInSAR has gained increasing interest for investigating glaciers and snow, although some are not exactly related to deformations. Several studies demonstrated the potential of this technique for monitoring glacier dynamics (e.g., ice flow and elevation change) and snow avalanches at long range and high resolution. In addition, this technique can be used to retrieve snow depth and snow water equivalent, but these are still at an early research stage.

Grounded theory

LaDona G. Knigge
California State University, Chico, USA

Grounded theory is an inductive approach to research discovered by two sociologists in the late 1960s as a way of systematically collecting and analyzing qualitative data (Glaser and Strauss 1967). The purpose of grounded theory is to generate or discover theory inductively from data that is free from a priori assumptions. The process of generating theory from data requires that concepts, categories, and most hypotheses emerge from the systematic process of data collection and analysis in order to create theory that is grounded in empirical data and thereby bridging the gap between theory and practice. While grounded theory has its roots in the collection and analysis of qualitative data, its application was never limited to qualitative data. It is flexible enough and often requires the collection and analysis of quantitative data.

Grounded theory is an inductive, recursive research method that involves successive iterations of data collection, analysis, and verification in order to reveal categories and their properties as well as evidence to be collected and analyzed in the next round of research. Comparative analysis is central to the grounded theory methodology (Glaser and Strauss 1967). Generating theory through comparative analysis involves coding of data for categories and their properties and recording the findings in memos. Comparative analysis of additional similar or dissimilar instances allows conceptual categories to emerge and inform the next round of data collection.

Grounded theory’s process of comparative analysis serves several purposes: to verify evidence, to broaden the scope of the theory through empirical generalization, to specify a particular concept, and to generate and verify theory. Conceptual categories and their properties are derived from evidence obtained through comparative studies. By comparison with other similar groups, evidence can be verified for accuracy and be used to illustrate the conceptual category (Glaser and Strauss 1967). Constant comparison reveals similarities and differences in the data and generates conceptual categories and their properties. This empirical generalization both limits the extent of the theory and broadens its applicability and explanatory power as well as specifying the properties of a particular concept. As the research process proceeds and theoretical hypotheses emerge, comparative analysis allows the researcher to test the relevance and extent of the categories and their properties, to explore the applicability to different areas, and to search for similarities and differences, all the while systematically building and modifying theory (Glaser and Strauss 1967).

The sampling framework associated with Glaser and Strauss’s method of comparative analysis involves theoretical (not statistical) sampling to generate conceptual categories from the data. According to Glaser and Strauss “[t]heoretical sampling is the process of data collection for generating theory whereby the analyst jointly collects, codes, and analyzes his data and decides what data to collect next and where to find them, in order to develop his theory as it emerges” (1967, 45). Theoretical sampling involves the collection of diverse forms of data that may consist of interviews, conversations, field notes,
existing reports, historical records, or other secondary data that provide different angles from which the researcher understands the category and its properties. Theoretical sampling is intent upon discovering categories and their properties in order to make determinations about their relationships in order to generate theory. In contrast, statistical sampling involves the use of a scientifically developed framework in order to determine statistical distributions of the group or groups sampled. While statistical sampling requires that all instances of the sample of the predefined population be considered, the groups and categories in theoretical sampling arise from the coding and analysis of data, with the addition of new groups and categories that are identified as the research process proceeds.

Theoretical sampling of additional instances that are similar or dissimilar to the conceptual categories continues with the addition of new categories and properties derived from the coding process which informs the next round of data collection. As the research process proceeds, the direction and scope of the theoretical sampling is shaped by the emerging categories and their properties which are coded and analyzed. The researcher is constantly coding, analyzing, and writing up the findings in field notes or memos. In the course of the research, some categories become higher-level, integrative conceptualizations that are explored until further sampling does not reveal any new data about the properties of the particular category. When the researcher starts seeing the same instances again and again the category is said to have reached theoretical saturation, and further sampling does not reveal any new data to develop the properties of the category (Glaser and Strauss 1967). The theory may be for a substantive area or several substantive comparisons may generate formal theory in a formal, conceptual area of social life (Glaser and Strauss 1967).

The history of grounded theory

The development or “discovery” of grounded theory by sociologists Barney G. Glaser and Anselm L. Strauss was the result of the methods used in their study of death and dying in public institutions in conjunction with Public Health Service Research Grant NU-00047 from the Division of Nursing, Bureau of State Services—Community Health that led to the coauthored book Awareness of Dying in 1965 (Glaser and Strauss 1967). While grounded theory was discovered by two sociologists, they came from quite different backgrounds. Barney G. Glaser was trained in Columbia University’s Department of Sociology and influenced by “Merton’s middle-range theory and Lazarsfeld’s quantitative methodology” (Glaser and Strauss 1967, vii). Anselm L. Strauss (1916–1996) obtained his BA and PhD at the University of Chicago, studying under Herbert Blume and was influenced by the “Chicago tradition” in qualitative research (Glaser and Strauss 1967, vii). Their collaboration was the result of perceived inadequacies in the approaches of both in their respective backgrounds.

Grounded theory has diversified over the years as it gained popularity in nursing, anthropology, information technology, geography, and many other disciplines. After their publication of The Discovery of Grounded Theory: Strategies for Qualitative Research (1967), Barney G. Glaser and Anselm L. Strauss pursued separate scholarly endeavors and grounded theory diverged into two schools. This split between Glaser and Strauss became apparent when Strauss published Qualitative Analysis for Social Scientists (1987) and coauthored The Basics of Qualitative Research with Juliet Corbin in 1990, which contain detailed steps for the grounded theory process. Strauss and Corbin’s expanded coding approach included open coding, axial coding, selective coding, and
coding for process. Open coding is first level, line by line coding to identify concepts and their properties. This includes in vivo codes taken from actual wording of the respondents. Axial coding is a second level form of coding that finds relationships and common dimensions to create linkages between categories, subcategories, and their properties. Selective coding integrates categories and their properties into interrelated, theoretically saturated central explanatory concepts in order to build theory. Coding for process is a way of relating the interplay between structure and process (Strauss and Corbin 1998).

Strauss and Corbin’s approach sometimes referred to as the Strausarian School of grounded theory has been cited widely and used extensively by researchers in many disciplines. The first edition, published in 1990, was intended to supplement prior work on grounded theory and serve as a prescriptive guide for inexperienced researchers (Strauss and Corbin 1998). After Anselm Strauss died in 1996, Juliet Corbin published the third edition of Basics of Qualitative Research, coauthored by Strauss posthumously (2008). It is interesting to note that this edition no longer contains the detailed coding strategies of the previous versions. Additionally Corbin reflexively addresses some of the critiques of grounded theory’s claims of researcher objectivity and the idea that theory exists and can be discovered. Corbin acknowledges the importance of reflexivity and her own positionality and biases in this volume. Noting the changes over time in her own approach to research, she identifies with the constructivist approach as well as feminist self-reflection and commitment to social justice (Corbin and Strauss 2008). The third edition also notes that while it is intended for inexperienced researchers, it “can be used by anyone regardless of whether their research aim is theory building; rich, thick descriptions; or case study analysis” (Corbin and Strauss 2008, 17).

The approach to grounded theory developed by Strauss and Corbin was the subject of criticism by Barney Glaser (1992) in the Basics of Grounded Theory Analysis: Emergence vs Forcing where he provided a correction of various subsections and book chapters of what he perceived as the misconceptions and inadequacies of The Discovery of Grounded Theory. Glaser was particularly critical of the detailed coding structure of Strauss and Corbin’s work that he suggested forced data rather than allowing theory to emerge. Barney Glaser stated numerous times that he felt that Strauss and Corbin’s work produces “a forced, preconceived, full conceptual description” that is descriptive rather than facilitating the discovery of theory (Glaser 1992, 3).

Barney Glaser has remained committed to the original tenets of grounded theory from the collaboration with Anselm Strauss. In 1978 he published Theoretical Sensitivity which further detailed the method. Much of his subsequent writing has been critical of Strauss and Corbins’s prescriptive approach which he contends forces data into preconceived categories rather than allowing the categories to emerge through the comparative approach. He continues to publish his work mainly through Sociology Press, which is referred to as “the foremost publishers of classic grounded theory methodology” (www.sociologypress.com) and other venues, including the open access journal The Grounded Theory Review (http://groundedtheoryreview.com) that are dedicated to furthering research using the Glassarian approach to grounded theory.

Grounded theory has also been adapted by other researchers. Kathy Charmaz developed a constructivist approach to grounded theory (2006). Starting from Glaser and Strauss’s invitation extending the flexible use of grounded theory to other users, Charmaz focuses on flexible guidelines for the principles and practices.
of grounded theory (Charmaz 2006). While Glaser and Strauss emphasize the discovery of theory from data that is separate from the researcher, referred to as objectivist grounded theory, Charmaz assumes an interpretive role for the researcher who constructs grounded theories that are admittedly subject to the researchers, past experiences, interactions, and perspectives (2006). While Charmaz’s constructivist approach to grounded theory acknowledges the social construction of data and analysis and the role of subjectivity in theorizing, it also adheres to many of the methods of earlier versions of grounded theory, including simultaneous data collection, coding, comparative analysis, and memo writing in order to construct theory grounded in empirical reality (2006).

Grounded theory in geography

Geography, with its focus on place, the interplay of human and physical processes, identity, regions, and visual representation, has a history of using mixed-methods approaches that includes grounded theory in combination with other methods, both quantitative and qualitative. While the discovery of grounded theory by Glaser and Strauss was in opposition to what both perceived as inadequacies in their own epistemological grounding, in the 1990s grounded theory was associated with positivistic assumptions by many sociologists who questioned the claims of researcher objectivity and that theory existed and was discovered by the researcher. Geography experienced its own quantitative revolution, followed by the cultural turn that questioned positivist epistemologies and the emphasis of spatial science. However, in the 1990s, geographers’ emphasis on mixed-methods research uncoupled epistemology from methodology and suggested that rather than having the choice of method dictated by the epistemology, mixed-methods research could be informed by a number of different epistemological stances. For geographers, mixed methods allow for diverse research techniques that cannot only triangulate or confirm results, but may also contradict findings, confirming that knowledge is situated, partial, and contextual. Feminist geographers, in particular, have used both qualitative and quantitative methods and data to integrate multiple forms of knowledge and that allows an understanding of both the general and the particular.

The mixed-methods approach in geography has been extended to include the use of GIS technologies. Recent developments in critical and feminist geography led to the emergence of new areas of study that include critical GIS, feminist GIS, and qualitative GIS that frequently combine grounded theory with other methods in a mixed-methods approach. Rather than viewing GIS as a positivist tool, research by critical and feminist geographers has sought to decouple GIS from its association with quantitative methods and claims of positivism and integrate it into studies from a variety of epistemological stances. For example, Marianna Pavlovskaya used grounded theory to analyze interviews and ethnographic data along with GIS maps to understand patterns of urban change in a study of post-Soviet Moscow (Pavlovskaya 2002). This mixed-methods approach facilitated the discovery of categories, patterns, and processes that would not have been detected using only one method or the other. Another example of the combined use of grounded theory and GIS in flexible, recursive rounds of data collection and analysis is the study of community gardens in Buffalo, NY. LaDona Knigge and Meghan Cope developed an iterative, reflexive method of analysis that combines the use of grounded theory with GIS, exploratory data analysis and visualization techniques in an approach that
they call grounded visualization (Knigge and Cope 2006). This approach iteratively and recursively integrates multiple forms of data (both qualitative and quantitative) and analysis in order to build theory that is grounded in empirical data.

Several other examples of integrative approaches using grounded theory and GIS can be found in Qualitative GIS: A Mixed Methods Approach (Cope and Elwood 2009) including further work by Knigge and Cope, Pavlovskaya, and others. In this edited book, Jin-Kyu Jung (2009) develops a novel approach to qualitative GIS that combines the coding strategies of grounded theory operating within a computer-aided qualitative data analysis software (CAQ-DAS) platform that is integrated with GIS. Jung creates an imagined grid that contains qualitative data (photos) within GIS with a hybrid relational database to link GIS and CAQ-DAS into what he refers to as a computer-aided qualitative GIS (CAQ-GIS). These examples demonstrate how grounded theory can be integrated into mixed-methods approaches by geographers and the flexibility and adaptability of the grounded theory method which will no doubt continue to be developed within geography and other disciplines in the future.

References

Groundwater is water that exists mainly in subsurface pore spaces but also in defined channels, such as those found in karst formations, which are created by dissolution of soluble rocks such as limestone. After the polar ice caps, groundwater is the next largest reservoir of freshwater on Earth, containing more than 100 times the volume of streams and freshwater lakes (Shiklomanov 1993). Groundwater plays an important role in the hydrologic cycle, in plant growth and soil formation, and in providing water for human activities. Since groundwater is difficult to observe and track directly, monitoring, mapping, and modeling efforts are crucial to the understanding of its storage, distribution, and patterns in flow through the subsurface, how it may be sustainably used, and how it may become contaminated. Humans have used groundwater throughout history, but the demand for it and the societal ability to consume and contaminate it have all increased exponentially over the past century. Uneven distribution of human populations combined with variations in availability and accessibility to groundwater have resulted in overexploitation of several major aquifers serving population and agricultural production centers in China, India, and the United States. Significant current and future threats to groundwater quantity and quality that require attention from policy and planning perspectives include climate change, fossil fuel exploration and extraction, natural contaminants such as radium and arsenic, underground storage tanks and industrial contaminants, and agricultural use and pollution.

Groundwater: natural and physical science perspectives

Groundwater’s place in the water cycle

More than 68% of fresh water is found in polar ice caps and glaciers and is thus largely unavailable for societal use (Shiklomanov 1993). Approximately 30% of global fresh water is groundwater, whereas only 1.2% is found in streams and lakes. Geologic formations that yield a significant amount of water to wells or springs are called aquifers. An aquifer consists of two or more permeable layers in the subsurface separated at least locally by intervening layers that impede groundwater movement but do not significantly affect the regional hydraulic connectivity of the system. With the exception of fossil aquifers, groundwater is replenished mainly by precipitation falling within the recharge area of an aquifer. Precipitation on land flows horizontally across the surface or infiltrates into soil and moves either horizontally or vertically within the subsurface. Groundwater consists both of water that remains in the unsaturated or vadose zone (also often termed “soil water”) and
of water that reaches the saturated zone (aquifer) where pore spaces are completely filled.

Global distribution of groundwater

Groundwater may be found almost anywhere on Earth if one digs deep enough, but most accessible groundwater is generally found within 1 km of Earth’s surface (Hess 2014). Beyond this depth, groundwater availability decreases gradually and quality is often poor due to high salinity and mineral concentrations. Worldwide, approximately 36% of the land surface (excluding Antarctica) is underlain by major aquifers, primarily composed of sedimentary rocks, while another 18% of the subsurface is dominated by aquifers of more complex and heterogeneous geology (Richts, Struckmeier, and Zaepke 2011, WHYMAP, Table 1). The remaining approximately 47% of the land surface is underlain by local and shallow aquifers along stream valleys and lowlands. There are significant regional variations in the distribution of aquifers. For example, shallow local aquifers dominate much of North America, whereas major regional aquifers spanning thousands of square kilometers are the predominant aquifer type throughout much of continental Europe (Table 1).

Currently, approximately 24% of global aquifers are highly overexploited; the major driving factor is irrigated agriculture for feeding human and livestock populations (Gleeson et al. 2012). Pumping from the most exploited aquifers (Upper Ganges, North and South Arabian, Persian, Western Mexico, and High Plains or Ogallala) is on the order of tens of times the natural recharge rate, and may also act as a limiting factor in future agricultural output (Figure 1). Although 76% of aquifers are not being significantly exploited, overexploitation of a few large aquifers has led to a total groundwater footprint of more than 3.4 times the global area of aquifers (Gleeson et al. 2012, Table 2). If 1 and 2% of the largest pristine or unexploited aquifers (7 and 15 observations from 748 considered in Table 2) are removed from consideration, the composite average of the groundwater footprint rises to 4.81 and 6.34 (39 and 84% increase, respectively) indicating that a few outlying pristine aquifers have undue influence on the composite average of the global groundwater footprint. Similarly, if 1 and 2% of

the aquifers representing the largest footprints (7 and 15 observations from 748 considered in Table 2) are removed from consideration, the composite average of the groundwater footprint falls to 1.52 and 0.93 (56 and 73% decrease, respectively) indicating that a few outlying aquifers with large footprints also have undue influence on the composite average of the global groundwater footprint. In contrast, the median of the global groundwater footprint of 0.11 is robust and is not significantly impacted by the extreme outlying values of aquifer areas or groundwater footprints.

Exploitation of aquifers also varies significantly within aquifers. For example, the average water level in the High Plains (or Ogallala) aquifer of the central United States has declined by more than 4 m since before World War II. However, this includes some areas where water levels have increased by up to 20 m and others that have decreased more than 70 m (McGuire 2013). Total water storage in the High Plains aquifer has decreased by approximately 8%, but storage in 5% of the aquifer area decreased by over 50% (McGuire 2013).

Types of aquifers
The unsaturated zone of an aquifer is immediately below the land surface where the soil/rock pores contain both water and air, but are not totally saturated with water. It differs from the zone below which is saturated with water. The top of the saturated zone is referred to as the water table (USGS 2014a). Aquifers may be classified by whether they are confined or
unconfined and by their geologic composition. Confined aquifers exist between two impermeable layers, often comprised of clay or clay-derived rock. Unconfined aquifers lack a confining layer above the water table, and are thus vulnerable to pollution from the surface. Unconsolidated aquifers consist of sand, gravel, and other materials that have not been cemented together, and where water fills up spaces between the particles. In contrast, water-bearing formations that have been cemented together are termed consolidated aquifers. Relatively large pore spaces in unconsolidated aquifers and solution channels in carbonate aquifers can hold significant amounts of groundwater with high hydraulic conductivity. In contrast, only the presence of fractures and joints in igneous and metamorphic rocks allow water to enter and move through the formations. Sand and gravel aquifers are generally unconfined, and can be several hundred feet thick. They are comprised of alluvial or glacial deposits and found in valleys, depressions, and lowlands. Alluvial aquifers were formed over hundreds to thousands of years by water deposition of sand, silt, and clay particles. These alluvial deposits can contain large groundwater reserves that are fairly accessible and easy to withdraw. Sand and gravel aquifers of glacial origin may also have large reserves of groundwater that are fairly easy to withdraw, but hydraulic conductivity in such aquifers may be quite variable due to lack of sorting in glacial till.
Groundwater

Carbonate rock aquifers are comprised primarily of limestone or dolostone formed in ancient marine environments. Weak carbonic acid in rainwater dissolves carbonate rock and over thousands of years has in many areas formed karst landscapes characterized by numerous solution cavities, caverns, and sinkholes through which water can move rapidly. Where carbonate layers are exposed to the surface, runoff from precipitation or entire streams may connect directly with groundwater, resulting in significant contamination potential. Sandstone aquifers and igneous and metamorphic rock aquifers typically store and transmit water only along bedding planes, joints, and other cracks and fractures. Hydraulic conductivity in such aquifers is low, but large regional aquifers can yield high total volumes of groundwater.

Groundwater flow and wells

The geology of the aquifer influences water storage capacity as well as hydraulic conductivity, or the ability of aquifer materials to transmit water. Factors affecting hydraulic conductivity and storage capacity include porosity (proportion of pore space) and permeability (connectedness) of the pore spaces. Groundwater flow is down-gradient from high to low pressure, which often corresponds with moving from high to low elevation. An exception to this occurs in the case of confined aquifers contained within tilted rock formations where considerable pressure builds up in the lower reaches of the aquifer. In such cases, a well or a spring located at a point where the potentiometric surface (or water table) is higher than the land surface will flow freely without the need for pumping; such wells or springs are termed artesian.

Wells drilled into unconfined aquifers or confined aquifers with insufficient pressure to flow naturally require pumping to bring water to the surface. Some level of drawdown (or reduction in the height of the potentiometric surface) occurs with pumping of water from aquifers. During pumping, a cone of depression (Figure 2) forms around wells – the shape, size, and depth of the cone of depression as well as the rate at which the well water level recovers depend upon the pumping rate and duration, aquifer characteristics such as hydraulic conductivity, and the presence or absence of nearby wells. Pumping tests are done to determine whether the aquifer will provide an adequate yield (measured in gallons or liters per minute) for the intended purpose of the well.

Soil formation

As it moves through soil, water dissolves chemicals and sometimes deposits them at lower levels. This leaching process can deplete the topsoil of essential nutrients (Hess 2014). Fine particles such as clay are picked up by water and carried in suspension and deposited elsewhere at greater depths. Water, thus, constantly changes the physical, chemical, and biological makeup of the soil as it moves downward due to gravity, or sideways depending on available openings. When silica is removed by dissolution leaving behind...
the more insoluble iron compounds, reddish colored soils such as latosols are produced in tropical and subtropical regions of the world. In mid- and high latitudes, water removes minerals like oxides of aluminum and clays and forms shallow acidic soils like podzols. Gley soils are acidic and oxygen-poor and develop in waterlogged conditions in cool climates. In the more arid and semiarid regions, capillary action brings up soil moisture, which evaporates leaving behind salts like chlorides and sulfates. Soil salinization is exacerbated by inadequate drainage and low precipitation rates, resulting in calcic and other salt hardpans.

Groundwater chemistry

Groundwater quality may be affected by contaminants of both natural and human origin. Factors that determine groundwater quality include the thickness of the aquifer, aquifer structure, mineral composition of the aquifer, presence or absence of a confining layer, presence of direct conduits (e.g., abandoned wells or sinkholes) to the aquifer, and in the case of unconfined aquifers, presence of pollutants on the overlying land surface. Unconfined aquifers are more susceptible to contamination from human activities because of their proximity to pollution sources. The age or residence time of water in the aquifer is also a significant factor affecting groundwater quality as longer residence times provide more opportunity for dissolving minerals.

Many substances may be dissolved by groundwater as it moves through the subsurface. The most common chemical constituents in groundwater include sodium, calcium, magnesium, potassium, chloride, and sulfate. However, depending on mineral composition of the subsurface and on length of exposure, high levels of arsenic, fluoride, iron, manganese, or radionuclides may also be found.

Modeling and visualizing groundwater

The importance of modeling groundwater

Because of its intractability, understanding the processes associated with groundwater is more complicated relative to those associated with surface water. Hence, monitoring, mapping, and modeling efforts are crucial for this purpose. As in any area of inquiry, however, the applicability and accuracy of groundwater models is highly dependent upon (i) the quality of the input data (i.e., knowledge of initial conditions and the existence of adequate hydrogeological data) and (ii) the “fit” between the modeling approach (assumptions and equations) and the scope and purpose of the problem being explored.

Many groundwater models in one, two, or three dimensions rely at least to some degree upon Darcy’s Law (Henry Philibert Gaspard Darcy, 1803–1858), which among other things allows for estimating water velocity in an aquifer as well as time required for water to travel between points within the aquifer, and which holds for nearly all hydrogeological conditions. In brief, Darcy’s Law provides that water flows only when there is a gradient, that water flows down-gradient from high to low head (pressure), that flow velocity is proportional to head loss, and that velocity is modified by the hydraulic conductivity of the aquifer materials.

Modeling approaches and data needs

There are three types of groundwater models: analytical element, finite element, and finite difference. The latter two are data driven and are calibrated or fitted with extensive field data. The simplicity of the analytical element method is in
its assumptions. It uses points, lines, and polygons to spatially represent contaminant sources, rivers, flow barriers, and groundwater zones. Assumptions such as flat water tables, uniform aquifer thickness, and constant conductivity are typical in such modeling efforts. However, such models may not accurately represent the complex geometry and heterogeneity of the real world of subsurface groundwater (Bennett 2014).

Depending on the scope and purpose of modeling efforts, data of varying quality at compatible scales may be required. Generally, the data required includes hydrologic measurements (e.g., precipitation, infiltration, evapotranspiration), initial and boundary conditions (e.g., potentiometric surface height, presence of confining layers), subsurface characteristics (e.g., thickness, composition, hydraulic conductivity), and human conditions (e.g., presence and pumping rate of wells, surface modifications). There is much more detailed hydrologic and subsurface data available in developed nations than in developing nations. For example, in the United States, vast amounts of hydrologic data may be obtained from federal government agencies such as the US Geological Survey and the National Oceanic and Atmospheric Administration and most states require submission of well boring logs to permitting authorities for every well that is drilled, resulting in a slowly increasing store of knowledge of the subsurface. In recent decades, satellite technology has also been employed to search for signs of groundwater (e.g., landforms such as ancient lake beds) or overexploitation of groundwater (e.g., changes in surface elevation) over time.

Software use in groundwater modeling

Many commercial and open-source software packages exist for purposes of modeling and displaying various aspects of groundwater quantity and quality, including flow, transport, and geochemical reactions. A selected list of open-source software for groundwater models is provided by the US Geological Survey (USGS 2014b).

MODFLOW is the USGS’s three-dimensional (3-D) finite-difference groundwater model (USGS 2013) that is considered an international standard for simulating and predicting groundwater conditions and the interactions that take place between ground and surface water. Originally developed and released in 1984 as a computer code for simulating groundwater flow, its modular structure provides a robust framework for integrating additional features. Current capabilities include simulations of coupled groundwater and surface-water systems, solute transport, variable-density flow (including saltwater), aquifer-system compaction and land subsidence, parameter estimation, and groundwater management (USGS 2013).

To enable users to make appropriate software selections, Kumar (2012) has provided a review of the capabilities and limitations of available groundwater modeling software. 3-D groundwater computer software uses borehole stratigraphy, geologic layers, cross sections, and terrain data (for example, digital elevation models) to construct 3-D models of the subsurface (Strassberg, Maidment, and Jones 2014). With its ability to provide preprocessing data input to MODFLOW, and store results from MODFLOW, the Arc Hydro Groundwater data model of the flagship software company ESRI of California (Strassberg, Maidment, and Jones 2014) has created a very rich and comprehensive environment for groundwater modeling and visualization.
Groundwater models and geovisualization, selected examples

Hydrogeologists often use diagrammatic representations (Figure 3) to characterize and visualize the subsurface flow systems and the influence of geology and climate on such systems over time. The movement of groundwater in the subsurface of the Death Valley Regional Flow System (DVRFS) is captured and depicted in Figure 3 (Faunt, D’Agnese, and O’Brien 2010). It shows the flow paths of groundwater movement under the influence of hydraulic gradient through varying zones of permeability, from recharge to discharge areas in a regional context.

In addition to testing local aquifers to determine well or aquifer yields, and using well data to describe subsurface flow patterns, models are also used to understand groundwater both at spatial (local to regional aquifers) and temporal (e.g., tracing historical contamination to its source) scales. Two examples of 3-D groundwater modeling efforts are provided below and include predicting the migration of a uranium plume (Figure 4) and assessing risk of encountering high arsenic concentrations at various depths (Figure 5).

To construct 3-D images for visualizing concentrated plumes of contaminants such as uranium in subsurface sediments of waste sites, as shown in Figure 4, scientists at the US Department of Energy (2009) have developed groundwater models. Such models enable the prediction of movement of contaminants such as uranium over tens to hundreds of meters on temporal scales ranging from hours to years.

Arsenic contamination of shallow groundwater and its impact on the health of affected populations is one of the most serious environmental...
problems in developing countries. In Figure 5, the authors of a study (Winkel et al. 2011) on groundwater contamination of the Red River Delta in Vietnam show the probability of Arsenic (As) concentration exceeding 10 μg/l at 10 m depth intervals. Such analyses resulting from models enable us to study the connections between large-scale pumping of groundwater and the resulting vertical migration of arsenic in the subsurface.

Social, political, and planning aspects of groundwater

Historical access to and use of groundwater

Throughout history, humans have accessed groundwater in several different ways, likely beginning with locations where seeps or artesian upwellings occurred, progressing to hand-dug wells and wells accessed via windlass and bucket,
and finally tube wells with electric or fossil fuel-powered pumps.

Qanats, or hand-dug tunnels with numerous vertical shafts that access groundwater and deliver water by gravity for irrigation or domestic use, have been in use for more than eleven centuries throughout much of the Middle East, western Asia, southern Europe, northern Africa, and Central America. This technology is believed to have originated in Persia and spread via trade routes and expansion of Arab and Roman empires. Water from qanats was historically viewed as a community resource to be shared, and the maintenance and cleaning of qanats was also a laborious and challenging exercise. Thus the use of qanats for accessing water in effect demanded a cohesive community to successfully maintain channels. Flow in qanats varies with the level of the water table in the aquifer, which ensured sustainable use of the aquifer but also may have limited use for crops (and therefore crop yields) or other uses during periods of low recharge. Although qanats are still in use in many regions, their importance for domestic supply and irrigation has decreased due to increasing use of the same aquifers by powered pumps or other hydrological modifications that may have reduced recharge (e.g., as in the case of Morocco’s Tafilalet oasis and aquifer system).

Rapidly growing urban populations with increasing water use and consumption during the twentieth and twenty-first centuries have
stressed aquifers with relatively high withdrawal rates. In the case of coastal megalopolises such as Houston, New York, and Chennai, the increasing water use rates have outstripped recharge rates, thus enabling saltwater intrusion into coastal aquifers. Human population and agricultural centers have not all been developed in close proximity to locations with ample surface or groundwater resources. Major river systems or areas of significant precipitation often give rise to the highest yielding alluvial freshwater aquifers. Large human settlements in arid and semiarid regions and areas overlying saline groundwater have long been water stressed.

Groundwater rights

Modern groundwater rights are most often determined by ownership of overlying land, or, where legally permissible, by leasing or purchasing the rights to groundwater residing beneath lands owned by others. The pumping or abstraction rate may be determined by principles such as absolute ownership (pumping without regard to depletion or conflict with others), correlative rights (considering the rights of other users), or a permit that specifies a maximum pumping rate. Historically, groundwater pumping rates have not been of significant concern, except in water scarce regions.

In recent decades, with increasing groundwater consumption for irrigation and other purposes, and with more complete information about aquifer extents, capacities, and depletion rates, pumping has become increasingly regulated in semiarid regions. In some situations (e.g., Texas, United States), groundwater rights may be separated from the overlying lands and may be purchased or leased and exploited by individuals or entities who do not own the land. Groundwater rights in some locations are also affected by the distinction between percolating groundwater (e.g., as in a sandstone aquifer) and groundwater flowing as a subterranean stream in a defined channel (e.g., as in a karst formation).

Groundwater, conflict, and transboundary aquifers

The destruction, deliberate draining, or poisoning of wells has been a feature of many conflicts throughout history; instances include Assyria’s use of rye ergot to poison enemy wells in the sixth century BCE, Saladin’s sanding of wells in the defeat of the Crusaders in the twelfth century CE, poisoning of wells in German Southwest Africa by retreating German troops in 1915, Japan’s use of biological weapons to contaminate wells in China in 1939–1942, Serbian cut-off of well water to Bosnians in Sarajevo in 1992, Botswana troops’ destruction of Khoisan (Bushmen) wells in 2002, and intentional contamination of Darfur wells in 2004 (Gleick et al. 2012).

There are numerous transboundary aquifers worldwide, some of which are shared by more than two nations. The nature of aquifer sharing includes several different types of situations, for example:

- two or more nations overlie an unconfined aquifer;
- two or more nations overlie a fossil aquifer with no meaningful recharge;
- one nation has the recharge zone and part of an unconfined aquifer within its territory, whereas down-basin nations have access only to the water in the aquifer (Eckstein and Eckstein 2005).

With some exceptions, and despite the catastrophic potential impacts of aquifer contamination and depletion, there has been relatively little progress on the international management of groundwater. In 2008, the United Nations adopted Resolution A/RES/63/124 on the Law
of Transboundary Aquifers, which provides a set of guidelines and recommendations to assist nations in establishing bilateral and multilateral agreements. More recently, the UN has discussed establishing a more formalized convention on transboundary aquifers. Key issues in the management of transboundary aquifers include prior use patterns, military conflict, economic growth, population growth, irrigated agriculture in arid or semiarid lands, land use, climate change, and the proportion of overlying land or recharge area controlled.

There are several notable regional conflicts in which groundwater plays an important role. Groundwater is interwoven into the Israeli–Palestine conflict because the Mountain Aquifer provides a significant proportion of the domestic and agricultural water to Israeli territory, but the recharge zone lies nearly entirely within the West Bank. The lack of stable and durable peace in the region makes it difficult to manage and use the resource efficiently and also construct and operate water and wastewater treatment facilities in the West Bank so as to protect the highly vulnerable aquifer.

The Nubian sandstone aquifer is a fossil aquifer in northern Africa shared by Libya, Egypt, Sudan, and Chad. In 2013, these four nations adopted the Regional Strategic Action Plan on the Nubian Sandstone Aquifer in response to declining water levels, increased salinization in the Post-Nubian System (north of the Nubian System), and the declining health of dependent ecosystems.

Key issues related to planning and future sustainability of groundwater resources

Water quantity: climate change

Climate change is already impacting groundwater and will continue to impact it in at least two important ways: (i) groundwater may become a more valuable resource in a changing climate, where precipitation becomes less predictable and more “flashy,” and (ii) aquifer recharge may also be altered by changes in precipitation patterns and evaporation rates. Climate change impacts on groundwater resources may be most significant in areas that have scarce precipitation or which already are water stressed, as well as in monsoon regions.

Water quantity: over abstraction

In addition to the 15 highly overexploited aquifers of the world (shown in Table 2), over-abstraction or mining of groundwater for agriculture (e.g., San Joaquin Valley, California, United States), industrial use, and drinking water supply (e.g., Osaka City, Japan) has occurred in numerous other aquifers worldwide. In many locations, such overuse has caused permanent compaction and aquifer capacity reduction and accelerated sinkhole formation in karst regions. Resulting land subsidence of several tens of meters in some cases (e.g., Houston, Texas, United States) have increased the vulnerability of such areas to flooding. Due to approximately 8 m of subsidence in the last century, numerous buildings in Mexico City have been damaged and significant repairs have been necessary to much of the subsurface infrastructure, including subways, sewers, and potable water pipes.

Groundwater quality issues

Arsenic (arsenicosis), fluoride (fluorosis), and radionuclides (mutations, cancer) are all found in groundwater in some regions and have significant human health impacts. For example, relatively low concentrations of arsenic can be found in groundwater in many regions; however, the highest concentrations consumed as
potable water appear to be found in the southern Asian nations of Bangladesh, India, and Vietnam (Mukherjee et al. 2006; Winkel et al. 2011). Other groundwater constituents tend to have impacts that are less health-related but significant nonetheless. For example, the main impacts of calcium and magnesium are the formation of scaly deposits on pipes and reduced performance of soaps and detergents. Sulfur compounds typically affect the smell and taste of water, whereas high levels of iron can leave reddish stains on fabrics washed with groundwater.

Groundwater contaminants of human origin include industrial discharge, landfills and legacy waste disposal sites, agriculture, toxic chemical spills, leaking underground storage tanks (LUSTs), and domestic sewage discharge. The behavior and toxicity of contaminants varies widely, as does the ability to remediate and restore groundwater quality. Nitrate, the most common agricultural groundwater contaminant, is highly soluble in water, but its presence in affected aquifers may be significantly reduced by source reduction or prevention. Other contaminants that are less soluble and less mobile may be extremely difficult and expensive to remove from aquifers. Dense nonaqueous phase liquids (DNAPLs) such as trichloroethylene (TCE) tend to sink toward the bottom of aquifers where they may slowly degrade and release toxic by-products. Gasoline from leaking underground storage tanks is perhaps the most common light nonaqueous phase liquid (LNAPL). Benzene, toluene, ethylbenzene, and xylene (BTEX, four of the major hydrocarbons found in petroleum products) spread in plumes at different rates throughout the top of the aquifer. Microbial contaminants may be introduced to aquifers by improperly sited septic tanks as well as by untreated or inadequately treated municipal discharges above unconfined surficial aquifers.

Significant and growing threats to groundwater: agriculture

Agricultural productivity has increased significantly over the past several decades. Yields have risen due to increased use of pesticides, fertilizers, and irrigation (often from groundwater sources), as well as to expansion of cultivated areas. But gains in productivity have been accompanied by increasing groundwater degradation and depletion. For example, herbicides such as atrazine and alachlor (used respectively on cereals and fruit trees) have been extensively detected in groundwater in Europe and North America; and in South Asia, commonly used insecticides including carbofuran and lindane have been widely detected in groundwater (Mateo-Sagasta and Burke 2011). Elevated nitrate levels, sometimes exceeding the US Environmental Protection Agency (EPA) maximum contaminant level of 10 mg/L are nearly ubiquitous in unconfined shallow aquifers in major breadbaskets such as the Midwestern United States.

Significant and growing threats to groundwater: fossil fuel exploration and extraction

Hydraulic fracturing or “fracking” is a drilling technique used to obtain natural gas and oil from shale rock and other nonconventional sources (Bigham 2013). For every fracking well, between 8 and 20 million liters of water along with sand and hundreds of compounds (e.g., for lubricating, anticorrosion) are injected to fracture deep tight rock formations, releasing gas and oil from small pores within them (Figure 6). Groundwater contamination associated with fracking operations appears to be associated mainly with (i) the disposal of “produced” water and infiltration into shallow unconfined aquifers, and (ii) well barrier and integrity failures, which
Fracking for fuel
Hydraulic fracturing is used to access oil and gas resources that are locked in nonporous rocks.

Water recovery tanks
Polluted flowback water may be injected into a deep storage well, recycled, or sent to a treatment plant.

Leakage of fracking fluid from the fracture zone is highly unlikely.

Figure 6  Hydraulic fracturing. Source: Howarth, Ingraffea, and Engelder 2011. Reproduced by permission of Nature.
may allow migration of methane and fracking fluids to aquifers used for drinking and irrigation. Davies et al. (2014) indicate well failure rates are highly variable (1.9–75%) depending upon when and where they have been drilled. Other recent studies indicate that groundwater in close proximity to fracking operations is much more likely to be contaminated with produced water and methane, and that in some cases the chemical composition of methane found in drinking water aquifers was quite similar to the gas found in the much lower shale formations (Jackson et al. 2013; Gordalla, Ewers, and Frimmel 2013).

To facilitate rapid exploration and recovery of crude oil and natural gas, changes have been made to existing legislation such as the United States’ Safe Drinking Water Act to exclude hydraulic fracturing from the definition of underground injection, a practice that was until the early 2000s largely prohibited or tightly regulated. Within the United States, fossil fuel exploration is mainly regulated at the state level, but the US EPA has recently undertaken a nationwide study on fracking and may issue nationwide regulations in the future. Hydraulic fracturing is already being employed or planned in Germany, the United Kingdom, India, and China (Gleick et al. 2012), and numerous suitable formations for exploration and extraction of resources via hydraulic fracturing exist on every populated continent.

Strategies for protecting and replenishing aquifers

At least in part due to difficulties in directly observing groundwater, efforts to conserve and protect the quality of groundwater resources have lagged behind such measures for surface water. In addition to international cases noted above, this is also true at national scales. For example, whereas the Clean Water Act is aimed at protecting surface water, there are no federal environmental laws focused on groundwater in the United States. Much of the regulation of groundwater is then left to individual states. But since aquifer and state boundaries rarely coincide, this leads or has the potential to lead to problems similar to those faced with international aquifers. One major policy need, therefore, is to “scale up” policy related to protecting and conserving aquifers.

Numerous strategies have been proposed for situations in which aquifers are stressed due to over abstraction from irrigated agriculture, including substituting dryland-adapted crops (e.g., wheat, sorghum, millet) in place of rice or maize, developing drought-tolerant strains of rice or maize, reducing tillage, reestablishing native grasslands, limiting drilling of new wells, and using moisture sensors and ultra-efficient irrigation technologies. In urban areas where aquifers are depleted, strategies such as aquifer recharge via infiltration ponds or galleries and injection of surface water or treated municipal wastewater are being increasingly employed.

The concept of the growth machine refers to systemic properties operating within capitalist cities which generate growth around the intensification of land use. This often happens despite pressures and political interests opposed to such growth. The term “growth machine” can also refer to coalitions of business and local government interests seeking to attract inward investment, promote redevelopment, and market the city. The growth machine concept was first proposed by the American urban sociologist Harvey Molotch in the 1970s (Molotch 1976). It was subsequently refined into a thesis about the tensions between use and exchange value arising from unregulated capitalist forms of urban growth (Logan and Molotch 1987). By connecting urban political agency to certain systematic properties of capitalism, the growth machine thesis was able to transcend some of the shortcomings of social scientific analysis of urban power structures in the USA.

Logan and Molotch (1987) suggested that the activities of rentiers – land development interests – lie at the crux of understanding the behavior of growth machines. Rentiers prepare the ground for land-use intensification and profit-making in the city. Often this is to the benefit of a wide range of business interests and organizations, such as corporations, contractors, the local media, universities, utilities, sports franchises, chambers of commerce, trades unions, and so forth. Local government is not a disinterested party in this process as it strives to influence land-use outcomes in ways that enhance the local tax base and foster a sense of community solidarity. Growth coalitions tend to converge around those levels of government having fiscal resources and land-use powers necessary for delivering growth and jobs.

For urban geographers, the growth machine thesis has provided fertile territory for critique and further refinement (Jonas and Wilson 1999). Some critiques have highlighted how its focus on the tension between use and exchange value subverts knowledge of class tensions and progressive urban politics. Others examine the discursive tools deployed by growth machines and their effects on marginalizing the voices of minorities in the city. Then there are those who have sought to apply the thesis to settings outside the USA, finding that the national state is a more powerful driver of urban development than local growth coalitions. However, the jury is still out in respect of whether the growth machine thesis is conducive to the international comparison of urban development politics.

Urban scholars today argue that knowledge of power structures operating in cities requires a shift in focus away from territorial growth coalitions and towards relational processes and networks operating beyond the city limits. Nevertheless, the growth machine remains an attractive thesis for critical urban geographers. National and local states in many countries are incentivizing local public–private partnerships in a manner which suggests that growth machine-like processes are compatible with neoliberal urban development. Moreover, the growth machine offers a seductive argument about how the infrastructural conditions of
GROWTH MACHINES

urban growth can be sustained even under conditions of fiscal austerity.

The idea of growth poles

For a long time, economic development had been regarded as an expansion of a balanced system within which resources were mobilized and allocated proportionately in various sectors. Such an equilibrium understanding of economic growth is inconsistent with real development processes and rules out structural changes of economies. Starting from a different point, Perroux interpreted economies as being composed of units, firms, and industries with asymmetrical powers and relations. For economic or institutional reasons, some firms and industries would take a dominant position over other units in market transactions. These asymmetrical interrelations of firms and industries result from their big size, input/output structures, technical advances, or some institutional arrangements. For Perroux, what is crucial for economic development is that these dominating firms and industries can stimulate structural change for the whole economy (Perroux 1950a). Inspired by Schumpeter’s emphasis on innovation and the role of large corporations, Perroux argued that propulsive industries (industries motrices) with high rates of growth, advanced technologies, and innovation capabilities can drive the growth of an economic system through their intensive linkages with other industries (industries mues). From this, he developed the idea of growth poles and defended it convincingly as “growth does not appear everywhere at the same time; it becomes manifest at points or poles of growth, with variable intensity; it spreads through different channels, with variable terminal effects on the whole of the economy” (Perroux 1970/1955, 94).

An important point for interpreting Perroux’s idea of growth poles is that although not denying an understanding of growth poles in a geographical setting, Perroux originally defined the concept in an abstract economic space constructed by transactions and relations of different units and activities (Perroux 1950b). As original as the idea of growth poles was, it was initially quite elusively defined, far from the clear development strategy that was so popular later on. It is safe to say that the original concept of growth poles did not explicitly address the problem of regional development, but was merely a dynamic understanding of unbalanced economic growth. What is central to the idea is how new and propulsive firms and industries can induce the development of other units through material exchange and information flows.

The concept of growth poles was later transformed from an idea framed in an abstract space into an entity in a geographical setting through a process in which new elements were included in the concept (Boudeville 1966; Hansen 1967). From a spatial perspective, it may be natural to expect that propulsive firms and industries are located in some regions, which makes these areas develop at an extraordinary rate and
become growth centers of regional and national economies. But from Perroux’s idea of how propulsive units affect the growth of other units, it cannot be taken for granted that induced activities would occur in surrounding areas. In other words, an argument of regional development supported by development poles or centers has to be established on some further rationale besides Perroux’s original conceptualization. Another important question behind a spatial version of growth poles concerns why, if propulsive units are a set of firms or industries, rather than a single unit, these firms agglomerated in growth centers. From here, growth poles meet with location theories and urban and agglomeration economics with similar questions. In response to these questions, external economies, broadly interpreted as including availability of public and business services, development of specialized suppliers, attraction of consumers, labor market sharing, and exchange of ideas and technologies, were later given greater emphasis to back up growth poles in geographical settings, which may be titled differently as growth centers or development poles (Cameron 1970).

Growth poles in a spatial reading for regional development are further articulated by two prominent economists in Europe and North America. Also unsatisfied with an equilibrium understanding of economic growth, Myrdal (1957) and Hirschman (1958) developed similar ideas of unbalanced development processes, but in concrete regional contexts, which endowed the concept of growth poles with more practical meanings. Myrdal (1957) and Hirschman (1958) clarified and enriched the relations between growth poles and hinterland areas with “backwash” or “polarization” effects and “spread” or “trickling down” effects. Unlike Perroux, who viewed growth poles only in a positive way, Myrdal and Hirschman proposed that at early stages of development, core areas would develop at the expense of periphery areas by attracting talents, investment, and resources (“backwash” or “polarization” effects). Besides consuming skills and inputs from hinterlands, competition from industries in growth centers will restrict the development of similar activities in backward areas. However, on the other hand, the growth of poles or centers also provides positive influences for surrounding areas in relation to demand for goods from hinterlands, investment opportunities, and diffusion of technologies, together described as “spread” or “trickling down” effects. It is argued that positive effects would predominate in later stages of development since the concentration of resources and activities in growth poles will finally drive up production costs and bring about external diseconomies. In this period, regional disparity would be expected to decrease.

With a large body of literature in the 1960s and 1970s, growth poles were widely accepted as a general understanding of how regions grow in an interactive way and turned into a popular idea of economic development in policy arenas. An important reason for the adoption of the concept of growth poles by policymakers is that it describes a regional development process, which is not only flexible enough to be consistent with different policy goals in various settings but also quite specific, thereby helping governments direct resources and investment spatially.

**Growth poles as regional development strategies**

It is worth mentioning that the wide acceptance of growth pole strategies in many countries in the 1960s and 1970s should be interpreted in the historical context (Polenske 1988). For both developing and developed countries, after World War II, economic recovery and restructuring...
was a major concern for governments of various levels. It was a period when strong government intervention in economic activities was in high demand. Growth pole theory thus provided a theoretical reference point to justify many economic projects and plans in that period. As regional development strategy, the concept was implemented in different settings with different rationales targeting various goals. Within cities, large plants were built as propulsive units to stimulate urban economic development (Ryder 1990). In metropolitan contexts, growth poles were established in suburban areas to alleviate an over-concentration of population in large cities (King 1974). In some regional backgrounds, large industrial complexes based on heavy industries were planted to create employment in surrounding areas (Roberts 1995; Florio 1996). In some planned high-tech industrial complexes, such as Sophia Antipolis, several large firms were established and a pole of propulsion was expected to promote manufacturing growth in nearby regions (Hansen 1990). In broader regional contexts, some towns and cities were designated as growth centers to induce development in rural areas (Shah 1974; Katzman 1975; Widner 1990). In national contexts, growth pole strategies were even adopted to balance uneven patterns of economic development (Semple, Gauthier, and Youngmann 1972; Richardson and Richardson 1975; Kinsey 1978). To a large extent, growth pole strategies were regarded as a panacea to deal with almost any issue of economic development.

As development strategies, the meaning of growth poles or centers is interpreted by policymakers quite loosely; in many ways such interpretations do not comply with the theoretical content. In theory, although with different emphases, growth poles are generally discussed on the subject of units of economic activities, such as firms and industries. In reality, in many contexts, cities and towns, regardless of their industrial structures, are treated as being equivalent to growth centers for regional and national economies. In the concept of growth poles, propulsive units are linked with others in economic, technological, and social ways. As a policy instrument, propulsive firms and industries are narrowly selected on a basis of static input/output structures. Of course, there are practical concerns for relying on simple and observable parameters to operationalize such a theoretical concept in designing development policies. However, a pitfall of this is that, in doing so, the concept may be misunderstood and its originality may be lost in operationalization. Unfortunately, this is the case for growth poles. In degenerating into an input/output analysis, growth poles lost their core content of emphasizing innovation and structural changes in the course of economic development.

When cities and towns were carelessly included in development poles, a different argument developed in response to how to implement growth center strategies. For policymakers, a key question of the strategies is the selection of growth poles for public investment. Besides some planned poles that are created from scratch, the choice of specific areas as growth centers requires another rationale that the theoretical concept of growth poles could not offer. The rationale develops from decreasing returns of investment. To maximize the welfare of the whole economy, it is argued that public investment be invested in places with highest returns. In large metropolitan areas, investment cost is high and congestion and external diseconomies make such an investment less profitable. On the other hand, infrastructure development in rural regions and small towns may not pay off because railroads, highways, and other facilities would not be efficiently used. From an economic perspective, growth center strategies are believed to be best targeted at medium-sized cities (Cameron 1970).
GROWTH POLES AND GROWTH CENTERS

Clearly, a growth center policy in this sense distracts from the original idea of growth poles, which rests on relations of economic units. In some cases infrastructure projects are directed to connect poles and surrounding areas, with little consideration of how local economies grow. By blindly assuming induced development will occur automatically, growth poles in these contexts are changed into a tool to justify investment in certain areas. For noncenter regions, it becomes an excuse for place discrimination in allocating public resources, a point which is used in criticism of growth pole strategies.

In some other settings, growth pole strategies were practiced in a way that seems to be closer to its theoretical meaning. Large firms are carefully selected on the basis of intensive input/output linkages and implanted in industrial complexes in order to solicit the development of related industries in local and nearby areas. The rationale behind these planned growth poles is traded linkages of economic activities. This may be partly related to the idea of the dominating relations of propulsive units over others. But it is not in line with the core of Perroux’s original idea in two fundamental ways.

First, with calculated input/output analysis in these policies, growth poles are interpreted in a static manner. Connections between economic units are restricted to transactions, which excludes dynamic dimensions of interfirm relations, such as social interaction and innovation spillovers. Without considering these nontraded linkages of economic units, these growth pole strategies in fact presume a mechanical and banal picture of economic development. In many industrial complexes, it is believed that the structure of local economies can be planned. This is in sharp contrast to the original meaning of growth poles, which emphasized innovation and structural changes of economic development.

Second, even if unbalanced relations of economic units are only understood in the sense of traded linkages, these policies confuse industrial complexes in a concrete geographical setting with growth poles defined in an abstract space. In an abstract economic space delineated by various degrees of influence of propulsive units, related firms or industries may be induced to grow. However, there is no strong reason in growth pole theory to expect that suppliers and related industries would develop in the vicinity of propulsive units, which is usually the goal of many industrial complexes. In Hirschman’s (1958) theoretical model, there are only two places, the developed North and the developing South. In theory, congestion effects and external diseconomies in the North in the end will force economic activities to move to the South because there is no other locational choice. In reality, there are so many places for firms to choose. It is untenable for policymakers to expect that related activities have to develop in nearby regions.

As illustrated by the above, when the concept of growth poles was widely accepted in policy arenas as a development strategy, intentionally or unintentionally, its meaning was abridged and modified for practical purposes. In many ways, the concept lost the richness of its content in empirical analysis. With hindsight, it is not surprising that most growth pole strategies were later abandoned by policymakers for failing to fulfill their initial goals. Although in some contexts growth pole policies were targeted at goals that were too ambitious, such as balancing spatial patterns of national economies, in many cases these strategies were also not successful in bringing about promised changes that were less demanding in local economies (Ryder 1990; Widner 1990; Florio 1996). There are many reasons for the failure of growth pole strategies, such as insufficient resources to sustain these policies, low
commitment of new government, wrong selection of growth centers or propulsive industries, and so on (Higgins and Savoie 1988). However, besides these individualistic factors, there is no doubt that limitations of the concept per se are also responsible for its failure in practice.

First, growth pole theory does not explain the development of innovative activities in pole areas, which is a fundamental issue for economic development. Propulsive units, characterized by advanced technologies, are taken for granted in the analysis of growth poles. In a simple understanding, economic growth can be described in two stages, (i) the creation of new products and solutions, and (ii) the diffusion of innovation to the rest of an economy. Although Perroux may initially intend to emphasize the whole process, growth pole theory unfortunately only captures some features in the second stage. Theoretically, Perroux and his disciples emphasized the significance of innovative units for economic development. Empirically, the focus of growth pole strategies is usually the development of nonpole areas. Unable to explain how propulsive activities are established, growth pole theory is naturally read as suggesting that less developed regions cannot grow by themselves, but have to rely on the inducement of development poles or centers. An endogenous growth process, which is crucial not only for less developed regions but also for those pole areas, is excluded in growth pole theory. By focusing on input/output relations, large firms are often in policymakers' favor in growth pole strategies. Small and medium-sized firms and entrepreneurship, which are crucial for innovation and employment creation, are thus little considered because they are not significant in growth pole theory.

Second, it may also be admitted that one remarkable weakness of the concept of growth poles is that it is defined very elusively and inconsistently. The concept of growth poles is built on Perroux's broad thinking of economic development, especially on his works of different types of space and the domination effect of economic units. Although there are insightful ideas in these terms, they are described in a very abstract way by Perroux. For example, in his explanation of propulsive industries, Perroux initially thought that key industries could not be specified by their technical characteristics, but should be defined relatively on a basis of the activities influenced by them (Perroux 1970/1955). It becomes a chicken-and-egg definition because propulsive industries delimit their affected activities which are used to define propulsive industries themselves. This generally denies a clear identification of propulsive units, and makes Perroux's original idea of growth poles very hard, if not impossible, to be properly operationalized.

The most confusing point of the concept of growth poles is its geographical dimension. Although Perroux initially did not define growth poles in a geographical setting, the concept was widely interpreted in a concrete context, especially in policy arenas. It should be mentioned that even Perroux defined growth poles in different ways in his writings. Unlike in his first paper on growth poles in 1955, he later accepted a geographical understanding of the concept and defined growth poles as “the concentration of productive agents, organized resources and technological and economic capacity within a non-geographical matrix, or a structured group of individuals in a geographical entity” (Perroux 1983, 98–99). As analyzed before, growth poles in nongeographical and geographical settings involve very different theoretical arguments. These inconsistent definitions of growth poles impair the concept and give it less clarity and rigor.
GROWTH POLES AND GROWTH CENTERS

Third, a mixed spirit of being both explanatory and normative puts growth pole theory into an irrefutable position. Fundamentally, growth pole theory is built on the basic fact that growth is geographically uneven. As a large part of growth pole theory, the concepts of propulsive activities and polarization effects are developed to describe and explain this unbalanced spatial pattern of economic development. Beyond this explanatory content, growth pole theory further foretells that growth will spread out to nonpole areas, an argument that is scarcely substantiated with evidence. By combining the two development stages, growth pole theory presents an economic development process with an unusual quality of being both explanatory and predictive. Broadly interpreted, it provides an answer to many different questions, such as why some regions grow, why others do not grow, how regional economies will grow in the future, and how regional growth can be promoted. For many students and policymakers, there is no need to test growth pole theory before it can be accepted and implemented because growth pole theory tells a “truth” of regional uneven development. In many economic development plans, the theory becomes a belief of how regional growth should be. To some extent, it is hard to disagree with growth pole theory since it could be interpreted in many ways, being simultaneously an argument, a belief, or even a “fact.” As a result, it may not be surprising that growth poles were wrongly treated as a panacea for regional development issues.

In many ways, a loose definition and explanation of growth poles facilitated the acceptance of this concept in various settings. However, the popularity of growth poles in policy arenas did not help consolidate the concept, but instead ruined it in the end. From this, growth pole theory gains nothing but failure in its operationalization process. An important lesson that can be learned from growth poles is that it could be very dangerous for a theory or concept to be widely accepted and implemented before it has been scrupulously examined, critically debated, and solidly evidenced.

Growth theory

Simon Xiaobin Zhao
University of Hong Kong, China

Growth theory is an umbrella term for a number of different theories concerning the economic development of nations. It is a loose school of thought that emerged in the post–World War II era from a number of different economists with differing theories. The basic aim of these theories was to explain how so-called third world countries might achieve economic development and convergence with the First World (developed countries). Growth theorists first sought to understand the varying factors that contributed to economic growth in the developed world; they then attempted to apply these theories in order to create a universal model for economic development. Growth theories were also shaped by the political climate of the 1940s and 1950s, particularly the Cold War politics that was emanating from the United States of America and Western powers. The political context for growth theory is most pertinently shown by Walt Whitman Rostow’s The Stages of Economic Growth: A Non-Communist Manifesto (1960); a reaction to economic growth theories emanating from the Soviet Union (USSR) at the time.

Modern growth theory economics is in part a reaction to the previously existing neoclassical models, namely the Harrod–Domar model (Harrod 1939; Domar 1946) – an example of post-Keynesianism – which later led to the development of the Solow–Swan model (Solow 1956; Swan 1956). The Harrod–Domar model, the earliest example of growth economics, explains the long run economic growth of an economy in terms of the level of national savings within the economy and the productivity of the capital available, with an increase in either resulting in economic growth. The model does not subscribe to the idea that economics should experience balanced growth; according to the Harrod–Domar model there are three distinct types of growth: warranted growth, actual growth, and the natural rate of growth. The Solow–Swan model instead focuses on the rate of technical progress as the key focus for economic growth and development and was the first growth model to distinguish between the vintages of the capital. The model shows that growth can be achieved by increasing investment or reducing taxes that directly relate to new capital accumulation, thus increasing the productivity of the economy. The Solow–Swan model growth is only short term in nature, as in the long run the natural growth rate of an economy converges towards a steady state. Both models are criticized for assuming too much within their framework: the Harrod–Domar model assumes that economic growth will result in full employment; the Solow–Swan model assumes that too many of the factors of production are fixed and that capital is subject to diminishing returns in a closed economy.

Rostow’s (1960) linear stages of growth model is a simple stage theory that explains the process of economic development based on the historical experience of the industrialized powers. Rostow’s model builds off of Harrod–Domar’s growth theory, emphasizing the role of savings (investment) in stimulating economic expansion. The premise of this structuralist theory was that economic growth for all countries followed a set
GROWTH THEORY

pattern, and therefore economic growth could be shown to progress through five distinct stages of varying lengths. The five stages are traditional, preconditions for takeoff, takeoff into self-sustaining growth, drive to maturity, and age of high mass consumption. The traditional stage is characterized as an almost completely undeveloped primary sector economy. The preconditions to takeoff involve the development of excess production of raw materials, mainly cash crops, in order to utilize the surplus coupled with an expansion of the technological frontier. The takeoff into self-sustaining growth involves the expansion of the secondary sector, mainly in the form of a few key leading industries. It is then followed by the drive to maturity in which the industries of the secondary sector are grown, diversified, and developed away from capital goods towards consumer-driven goods (e.g. apparel, household appliances). The final stage is the age of high mass consumption, characterized as an economy that is heavily reliant on the secondary and tertiary sectors, with the primary sector greatly diminished, and where the consumption of high-value goods is widespread.

According to Rostow, the onus for an economy to emerge from being traditional to the takeoff stage is the mobilization of internal savings in order to fuel investment endogenously; however, this can be replaced by the exogenous injection of foreign aid or capital. Rostow’s model assumes that the developing countries will follow the same patterns of growth that had been observed in the developed countries of the period, which is the major criticism of this theory.

As a result of the rigid nature of Rostow’s theory it has been considered less analytical and less historically sophisticated than other models. A similar but contrasting model was developed by Alexander Gerschenkron – the “backwardness” model. Gerschenkron (1962) theorizes that some economies, particularly those in Eastern Europe, are more “backward”; although he never provides a specific definition for “backwardness,” he relates it to low income per capita, savings rates, human capital, and levels of technology. The “backward” nature of an economy creates a greater chance that the country will lack economic prerequisites and therefore the industrialization process will involve substitutions to achieve these – a focus on the production of producer goods instead of consumer goods, the reliance on imported technology rather than indigenous technology, and the use of specialist institutions (the state in the case of Russia) to facilitate the use of human and physical capital in designated industries. Gerschenkron’s model, like Rostow’s, is more of an observation on development rather than a fully functioning model.

A successor to Rostow’s theory, which came to the forefront of the discussion in the 1970s, was Lewis’s (1954) structural change model. Lewis’s model is an analysis of the internal process of change that a developing economy will undergo in order to generate economic growth. The Lewis model, also Keynesian in inspiration, theorizes that a developing country’s economy has two sectors, primary (agriculture) and secondary (industry). In the model the factors of production, predominantly labor, are underutilized in the primary sector, which results in a marginal productivity of effectively zero; this means labor can be extracted from the primary sector without reducing its output. In order for the economy to grow and develop, the factors of production, normally labor in the case of agricultural societies, need to be reallocated towards the secondary, urban, industrial sector enabling the economy to grow off the back of cheap, plentiful labor. To encourage labor to migrate, Lewis assumed that the urban wage would have to be approximately 30% higher than the wage, or equivalent, available in the rural
sector. The profits created within the economy from exploiting cheap labor can be reinvested towards capital accumulation, which can lead to self-sustaining economic development. However, this ignores the potential for capital to replace the need for labor – as happened during the Industrial Revolution in England, leading to the Luddite movement that emerged as a reaction to the resulting unemployment. The model also assumes a perfect, competitive labor market, which is unlikely in a developing economy.

Following the focus on Keynesian economics that the previous growth theories had been based around, the neoliberal counterrevolution, which occurred primarily under the Reagan and Thatcher governments, was a monetarist approach. The Chicago School of Economics is credited as being the intellectual source of the neoliberal movement, with Milton Friedman developing the *laissez-faire* economics and Friedrich Hayek developing the model’s political roots. Friedman sought to remove as much of the state’s influence on markets as possible in order to maximize their efficiency. The change of policy within key Western governments towards the neoclassical approach was both a political and an economic shift, and was heavily influenced by the Cold War geopolitical situation. The privatization of many nationalized companies in the United States and the United Kingdom, for example British Telecom, resulted from a notable shift in government policy. Neoliberal policymakers chose to focus on supply-side macroeconomics, privatization of public companies, and reducing, or eliminating, the controlling role of the state over economies. The main argument of the neoliberal counterrevolution is that underdevelopment and stagnation occur due to poor resource allocation by the state due to the rational expectations of the market being usurped, and instead free markets should be trusted to optimize resource allocation. The fundamentals of neoliberal economic thought are reliant on a strong legal grounding to create the ideal environment for the *laissez-faire* economics to be effective. This requires a transparent legal system with strong property rights enforcement and market-friendly institutions to support economic policies. On a global level, neoliberal policies are promoted by organizations such as the International Monetary Fund (IMF) and the World Trade Organization (WTO), which are heavily influenced by Western powers. Developing countries’ ability to receive foreign aid was, in part, based on the adoption of neoliberal economic policies.

Prior to the 1980s, most growth models were based on the assumption of exogenously driven long run growth, the savings rate for the Harrod–Domar model, and the rate of technological progress in the Solow–Swan model. In contrast, most contemporary growth theories are based on endogenous growth, even though many of these still exist within a Keynesian framework. The late 1980s saw the emergence of a neoclassical growth model that allowed for endogenous growth, called a new growth theory (Romer 2011). The impetus behind the development of the new model was the disenchantment with other neoclassical models’ ability to explain the increasing disparity between the developed and less developed economies. The major difference is that the new growth theory regards knowledge and technological development as, at least partly, endogenous as the economy will internally develop technology through research and development. This also applies to human capital, which can be improved endogenously through increasing investment in schools and training. Another difference between the new growth model and the older neoclassical models is that in the newer model the traditional neoclassical assumptions of diminishing marginal returns on capital and
increasing returns to scale in aggregate production are negated. However, the theory still utilizes many of the assumptions of the original neoclassical models that may not apply to the real world, such as the assumptions of perfect information for the labor market and the free mobility of capital. The natural inefficiencies are not accounted for by the model and may reduce the potential of the less developed economies to grow.

The evolution of growth theory is clearly a reflection of the prevailing political and academic thought paradigms, which are often dictated to the developing world from the developed world. One of the difficulties faced by growth theorists is attempting to develop a nomothetic theory when faced with an idiographic reality; this is reflected in the different developmental paths observed in different parts of the world (see Dependency theory and World-systems theory). Growth theory continues to be a key global political and economic issue driven forward by both international organizations and countries.

Habitat destruction and fragmentation

Jing Sun
Michigan State University, USA

Habitat destruction and degradation, as a result of land-use and land-cover changes (LULCCs), and consequent fragmentation are becoming central themes in understanding environmental and socioeconomic changes at scales from local to global. The global map produced by Ellis and Ramankutty (2008), and the derivations included here, are perhaps the most interesting geographical representation of the extent of LULCC. The area of habitat destroyed loses most of its plants and animals, and so research has focused on remnants, often as islands, with particular attention to their edges. These fragments are one part of a continuum that has been quantified and mapped globally by Riitters et al. (2000). The role of the converted land, however, is still important. Effects are at species level, community level, and broader (Malanson 2014).

Processes and stages of habitat destruction and fragmentation

Given the recognition that LULCCs are a matter of spatial pattern and process, steps of spatial change have been identified: dissection, perforation, fragmentation (the cutting into pieces), shrinkage, and attrition (Forman 1995) (sometimes referred to in sum as “fragmentation”).

Perforation is the creation of holes in a pre-existing habitat landscape. Perforation in the absence of roads is not likely, but it could be the process that initially decreases the amount of interior habitat while creating edges. In this stage, connectivity of habitat remains generally high. Perforation occurs with low-density settlement.

Dissection is primarily the result of roads. It has a small effect on area, but can create isolation and edge effects. Dissection can be complete, as in the case of roads cutting through a habitat or placing a grid on one, or less so, as with a network partially penetrating a region.

Fragmentation occurs when multiple pieces of habitat are isolated by the expansion of roads and new LULCCs. Fragmentation as a process occurs through the expansion of LULCC after the initial perforation and dissection stages.

Shrinkage is the simple reduction in area of the fragments of habitat created by the above processes. Area declines while isolation increases and edges may never stabilize. Extensive agriculture or forestry and high-density settlement lead to shrinkage.

Attrition is the culmination of these LULCC processes, when individual remnants disappear. Only new land uses remain. This stage is most likely with very extensive agriculture or more intensive development.

Another stage is recovery. New land uses in fragmented landscapes are not static and some degree of recovery toward the pre-existing habitat is possible. Recovery will often depend on the degree of initial destruction or modification within the new land use as well as on the continuing use or nonuse, but it will also depend on the characteristics of a given ecosystem. These characteristics are often summarized as resilience, a term with alternate definitions, which summarizes how close recovery can bring
HABITAT DESTRUCTION AND FRAGMENTATION

an area to its pre-existing landscape and how fast and by what pathways it changes.

Conceptual basis for the effects of habitat destruction

The effects of habitat destruction are greatest in the area of the LULCC, where species and their communities are at least locally eliminated, but what happens in the remnants is of interest. LULCC processes usually disconnect conterminous habitat areas and thus change the spatial properties of ecosystems, in particular, landscape connectivity. The reduced connectivity limits food sources and behaviors of wild animals, as well as the flow of material, energy, and plant propagules. The consequences of the resulting spatial patterns are often the focus of studies of the changes in species composition or ecosystem function.

Habitat destruction has been identified as having five spatial aspects important for surviving biota: sample effects, forest area, isolation of forest remnants, edge effects, and the effect of the surrounding “matrix” on all of these (and their interactions) (Kupfer, Malanson, and Franklin 2006).

A sample effect exists because the organisms in the remnants are possibly a biased sample of those in the pre-existing habitat. This effect will have consequences for the next four conditions.

Reduced area of habitat has three primary consequences: reduction in resources, metapopulation dynamics, and altered disturbance regimes. Area is the primary basis for the resources available for organisms and thus affects population sizes and the probabilities of local extinction – which then affect metapopulations. In some cases, such as for species at higher trophic levels that must have an extensive hunting area, even individual survival is area dependent. Reduced area also results in a reduction of the range of habitats and thus in lower diversity and lower probabilities for species interactions. Disturbance regimes are also area dependent on the probability of events. The notable secondary consequences, and the driver of many studies of fragmentation, are that the diversity of species depends on area because it depends on the probability of extinction (MacArthur and Wilson 1967).

Fragmentation, by definition, increases isolation and so the division of populations into metapopulations and the probabilities of immigration versus local extinction (and again, diversity). Isolation also affects the disturbance regime for those that spread. The degree of isolation, the very meaning of distance, will vary with the motility of the species or the disturbance as well as with the characteristics of the surrounding landscape (i.e., corridors or stepping stones).

Fragmentation creates edges, which are habitats themselves, often because of a different microclimate, for different species – and sometimes invasive species in particular. Edges also change the function of the forest in relation to the flux of energy and matter, and so exports and imports tend to increase, but they can also be filters and sinks. Edges also elevate further human influences, such as noise, simply by being the location for activities.

All of these can interact, and so fragmentation becomes a multidimensional spatial process. The area of converted land can affect all the above interactions, but the processes will depend on the nature of the new land use and land cover. The matrix may provide usable resources to the organisms in the remnant; it may provide connectivity among populations; it can be a source, conduit, or barrier for disturbances; it will alter the flows of energy and matter to and
away from the edges; and its use will determine the continuity of human pressure on the remnants. The new land use can also be long- or short-term. And single land covers may have different types or intensities of land use.

The details of spatial patterns matter in the processes of LULCC and fragmentation, and these are best seen in the methods applied in research.

The major methodological area of LULCC is remote sensing. Remote sensing has quantified the extent and pattern of LULCC at most scales. Global- and regional-scale remote sensing provides new views of the planet. At local scale, remote sensing is a primary source of data for quantifying the spatial pattern that affects the processes. A variety of spatial metrics have been developed in association with habitat destruction and fragmentation. Simulation modeling is another important method because it can include the details of spatial patterns (in area, isolation, edge, and matrix) that are not possible in real landscapes – and with replication.

Remote sensing is covered elsewhere in this encyclopedia. Here, it provides the primary data for spatial metrics. Too many spatial metrics exist: they are redundant and confusing. Riitters et al. (1995) improved this situation by identify six metrics that represented the most important factors of fragmented landscapes: average patch compactness, overall image texture, average patch shape, patch perimeter-area scaling, diversity, and fractal dimension. Understanding LULCC at multiple spatial scales is a challenge. Newer metrics address changing spatial and temporal dimensions with spectral and wavelet analyses to capture modifiable areas and time series. Spatial information that captures the processes of fragmentation with more nuance can be seen in morphological spatial pattern analysis, a metric based on image morphology that can be used to identify spatial patterns from a single-layer binary map (e.g., forest and nonforest maps) and describes the size, shape, and other geometric characteristics of spatial entities (Soille and Vogt 2009). In addition, some metrics from graph theory are also for quantifying connectivity.

Locations of LULCC

The most interpretable view of LULCCs is that of the areas mapped as wildlands or as “remote” forests and rangelands (Figure 1). Among these, the remote forests are the frontiers of LULCC and habitat destruction, and the remote rangelands can be subject to overgrazing. Wildlands may exist to some degree in Amazonia, the Arctic, and the barren deserts. The changes, even from 2000 to 2009, are among the most significant global changes created and faced by humans.

As an example of slightly less extensive fragmentation, Riitters et al. (2002) analyzed land-cover maps for the continental United States, which used 1992 Landsat Thematic Mapper imagery. They summarized indicators of four aspects of forest fragmentation – patch size, edge amount, interpatch distance, and patch contrast – and found that while most forestland in the United States was reasonably well connected over large regions, especially in places where forest was generally dominant, much of it was highly fragmented and in close proximity to roads (Figure 2).

The future of fragmentation

Kupfer, Malanson, and Franklin (2006) identified the most important areas where information on fragmentation is lacking:
Figure 1  Anthropogenic biomes of the world. (a–d) Ellis et al. (2013). © 2013, The Trustees of Columbia University in the City of New York; (e) Reproduced from Center for International Earth Science Information Network (CIESIN). © 2009, The Trustees of Columbia University in the City of New York.
Figure 1 (Continued overleaf).
corridors and connectivity,
• natural heterogeneity,
• edge-mediated dynamics,
• species-specificity,
• landscape metrics.

And they noted that the approaches to these areas needed to address variability in habitat quality in fragments, feedbacks and thresholds, and the methodologies for quantifying heterogeneity. They further made three recommendations for addressing habitat destruction and fragmentation directly: (i) promote connectivity using a variety of approaches; (ii) maintain stand structural complexity and landscape heterogeneity; and (iii) embrace risk-spreading and recognize the importance of different conservation strategies at different spatial scales.

Current work on habitat destruction is linked to climate change and global trade. In the world beyond academics and research, the most important effort in this regard is the United Nations collaborative initiative on Reducing Emissions from Deforestation and forest Degradation (UN-REDD) in developing countries (www.un-redd.org). This program aims to reduce forest destruction and degradation, and provides guidance to partner countries in their efforts.

Habitus

Tom Lusis
University of Guelph, Canada

At the time of his death on January 23, 2002, Pierre Bourdieu was considered by many to be the most influential intellectual in France. Born on August 1, 1930, Bourdieu began his academic career studying philosophy but later changed disciplines to anthropology and sociology, where he investigated French cultural, educational, and class systems. One of his key theoretical contributions was habitus, the origins of which are found in Aristotle’s concept of *hexis* – an acquired set of moral characteristics that guide an individual’s feelings and emotions, and, by extension, their actions. Bourdieu built on this idea, and habitus became central to his theory of an economy of practices that recognized how social conditions shape, influence, and inhibit individuals and social structures in society.

Bourdieu first introduced habitus in *Outline of a Theory of Practice*. He defined it as a system of lasting, transposable dispositions that integrate past experiences and function as a matrix of perceptions, appreciations, and actions (Bourdieu 1977). Dispositions are shaped by social conditions (e.g., family background, education) and are socially reproduced as habitus generates practices that reflect the structures that originally created them. Although they may be long-lasting, dispositions and the habitus that formed them are not unchangeable. They can be eroded, modified, or even reversed through pedagogic effort, new experiences, education, or training.

Arguably Bourdieu’s most famous application of habitus has been in his book *Distinction: A Social Critique of the Judgement of Taste*. Here Bourdieu (1984) illustrates how “taste” is the product of distinct social experiences and can be common to those with comparable social conditions. The bourgeoisie habitus, for example, is characterized by food, art, music, and clothing associated with aesthetic indulgence. In contrast, the working-class habitus and consumption patterns are more functional in nature. Thus habitus is key to understanding how classes set themselves apart from one another in the field of cultural consumption.

Bourdieu’s ideas have been employed by researchers in feminist thought, women’s studies, organizational research, literary history, anthropology, educational research, urban studies, and medical/health studies. The concept of habitus has caused some debate in geographic circles. In 2001 Edward S. Casey initiated a discussion in the *Annals of the Association of American Geographers* when he suggested the concept could be used to answer the question “what ties place and self together?” He envisioned habitus as a mediating third term, a way to better understand the relationship between lived space and the geographic self. Others countered that habitus had limited geographic value due to its implicit reductionism of place as a theoretical concept. Critiques notwithstanding, habitus has been used by geographers in a range of research areas. Select examples include: religious geographies and the role social institutions play in regulating behavior outside the church; economic geographies such as the entrepreneurial activities of youth in India or the labor market integration of immigrants in Canada; rural geographies where moral...
landscapes influence agricultural activities; urban geographies and how consumption and “taste” delineate city neighborhoods; and immigration studies that explore the transformative nature of transnational migrations.

Bourdieu once argued that habitus is important and indispensable to understand human action and is a tool that can be used in relation to geographic and social space (Bourdieu 2002). Judging by the impact habitus has had in many different disciplines, it seems that many academics and researchers would agree.

Health and development

Robert Huish
Dalhousie University, Canada

Health may not always be the goal of international development, but it will always be the outcome. For geographers the goal is to understand how the organization of space and the nature of place matter in influencing these outcomes. The connection between international development initiatives and health outcomes runs deep. As Phillips and Verhasselt (1994, 3) argue, “it implies complex interaction between humans and their environments, more particularly between social and economic factors, physical environment and biological environment.” Disease ecology, a subfield of medical geography, influenced by Jacque May, acknowledged this complexity as early as the 1940s. Today, it is well understood that the lived health outcomes of these complex interactions are strongly governed by social inequities within societies, rich or poor (Cockerham 2013). Development influences the health of place, as access to resources, economic opportunities, human rights, and environmental stewardship all matter greatly for the maintenance of good health (Meade and Earickson 2000; Phillips and Verhasselt 1994). Development is a contributing factor to good health, and yet good health is also a contributing factor to development. Education levels, exposure to conflict, work opportunities, safe working environments, and local autonomy are easier to guarantee to a healthy society, and at the same time these elements are needed for a healthy society. These are all priorities for the study and practice of international development.

Despite such an intimate relationship between health and the outcomes of development, the overwhelming amount of funding for research and practice of health within international development is currently focused on developing innovative curative practices, vaccination routines, and public health interventions through new technology. Private foundations, such as the Gates Foundation and the Clinton Foundation, handle the majority of funding for health projects within the development sphere. Organizations like Grand Challenges give enormous sums of money for research that employs technology to address disease-specific health problems. Government interventions, such as the President’s Emergency Plan for AIDS Relief (PEPFAR), are invariably disease focused. In this sense, the interaction between health and development has been generally labeled as “Global Health.”

Medical practitioners seldom engage in practices of development in the course of their efforts, even though global health, a field intent on connecting health to development, is a subject of increasing popularity. Within medical schools global health is a loosely defined field that deals with improving quality of care in marginalized communities throughout the Global South. Often, global health programs focus entirely on curative care, short-term health interventions by Northern practitioners in the South, and provision of human and material resources to underfunded clinics. Little attention is given to the geographical connection of health to place. On the medical side, the approach to development is overwhelmingly focused on costly and reactionary interventions rather than laying foundations for improved
HEALTH AND DEVELOPMENT

social and environmental conditions of a particular place that promote good health (Farmer 2005, 200).

The relationship between health and development is deeply intertwined, and even though both development practitioners and medical professionals have interests in improving health outcomes in marginalized communities, the formal connection between health, place, and development remains narrow. Very little development practice is done, either on the medical or on the development side, to specifically improve health outcomes by addressing the social determinants of health. For geographers, the lack of practical and scholarly attention to connect health to place within development practice should be taken as an opportunity to fill a looming knowledge gap. What is more, geographers have an important role to play in understanding spatial and temporal spheres that interact to create healthy spaces (Lewis and Kieffer 1994). The disconnect between the well-established knowledge of how inequities lead to poor health and the necessary action for improved health outcomes shows the need for research that connects health and place to improved practices of development work. In particular, greater attention is warranted to understand how inequitable health landscapes emerge through the uneven consumption of health-care services (Peet and Hartwick 2009), the interaction between individuals and the environment, and social inequities within place (Harvey 2006), and to then connect this knowledge to pressing global health challenges.

A brief history of global health

Acknowledging the connection between place and health dates back centuries; however, the dedicated effort to improve health conditions in another country, with seemingly little benefit to one’s national compatriots, begins in the early twentieth century. According to Palmer (2010), global health begins in 1913 with the Rockefeller Foundation initiative to rid hookworm disease in Central America and the Caribbean, where workers were falling ill on plantations and in infrastructure projects such as the Panama Canal. Before then, it was rare for one nation to take a vested interest in another nation’s health status. In the years leading up to World War I, a great deal of American capital was invested in the region, mostly for fruit production. The Rockefeller Foundation took it upon itself to deliver hookworm medicine in the region, building on a 1910 investment to eradicate the disease in the Southern United States. In a sense it was an effort to extend an already tested method into a region deeply impacted by US capital. The intervention was purely pharmaceutical and it did not involve the establishment of long-term medical facilities or Foundation-run services.

In contrast, the British government also engaged in a form of global health in its colonies through the establishment of public health infrastructure that had a much greater focus on the role of place. Great Britain attributed good health to be the result of sound planning that addressed hygiene and proper sanitation. As a result, the British military encouraged the construction of public health infrastructure in its colonies. To the Rockefeller Foundation, as well as the US government, the idea of constructing public health infrastructure smacked of old world colonialism. The pharmaceutical approach expressed sentiments of modernity and compassion without having to physically design a country’s infrastructure (Palmer 2010). This approach, from eradicating smallpox to combating HIV/AIDS (human immunodeficiency virus/acquired immune deficiency syndrome),
set the tone for the relationship between health and development for the twentieth century as focusing on curative initiatives with intentionally minimal intervention in the organization of a nation’s health system.

In international development circles, attention to health dealt with eradicating certain diseases through the assistance of foundations and nongovernmental organizations well after the rise of the post-World War II development era. The United Nations established the World Health Organization (WHO) in 1948 and its constitution laid out one of the most progressive definitions of health to date, as “a state of complete physical, mental, and social well-being and not merely the absence of disease or infirmity” (WHO 1948). Despite a constitution that grounds the understanding of health in a social determinants approach, the mandate of the WHO has been mostly for coordination of international health initiatives that are often disease focused. Its role is to coordinate campaigns and to provide national governments with technical assistance if requested in order to fulfill long-term health objectives. The coordination efforts have paid off in the eradication of smallpox and the near elimination of polio, as well as for campaigns to quell tuberculosis and malaria. National-level campaigns in the Global South, coordinated with the assistance of the WHO, have typically involved vaccine strategies, pharmaceutical therapies, and prophylactic regimens.

Rarely have there been effective WHO-coordinated national-level campaigns that address health lifestyle challenges related to social or economic status. In part, this lack is due to the paltry resources that nations in the Global South are able to contribute towards health systems. While the WHO, despite its holistic definition of health, approaches health needs through an overly medicalized lens, global development institutions such as the World Bank and the International Monetary Fund engage in development in the South with an overtly monetary view of progress. Through decades of loans for infrastructure development funded by the World Bank, many poor countries were put in debt and were then forced to satisfy their balance of payments by reducing public spending on public health and education initiatives. In the post-World War II era until the end of the twentieth century, health and development were widely divided between a medicalized disease-focused framework and that of a monetary-focused approach to development. In an era when some of the wealthiest nations struggled to secure their own national health systems, it was assumed that poor nations needed to overcome poverty before securing quality health and health care.

In 1984, Wilbert Gesler showed that regardless of the economic status of a nation, all societies strive to be healthy. Even if conditions of poverty lack adequate health resources, it does not quell the desire to be healthy in any way. When modern medical resources are absent, poorer populations turn to traditional practitioners, green medicine, and local knowledge. Gesler correctly pointed out that it is the goal of national governments “to increase the availability of modern medicine. Thus in the late twentieth century the challenge remains – to deliver health care to a largely poor, often rural, population in the context of a sometimes bewildering variety of local beliefs and traditions about illness and its treatment” (Gesler 1984, 4). The drive to bring modern medicine to the poor established a link between health and development scholars through formal evaluations of medical systems, and on a smaller scale, program evaluations of disease-specific interventions. This line of research triggered a more critical
HEALTH AND DEVELOPMENT

...turn in the social sciences to suggest that pushing the knowledge of modern medicine over traditional knowledges of health and wellbeing serves as a destructive form of neocolonialism. This is to say that medical knowledge is loaded with discourses of power and hierarchy that can enforce, and reinforce, colonial power structures in a development landscape. While medicine brings about important health improvements, the manner in which medical knowledge is delivered can subjugate vulnerable populations to power relationships that are seemingly inherent to medical practice. The “critical turn” in geographical thinking raised important questions as to the relationship between health and development, particularly in how health needed to be taken into consideration in its own right as something more than the consequence of economic development, or the receipt of modern medical treatment (Phillips and Verhasselt 1994).

The critical turn in geography echoed through the social sciences and created a tense relationship between medical practitioners and critical development scholars who believed that processes of colonialism through medicalized interventions created ethical challenges, as well as harm to marginalized communities. Paul Farmer, a physician and anthropologist, negotiated this tension well and called for an approach to health and development that embraced local autonomy and encouraged access to modern medicine. Working in Haiti, Farmer (2005) argued that all communities desire good health and often pursue it through both modern and traditional methods. It becomes an ethical problem when knowledge exists to help communities in need, but society fails to deliver assistance. Farmer called for the strengthening of public health resources in the Global South in order to prevent suffering, as well as to relieve it. He further suggested that it is no accident that most of the global health burden impacts the poor. Diseases like tuberculosis, malaria, HIV, and cholera systematically impact the marginalized over the affluent. An individual who succumbs to tuberculosis is not just suffering from a bacterial infection, but from the embodied effects of poverty, inequity, and harmful social relations.

Even though the majority of funding for health and development remains limited to disease-specific interventions and innovations, Farmer’s approach demonstrates how deeply connected development, place, and health are. It suggests that health is not the result of development, but rather it is implicated in it. Failure to approach health in this way works to disconnect understanding of how health and development are congruent rather than consequential to each other. Many development practitioners continue to approach health as an inevitable long-term outcome of economic development through modernization and urbanization. This situation often results in needless suffering, as immediate attention to health concerns can be neglected in favor of pursuing economic goals. This result can be seen in how health-care workers are employed, how environmental determinants impact health, and how many diseases of poverty abound.

Health-care workers

The majority of global mortality occurs in nations where human resources for health are the weakest, creating a global landscape of massive spatial inequality. Health workers in Southern Africa, for instance, are limited to begin with. There is one physician for every 1300 people in South Africa, one for every 8300 people in Zambia, but in Malawi, a country with scarcely 300 doctors for over 12 million people, there is one physician for every 50 000.
HEALTH AND DEVELOPMENT

people. These numbers are a stark contrast to Europe where the widest ratio is 1 doctor for every 500 people in Albania, and the smallest 1 physician for every 200 people in Greece. To makes matters worse, Southern Africa experiences a “brain drain” of qualified persons out of their home countries to serve in wealthier health systems. The brain drain is considered a significant global health problem, with many nations struggling to develop retention strategies for their health workers. The Philippines government and the World Bank, however, embrace outmigration of health workers as an economic development strategy. The Philippines Off Shore Worker program encourages the training of nurses, among other professions, to head overseas and send remittances home. In 2004, the Philippines received the fourth largest volume of remittances in the world, with over $11 billion being sent from workers abroad. In 2003, over 160,000 Filipino nurses worked in over 80 countries; however, only 29,466 nurses remained in the country to meet the needs of roughly 94 million people. The push for outmigration, while bringing in much-needed hard currency, has not allowed for the development of a robust health system to attract and retain health workers. The result is that entire islands are without health workers, and those who are present in rural areas of the country are underpaid compared to their offshore colleagues, and work in challenging circumstances. The 2013 Typhoon Haiyan exposed the fragility of health-care services in the Philippines as millions were left to cope in the storm’s aftermath without access to quality care. In sum, development objectives of increasing remittance income through the outmigration of health workers has increased the spatial vulnerability of the poor and demonstrates a noticeable disconnect between development objectives and health needs of marginalized places in the Global South.

Environmental determinants of health

The environmental determinants of health are broad, complex, and deeply associated with the interaction of land and life. Agents that alter the state of health in individuals can be found in any society. In poor communities, difficulties arise in securing the resources to identify, measure, and react to environmental agents that negatively impact health. Vulnerable populations have increased chances of being exposed to harmful agents and chemicals associated with heavy industry, agriculture, and extractive industries. When national-level regulations are compromised due to austerity, it becomes incredibly difficult for countries in the Global South to address environmental health concerns. Furthermore, the sorts of health conditions that develop from exposure to harmful chemicals and agents over the long term tend to be chronic illness, rather than vector-borne illness.

The African continent is facing an alarming increase in cancers in the past decade that are thought to be associated to increased exposure to harmful environmental agents (Livingston 2012). In both men and women, young and old, cancers are increasing on the African continent at rates higher than ever before seen, creating tremendous geographical inequality to the point where illness is experienced in radically different manners depending on place. This trend is true too in the Global North; however, in the North, health systems have made impressive efforts to respond to cancer care through advanced research, treatment, and hospice services. African health-care systems are completely unprepared to handle advanced-stage cancers. The mortality rate of breast cancer in Nigeria is 22 per 100,000 while it is only 17 per 100,000 in the United States. Prostate cancer deaths in Uganda are 33 per 100,000, which is exponentially higher than Canada’s rate of 13 per
100 000. Even though cancers are pervasive on the African continent and contribute to a growing burden of suffering and mortality, oncology aid to the continent is incredibly limited. The United States contributed over $7.7 billion to HIV in Africa in 2009. Close to $4.4 billion went to tuberculosis in 2012, and $32 million went to Guinea worm treatment in West Africa. But US donors raise not even a million dollars for oncology treatment in the African continent. Most of it is earmarked for the human papillomavirus (HPV) vaccines associated with the PEPFAR initiative. It is a telling example of how health and development issues in the African continent are assumed to be vector-based infections, rather than complex chronic illnesses that require advanced medical care. This assumption stems from a lack of understanding of emerging disease trends and the connections vulnerable populations have to them.

Social determinants of health

Two examples of illness that could be totally eradicated with improved social determinants are tuberculosis and cholera. Tuberculosis and cholera systematically target the poor, and both require poverty in order to flourish. These illnesses are preventable and avoidable, yet they have a devastating impact almost entirely in poor places. In international development circles the response to these illnesses comes in the form of coordinating reactionary care. The medicines are very effective. They can be costly, however, and do nothing to prevent the onset of the illness. Tuberculosis and cholera are entirely preventable. In order for these diseases to thrive they require poverty, just as much as a human host. Poor housing, poor ventilation, lowered immune systems, and poor diet will all give tuberculosis the advantage over the poor. Cholera requires inequitable geographical landscapes that involve poor water and sanitation in order to survive. These factors are entirely dependent upon development policy that maintains an unhealthy place and yet the funding and political attention to these illnesses is almost exclusively directed towards reactionary care, rather than dealing with the structural inequities of the landscape in the first place.

Addressing the social and economic conditions that lead to poor housing, unsafe water, and bad sanitation requires a policy package that deeply appreciates the structural barriers to health. Yet, with these illnesses the development funders pursue a reactionary course of action of drug therapy. The question remains as to whether the reactionary method persists because it is easier or if it is due to a lack of understanding of how to effectively address the social determinants within a particular place.

Concluding remarks

The Millennium Development Goals are all health related, and in 2015 the world failed to achieve each and every one. This defeat may well be the result of the loose epistemological connection between health, place, and development, and it may well signal the need for a deeper association and paradigm shift towards a social determinants approach to health and development. Rising from the ashes of the Millennium Development Goals are the new United Nations Sustainable Development Goals. With a deeper commitment to studying and acting upon the links between health and development it can only be hoped that the new goals will produce more fitting actions based on sound knowledge of what links health to place.

Health and wellbeing

Sarah Atkinson
Durham University, UK

The last two decades have witnessed a shift in policy goals from economic security, growth, and material prosperity to a more generalized attention to wellbeing. The growth of interest in wellbeing reflects serious effort to shift the assumptions of governments and their constituent populations away from the idea that doing well, whether as a nation or as an individual, is primarily evaluated by material prosperity to the idea that doing well should be assessed by considering some variant of wellbeing. Thus the decision to emphasize wellbeing as the ultimate goal for policy intervention repositions concrete policy goals, such as economic growth and material prosperity, as merely the means to human flourishing rather than as the ends themselves.

While an interest in assessing the elements that constitute a good life is not new per se, more recently governments and policy communities across several countries, including the United Kingdom, France, Canada, and Australia, have given increased attention to assessing personal or subjective wellbeing, following the lead of Bhutan and its long-established national Gross National Happiness Index. This move toward the personal and subjective in wellbeing has been reflected across the social sciences, including human geography: however, the term “wellbeing” has had a high-profile use in the domain of health since the World Health Organization (WHO) mobilized it in its 1948 constitution and defined health as complete physical, mental, and social wellbeing and not merely the absence of disease or infirmity. There is therefore a widespread assumption that wellbeing, and particularly subjective wellbeing, is primarily an aspect of health; within geography, subjective wellbeing to date has been primarily the remit of health geographers.

The study of medicine, health, and wellbeing within geography has a history of research trajectories that is similar to that of many other social sciences, and has been strongly influenced by the support given to social medicine, disease prevention, and health promotion by the WHO. Early studies focused on the distribution of diseases, associated factors, and availability and accessibility of appropriate care, thereby developing a distinctly geographic spatial epidemiology. In the early 1990s, however, geography spawned an almost parallel subdiscipline mobilized through a positive understanding of health and health care, rather than only disease and clinical medicine, and concerned with the domains of social, cultural, and political life. For this newly emergent health geography, wellbeing afforded an invaluable construct which not only enabled a model of health that went beyond the constraints of a biomedical science, but which was additionally legitimated through the WHO’s seminal definition of health. Nonetheless, the subdiscipline has, until now, self-identified as the geographies of health rather than the geographies of wellbeing, and it has been a broad notion of health that has been the primary research focus.

Since the mid-2000s, as wellbeing has been given prominence within the public policy agenda, geographers have returned to considering the notion of wellbeing itself as the primary research focus. This return is reflected
in the publication over recent years of collections of essays by geographers on wellbeing (see Schwanen and Ziegler 2011; Atkinson, Fuller, and Painter 2012; Schwanen and Atkinson 2015).

Geographies of wellbeing

Defining wellbeing for the purposes of measurement, evaluation, research, and policy is commonly identified as a major problem. Debates on what the key aspects of a good life might be range across objective and subjective approaches. Different positions on what constitutes wellbeing are closely connected to different positions on the kinds of actions and interventions appropriate to improve wellbeing. Such positions are informed in turn by a mix of political, cultural, and social values related not only to what constitutes a good life, but also to what constitutes personhood, society, the relationships between them, and with whom and where responsibility is placed for enabling wellbeing. Wellbeing, then, can offer a broad and encompassing concept through which to engage and question many debates that are central to the social and spatial sciences and to public policy. Moreover, regardless of how wellbeing is defined, it is always understood as embedded within the when, where, and how of everyday lives and as such is first and foremost inherently geographical.

Geographical engagements highlight several important features of contemporary concerns with wellbeing. First, the definitions of wellbeing, of where we understand wellbeing as residing and the contingent influences on wellbeing, may differ greatly across time, place, culture, gender, age, and so forth. Second, not only can wellbeing be examined at different scales of analysis, but it is also inherently multiscalar in production and expression. Third, a tendency to understand wellbeing as always located as the endpoint or outcome of policy is a misrepresentation of dominant usages. Last, wellbeing is almost always positioned as an individual attribute that is either an outcome or a determinant of other factors. Relational and emotional geographies offer a different engagement in which wellbeing becomes understood not as an attribute but also as an effect.

Dominant definitions and influences

The majority of contemporary approaches to wellbeing, whether objective or subjective, locate wellbeing at the level of the individual. This is an important point to reflect on as engagements with wellbeing have not always focused on this more personal or subjective aspect. Indeed, wellbeing as a concept has not even always been understood as an individual quality. In an analysis of the roots and development of the concept of wellbeing into its current usage through a review of British newspapers, sociologist Eeva Sointu has described an understanding of wellbeing in the 1960s and 1970s as a collective concept, most commonly used in the context of the economy. This more collective understanding of the term was elaborated within geography by David Smith, who examined inequalities in wellbeing in the 1970s through developing multidimensional social and objective indicators to compare territorial units, and used the concept in relation to the moral attitudes to social and environmental inequalities (Conradson 2012).

As an individual attribute, the acknowledged complexity of the concept of wellbeing is broken down into component elements that can be measured for assessment and for the identification of determinants. There are various lists of factors, both objectively and subjectively assessed, which are posited as either constituting wellbeing or influencing wellbeing (see, e.g., the work of the
Commission on the Measurement of Economic Performance and Social Progress: Stiglitz, Sen, and Fitoussi 2009). Lists may include participatory consultations of what communities or populations themselves consider their priorities for wellbeing, as took place in the United Kingdom through a national consultation by the Office for National Statistics in 2011–2012. A 2008 report for the Department for Children, Schools and Families in the United Kingdom usefully spelled out series of binaries on which various definitions of wellbeing may differ, and on some of which they found understanding did differ between different government departments: individual versus collective; subjective versus objective; permanent versus temporary; general versus specific; reducible to components versus an irreducible holistic totality; responsibility through structure versus agency; a neutral state (nothing wrong) versus a positive state (better than neutral); a state or place versus a process or journey; an end in itself versus a means to another end. In reality, most approaches treat wellbeing as individual, in which any collective assessment comprises the aggregated individual measures of socially or territorially defined groups. Wellbeing is taken to show some permanency, at least in the short to medium term, and almost all approaches handle the abstract and complex nature of wellbeing by breaking it down into reducible parts, in what has been called the components approach (Atkinson 2013).

The impetus for interest and the growth of investment in measuring wellbeing has emerged in the high-income countries of Europe, Australia and New Zealand, and Canada. Some attention to wellbeing has been given to other locations beyond the initiatives in Bhutan. The research program on Wellbeing in Developing Countries (WeD) at the University of Bath explored wellbeing in low-income countries through both objective and subjective measures that drew conceptually on the capabilities approach of Amartya Sen and needs-based approaches in development studies. The research in this program emphasized the importance of the collectivities within which everyday lives are shaped and the tradeoffs that have to be made between different components of wellbeing. The WeD researchers also promote a “messy” definition of wellbeing that allows for both local specificity and universal rights. Despite evident differences in detail and expression of the components constituting wellbeing or the components influencing wellbeing, most lists include what can be seen as universal components of at least income, social relationships, and health.

In relation to the growth of interest in subjective wellbeing, these factors become influences or resources for subjective wellbeing to flourish. Subjective wellbeing is typically captured through either an economic, utilitarian approach and associated with the idea of happiness and the work of Richard Layard, or a psychological approach associated with ideas of meaning, purpose, and self-worth exemplified by the work of Carole Ryff and colleagues. This distinction is described as not only disciplinary (economic or psychological), but also as philosophical, hedonic compared with eudaimonic, or in popular terms as happiness- and pleasure-based compared with fulfilment- and meaning-based. Examples of different sets of components in circulation are summarized in Atkinson, Fuller, and Painter (2012), and associated factors and methodological questions are summarized in Schwanen and Wang (2014). Tensions between the hedonic and eudaimonic variants of wellbeing have been drawn out across many different settings (see various examples in Atkinson, Fuller, and Painter 2012). Hedonic wellbeing may be nurtured through physical gratifications, through individual gain, and through unsustainable consumerism, gains that may be in explicit
conflict with gains for eudaimonic wellbeing, which are nurtured through social and ethical purpose. Moreover, whether hedonic or eudaimonic wellbeing is privileged will vary depending on both setting and scale. Although we might expect the gains for eudaimonic wellbeing in terms of purpose and meaning in life ultimately to trump the conflicting hedonic goals, the hedonic wellbeing from contemporary and individualized consumerism has been cast as a threat not only to individual wellbeing but also to societal and even global wellbeing.

Conceptualizing wellbeing as a set of entities that can be individually acquired brings a number of advantages for both research and policy practice. First, it enables us to ascribe stability to subjective wellbeing, at least in the medium term, and ascribing stability is essential if the measurement of wellbeing is to be meaningful. Thus, second, the measurement through which to identify and monitor trends and to assess interventions at different levels of governance can be based on individual assessments, which are then aggregated into appropriate or comparative social units. Third, changes in subjective wellbeing can be related to changes in those opportunities and resources, whether external or internal to the person, which may facilitate the acquisition of the various components. These components can then be evaluated through the standard designs of “before and after” assessment or cross-sectional comparisons.

Multiscale geographies of wellbeing

As the geographies of wellbeing as a field of research grows, one of the most important insights is that “spatial differences in subjective well-being are multiscalar” (Schwanen and Wang 2014, 835). The intimate scale of subjective wellbeing, personalized and individualized, provokes a tendency to examine determinants of wellbeing operating at a similarly individual or local scale. This tendency may be exacerbated by participatory approaches that aim to identify people’s own criteria for subjective wellbeing in terms of what is important to them. This approach, while respectful and cognizant of both contextual and personal variations, is most likely to elicit the identification of “intentional” aspects of life, those aspects that participants are most aware of and confront on a daily basis, while determinants that operate beyond the everyday encounters are less likely to be identified. Moreover, the observable change in the dominant understanding and usage of the term “wellbeing” toward an individual and subjective entity has been explicitly located as part of those changes associated with the emergence of contemporary forms of neoliberalism. An individualized responsibility for self-actualization has been positioned as a significant feature of Western society within a Foucauldian analysis of contemporary forms of governance. Indeed, the only trace of a more collective understanding to be found in current uses of wellbeing remains in relation to environmental sustainability. The broad political critique leveled at this approach to wellbeing is twofold: first, that subjective wellbeing is predicated on predefined qualities, attitudes, and ways of being that constitute the desirable citizen; and, second, that achieving these qualities is presented largely as an individual and internalized task of self-management, such that a failure of subjective wellbeing can be positioned as a failure of responsible citizenship. Seen through this lens, subjective wellbeing is an outcome of individual agency rather than societal structures, inequalities, or context.

Spatial differences in wellbeing have been described at a range of scales commonly investigated in geographical inquiries – international,
national, interurban, intraurban, neighborhoods—and are shown to involve both physical and social dimensions of geographical space. Subjective wellbeing tends to be lower in more densely populated, urban locations although not consistently, and this is countered by a tendency for wellbeing to be higher with easier access to shops, schools, transport, health facilities, and so forth. More particularly, geographic studies have demonstrated the tendency for area-level and nation-level deprivation, prosperity, and resource availability to influence local and individual levels of subjective wellbeing (summarized in Schwanen and Wang 2014). At a global scale, studies in peri-urban districts of the new economies in Latin America and Asia illustrate how global trends toward an individualized aspiration and consumption are in tension with traditional values of community cohesion and unity (see examples in Atkinson, Fuller, and Painter 2012).

The importance of geographical work on spatial variations and inequalities in wellbeing across different scales can be illustrated through the body of work on the relationships between income and subjective wellbeing. Income has attracted disproportionate attention in association with subjective wellbeing because of its centrality in policy debates. The policy move toward wellbeing is founded on a line of argument that proposes that economic growth has not been matched by comparable growth in some notion of subjective wellbeing, such as satisfaction with life or happiness. The argument traces its lineage back to a foundational and influential study by Easterlin, generating the so-called Easterlin Paradox. Easterlin examined life satisfaction and GDP per capita for the American population during the postwar decades. His striking results demonstrate a steady rise in the country’s economic growth, but by contrast the levels of self-reported life satisfaction flatlined. This result thus underpins the argument that there is no link between a society’s economic development and its average level of happiness once what is a surprisingly low level of average per capita income (indicated through GDP per capita) has been reached. Moreover, the result dovetails with arguments that it is the extent of relative inequalities, rather than absolute values in material aspects of life, that drives associated inequalities in quality-of-life outcomes such as health status. In Wilkinson and Pickett’s “Spirit Level” hypothesis (the title of their 2010 book) the importance of relative inequality in income for health is likely mediated by some kind of dissatisfaction through a comparison resonant with a notion of subjective wellbeing.

This argument not only fuels the growing attention to subjective wellbeing as the endpoint of policy intervention, but also indicates income redistribution through progressive taxation as the appropriate policy to increase average levels of subjective wellbeing. The primary argument of the Easterlin Paradox has not passed without contestation; for example, Betsy Stevenson and Justin Wolfers have presented several analyses that show both a clear positive association with average levels of subjective wellbeing and GDP per capita across countries, and the absence of evidence of a satiation point from which no further gains are made in subjective wellbeing in the richer countries. They find the same association within countries between individual income and individual subjective wellbeing over time, and argue for a renewed attention to absolute income as a determinant of subjective wellbeing.

Geographers have made important and critical contributions in exploring the determinants of subjective wellbeing by drawing attention to the complexities of scale and place for subjective wellbeing. First, comparison across very different settings confronts cultural factors that can affect
HEALTH AND WELLBEING

the extent to which subjective wellbeing or happiness is expressed. Second, given the key policy debate about the importance of relative inequality and social comparison versus absolute levels in measuring determinants of subjective wellbeing, far greater understanding is needed of with whom and at what scale we compare ourselves. While the majority of researchers have tended to examine relative inequality locally within the neighborhood, Dmitris Ballas and Danny Dorling (2013) suggest it is comparison across the nation-state that is crucial. Third, the importance of determinants for subjective wellbeing varies across space and across time. Spatially informed research using large European datasets has shown important influences on subjective wellbeing for a range of macroscale factors. Furthermore, the debate over whether the absolute or the relative value in income and other indicators is key for subjective wellbeing gets a new direction with evidence that it varies across different regions and countries (Aslam and Corrado 2012). This evidence highlights the importance to understanding subjective wellbeing of considering the particular macropolitical, economic, and historical trajectories of a given setting. These kinds of studies, working with large datasets, both emphasize the complexities involved in developing and evaluating policy interventions and expose a range of issues that need consideration across different scales of governance.

Subjective wellbeing as process

In the rhetoric and practice of policy-facing research and discussion, subjective wellbeing is located as the outcome, the desirable endpoint of other aspects of daily life and of governance, of policy and of intervention. Susan Smith and Donna Easterlow (2005) argued, in relation to the geographies of health, that positioning health as always and only the outcome in research produced a “strange geographies of health inequalities” that was unbalanced in not examining how differential health experiences may influence other aspects of life. Similarly, research across geography and development studies has begun to revise the one-sided approach to subjective wellbeing as only the outcome of a variety of factors including policy measures, to understand subjective wellbeing as also an important process factor for other outcomes, and to complicate this relationship in ways that challenge the political implications of an individualized, subjective wellbeing and that question the best routes for policy intervention. The implications of positioning subjective wellbeing as not only a possibly desirable endpoint but also a significant process factor have been drawn out through several strands of geographical research.

The first of these research strands is a challenge to the calls (and indeed large amount of funding that is being invested) to identify a tighter definition of the concept. The justification for this follows an argument that an ill-defined understanding of subjective wellbeing not only makes it difficult to evaluate interventions, but also creates barriers to communication across different sectors. In a counterargument, research with local governments in the United Kingdom has demonstrated how an imperative to develop strategies and indicators for wellbeing opened up a space in which competing discourses of wellbeing could be aired and deliberated, and thereby generated discursive shifts in the underpinnings of longer-term policy formulation (Scott and Bell 2013). Thus, wellbeing, exactly because of its vague and all-embracing character, offers a conceptual unifier across different sectors through acting as part of the process of policymaking as much as being an outcome of policymaking. From this perspective, establishing a tight and measurable definition of wellbeing in
order to evaluate outcomes would seriously limit
the scope of the policy work that the concept
has the potential to achieve (Atkinson 2013).

Second, thinking of wellbeing as process
challenges the separation of subjective wellbeing
from the objective material aspects of living and
from health status. Increasingly, both in research
and in popular imagination, wellbeing is equated
at an individual scale with various terms of pos-
itive affect. Happiness has tended to be the term
to capture this, partly because of its populist
currency and partly because it fits well with
an economic approach to flourishing through
utility: that is, subjective wellbeing as happiness
can be positioned as the utility that people want
to maximize in their lives, as the driver of their
choices in life, and as the entity to be enhanced
through policy. The argument of Richard
Wilkinson and colleagues that inequalities in
health relate strongly to relative inequalities in
the distribution of material and developmental
resources, however, is strongly suggestive of a
mediating role for a experiential happiness with
one’s circumstances that is first and foremost situ-
ated in comparison with the norms of one’s social
settings and that then impacts other outcomes
such as health status. It is difficult to distinguish
which of happiness, health, and wealth is the
process and which the outcome. Research that
only considers the local scale, rather than a mul-
tiscalar perspective, may gloss over problematic
aspects of how subjective wellbeing is expressed.
In the context of Wilkinson’s relative inequalities
thesis, those who benefit from advantages in
life may express contentment and happiness
without regard for the global and local relations
of inequality underpinning such advantage. This
may be informed by naivety, ignorance, or com-
placency and a lack of care for the circumstances
of others. On the other hand, those living with
deprivation and disadvantage may express con-
tentment and happiness that is based on a lack of
aspiration and an acceptance of social injustices.
In all of these scenarios, subjective wellbeing is
founded on various cognitive and affective states
that can be considered deficient or undesirable.
Further, in these scenarios, subjective wellbeing
is not only the outcome; it not only reflects but
also feeds a lack of critical reflection on society’s
values or a lack of imagination with respect to
alternative possibilities (Atkinson 2013).

Third, certain psychological approaches to
subjective wellbeing, defined as some variant
of positive affect, increasingly position this
positive affect as under internal and individual
control. The growing body of research on the
determinants of subjective wellbeing, including
spatial analyses of inequalities, identifies deter-
minants that are both internal and external to
the individual. The internalized experiential
happiness that mediates outcomes in Wilkinson’s
relative inequalities thesis is clearly shaped by
the comparison of external material resource
differentials; however, in the literature informed
by the positive psychology movement, subjective
wellbeing is very differently positioned as no
longer primarily an outcome of external factors,
the proper concern of local and national gov-
ernments, but a process of internal management
and the object of personal responsibility. This
emphasis on personal action effectively positions
many of the components that typically make up
psychological definitions of subjective wellbeing
as influences on various other personal out-
comes and socially recognized criteria of success.
These outcomes include health conditions and
health-related behaviors, employment and earn-
ing capacity, and productivity at work. Although
geographers have not engaged greatly with this
literature to date, there are clear spatialities to
be explored in relation to where wellbeing is
located, where responsibility is located, and
where policy intervention is located.
HEALTH AND WELLBEING

The promise of the power of working on one’s own internal wellbeing, happiness, or positive affect logically leads to policy responses that similarly focus primarily on individual deficits in fostering and sustaining positive wellbeing. For example, cognitive behavioral therapy has become very popular across a range of conditions and social contexts, while Buddhist-inspired practices of mindfulness are also attracting increasing policy interest. Geographical critiques of the responsibilization of the individual for his or her own health outcomes are being extended to the internalized and universalized presentation of wellbeing; subjective wellbeing as personal responsibility becomes no longer an outcome but rather part of the processes through which our conduct is directed according to the requirements of the political or economic imperatives of others. This is exemplified in the rise of the modern spa as a site explicitly dedicated to enable wellbeing through self-care, in which a series of power relations mediated through gender and identity enable the regulation of the body (Little 2012). Further critique indicates that viewing the acquisition of the objective material resources commonly understood as part of a flourishing life is largely determined by internal attitudes and assumes a meritocratic society in which inequality can be dismissed as a result of personal deficiency (Atkinson 2013). A focus on personal deficiency, in what Lynne Friedli has called a shift from welfare to wellbeing, takes concrete form in current policies related to unemployment benefits in the United Kingdom, whereby those who are unemployed have to perform approved attitudes and behaviors or attend positive attitude training to stay in the benefit system. Although such policies appear benign or even helpful, Friedli argues that they expose a growing governance of personality in which only quite a constrained definition of attitudes and behaviors is considered acceptable.

Subjective wellbeing as effect

Subjective wellbeing is most commonly located in or with the individual: it is measured as individually experienced and expressed, as determined by or as a determinant for other factors, and collective wellbeing is captured as the aggregate of individual experiences. The movement within geography toward greater engagement with the emotional, the relational, and the nonrepresentational domains of social life has been expressed within the geographies of health through very different conceptualizations of wellbeing in which emotional and imagined connections to place are central. Research on housing and wellbeing has demonstrated how affective bonds shape housing choices and thereby shape neighborhood health status, and how affective tensions between investments in housing as an asset and as a home are strongly reflected in differential wellbeing. Owners who are primarily preoccupied with financial returns consistently express low wellbeing scores. These housing studies describe the inseparability of emotion, investment, place, and time. This investment in an idea of home takes on particular poignancy for wellbeing as people age. The emotional and embodied connections with the home can be vital to the wellbeing of older people, through a mixture of a sense of belonging, emotional attachments from memories, and a sense of familiarity with the immediate surroundings. Research thus indicates the need for social support to enable continued residence at home rather than a move to a residential care facility. On the other hand, when older people have become frail and unable to travel independently, continued residence in their own home may bring increasing risks of social isolation, with associated deterioration of wellbeing through feelings of loneliness and depression. New technologies to support older
people in their own homes tend to focus on surveillance and physical risk; however, the value to wellbeing of caring for another has generated interesting experiments with robotic pets for the elderly that can provide a companion needing emotional care.

How the experience of being in a given landscape or environment interacts with subjective wellbeing has given rise to a substantial body of work shaped through the concept of therapeutic landscapes or spaces. Wil Gesler first elaborated the concept of therapeutic landscapes and emphasized the multiplicity and interrelatedness of the factors that can contribute to what makes a place beneficial for wellbeing. Research on therapeutic landscapes has expanded from the original application to designated exceptional sites to examine a range of different places and spaces, including the everyday and the imaginary (Williams 2007). In relation to wellbeing, geographers have given particular attention to the benefits that come from being in natural spaces, from urban parks and ponds, the greenspace and bluespace of plants and water, and from the activities of nurturing these through gardening or spiritual investment. Peter Groenewegen has dubbed the benefits of greenspace vitamin G, suggesting that improved access to existing urban parks and investment in new ones may be a cost-effective strategy for public health and health promotion. These engagements from a European or North American health geography tend to position the so-called natural environment predominantly as an instrumental factor for wellbeing and health. In some settings, such as among Aboriginal communities in Australia, wellbeing is incomprehensible if thought of as separate from the community’s relation to the natural environment; the wellbeing of people is the wellbeing of the land, the rivers, and all coexisting life forms (Gibson 2012). Health geographers have also challenged the dominant presentation of natural environments as beneficial, re-emphasizing the complexities of therapeutic landscapes and exposing the alienation of some from natural environments or the therapeutic value of unvalued, risky, or spoiled settings.

Therapeutic landscapes, then, involve a complex web of interactions between what qualities they present and what meanings are attributed to them in any given time and social setting. Human geographers have promoted an understanding that place and people mutually constitute one another, a relational understanding of geography that enables complexity and plurality as well as temporal and spatial specificity. This relational approach has been drawn on within health geographies to advance our understandings of therapeutic landscapes and spaces. In a relatively early attempt to capture the complexities and relationalities of both objective and subjective wellbeing through a geographical lens, Fleuret and Atkinson (2007) proposed what has become known as the spaces of wellbeing approach. The approach explores how different social and spatial contexts may facilitate wellbeing, and proposes that wellbeing is emergent through four interrelated spaces of resource mobilization: capabilities, social integration, security, and therapeutic processes. This framework served to expose the emphasis within studies on wellbeing, in both geography and other disciplines, on either the components of wellbeing or the factors associated with it. The framework demands a greater attention both to the relationalities between the different spaces of wellbeing and to the processes through which wellbeing, and particularly subjective wellbeing, may be enhanced. Subsequent work on the geographies of wellbeing have both built on the spaces of wellbeing approach and drawn on other trends within the discipline as a whole.
to offer several new directions and expose new underresearched topics and fields. A relational geography demands that we think of wellbeing not as an entity that can be acquired or attained but as an emergent effect of any space and time. The spaces of wellbeing approach offers a first framework to shape research on the processes, resources, and relations through which wellbeing may be emergent as an effect rather than an acquisition. But, similarly to components approaches or sets of objective and subjective variables, how such different resource spaces relate to one another is underresearched beyond preliminary suggestions that such spaces are not hierarchical but mutually reinforcing.

The implication of thinking of wellbeing as effect is that wellbeing is rendered potentially unstable, always emergent and becoming. At the same time, wellbeing appears to manifest relative stability, at least in the short to medium term, without major disruptive life events, allowing wellbeing to be meaningfully captured through measurement. Geographies of wellbeing have begun to explore theoretical and conceptual resources not only from a relational geography, but also from Deleuze and Guattari’s work on assemblage and on striated and smooth space, from attention to embodied experience and from nonrepresentational theory (Andrews, Chen, and Myers 2014; Atkinson and Scott 2015). These conversations allow wellbeing to be an effect that is emergent and becoming, but also to be simultaneously stable and unstable, fixed and changeable. Research on how behaviors, norms, social structures, and so forth become fixed can provide insights for understanding how an emergent and becoming wellbeing may similarly be fixed. Similarly, research on how assemblages and atmospheres may be disrupted, on flows and stickiness of affects, may offer insights for understanding how a fixed wellbeing may be destabilized and amenable to change.

New directions in the geographies of wellbeing

The last few years have witnessed a rapid rise in geographical research that is engaging with wellbeing from a range of important and critical directions. Two research elements of an agenda for a geography of wellbeing to take forward are implicated from existing recent endeavors.

First, several different approaches to wellbeing have emphasized the importance of time, whether through the variations in wellbeing across a life-course, through transitional moments that destabilize wellbeing, or through the trajectories of different nation-states. Geographers have barely engaged time into experiential studies of wellbeing. A recent study by Tim Schwanen and Donggen Wang (2014) draws on the various strands of time-geography and demonstrates how the relations between social contacts and subjective wellbeing extend across multiple timescales. Geographical engagements with time–space have the potential to offer an important corrective to more static understandings of wellbeing and to contribute to elaborating the interactions of time with wellbeing in those areas where time is already identified as significant. Second, the idea of wellbeing as a collective entity has had limited traction within contemporary policy agenda. The attention to the emergence and becoming of wellbeing decenters the individual person as the primary focus of research; instead, the primary focus is on the assemblage, the atmosphere, the movement of affects, or the tensions between the habitual and disruptive and destabilizing embodied experiences. This decentering, from a geography that emphasizes emotionality, relationality, assemblage, and nonrepresentational theory, may afford the concepts and theories through which to comprehend wellbeing as collective, beyond the aggregation of individuals.

Geographers have long-standing interests in the ecology of disease and the spatial organization of medical services. From the early 1990s, a new approach emerged, centered on the dyad of health and place. The focus on health entailed looking beyond geographers’ traditional concerns for pathological matters to encompass positive conceptualizations of mental and physical wellbeing. The concern for place involved a shift away from spatial-analytic approaches centered on distribution and diffusion toward engagement with everyday contexts that are sites of meaning and familiarity. Critically, health and place were not envisioned as separate categories, but as mutually constituted: the health status of the population and localized provision of care shape the character of place; at the same time, the physical, social, and cultural qualities of place influence individual and collective health.

These developments within geography emerged in the context of broader transformations in global public health. At a conceptual level, it was increasingly shifting away from a biomedical model centered on the causation and treatment of disease, and toward a socio-ecological model recognizing the multiple (and overlapping) social, institutional, and environmental influences on health. Related to this shift were changes in practice, including an increased emphasis on prevention and a stronger focus on primary care, often provided at the local level. Helping to underpin these changes was the growing influence of the World Health Organization’s positive definition of health as “a state of complete mental, physical and social wellbeing and not merely the absence of disease or infirmity.”

The specific case linking these changes to the need for a new approach within geography was articulated by Kearns, who argued that the established subdiscipline of medical geography was preoccupied with “spatial relationships between individuals, place and institutions, rather than with the health-related characteristics of places themselves” (Kearns 1993, 140). Specifically, medical geography envisioned “places” as locations and as regions, but not as sites of meaning that influence health experiences and outcomes. Related to this constrained understanding was a lack of engagement with humanist and structural theories of place that were influential elsewhere in human geography, and a limited ability to conceptualize the increased importance of place in the philosophy and practice of public health.

In light of these limitations, Kearns argued that the concerns of medical geography should be supplemented by a “geography of health” centered on “the dynamic relationship between health and place and the impacts of both health services and the health of population groups on the vitality of places” (1993, 145). This new approach was envisioned as having strong connections to social and cultural geography, and the developments that were animating those fields such as concerns for identity, postmodernism, and structure–agency. Two case studies were pre-
sented to sketch out potential approaches within the geography of health. The first centered on women’s experiences of planned home birth, which entailed a conscious rejection of the institutional environments so often central to medical geographers’ analyses. The second offered a new perspective on primary health-care centers, by focusing on their contribution to the collective health of community rather than on the treatments received by individual patients. Both studies were informed by qualitative methods (interviews and partial participant observation, respectively), in contrast to the quantitative methods dominant within medical geography. As Kearns argued, interpretive and qualitative approaches were especially well suited to exploring “the subtle contribution of health practices to the social geography of places” (1993, 144).

This call for change – and diversification – in geographers’ approaches to issues of wellness, illness, and care prompted considerable debate. Critically, a new body of research – and a new subdiscipline of geographical inquiry – rapidly emerged along the lines suggested by Kearns (Andrews et al. 2012). This new geography of health can be characterized in a variety of ways. For Kearns and Moon (2002), it was defined by a focus on place, adoption of theory, and critical approaches – played out across diverse thematic interests. Arguably, foremost among these themes was the idea of therapeutic landscapes, first articulated by Gesler (1992), and considered in more depth later in the entry. A review by Kearns and Collins in 2010 added concerns for individual experience, and the sociospatial constitution and negotiation of risk, to this set of characteristics. Most recently, Andrews et al. (2012) highlighted health geography’s contributions across three substantive areas of inquiry: health-care settings (encompassing political and economic pressures for reform, professional organization, and individual experience); public health (encompassing socioecological influences on population health and the role of place in health promotion); and environmental health (encompassing spatial correlations between exposures and ill-health, as well as concerns for environmental inequalities).

This tripartite conceptualization highlights the ways in which health geography retains connections to the medical geography field from which it emerged, consistent with Kearns’s original proposal for “two inter-related streams … within the medicine/health/geography nexus” (1993, 144). With regard to health-care settings, medical geographers have a long-standing interest in the spatial organization of such facilities at local, regional, national, and international scales – and in related issues of accessibility and utilization. Health geographers share a concern for medical systems and sites of treatment, but generally approach them from a different perspective – emphasizing policy frameworks, and experiences of the production and consumption of care – and are more likely to use qualitative methods and social theory in their analyses. With respect to public health, the subdisciplines have a common concern for the prevention of disease and injury, although health geographers’ contributions again tend to be distinguished by more theorized and politicized perspectives. In the third field, environmental health, subdisciplinary boundaries are particularly blurred, as quantitative approaches predominate and there is a mutual concern for identifying inequalities (Andrews et al. 2012).

These areas of overlap complicate efforts to map out a clear distinction between medical and health geography, something that is reflected in ongoing slippage in the use of these subdisciplinary labels (Kearns and Collins 2010). Nevertheless, they are typically held to differ in overall emphasis and approach. One point of contrast is the distinction between “applied”
and “theoretical” epistemologies. Medical geography has been seen to have a more applied focus, producing knowledge of both disease and health-care organization that is directly relevant to practices of disease control and systems of treatment. By contrast, work in health geography has been more likely to be overtly theorized and to incorporate a critical stance toward biomedicine. This stance has extended to criticism of geographical work perceived as being in the service of medicine (Andrews and Evans 2008). However, the tension between these two approaches should not be overstated. Health geographers have emphasized that medicine is neither monolithic nor unchanging, and that it is increasingly oriented toward health (Kearns and Moon 2002). Moreover, the broad field of health care is not reducible to medicine (Andrews and Evans 2008). In addition, the field of medical geography has continued to evolve, including via the adoption of new approaches (e.g., political ecology) and thematic concerns (e.g., socioeconomic inequality) that overlap with the concerns of health geography, as well as new methods (e.g., multilevel modeling) that help to explicate the relationship between health and place (Mayer 2010).

Diverse interests

One of the distinguishing features of health geography is its remarkable breadth, encompassing an array of substantive concerns, theoretical positions, and methodological approaches. This diversity stems from a number of factors: connections to other social science perspectives on health, which have also proliferated since the mid-1990s; the magpie-like tendencies within the parent discipline, manifest in a willingness to adopt and adapt ideas from other fields; and the flexibility of health geographers themselves in selecting projects and approaches. It follows that health geography is characterized not only by enduring links to medical geography but also by connections to myriad other fields of inquiry that speak (empirically and/or theoretically) to the interconnection of health, care, and context. A useful conceptualization of the diversity within health geography is provided by Andrews et al. (2012), who identify three categories of difference. They note it has contributed to specific subjects of in-depth inquiry (e.g., complementary medicine, intoxicants, sport and fitness), to established fields of knowledge (e.g., aging, mental health, disability), and to overarching research themes within the social sciences (e.g., gender, the body, globalization). In making these diverse contributions, health geographers have necessarily engaged with work located in other academic disciplines (e.g., disability studies, sociology, gerontology). To illustrate these points, one subject area receiving increasing attention within health geography is smoking, with studies exploring spatial variations in prevalence and levels of restriction, as well as place-based meanings of smoking and exposure. This research has brought health geographers into contact with particular fields (e.g., health promotion, social marketing, and tobacco control) and with larger questions about power, rights, and inequality. It has also involved engagements with other disciplines, particularly via theories of stigmatization and denormalization adopted from sociology and social psychology, respectively (Collins and Procter 2011; Pearce, Barnett, and Moon 2012). The variety of theoretical approaches utilized in health geography (discussed in further detail later in the entry) speaks to the flexibility of researchers as well as the porous nature of subdisciplinary boundaries.

This porosity is linked, in part, to the positioning of health geography within the domain of public health. As Andrews et al. (2012, 358)
HEALTH GEOGRAPHY

outline, public health encompasses “a rather monstrous assemblage of laws, bureaucratic institutions, health professionals, materials and practices which aim to prevent disease and injury, create healthy environments, all for the broader purpose of securing and promoting the general health of the population.” Health geographers have engaged with this “monstrous assemblage” in two broad ways: first, as participants seeking to contribute to its overarching purpose; and, second, as critics seeking to elucidate its assumptions, silences, and consequences. In the former role, health geographers have explored the ways in which health-related resources, behaviors, and socioeconomic structures vary across diverse physical and social contexts – and how these contexts might be reworked to support public health goals. Neighborhoods have been a prominent area of interest, with studies connecting their socioeconomic characteristics and built form to variations in levels of alcohol use, active travel, outdoor recreation, obesity, smoking, and so on. In the latter role, health geographers have considered public health as an object of critical inquiry, exploring the medical, social, and political dimensions of its historical development, as well as its contemporary functions across population surveillance, health promotion, risk reduction, and policy intervention. Much of this work draws on theoretical insights originating with Michel Foucault (1926–1984) to examine the role of public health in organizing and governing bodies, space, and power.

In both of these capacities, health geographers contribute to themes and concerns developed across many fields of academic inquiry, spanning the humanities, social sciences, and natural sciences. In particular, they have engaged with contemporary public health research, which since the adoption of the socioecological model in the 1970s has been attentive to diverse contextual factors (e.g., relationships, institutions, communities, policies) shaping individual and collective experiences of health. One consequence of a heightened concern for context is a “spatial turn” manifest in converging concerns for the health implications of home, workplace, neighborhood, city, and region (Andrews et al. 2012). Moreover, opportunities for – and expectations of – cross-disciplinary engagement exist at many stages of the research process (e.g., in developing funding proposals, presenting at conferences, and submitting work for peer review). It follows that health geography is by no means an insular endeavor. The same is broadly true for medical geography, with Mayer (2010) emphasizing interconnection with fields as varied as bacteriology, social epidemiology, and development studies.

A central theme

In light of these observations about diversity, it is reasonable to ask whether there are points of commonality that give health geography a sense of identity and coherence. The defining feature of the subdiscipline is its emphasis on “the centrality of place in the study of health” (Kearns and Collins 2010, 16), which provides a shared focal point for inquiry, although there are multiple interpretations of both key terms. In first proposing a focus on health and place, Kearns (1993) conceptualized a two-way interconnection: place both influences health and is partly constituted by the provision of local health services and the health status of the local population. Over time, the former relationship has received substantially more attention. Indeed, perhaps the most common question asked in health geography scholarship is “How does (this) place affect health?” While this work is often qualitative in design, there is a sense in which it is concerned with causation and envisions health as a dependent
variable – if only implicitly. This approach confers some benefits in that it connects health geography to broader concerns for the determinants of health. It also allows for place to be envisioned as a site of therapy as well as a site of risk (Andrew et al. 2012). However, there is a sense in which concern for the connections from health to place has been overshadowed, notwithstanding some studies considering the ways in which health-care institutions seek to create place identity and contribute to a broader sense of community.

In terms of how place is conceptualized, three distinct understandings have been identified (Kearns and Moon 2002; Kearns and Collins 2010). First, a large body of work examines particular localities, both urban and rural, for the ways in which they support or undermine health. Within these locality studies, approaches vary from humanistic explorations of the meaning of place to positivist examinations of exposure to localized risk factors, such as air pollution. Andrews et al. (2012) note that studies in low- and middle-income countries often focus on environmental issues and policy interventions in places, whereas those in high-income countries tend to involve more theoretically oriented investigations of place effects on health. Another characteristic of this work is that a great deal is known about certain places and very little about others. This selective focus is evident across multiple scales. Internationally, health geography research has been concentrated in high-income, predominantly English-speaking countries – the subdiscipline’s “Atlanto–Antipodean hearth” (Kearns and Moon 2002, 608). Moreover, within these countries, places proximate to university-based health geography research programs have received the most attention.

Second, landscape analysis has been a hallmark of health geography. The term “landscape” is generally interpreted as referring to the converging layers of history, social structure, and built environment at particular sites. The most prominent approach follows Gesler’s (1992) identification of therapeutic landscapes – a concept that has contributed substantially to the profile and purchase of health geography. Originally an overtly theoretical approach that drew on humanist, structural, and cultural materialist interpretations of landscape, it was subsequently applied in empirically oriented investigations of places as varied as “natural habitats, towns, beaches, retreats, clinics and homes” (Andrews et al. 2012, 354). This proliferation of case studies has prompted some criticism, including that the “therapeutic landscapes” label may be applied in descriptive and uncritical ways. Another concern is the lack of specificity in identifying the qualities of place that support restorative experiences and enable health (Duff 2011). Health geographers have also conceptualized landscapes that have a more ambiguous relationship with health. This approach has included adopting Dear and Wolch’s (1987) understanding of landscapes of despair to provide insights into geographies of mental health and addiction that emerged after the widespread deinstitutionalization of the 1970s and 1980s.

A third distinctive perspective on place is evident within multilevel modeling studies. The expansion of work in this area reflects the refinement of statistical methods, increasing availability of large datasets, as well as “an enduring quantitative tradition based around the application of the generalized linear model to questions of health equality/inequality” (Kearns and Moon 2002, 611). It conceptualizes place as the context (often understood in principally socioeconomic terms) in which individuals are situated, and seeks to attribute variations in health status and experience to these different levels. This work is often conducted at the
neighborhood scale, where unpacking the relative importance of context (the characteristics of place) and composition (the characteristics of residents) is of central analytical importance (Macintyre and Ellaway 2003). While the understandings of place produced by this multilevel modeling are in part a function of data availability, the relative complexity of its statistical methods contributes to its purchase in a broader research environment that privileges “robust” quantitative approaches (Kearns and Moon 2002). This environment has been shaped by the rise of evidence-based health care, which has privileged certain quantitative methodologies.

In terms of conceptualizations of health, there has been a broad shift away from classical biomedical preoccupations (e.g., pathogens and patients) toward a more contextual, collective, and positively oriented understanding of the term (Kearns and Collins 2010). This shift is reflected in attentiveness to the social/cultural, political, built, and natural components of place-based communities; in concern for identifying and promoting health-enabling places and policies at multiple scales; and in an overarching interest in protecting the wellbeing of the entire population (a preventive rather than curative focus). Widespread adoption of the term “wellbeing” within health geography signals a desire to frame health as more than a state of absences, for example as an empowering resource or capacity. This is not an idiosyncratic approach, as more holistic and positive conceptualizations of health have accompanied the adoption of the socioecological model and an increasing emphasis on population health perspectives within both public health and medicine.

A focus on health and wellbeing helps to connect health geography to important empirical developments and a changing landscape of health research, but it also raises questions as to whether health geographers can or should continue to engage with pathological matters and places of (conventional) health-care provision. In practice, there has been considerable emphasis on individual experiences of illness and wellness (encompassing not only physical health issues but also mental and social wellbeing, as well as disability), and individual accounts of finding and receiving health care. Recent examinations of the accounts of medical tourists extend the latter theme in an international direction. Work in these areas is interpretive and experiential, speaking to the enduring influence of humanism within health geography; at the same time, the focus remains “‘downstream’ of health care work” and thus it seldom engages directly with health-care providers or clinical practices (Andrews and Evans 2008, 762). Indeed, a subdisciplinary desire to be “postmedical” risks a disconnection from (and even dismissal of) the domains of biomedicine and health care. This tendency is problematic, because it narrows research opportunities, potentially blinding geographers to the ways in which these domains continue to evolve to promote health across multiple settings.

Theoretical perspectives

As described, the emergence of health geography implied a shift in the theorization of place and health by geographers interested in culturally sensitive, “postmedical” perspectives. In this vein, health geographers have conceptualized both “place” and “health” as constructed and experienced phenomena rather than understanding place as a neutral backdrop against which events unfold, and health as something that can be measured as a state of absences (in terms of the incidence of disease or mortality, etc.). These shifts reflected a wider “theoretical turn”
that began decades ago in the parent discipline of human geography as well as more recent theoretical reformulations in subdisciplines such as cultural geography that placed greater emphasis on process, power, resistance, and identity (Gesler and Kearns 2002).

What has distinguished health geography since its inception is a reluctance to take place and health for granted: both cultures of place and cultures of health matter when it comes to health experiences and health-care provision. This orientation, paired with a good deal of openness to philosophy and theory from outside the discipline of geography, has stimulated the theoretical diversification that health geography is known for today. The self-conscious application of social and cultural theory to place and health, and an attraction to “critical” theory in particular, has helped to distinguish health geography from the primarily positivistic subfield of medical geography. This theoretical “equipment” has provided a greater sensitivity to place-making, its intersection with multiple axes of difference (such as class, ethnicity, race, gender, and ability), and its role in shaping personal experiences of illness and disease, social exclusion, and health inequalities.

Health geography’s theoretical diversity can be organized into five general perspectives that reflect selective engagements over the past 20 years. First, the most enduring engagement with social theory by health geographers has been with perspectives that conceptualize social differences such as class, gender, and age. In particular, structural perspectives (e.g., political economy) have provided the theoretical basis for scholarship linking social inequalities in health to place. For example, Barnett, Pearce, and Moon (2009) show how in New Zealand, a country experiencing rapid restructuring, smoking cessation is more evident among European-background populations than Maori populations, and that cessation may be mediated by levels of relative deprivation in local environments. Second, theoretical engagements with humanistic perspectives that draw attention to personal experience and symbolic meaning of place have also been foundational. Taking cues from philosophies of meaning, such as phenomenology and existentialism, health geographers have highlighted the role of human agency in the creation of “lifeworlds” relevant to health and wellbeing.

Third, attempts to integrate these two perspectives represent another important theoretical perspective. This endeavor has entailed a search for theoretical balance between the constraints laid down by social forces and the freedoms individuals exercise in making decisions and taking action in the world. The potential value of such an approach was initially signaled by Kearns (1993), who called for engagement with the structure–agency dynamic that was animating many areas of social science inquiry. Important applications of this theory included Dear and Wolch’s (1987) examination of the ghettoization of discharged psychiatric patients within deprived inner city neighborhoods in North America. Subsequently, health geographers analyzed health-related behaviors and experiences as the product of the interaction of social structures and individual agency in particular locales. Today, the structure–agency debate is less prominent but its tenets still influence health geographers interested in landscapes of care, the dynamics of marginalization, and health promotion.

Fourth, health geography has been heavily influenced by postmodern and poststructural perspectives. Postmodern theories have been particularly significant given their emphasis on diversity in social and cultural life and their skeptical stance toward universal narratives that leave little room for difference. Postmodernism’s predilection for local knowledge has resonated
strongly with health geography’s quest for place-sensitive accounts of health and health care. Poststructural theories have been important to health geographers insofar as they problematize social categories such as gender, race, and class by showing how they are dependent on processes of differencing (distinguishing between like and different) and negation (privileging like over different) that are grounded in – and proceed through – space and place. Imbued with power relations, these systems of sociospatial exclusion provide individuals with sources of meaning and identity. This particular application is well executed by health geographers exploring “postasylum” geographies. Parr’s (2008) work demonstrates the strengths of a poststructural perspective. It explores how mental health clients experience community-based care; particularly its emphasis on sociospatial othering of people with mental differences and clients’ related attempts to rescript their lives in the community, demonstrates the strengths of a poststructural perspective. Here, the ideas of Foucault have been highly influential. Concern with discourse, as a medium of knowledge and power, is common within health geography, especially in analyses of landscapes and health policy. Foucault’s conceptualization of power, and its links to notions of discipline and governmentality, have received particular attention. Governmentality theory has found application in critical examinations of public health where it has been used to illuminate the political rationalities and power modalities invested in both run-of-the-mill and exemplary health policies.

Fifth, health geography has come to be influenced, more recently, by what can be called “relational perspectives” (Gatrell 2005). These perspectives are connected, by way of extension or critique, to the poststructural theories introduced earlier. They view individuals as embedded in multiple networks across time and space, and draw attention to the processes and interactions between people and social and material resources in the environment over time. One example is “complexity theory,” which in the context of health geography can be used to understand disease ecologies, health inequalities, health care, and health policy as complex systems characterized by emergent, nonlinear, and self-organizing interactions between a large number of elements, both human and non-human. Another example is actor-network theory, which treats phenomena such as “health” and “place” as enacted and relational effects of particular webs of association between people, material objects, and discourses (Duff 2011).

While each of these five perspectives brings strengths to health geography, various gaps remain. The status of the body, particularly its materiality, has maintained an uneasy and underexamined presence within health geography. In the early 1990s the notion of “body politics” (addressing the body as a site of representation, identity, and experience) was part of the debates that launched health geography; yet, a fully embodied health geography has been slow to develop. Writings on the body by health geographers have focused primarily on issues of representation and the body’s role as a site of medical inscription. The importance of the real and material physicality of the body has in some ways been overlooked, existing only in the shadows of humanistic and poststructural approaches.

A final dimension of theory in health geography pertains to the idea of “criticality.” On the one hand, invocation of critical theory has signified opposition to health inequality and an affinity with social justice and progressive social change. For example, critical geographies of health have included scholarship contextualizing health inequalities in specific localities, often linking these health outcomes to state restructuring (Barnett, Pearce, and Moon...
2009). On the other hand, the invocation of critical theory points toward interrogations of the very relationship between health and society (Parr 2004). For example, critical geographies of health have included Foucauldian-inspired scholarship on new public health, which illustrates how populations and individuals are managed and regulated through health discourses and related practices (Brown and Duncan 2002). While matters of criticality are often associated with cutting edge theories from outside the discipline, “applied” quantitative approaches are, in many ways, equally critical and instrumental to social change (Kwan and Schwanen 2009). Finally, many health geographers have come to practice criticality beyond academia via community engagement and, on occasion, overt political activism. In this regard, Parr (2004) distinguishes between praxis and critical thinking, the former referring to forms of activism and the latter referring to ideas and theoretical possibilities that open doors for new forms of praxis.

Methods

Health geography encompasses a wide range of research approaches, techniques, and materials. Census data and population health data gathered through randomized surveys are commonly used, as are quantitative techniques such as statistical and mathematical modeling approaches. These methods are typically combined with structural perspectives to quantify the relationship between place and health. In addition, maps and geographic information systems (GIS) have been instrumental in visualizing spatial variations in health and disease. As far as methods are concerned, however, health geography is renowned for the utilization of interpretive approaches that rely on qualitative techniques to gather together a wide range of texts and images for analysis. Given their sensitivity to context and meaning, qualitative approaches are well suited to a cultural focus on place and health. They are also aligned with health geography’s interest in the everyday contexts of health within and outside of formal spaces of medical care.

Common methods include interview and focus group techniques that allow people to speak in their own words. For instance, they have been used to decipher people’s views of environmental risks in the context of particular locales, and to decenter medicalized approaches to illness, health, and care, making room for subjugated knowledge and resistance. Whereas these talk-based methods offer insights into the meaning of participants’ experiences, more immersive techniques, such as observation, involve direct engagement with health-relevant settings. Observational techniques allow health geographers to construct interpretations of particular contexts through physical presence, and varying levels of participation in activities and events (Gesler and Kearns 2002). Bodily differences in terms of race, age, or ability can present barriers as far as interpersonal relations are concerned, and participating in field settings can require researchers to present themselves or to perform their bodies in challenging ways. Health geography has remained particularly sensitive to the complexity and politics associated with “fieldwork.”

Textual methods represent another common approach utilized by health geographers, and include a wide range of specific theoretical approaches including content analysis, semiotic analysis, and critical discourse analysis. They have also engaged with a diverse array of “texts.” Everyday texts from popular culture (e.g., film, literature, music) have served as rich data for unpacking health-place relationships. Health policy, both past and present, has also been an important data source. For example, health
geographers have analyzed health policies for the ways in which they represent the body in relation to broader ideological systems and associated power relations. Finally, landscapes themselves have served as important sources for textual analysis. Here landscapes are understood as sociocultural repositories which can be read as texts using methods such as semiotic analysis or critical discourse analysis. Such readings have been particularly influential in the development of the therapeutic landscapes concept, as well as in work interrogating the consumer landscapes of contemporary health care.

While health geography has a special affiliation with qualitative methods, quantitative approaches remain important. Moreover, as health geographers have engaged with specific theoretical debates, such as structure–agency or the complexity of health phenomena, they have been more inclined to utilize mixed method approaches that combine quantitative and qualitative data and analytical techniques. When combined, quantitative and qualitative methods may offer an especially comprehensive approach to understanding the richness of place and its relationship to health; however, the (in)compatibility of their underlying epistemologies – positivism and postpositivism – raises challenges, particularly in research seeking a “postmedical” orientation.

Finally, connected to health geography’s kinship with critical geography has been engagement with research approaches that seek to empower participants (Andrews et al. 2012). It is becoming more common for health geographers today to see their own vocation as being partly academic and partly activist, leading more health geographers to engage directly with institutions in civil society using participatory action research frameworks. These frameworks democratize the research process by involving, even empowering, those typically regarded as “subjects” in conventional research designs. Moreover, approaches such as “arts-based” methodologies involving film and photography have opened new doors to collaboration between geographers and research participants.

Key foci

Health geography encompasses an array of substantive concerns, theoretical positions, and methodological approaches, which give it remarkable breadth. To help give this diversity and pluralism some order, it is helpful to consider two key foci in health geography studies. First, health geography has advanced understandings of environment and health relationships, generally reflecting a fundamental concern about “unhealthy places.” Second, health geography has advanced understandings of therapeutic settings, generally reflecting a fundamental interest in “healing places.” In some ways, these key foci speak to the traditional concerns of medical geography – disease ecology and access to health care – and their continued relevance. They could also be interpreted as reflecting a broader tendency to see the environment itself in terms of either risk or care (Andrews et al. 2012). The story of health geography is very much about the myriad ways these original foci, as well as themes such as risk and care, have been modified through a reformulated understanding of place (as a complex cultural and symbolic phenomenon constructed through relationships between people and their everyday worlds) and expanded understandings of health (understood, for example, using socioecological frameworks or other theoretical perspectives).

The first focus, environment and health, encompasses fundamental interests in the various pathways by which environments deleteriously
affect health. This scholarship can be organized into three categories: environment and disease, environmental health, and environment and health inequality. Gathered together under environment and disease is scholarship dealing most directly with the relationship between contagious disease diffusion and natural and social environments. Environmental health scholarship, on the other hand, draws on perspectives such as environmental epidemiology to focus attention on the susceptibility and exposure of individuals to environmental pollutants in the air and water. Here one also finds a concern about the inequitable distribution of environmental risks, and political commitments to environmental justice. Finally, environment and health inequality refers to scholarship interested in the linkages between the kinds of places people occupy (e.g., deprived neighborhoods), health-related behaviors, and social inequalities in health. Cutting across all three categories is the important theme of risk. Whether it be neighborhoods, environmental contaminants, or behaviors, ascribing risk is an important practice in the “new” public health movement by which populations are governed.

The second focus, therapeutic settings, encompasses a wide array of research concerned with the healing process and how it unfolds in particular situations, settings, and milieux. Smyth (2005) has organized this scholarship into three categories: therapeutic places, therapeutic spaces, and therapeutic networks. Gathered under therapeutic places is the burgeoning scholarship undertaken in the therapeutic landscapes tradition, which seeks to understand how certain places acquire and sustain their reputation for healing. Therapeutic spaces encompasses varied scholarship on spaces of health care concerned with issues of accessibility, utilization, and more culturally sensitive work interested in the influence of consumerism on health-care landscapes. Work on therapeutic networks includes scholarship exploring the informal arrangements of care that exist outside biomedicine and draw on actors in civil society. A prominent theme cutting across therapeutic places, spaces, and networks is the notion of care. Acts of service, guidance, or protection engender diverse landscapes of compassion at multiple scales. Hence, for geographers care is something that simultaneously invokes moral feelings, interpersonal connections, and relationships between people, spaces, and places. In other words, health and wellbeing are always shaped by, and situated within, broader landscapes of care.

Increasing engagement with notions of care speaks, once again, to health geography’s breadth. Yet, as with any subdiscipline, certain limitations and silences remain. First, the field’s origins in high-income, predominantly English-speaking countries continue to delimit inquiry in certain ways; engagement with themes of global health and development is limited and conversations with work situated in other language traditions (e.g., French health geography) remain relatively rare. Second, it has arguably been slow to incorporate the insights offered by recent developments in social theory, such as those related to mobilities and posthumanism (the latter offers a potentially valuable counterpoint to the anthropocentrism inherent in health geography). Third, in terms of methodology, historical approaches remain scarce, and much could be gained from situating the health–place dyad in historical perspective. This said, the rapid development and diversification of health geography since the mid-1990s speaks to an inherent flexibility and an ability to respond to such challenges and opportunities.

References

Health inequalities are differences among human populations in physical or mental health that are associated with sociogeographical position and environment. Geographical inequalities in health exist both between and within countries at multiple spatial scales, ranging from differences between world regions and countries at the global scale to the level of local neighborhoods and individual people. For example, at the global scale, the World Health Organization (WHO 2014) publishes, in its Global Health Observatory Data Repository, information on the health of populations in different countries around the world. Data for 2011 showed that age standardized death rates per 100,000 population (which control for differences in the age structure of populations) varied from less than 350 in relatively highly developed countries, such as Japan, Switzerland, and Italy, to values over 1950 in countries with low levels of human development, such as Sierra Leone, Lesotho, and Swaziland. Even within regions of the world, international health inequalities are clearly evident. For example variations among European countries are reported (Richardson et al. 2013). Furthermore a study by Mackenbach et al. (2008) demonstrated that inequalities in mortality within national borders were relatively small in some southern and Scandinavian European nations but large in most countries in the eastern and Baltic regions, suggesting that the processes contributing to health inequalities vary among countries in Europe.

Health inequalities among countries are associated with differences in socioeconomic conditions and levels of human development. Evidence of this type points to the existence of a social gradient in health such that social groups (and geographical areas) that are more deprived typically have worse health than those that are more advantaged, and health outcomes worsen progressively in association with worsening social conditions.

Health inequalities within populations of countries are, in many cases, seen to be persistent or widening, even in situations where average health of the population is improving. Such persistence of health inequalities occurs despite knowledge that they are, to a large extent, avoidable. Health inequalities can be reduced if societies, communities, and individuals invest effort and resources to address health inequalities by tackling the causes of ill health, especially for those who are most disadvantaged. Health inequalities therefore represent a significant challenge for societies globally and often constitute a form of injustice, which is why differences in health in human populations are sometimes referred to in the literature as health inequities, rather than as health disparities.

Geographical perspectives on the “determinants” of health inequality

In geography, as in other disciplines focusing on health inequalities, research focuses on the “determinants” of health: processes which contribute to health variation. Some of these
determinants are associated with geographical factors that interact with health-related practices of individuals and population groups. This association is illustrated, for example, in research on whether unequal access to environments offering opportunities for healthy lifestyle choices may contribute to differences in healthy behavior; however, individual health-related behaviors are not the only determinants of health inequality.

To some extent health inequality is also influenced by varying access to, and use of, health services relative to need for care (e.g., see Gatrell and Elliot 2009, Chapter 5). Some of the earlier work in countries such as the United Kingdom drew upon the idea of an inverse care law, which argued that provision and access to health care is worst in areas where people have poorer health and need to use health care most. There is a long tradition in health geography of research focused on sociogeographical inequality in access to health services within countries (e.g., Joseph and Phillips 1984; Meade and Earickson 2000). Furthermore, differences in health-care systems also have important implications for inequalities in access to health care. There is an international debate, for example, over the extent to which universal health-care coverage can help to reduce health inequality.

More fundamentally, health inequalities depend on social and geographical variation in nonmedical determinants of health that are not limited to variations in individual lifestyle practices and use of health care. These determinants encompass dimensions of the natural environment (e.g., air, water, and soil quality, access to green space) and of the built environments (e.g., housing quality and built infrastructures such as roads or public spaces in cities). They also include social conditions such as social cohesion, social capital, income, and education. Wider health determinants arise from broader processes such as global climate change, ecosystems, and economic processes, as well as finer-scale differences in living conditions and social relations in local communities. Curtis (2004) emphasizes, from a geographical standpoint, how these different aspects of health determinants create interconnected "landscapes" of inequality in physical and mental health, associated with processes such as unequal power relations, conditions of poverty and wealth, disparities in consumption and commodification of health care, geographical disparities in the quality of natural environments, and varying psychological and symbolic values attributed to geographical settings by different social groups.

There is a growing literature on how to define geographical indicators of inequality in health determinants, as well as measures of population health outcomes, and how these might be used to assess levels of inequality in healthy environments for human populations. Such indicators may be used to assess varying “need” for medical care in the population and can be used to help determine a fair allocation of resources in relation to need for services. In addition to the choice of components for such indicators, related methodological issues from a geographical perspective include the significance of the geographical scale of analysis and the units used to assess health variation and associated health determinants.

Interpretations of health inequalities

The literature on health inequality among geographical areas has also given rise to debates about how to interpret these differences and the complexity of the processes that may lead to health inequality. For example, arguments have focused on how far we can interpret geographical health inequalities in terms of: vulnerability versus resilience; context or composition; health selection; or socially, culturally, or individually contingent and
relational interpretations of what constitutes health and its determinants.

Much of the literature is consistent with the idea that greater disadvantage in terms of health determinants is associated with greater health disadvantage; however, this relationship is not universal and there is a growing body of geographical research exploring “health resilience” among deprived populations. This research illustrates how populations in some socioeconomically deprived areas enjoy somewhat better health than might be expected, given the level of socioeconomic deprivation that they suffer (e.g., Cairns, Curtis, and Bambra 2012). Work in this field offers important new insights into strategies that may help to mitigate the impact of challenges to health for disadvantaged groups. It also underlines that it is not necessarily helpful for health geography to represent deprived individuals and communities only as “weak” or “vulnerable,” since they often display remarkable strengths as well as disadvantages.

Geographers have explored the value of compositional and contextual explanations as ways to make sense of health inequalities. Compositional interpretations consider that health inequalities arise from uneven geographical distribution of individuals with better or worse health. Contextual explanations argue that characteristics of the physical or social environment in an area affect the health of all individuals in the area to some extent, and that health determinants can be attributed to characteristics of places as well as people. There has been an ongoing debate over the relative importance of compositional (individual) and contextual (area) factors for explaining place effects on health and health inequalities. More recent interpretations of these arguments suggest that the idea of “contextual effects” is valuable in that it provides a way to draw attention to the significance of places for health; however, it is theoretically difficult to separate out independent “compositional” and “contextual” processes and it is probably more helpful to think in terms of various interactions between individuals and their environment that are associated with health inequality.

Another stream of international literature has focused on the idea that health selection may help to account for social and geographical health variation (health inequalities among socioeconomic groups may be partly explained by unequal social and economic chances over the life course for people with health problems, resulting in selection into disadvantaged groups of those in worse health). Also, it is argued that, in part, the geographical variation in population health may arise because those in worse health tend to be “trapped” in disadvantaged areas, or to move into these places, while those initially in better health tend to move to wealthier areas.

The significance of social and cultural differences in perception and experience of health, and of social and physical environments, also leads to interpretations of health inequalities and their determinants which invoke relational interpretations of space and place (Cummins et al. 2007). Geographers have emphasized the contingent and variable nature of our experience of landscapes that may be variably therapeutic or damaging for health for different individuals (Conradson 2005). Viewed from these perspectives we can understand that health inequalities need to be understood in terms of very diverse individual lived experiences, as well as at the aggregate population health level.

The research on health inequalities is important for health policies designed to address health inequality. It draws attention to the need to address inequalities in (ill) health, and access to and use of remedial services, and also informs policies designed to “reshape” the physical and social environment in ways that will help to
HEALTH INEQUALITIES

reduce the geographical and social inequalities of health determinants.

Health systems

Mark W. Rosenberg  
Queen’s University, Canada

Health systems are generally among the most complex public, private, or not-for-profit systems in a country. Their complexity stems from competing theoretical perspectives, the goals of the health system, the legislative and regulatory frameworks in which they are constituted, the people who provide the services within them, where those services are provided, and the totality of the services. An alternative way of conceptualizing health systems is to think about them in terms of the underlying values on which they are based. From the definition of legislative frameworks to how and where services are provided, to the values that underlie them, health systems are manifestly geographically expressed and infused with geographic issues.

The components of a health system

Two competing theoretical perspectives dominate thinking in the discussion of any health system. On the one hand, there is the desire to design health systems that maximize some notion of equity, usually framed as providing all necessary medical services to everyone within a society, regardless of their socioeconomic status. What is meant by necessary and for whom will vary from jurisdiction to jurisdiction. Competing with this theoretical perspective is the desire to design health systems that are efficient. In those health systems that are mainly constituted around private provision, efficiency usually means some notion of maximizing revenues and minimizing costs to the providers of services. In those health systems that are mainly constituted around public provision, efficiency criteria usually focus on minimizing costs but often ignore or treat the maximization of revenue as a secondary outcome. Minimizing the fees that patients pay is also a goal in some health systems, but mainly in those that stress equity over efficiency and/or where public provision is emphasized. The efficiency/equity debate is one well known to geographers, especially in research on health systems that examine the location and allocation of health services (Tanser, Gething, and Atkinson 2010). For example, if the goal is to emphasize equity in the location and allocation of hospital services, then the solutions generally focus on covering the total population and minimizing the average distance traveled by patients. If the goal is to emphasize efficiency, then the solutions generally focus on maximizing the number of people covered within a set distance of a facility, even if this is at the expense of some part of the population being beyond the set distance. The efficiency/equity debate is also part of larger debates within geography about what constitutes social and spatial justice (Rosenberg 2014).

The second level of complexity comes from the definition of the goals of a health system. While at a global level all member countries of the World Health Organization (WHO) share an agreed definition of health based on the Alma Ata Declaration, operationally no such shared definition exists when national and lower-level (state, provincial, or regional) governments articulate the goals of their health systems. Operational goals depend on whether the focus is on curative,
Health systems are constituted through legislative and regulatory frameworks. Legislative and regulatory frameworks depend on whether the health system is centrally planned or planned at various levels of government. For example, in the United Kingdom, the National Health Service (NHS) is defined through national legislation to provide health care throughout the United Kingdom on a uniform basis. In contrast, the Canadian constitution devolves the responsibility for health care to the provincial and territorial governments, except for health care for the military and Aboriginal peoples under some circumstances. The federal government, however, plays a role in setting some standards through the Canada Health Act, but mainly the provincial and territorial governments define their health systems through their own individual legislation. In essence, the NHS can be thought of as one geographically based health system, whereas in Canada there are ten provincial, three territorial, and two federal health systems, each with its own internal geographies.

Equity versus efficiency, the mix of goals, and central planning versus regional/local planning are layered within the triangle of how people pay for their care. Generally, health systems are distinguished by whether a person pays privately for care, the government covers health costs through a public health insurance system, or a person’s health costs are paid for through a not-for-profit entity (e.g., a religious organization or a union). In reality, it is rare to find a health system which is purely private, public, or not-for-profit, even if health systems are often labeled as such. For example, the health system of the United States is often referenced as a private health system and, indeed, private-sector principles dominate the thinking about how the US health system is organized. The US health system is, however, not purely private in that millions of US citizens are insured through Medicare and Medicaid (federally funded public health insurance systems for the older and poor populations, respectively), veterans often receive their care through Veterans Administration Hospitals (i.e., publicly funded hospitals), and many people using either private or public health insurance receive their care from not-for-profit hospitals (often operated by religious-based organizations). In contrast, the Canadian health system is generally described as a public, universal, comprehensive health system but there are some parts of it that are not publicly insured (e.g., cosmetic surgery or dental care for most people). As developing countries switch from private to public health insurance schemes, either as substitutes or as complementary systems, health geographers are contributing valuable research to explain why some people and areas are enrolling in the new public health insurance schemes and why other people and areas are generally retaining the old
HEALTH SYSTEMS

systems of paying and choosing traditional health systems over “Western” medicine.

The private/public/not-for-profit triangle is a fourth level of complexity which manifests itself spatially in how geographers think about economic access, social cultural access, and geographic access to care (Ricketts 2010). The direct barriers to economic access are generally related to the inability to pay for a health service, prescription drugs, or medical devices (e.g., a properly fitted wheelchair). Sociocultural access barriers are often measured through ethnicity, race, immigration status, cultural and religious values, and the ability to communicate in the official language(s) of the health system. Geographic access has mainly been viewed in terms of time or distance to the nearest health service, and/or the density of health services within geographically defined neighborhoods, spatial statistical units (e.g., census tracts), or administrative regions (e.g., health regions). Health geographers have focused on whether geographic areas where people can be characterized as having the least ability to pay for health care are the areas where people have the lowest utilization rates, and poorer health status, and whether those areas have fewer health services within or near them. Social and feminist geographers have focused on issues such as the concentration of women in the poorest-paying parts of the service sector and how being in the low-waged service sector constrains their everyday lives. For example, the inability to get paid for time off to see a physician (i.e., an indirect economic barrier) has many ramifications for access to health services. Understanding indirect economic barriers to health remains a research area in which health, social, and feminist geographers might do well to collaborate to understand the complexity of health systems.

A fifth level of complexity stems from how nations define their health systems’ labor forces. These have evolved from relatively simple conceptions based on physicians and nurses to conceptions which now include general practitioners (or family practitioners), medical specialists, various types of nurse specialist, nurse practitioners, midwives, dentists, various types of technician, physiotherapists, occupational therapists, mental health therapists, health promotion workers, emergency first responders, and various types of alternative health care and traditional medical practitioner. The geographic variations in practitioners within health systems have been subjects of two types of study by health geographers. The most common type has been to determine the ratio of practitioners to a population for a given set of geographic areas (e.g., the number of physicians per population per county) to determine whether geographic areas are over- or underserved, and what factors explain the geographic distribution of practitioners. Early studies seeking to explain the geographic distribution of medical practitioners in particular were mainly carried out using ecological modeling. More recently, weighted spatial regression and spatial autocorrelation models have been employed to explain the underlying factors leading to over- and underserved areas. Underpinning the interpretation of underserved areas is the assumption that a spatially equitable health system is one where there are no under- or over-served areas.

Closely linked to how the labor force is defined is the question of how services are defined and where those services are located within a health system. Health systems are often conceptualized as being inherently hierarchical, both organizationally and geographically. Conceptually, the most medically specialized care is found only in tertiary care hospitals. These are usually the largest hospitals found mainly in the largest cities within a country, and are often associated with university medical schools. Following the
HEALTH SYSTEMS

hierarchy of the urban system, large cities have secondary care hospitals equipped and staffed to carry out many forms of specialist care, and then smaller cities and towns have secondary care hospitals only equipped and staffed to carry out basic emergency and surgical care. The smallest towns are likely to only have primary care health centers, or sometimes even only primary care physicians practicing in solo or small group practices. In developing countries, or even in remote locations within developed countries, there might not even be primary care physicians but only health care centers staffed by nurse practitioners or health care workers specially trained to provide basic services in rural and remote communities. Health geographers often contribute to the debates about what are the appropriate services and levels of service for a community, given its size and place in the urban system or as a rural or remote community.

The other way health services and labor forces are organized is through regionalization. For example, from its inception, the NHS was organized based on regional health authorities deciding on how resources allocated from the central government should be deployed. In many countries, health geographers have participated in debates on whether regional health authorities should be implemented, in contrast to central planning, on the basis of both efficiency and equity criteria. Those geographers who favor regionalization often argue that regional decision-makers are in a better position to understand the needs within their regions than central decision-makers, who tend to favor the largest urban places where they are based. These types of argument are often framed in terms of local equity versus central inefficiencies. Those geographers who favor centralization often argue that only through centralized decision-making can a government ensure that everyone in its jurisdiction receives the same benefits from the health system, regardless of where they live. They also argue that rural and remote regions often do not have the expertise or the resources to deliver higher-order health services, and that small population sizes make it inefficient to fund higher-order services which will rarely be used. Health geographers who frame their arguments in these terms are often arguing for a notion of overall equity and against local inefficiencies. More recently, whether health services and labor forces should be organized or reorganized has been discussed in terms of primary care reform, hospital restructuring, and, more generally, health care restructuring (Barnett and Copeland 2010).

Health systems without boundaries

An alternative way of conceptualizing health systems is to think about them in terms of the underlying values on which they are based. Globally, the most common health system is what is often referred to as the biomedical system of health or the Western medical health system. It is the dominant view of health and health systems thinking in virtually all developed countries, and it is rapidly overtaking other traditional health systems thinking in developing countries. The biomedical system has its origins in the ideas that transformed natural science and industry at the end of the nineteenth century and the beginning of the twentieth century. It is based on a positivist view of science, treating the body in terms of its parts and subsystems, specialization, and emphasizing curative medicine, technology, and the use of pharmaceuticals created in laboratories to overcome specific illnesses. In contrast, there are much older health systems which tend to be holistic in their philosophies and emphasize natural remedies. Throughout the Middle East and South Asia, there remain millions of people
who follow Ayurvedic or Unanic health systems. In China and throughout Southeast Asia millions follow health systems based on Confucian principles. Ideas and practices from these major health systems can also be found in various other forms of traditional medicine in the developing world and alternative or complementary health systems (e.g., homeopathy, chiropractic, etc.) in the developed world (Andrews, Adams, and Sargent 2010).

In the developed and developing world, many people now utilize services that reflect a mixture of health systems. They might seek help through the biomedical system and a complementary health system for what ails them, or seek help for one health issue through the biomedical system and see a complementary health practitioner for other health issues. In many countries, some (or all) of the biomedical and complementary health systems are licensed by the government and covered under the prevailing health insurance systems, while others are not and must be purchased out-of-pocket. Beyond what is provided by governments or can be bought out-of-pocket, people are also their own care providers and providers of care for their families and friends (informal care). Formal and informal care systems together are yet another way of thinking about health systems (Milligan and Power 2010). Health geographers are uniquely qualified to analyze the cultural values and social and economic institutions that people must navigate to seek help from the health systems that operate in their local communities.

The very fact that no two health systems are alike means that health systems create their own unique sets of border issues, and in some cases have become globalized health systems. For example, some US citizens cross the border to Canada or Mexico to get basic health care because health care in the United States is often more expensive. Canadian and Mexican citizens cross the border to the United States to take advantage of the relatively shorter waiting times for some health services, for services not offered in their respective countries, or the perception that the quality of health care is superior in the United States.

At the global level, “medical tourism” can be viewed as a product of the broader forces of globalization. The private health sector is taking advantage of the processes of globalization to create global health systems which mainly cater to persons in the developed world seeking health services at lower costs or health services unavailable in their countries but available in hospitals and clinics in the developing world. What distinguishes these global health systems from local health systems is that they are developed almost exclusively to cater to international medical tourists and the local level elites at the expense of spending on health systems which cater to the needs of the local population. The private health sector also takes advantage of the tremendous social and economic inequalities in some developing countries to market their services in the developed world to the elites of the developing world. Border issues among developed countries, medical tourism, and the marketing of private health to the elites of the developing world are creating new global health system geographies. Health geographers are already contributing much to the understanding of these new systems of health, and there is much more research to be done.

Whether health systems are defined through their composition, the values that underpin them as local or global health systems, or as a product of borders and globalization, what is apparent in virtually all countries is the pluralism that now characterizes health systems. Whether sanctioned by a government or covered under existing health insurance systems, people seek their health care from several health systems they can
HEALTH SYSTEMS

access, given their own values and socioeconomic conditions. Health systems defined in these ways are manifestly geographical and deserve the attention of geographical thinking.

**Health-related behaviors**

Jamie Pearce  
*University of Edinburgh, UK*

**What are health-related behaviors?**

Health-related behaviors refer to the “actions of individuals, groups and organizations, as well as their determinants, correlates, and consequences, including social change, policy development and implementation, improved coping skills, and enhanced quality of life” (Glanz, Rimer, and Viswanath 2008, 66, 12). Health-related behaviors including smoking, diet, alcohol, and physical activity are considered to be major public health intervention points for improving population health and reduce inequalities. Health promotion work has traditionally tended to focus on individual-level interventions such as smoking cessation services. This approach can be criticized for “victim blaming” and failing to recognize that health-related behavioral “decisions” are shaped by the political, social, cultural, and physical contexts in which they are made.

**Geographers and health-related behaviors**

Geographers have been prominent in shifting attention from individualistic accounts of health behaviors to recognizing a wider set of factors. This work has emphasized that space and place are integral to understanding societal processes affecting health behaviors, societal processes operating at multiple scales from the global to the local (Pearce, Barnett, and Moon 2012; Pearce and Witten 2010). Although these geographical categories are not mutually exclusive, the framing emphasizes the ways in which places constrain and enable different forms of behavior at various spatial levels.

**Global**

At the global level, transnational corporations have been implicated in the disease burden of health behaviors through the direct promotion of products that are damaging to health. Diet, for example, is influenced by global food production systems and international trade agreements. The efficiencies associated with the industrialization of agricultural production have resulted in a wider range of food options. But these changes have prioritized commercial interests over nutritional priorities resulting in various agricultural incentives (e.g., food subsidies) to promote increased consumption. “Less healthy” products such as high fructose corn syrup and other processed foods have received higher government subsidies and therefore tend to be less costly than “healthy” options (e.g., fresh fruit and vegetables). The result is an apparent “policy paradox” whereby governments are on the one hand advocating for reduced consumption of high fat, salt, and sugar items but at the same time supporting the overproduction of these items.

The tactics of large corporate interests in subverting various global public health goals have also been scrutinized. Transnational tobacco corporations have developed strategies to counter...
HEALTH-RELATED BEHAVIORS

global and national tobacco control measures. Ploys that have been applied include: claims of damaging economic development and harming trade agreements; portraying tobacco control as an agenda promoted by high-income countries; questioning institutional mandates; and suggesting that precedent would be set beyond tobacco (Weishaar et al. 2012). For instance, an analysis of tobacco industry documents demonstrates how the tobacco industry has successfully lobbied and undermined the German Health Ministry’s position on the Framework Convention on Tobacco Control. Similar corporate tactics aimed at influencing the regulatory environment and increasing consumption have been adopted by the alcohol industry despite the public health implications of excessive drinking.

In addition to affecting favorable public policy outcomes, global factors falling outside of the public health sphere have been implicated in understanding health behaviors. For instance, levels of physical activity are affected by patterns of trade associated with globalization and urbanization. These structural adjustments have been associated with a shift from manual (and often physically active) occupations to more sedentary employment opportunities. Other macro-level changes including the rise in social and economic inequalities which have accompanied the global emergence of neoliberalism have influenced health behaviors such as smoking prevalence and cessation. A sharp rise in social and economic inequalities can result in a social polarization of smoking and smoking cessation. Similarly, macro-level factors that account for high levels of residential segregation, particularly in North America, may influence health behaviors through several interrelated material (e.g., racism and healthcare provision) and psychosocial (local social capital and community norms) pathways with more segregated areas tending to have higher smoking rates.

National and regional

While global-level factors are increasingly important in understanding health behaviors, many aspects of the national context are also pertinent. Public health policies, such as reducing the prevalence of smoking, harmful alcohol consumption, and poor diet, are often implemented at the national level. Geographers have explored the health implications of legislation including the unintended wider spatial effects. For instance, national regulation or codes of conduct for advertising food, particularly to children, varies between countries. Different levels of advertising and other marketing strategies between countries may partially explain international variations in childhood obesity levels. Similarly, the urban design strategies of central and local governments are likely to influence the “walkability” of urban areas. Mixed land use and the variety of destinations and community resources that are accessible locally, such as places of work, parks, and retail outlets, increase opportunities for local residents to walk or cycle around their neighborhood.

Other examples include “smoke free” legislation, which is widely recognized as a public health success. In jurisdictions where smoking in public places has been restricted, the prevalence of smoking and exposure to secondhand tobacco smoke has reduced with health benefits for smokers and nonsmokers. At the same time, the social acceptability of smoking – a key strategy of tobacco control – has continued to decline. Yet as geographical accounts have emphasized, smoke free legislation has also had unintended consequences. Smokers are increasingly displaced to marginal places such as outside of public areas or smoking areas in hospital grounds (Collins and Procter 2011). Smokers are often socioeconomically disadvantaged in a number of ways and being banished from public and private social spaces may lead to “spoiled” identities and
associated feelings of low self-efficacy, powerless-lessness, and hopelessness. The stigmatization of smokers has led to active resistance to cessation efforts, ultimately undermining tobacco control initiatives.

Local

Geographers have paid a great deal of attention to the role of local context (e.g., neighborhoods, schools, and workplaces) in understanding health behaviors. Local context can facilitate or constrain behaviors through two interrelated pathways: the local “practices” which affect what is a normal activity; and the place-based regulation which implicitly or explicitly polices behaviors. For instance, residing in a neighborhood without access to nutritious, high quality, and inexpensive food (a “food desert”) has been identified as a significant environmental barrier to healthy eating. Similarly, supermarket offers on energy dense food, or the local availability of fast food options, may influence purchasing decisions, and ultimately nutritional intake. Smoking and drinking behaviors and patterns are also affected by the local retail environment, especially among younger people. Other work has indicated that local green spaces may encourage people to engage in physical activity by increasing the opportunities for walking and cycling.

Geographers interested in health behaviors have offered epistemological and methodological insights such as emphasizing the complexities of everyday life, and incorporating a wider set of issues including attending to the concerns of those with impairments, disabilities, or chronic illness. Others have emphasized that places are nonstatic and dynamic and that richer accounts of place and health behaviors require an appreciation of the reciprocal relationships between place and behaviors. Behaviors can be conceptualized as a set of social practices embedded in place, which in turn is represented and mediated by local populations. The concept of “collective lifestyles” explains how individual behavior, collective behavior, and series of resources can be brought together in local settings to explain the uneven geographies of health behaviors (Frohlich et al. 2002). The approach is useful because it considers the role of wider structural and societal forces at the same time as the mediating effect of local neighborhood particularities.

Conclusion

Geographical understanding of health behaviors is not only an academic concern. Policy responses that target encouraging individuals to change behavior are likely to be inadequate. Successful interventions to affect behavioral change require concerted efforts at a range of scales, but with a particular emphasis on modifying the social, physical, and cultural context in which individual-level decisions are made.

HEALTH-RELATED BEHAVIORS

Heteronormativity

Linda J. Peake
York University, Canada

A shorthand term for normative heterosexuality, “heteronormativity” is a powerful global ideology, deeply embedded in the ways we know ourselves and the ways everyday life is lived. Normative heterosexuality refers to the encompassing regime in which an individual, sexually attracted only to a person of the opposite sex, is assumed to be a natural and universal norm or way of being human. Hence, the sexed bodies of male and female, the gendered identities of masculinity and femininity, and the gendered desire for the other are assumed to align with each other, and to prioritize the male and the masculine in a gendered hierarchy, forming what is referred to as the “heterosexual matrix” (Butler 1993). The power of heteronormativity is evident in the privileging it lends to other supposedly natural signifiers with which it is most associated – monogamy and marriage. In other words, heteronormativity is understood as most completely institutionalized when performed in a family setting in which a man and a woman, or more than one woman (though rarely more than one man), are legally bound to remain with each other for life. Given the dominance, albeit a diminishing one, of this nuclear family form, it can be argued that heteronormativity undergirds the constitution of the social, so much so that its signifiers are also desired by some nonheteronormative individuals. The assimilation of heteronormative ideals into queer lives, referred to as homonormativity, is revealed, for example, in desires to be married, to form long-term monogamous couples, and to have children. The practices and ideologies that normalize heterosexuality also inscribe difference, leaving other forms of sexuality as inferior and deviant such that those whose desires are neither permanent nor for the opposite sex are considered to fall outside of what is deemed natural, as are their sexual desires. Their failure to reproduce the social group causes them to be valued differently and to be subject to a range of (homophobic) disciplinary practices (Bell 2009). But hegemonic control over non-normative sexualities is constantly in a state of slippage as those who fail to subscribe to the regulatory discourses of heteronormativity rework gendered and sexualized boundaries.

It was in the 1990s that the study of heteronormativity entered the already established geographical field of sexuality and space, which explores the complex relationships between bodies – sexed, gendered, sexualized – and space. Initially, this field focused on the sociospatial construction of (white) gay and, to a lesser extent, lesbian identities, the attention paid to the fluidity of nonheteronormative sexualities and sexual practices speaking to the predominantly queer sexual orientations of researchers in this field and their desire to highlight alternative sexual identities to the unspoken heterosexual norm underlying studies of gender relations pioneered by feminist geographers. Another identifying characteristic of this early period
HETERO-NORMATIVITY

was the conceptualization of identities and the spaces associated with them – for example, lesbian neighborhoods, gay gentrified neighborhoods – as “always already” gay or lesbian. Later, however, the understanding of space and identity formation as fluid, negotiated, and contextual meant that attention turned to the quotidian performative practices through which spaces became heterosexualized (or cisgendered). Space is brought into being as heterosexualized through the repetitive performativity of bodies in gendered and sexualized practices and norms – sex in the bedroom, holding hands in the street, the man putting out the garbage, the woman doing the housework, and so on. So naturalized is the day in, day out, repetition of heterosexuality that it becomes taken for granted and invisibilized. Norms, for example, regarding the form of family life – husband, wife, children – and its immediate spatial expression of the home, arguably the most concentrated space of heteronormativity (Bell 2009), saturate the spatialization of everyday life. In this sense the sociospatial order is heteronormative (albeit contested), with both public and private spaces regulated through disciplinary discourses that normalize and fix heterosexual gendered and sexual behaviors and practices while rendering invisible nonheteronormative bodies.

Social and cultural geographers especially have engaged with queer theory, which is crucial for developing an analytical framing that explores the ways in which various spatialities beyond the bodily are reproduced (and contested) through heteronormative practices and identities – the home, the urban, the national, and the global being the sites of most interest. Social geographers have theorized not only the street, the home, and housing as sites of sexual regulation, but also the spaces of sex education, workplace, leisure and retail spaces, landscapes of sex tourism and of commercial sex, and spaces of love, caring, and intimacy. Historical geographers have also highlighted the links between sex, intimacy, white supremacy, and governance in studies of empire formation; deciding who could or could not marry and who could have sex with whom, where, and when, was an important preoccupation of colonial administrators and companies. This sociosexual logic of maintaining and reproducing territorializations, boundaries, identities, and interests is also now being interrogated in critical geopolitics, which is just learning to see with a queer eye. It is at the urban level that research has engaged in showing how heteronormativity is further reinforced by the values attributed to spatialities, such that attempts may be made to keep “good” forms of heterosexuality spatially separate from “bad” or “immoral” forms, either overtly through planning that may, for example, exclude areas of commercial sex work from residential areas, or more informally through unspoken rules of exclusion (Hubbard 2008). It has been shown that such rules also serve to make those whose sexual identities do not conform to the heteronormative matrix feel out of place and as not belonging. And, while some queer public spaces may have a formality and longevity, such as suburbs or gay villages, others are fleeting and ephemeral in their temporality, either by necessity, such as queer venues in countries where homosexuality is still illegal or gay pride parades, or simply by the passage of time, as particular ways of being sexualized and the meanings attached to their associated spaces fall out of favor.

Geographers have also outlined how the nation-state is deeply implicated in regulatory regimes that define the contours of heteronormativity. It is through the family that the state regulates sexuality via the heteronormative matrix, including such factors as age of marriage and social welfare and taxation policies
that influence the kind of families that are state-supported — usually those headed by a heterosexual couple — and those that are not. Nonheterosexual individuals and unions are being increasingly, if unevenly, incorporated into the national social body in terms of the decriminalization of certain sexual practices (such as sodomy) and inclusion in the nation’s military, and through changing contours of sexual citizenship, with, in some places, same-sex civil partnerships and marriages being increasingly recognized. These demands of the “new homonormativity” (to be considered “normal”) can be seen as converging with the now dominant neoliberal agenda, with its emphasis on individual rights and freedoms and self-surveillance. Puar argues that, just as nationalism has increasingly infused LGBTIQ movements and identities, contemporary US nationalism relies on claims to progressive sexuality. Building on the concept of homonormativity, she outlines its geopolitical equivalent of homonationalism, a regulatory script through which collusion is generated between some homosexual subjects and racial norms (read: predominantly white and middle-class gays and lesbians) and American nationalism through the “normalizing impulses of patriotism after September 11th, 2001” (Puar 2007, xxiv–xxv).

Current work on heteronormativity, having shifted from a focus on identity to questions of practice and performance (Hubbard 2008), is now challenging the universalizing notions of heterosexual domination and queer resistance, and investigating how all sexual orientations are far from solidified and fixed but are fragmentary, defying a categorization that names one component at the expense of all others, and instead celebrating a range of nonheteronormative ways of being as well as considering the multiple desires and bodies that can be accommodated within the category of heterosexual. The Eurocentric and white nature of queer theory has also come under question with the realization that modern sexual identity politics does not necessarily travel well. As urban queer identities in the Global North have and still are gaining acceptance and visibility, they are now defined by some as constricting, as where homonormativity is most advanced. And in the Global South, while some are proudly proclaiming their queerness, in other places they exist under the heteronormative radar as the political space for queerness does not exist and may still be punishable by death. The study of heteronormativity is also entering a “postqueer” stage as critiques are emerging of queer as neither necessarily liberating nor progressive, its contingency resulting in it being utilized in the service of scripts both radical — when it critiques sexualities in relation to class, race, and gender — and hegemonic — when it is tied to white supremacy. This malleability of heteronormativity will ensure that it remains deeply implicated in the organization and reproduction of the social at diverse scales from the bodily to the global.

High-tech industry

Yu Zhou  
Vassar College, USA

What is the high-tech industry?

While the high-tech industry has attracted considerable attention from geographers since 1970, a clear consensus on what constitutes such industries hasn’t formed. One definition is based on the characteristics of production. Sectors spurred by new innovation or enabled by highly complex and dynamic technology – such as the information, telecommunications, biotechnology, medical, pharmaceutical, aerospace, and digital media industries – are deemed high-tech (DeVol 1999). However, distinctions between high-tech and traditional or low-tech industries are often ambiguous, as new technologies also transform traditional industries. Another way to define high-tech industries is through characteristics of the workforce. For example, industries with a high share of highly skilled professionals – particularly in STEM (science, technology, engineering, and math) fields – and research and development (R&D) personnel are considered high-tech (Bay-Area Council Economic Institute Report 2012). According to this definition, traditional extraction industries such as oil may also qualify. Beyond manufacturing, services such as engineering and design are also the core of the high-tech industry. It is also worth noting that what constitutes the high-tech industry is context specific. Sectors that are traditional in advanced countries, such as the automobile industry, are high-tech in developing countries.

Why study the high-tech industry in developed countries?

The high-tech industry emerged as a distinct analytical category during the 1970s and 1980s. Since the 1960s, technological advances in microelectronics, digital telecommunication, robotics, biotechnology, and other sectors have spurred the rise of new industries, such as information technology (IT), and transformed existing ones by reinventing organizational and production protocols. Facilitated by technological developments, labor-intensive manufacturing sectors, such as textile and low-end electronics production, gradually relocated to developing nations. Certain original manufacturing cores in industrialized countries suffered from steep decline and depression as a result of this shift while emerging high-tech industries experienced rapid growth. Labor and industrial statistics in the United States show that the growth of high-tech sectors outpaces that of others by a ratio of 3–4:1, and is the strongest contributor to regional growth. High-tech workers earn a substantial wage premium and enjoy far lower unemployment rates than workers in other sectors (DeVol 1999; Bay-Area Council Economic Institute Report 2012).

Global commodity chain and global value chain analyses by Gereffi (1994; 1996) suggest that the highest value-generating segments of production – usually the most high-tech and knowledge intensive – are concentrated in developed countries while low-wage
manufacturing activities are outsourced to developing countries. Global production network (GPN) theory argues that production processes are organized hierarchically. Top tier, large transnational corporations (TNCs) assume the strategic, technological, and organizational leadership of global production, and use developing countries as low-cost manufacturing or resources bases (Coe et al. 2004; Ernst and Kim 2002). Intellectual capacity, rather than physical input or natural resources, thus drives growth and expansion of new industries (Powell and Snellman 2004). The emergence and expansion of the intellectual property rights regime, especially the TRIPS (Agreement on Trade Related Aspects of Intellectual Property Rights) regime under the World Trade Organization, provides institutionalized political, economic, and ethical support for the knowledge-based high-tech industry. In short, high-tech industries have become the harbinger of industrial, employment, regional, and institutional growth in developed countries.

High-tech industry in developing countries

Interests in high-tech industry spread to developing countries in the 1980s. This is in part because some of the most successful newly industrialized economies – South Korea, Singapore, and Taiwan – have become prominent players in the global high-tech sectors. Their experiences demonstrated that technological catchup could occur through integration into global markets. As large countries such as China and India embraced globalization, they also experienced rapid development of their high-tech industries through integration into GPNs.

However, being a part of Western-led GPNs and intellectual property regimes also creates anxiety in developing countries. Political and industrial leaders worry that being locked into Western orbits may limit opportunities for indigenous technological development, permanently trap their economies in low-end manufacturing, and create dependency on imported intellectual property rights. Large developing countries such as China, India, and Brazil have vast human resources and large domestic markets, thus have long aspired to achieve technological autonomy from the West.

China is the most aggressive in promoting R&D investment from domestic sources (Zhou 2008). The technological content of China’s exports rose steadily as more multinational firms outsourced their upstream production to China from 2000, and as China's indigenous firms and research institutes increased their R&D spending. Patent applications and other scientific indexes also rose sharply in China (Crookes 2012). However, a study on Apple products showed that even though final assembly of the most innovative products takes place in China, the contribution of China to value-added is only a tiny fraction of the total (Xing 2014). This suggests that while China is making high-tech products, technological upgrades are still largely driven by external sources with limited indigenous inputs.

In India, the debate on the high-tech industry revolves around its contribution to the national economy. India is the world’s largest exporter of computer software and tech-services (Gregory, Nollen, and Tenev 2009). As the most prominent and dynamic sector of India’s economy, IT has transformed the lives of many middle-class Indians and inspired a new optimism and confidence in the country. Yet, IT growth has been overshadowed by the continued poverty of the vast majority of the Indian population, and by slower change in the rest of the Indian economy. Some argue that dependence on a relatively
small proportion of the labor force has failed to engender broader social development in India (Barnes 2013; Gregory, Nollen, and Tenev 2009; Xiang 2007).

Brazil has long had some of the most technologically sophisticated manufacturing industries in the developing world, including its IT, automobile manufacturing, and aerospace sectors. However, commodities and raw material extraction dominate its economy (Schoonmaker 2002). Brazil’s dependency on large foreign TNCs also raises similar questions about indigenous capacities as those raised in China and India.

Examples of high-tech development in developing countries suggest that, while the industry can enjoy spectacular growth in these countries, it does not necessarily lead to transformations of indigenous capacities or higher levels of economic or social development. Despite the difficulties and occasional disappointing results, what is certain is that the desire, expertise, and supporting institutions for high-tech development are here to stay.

Where does most high-tech industry locate?

The rise of IT makes it tempting to think that location no longer matters for the high-tech industry. But this is not the case. Scholars have found that the global diffusion of high-tech industry coexists with regional clustering. Several scholars explain the existence of innovation hubs through the provision of human resources. Florida (2002) argues that “the creative class” – highly educated and innovative populations – is instrumental in creating an environment conducive to the high-tech industry. Others stress the roles of unique regional institutions that foster the social, cultural, and organizational synergy underlying sustained technological dynamism (Storper 1997; Scott 1988; Saxenian 1994). Still others focus on the role of public policies and investment in inducing high-tech development (Markusen et al. 1991; Castells and Hall 1994; Lazonick 2007).

Governments around the world encourage high-tech growth through infrastructure improvement, preferential land and tax policies, grants to universities, targeted industrial policies, tariff reduction, environmental regulation, and so on. Not all have succeeded. However, Silicon Alley in New York City, Silicon Glen in Scotland, Tel Aviv in Israel, Hsinchu in Taiwan, Zhongguancun and Shenzhen in China, and Bangalore in India are examples of a global network of innovative high-tech centers.

HIGH-TECH INDUSTRY

Hillslopes

Carol P. Harden
University of Tennessee, USA

A hillslope is the flank of a hill—a topographic feature of a size that would require minutes to hours to ascend on foot. Hillslopes are sloping land surfaces mantled with soil or other unconsolidated materials and, in most environments, covered with vegetation. In studies of hydrological processes, hillslopes may refer to all portions of the land surface except surface water bodies. Hillslopes are local places that affect the human experience in a landscape. The downslope movement of Earth materials and water on hillslopes creates localized differences in the physical characteristics of a place, thus presenting a range of opportunities and challenges for people, as well as for other species of plants and animals.

Hillslopes may appear everlasting to human beings, but they are dynamic environments that, like entire mountain ranges, change over the span of geologic time. Rates of change on hillslopes vary, from slow, almost imperceptible changes brought about by soil creep and soil erosion, to rapid, dramatic changes caused by landslides and debris avalanches. Gravity pulls everything downward on hillslopes, including raindrops, rocks, soil, skis, and skateboards. Geomorphologists (who study landforms and land-forming processes) are drawn to hillslopes as places to examine landscape change, while city planners, engineers, skiers, and homeowners need to know whether hillslopes are stable so that they can avoid hazards that slopes may pose to people and structures.

Hillslope form

A hillslope can be viewed as the inclined hypotenuse of a right triangle (Figure 1). The angle (\(\alpha\)), the slope gradient, can be measured directly with a protractor or clinometer, or calculated when the height (\(y\), the difference in elevation between top and bottom) and length (\(x\), horizontal distance) are known. Mathematically, this \(y/x\) ratio (called “rise/run” by carpenters) is the tangent of the slope angle. Multiplying the \(y/x\) ratio by 100 expresses this gradient as a percentage; alternatively, the arctangent function expresses the gradient in degrees (e.g., a \(y/x\) ratio of 0.25 (25%) represents an angle of 14°).

Human perception frequently exaggerates the steepness of hillslopes. A 100% gradient is the equivalent of a 45° angle. People rarely venture onto such a steep slope. The seemingly vertical slopes of ski jumps in international competitions rarely exceed 36°: the steepest portion of the in-run has an angle of between 28 and 36°, and the steepest part of the landing is between 35 and 36° (Ski Jumping 2016). Even indoor stairways rarely have gradients greater than 30°. In the United States, the maximum allowable grade on interstate highways is 6% (3.4°), with some exceptions in mountainous terrain. Gradients of roads that merit special warning signs for vehicles (Figure 2) may appear insignificant when drawn on paper.

The parts of hillslopes are named anatomically, with the top of the hill called the head of
HILLSLOPES

Figure 1 The gradient of a hillslope (α) is the angle between the slope and an imaginary horizontal line. The length of line x represents the length of the horizontal projection of the slope; the length of line y represents the difference in elevation between the top and bottom of the slope.

the slope, the lowest part called the toe, and the lower portion above the toe called the footslope. Gravity moves materials from higher to lower slope positions over time; thus, the footslope contains material derived from upslope sources. Soils tend to be thinner on upper slopes, which are sites of erosion, and thicker on footslopes, which are sites of deposition. These characteristic, hillslope-related differences in soils are known to soil scientists as a soil catena or topo-sequence. Hillslope position is thus an important component of the classification and mapping of hillslope soils.

The shape of the longitudinal profile of a hillslope is affected by its geologic history, structure, and materials, and by the influences of climate and vegetation on hillslope-shaping processes. Where hillslope materials are cohesive and do not readily break down into smaller particles, the processes that move slope materials are considered to be weathering limited. In this case, a scarcity of movable particles, relative to the capacities of gravity and flowing water to cause movement, causes the hillslope shape to be controlled by the form of the underlying rocks or cohesive materials. In the opposite case, on transport-limited segments of hillslopes, unconsolidated materials accumulate and reshape the hillslope. Often, hillslope processes at the head of a slope are weathering limited (where sediment transport exceeds sediment production), while those at the foot are transport limited (sites of accumulation). In between, where weathering and deposition are in sync with erosional processes, a hillslope can maintain a constant profile. On slopes where erosion by flowing water is a dominant process, the differences between the erosional and depositional regimes of upper and lower slope segments produce a concave profile, with a steeper, weathering-limited, upper portion and a less steep, transport-limited, portion at the toe. Some hillslopes, undercut at the toe by a river or by anthropogenic excavation, are convex in profile, as are hillslopes on which soil creep is a dominant process.

Hillslope dynamics

In the physical system of a hillslope, the angle of the slope determines the proportion of the force of gravity that can move water and materials downhill. Gravity can be illustrated as a vector of force aimed at the Earth’s core. Conceptually, that vector can be subdivided into two components: one component of the force of gravity that pulls materials toward the Earth and one pulling materials (e.g., soil particles, rocks) downhill, parallel to the slope (Figure 3). If the land surface has no slope, the entire force of gravity acts to pull materials toward the Earth’s core, thereby holding them securely in place. When a hillslope is steep, the downslope component of the force of gravity can exceed the combined resistance to motion provided by friction, cohesion, and the component of gravity that pulls materials toward the slope. In this situation, gravity pulls the materials downslope. People become acutely aware of the
downslope component of gravity when frictional resistance is low, as when a sloping surface (e.g., a parking lot) is covered with ice.

On hillslopes, the potential energy of materials at rest is determined by the height of the slope, the mass of the material, and the downslope force exerted by gravity. This means that longer, steeper hillslopes store more potential energy. When materials (e.g., rocks, mud, soccer balls, or sleds) begin to move downslope, potential energy becomes kinetic energy. Kinetic energy \((KE)\), the energy of the mass \((m)\) in motion, is proportional to the square of the velocity \((v)\) of the moving mass \((KE = \frac{1}{2} mv^2)\). Small increases in velocity can substantially increase the kinetic energy of the moving material. Like the energy transferred to other masses by a cue ball on a pool table, the kinetic energy of moving snow or mud on a hillslope can transfer to other masses, such as more snow, more mud, or trees, houses, and cars, and set them, too, on a downslope course of motion. The transfer of kinetic energy by moving water on a hillslope dislodges and moves soil particles, causing soil erosion. Where slopes are steep and long, the speed and energy of gravity-driven mass movements of materials can be stunning. We recognize these rapid, dramatic movements as avalanches, landslides, and torrents.

**Hillslope processes**

Precipitation interacts with physical and chemical attributes of soil, bedrock, and vegetation on
HILLSLOPES

Figure 3  The force of gravity (g) on a mass (M) can be represented by two vectors of force, one (Mg sin α), which is parallel to the slope, and one (Mg cos α), which is perpendicular to it. As the slope angle (α) increases, the parallel (downslope) component of the force of gravity increases and the perpendicular component decreases.

hillslopes to determine the volume, timing, and chemistry of water that flows to streams. Water moves downslope over the land surface (overland flow) and through the soil (throughflow), with connections between these two pathways where throughflow emerges from or overland flow infiltrates into the soil. Water on hillslopes plays a key role in moving sediment and altering the shape of a landscape.

Downslope movements of materials can be categorized as soil erosion, the entrainment and movement of individual soil particles by flowing water, or mass movement, the downslope movement of masses of slope materials caused by gravity.

Soil erosion

Water flowing downslope can dislodge soil particles and push or carry them to a lower position on the hillslope or to another location beyond the hillslope. Rates of soil erosion depend on the exposure and erodibility of soil particles and the energy of the moving water. In the 1960s, researchers from the US Department of Agriculture published the Universal Soil Loss Equation (USLE) to predict annual soil losses (A) from hillslope plots in croplands by unchannelized rainfall runoff (Wischmeier 1976). An empirical relationship based on 10,000 plot-years of experimental data, the USLE has since been refined and extended. The outline of the equation, $A = RKLSCP$, serves as a checklist of factors contributing to soil erosion on hillslopes. The $R$ factor represents the erosivity of rainfall, recognizing that some locations receive more intense rain than others. Soil erodibility ($K$) represents characteristics of the soil that promote or resist detachment by rainfall. Some components of soil erodibility, such as soil texture, remain constant over periods of years, while others may change frequently. Soil moisture, for example, varies spatially and changes within hours, days, and seasons. The length ($L$) and gradient ($S$) of a hillslope affect the kinetic energy of flowing water, with longer, steeper slopes generating faster flow velocities. The $C$ (cropping) and $P$ (practices) factors reflect the nature of the vegetative cover on the hillslope and allow users of the equation to model the effects of different management practices on soil losses.

Hillslope soil erosion is a natural process that acts over scales of geologic time to redistribute materials and wear away the high points of a landscape, but human activities often increase erosion rates. Human interventions, including agriculture, construction, and mining, remove vegetation, thereby increasing the exposure of bare soil to the impact of raindrops and the effects of rainfall runoff. Practices that degrade the health of a soil, such as unsustainable farming or industrial pollution, reduce the ability of plants to protect the soil surface. Heavy vehicle use and overgrazing promote soil erosion both
by removing vegetative cover and by compacting the soil surface so that rainfall is more likely to run off than be absorbed and stored in the soil.

Some human interventions are designed to reduce soil erosion. These include decreasing slope gradient and length by building terraces, plowing along the contour, or interrupting flow with vegetated strips. Such practices reduce the occurrence of high-energy, erosive flow across the hillslope and facilitate infiltration. Farmers can reduce the erodibility of soil in agricultural areas by using no-tillage agricultural practices to preserve soil structure and promote the storage of organic matter in the soil, or they can reduce the duration of exposure of bare soil to rainfall by planting cover crops.

The amount of soil eroded is reported in linear units of the depth of land lost (millimeters per year) or as a mass of material per area (tons per hectare). Although soil losses in the range of millimeters per year are nearly imperceptible over a year or two, they add up over decades and centuries. Seemingly minor erosional losses may be important in the short term because the uppermost layer of soil, the first to be eroded, contains more nutrients and organic matter, and captures and retains moisture more effectively than underlying layers. Moreover, soil erosion on agricultural lands can also remove seeds, fertilizers, and other valuable inputs, making eroded hillslopes less productive.

On hillslopes, flowing water finds the path of least resistance. Once channels form, the flow of water becomes deeper, hence less affected by friction and therefore faster, with more energy to erode and transport soil particles. Rills and gullies accelerate the removal of soil and water from hillslopes and link hillslopes to stream channels. Away from their hillslope origins, soil particles alter aquatic habitats and occupy space in channels and reservoirs.

Mass movements

Whether, or when, hillslope materials move downhill depends on the balance of forces acting on them. Driving movement is the downslope component of gravity. Resisting movement are the component of gravity that pulls materials toward the Earth and characteristics of slope materials – cohesion, friction, and structural stability – that hold them in place. Over human timescales, the dynamic nature of hillslopes can be hazardous, or at least inconvenient, for human occupants and the infrastructure of human society. With the ever-present force of gravity working to move materials downslope, it is important to be aware of the conditions that promote the stability or instability of hillslopes. Armed with this awareness, people can avoid or alter places where slope instability would create danger or cause problems.

Engineers calculate a factor of safety when they determine the slope angle to build for a highway embankment or other constructed slope. In its simplest form, the factor of safety is the ratio of forces that resist movement (based on mass, strength, gradient, and cohesion of the materials, minus the reduction of cohesion by porewater pressure) to the gravitational force that drives movement (a function of mass and gradient). The factor of safety of a stable slope is well above 1.0. A factor of safety that approaches 1.0 for a constructed or natural slope indicates a threshold condition in which a very small change, such as added weight or an increase in porewater pressure, could tip the balance and cause a mass movement. Types of mass movement, ranging from rockfall to the failure and motion of entire hillslopes, are briefly described in the following paragraphs.

The simplest case of mass movement is rockfall. A rock falls from an outcrop onto a lower position on a hillslope when the force of gravity acting on the rock exceeds the forces that hold
the rock to the outcrop. Exposure of a rock to the effects of weathering processes creates cracks and chemically alters minerals within the rock. Both mechanical and chemical weathering processes reduce the resistance of the rock to the force of gravity. How far downslope a falling rock travels depends on factors that include the mass and shape of the rock, the slope gradient and length, the roughness (frictional resistance) of the slope, and whether any barriers are encountered. Rockfall is a common hazard in places where people have excavated rocky hillslopes to construct roads or have occupied lands below cliffs. Gravity causes the rock to fall, but additional factors, such as the expansion of freezing water in cracks or vibrations from human activity or earthquake, can cause a rock to fall sooner rather than later. A dramatic example of rockfall was documented in 2014 in Ronchi di Termeno (northern Italy), where two unusually large boulders tumbled from a cliff, rolled through a barn, and came to rest in a vineyard (Woo 2014).

Soil-mantled hillslopes frequently show evidence of the type of mass movement known as soil creep, a process in which the effect of gravity on soil particles causes them to slowly migrate downslope. Evidence of soil creep appears as tilted fence posts, tilted headstones, or bulging retaining walls. One cause of soil creep is that soils containing certain clay minerals swell when wet and shrink when dry. Swelling pushes particles outward, perpendicular to the slope surface, but gravity affects the direction of shrinking, pulling the soil vertically downward. The impact of raindrops landing on bare soil has a similar effect, in that most soil particles splashed up into the air will land downhill of their initial position. The net effect is the gradual movement of soil particles down the hillslope.

Entire hillsides can slide downslope, gradually or catastrophically. The release and movement of all or part of a hillslope is referred to as a landslide. Specialists subdivide landslides into categories based on the geometry and magnitude of the mass movement. In a planar landslide, a mass of the land surface slides over an inclined surface. Planar landslides occur where the substrate contains layers of rock or regolith, with contrasting characteristics of strength and permeability, which are tilted at approximately the same orientation as the hillslope surface. The surface material, possibly including forests and buildings, detaches and slides downhill over a subsurface layer. Gravity causes the movement, but the presence of water can contribute to instability by reducing cohesion and friction.

Some of the most dramatic mass movements in human history have been planar landslides. One was the Gros Ventre slide in Wyoming on June 23, 1925, in which 38,000,000 cubic yards of material, including a forest, slid down into a valley with so much momentum that some of the material traveled 90 m up the opposite hillslope. Eyewitnesses estimated that the entire movement took less than three minutes (US Forest Service 2016).

Other landslides, small to large in magnitude, rapid or gradual in speed, have curved surfaces of rupture. These are called rotational landslides because the head of the slide rotates before moving downslope (Figure 4). Slow-moving rotational landslides may be called slumps, especially if they are relatively small (e.g., on a roadside or streambank). The outward rotation of a mass of hillslope leaves a steep escarpment with one or more low-angle steps near the head of the slide. Water can accumulate on these steps, forming sag ponds. Seepage of ponded water can further destabilize the subsurface material and cause further movement at the same site.

The range of processes categorized as mass movements grades from gravity-only processes (e.g., rockfall) to downslope movements that...
involve increasing amounts of water. Water plays a key role in debris flows, which carry a mixture of rock-particle debris, water, and air downslope as a thick slurry. Debris flows require an accumulation of rocks and fine sediment and enough moisture available to initiate movement. More than 40–50% of the mass of a debris flow is sediment; the remainder is water. A debris flow can occur on an unchannelized hillslope, but more commonly follows a pre-existing channel. It can move quickly, ripping out trees and built structures. Acting like wet cement, the moving mass of debris can carry much larger rocks than could be moved by water alone (Figure 5).

Debris flows in steep channels can achieve velocities of meters per second and travel tens of kilometers. The size of the debris in debris flows ranges from clay to large boulders. When the flow stops, the material stops, characteristically as a deposit of fine sediment supporting a collection of larger particles. In wooded regions, debris flow deposits may contain woody as well as rocky debris. A mudflow is a special case of debris flow in which most of the grains are smaller than sand. Some of the most spectacular and devastating mudflows have occurred on the flanks of volcanoes, where abundant, movable volcanic ash combines with water from rain or melted ice to form a mobile slurry of debris. Examples of volcanic mudflows, called lahars, include the one initiated by the eruption of Nevado del Ruiz, which buried a portion of the city of Armero,
Figure 5  This debris flow in Iceland transported large boulders down the hillslope. Several cows near the fence in the foreground provide a sense of scale. Photo C. Harden.

Colombia, and the one caused by the eruption of Mount St Helens (Washington state, USA), which left deep deposits in the Toutle River valley.

The term earthflow is applied to slow-moving landslides, typically on hillslopes of less than 20°. Earthflows may remain active for years, with movement occurring when sufficient moisture is present. Earthflows in California and New Zealand move during periods of winter rain. They may move a few meters per year, leaving a lumpy or cracked topography that extends over hectares. On hillslopes underlain by permafrost, thawed surface soils slip downslope over the frozen layer in a mass movement process called solifluction. Solifluction is aided by the lubricating effect of liquid water on the impermeable frozen layer of soil.

Hillslopes as landscape subsystems

Hillslopes are essential units of analysis in hydrologic systems and watershed models. The surface characteristics of a hillslope determine whether precipitation will infiltrate into the ground or flow across and through the soil to join streams. In turn, this division of hydrologic pathways controls the rate, volume, and quality of water reaching streams, and it affects the
moisture available to plants, the rate of recharge of groundwater, the likelihood of a flood, the chemistry of the water, and the energy available to cause soil erosion. These factors are interrelated, with vegetation playing a key role in site-specific feedbacks involving moisture, soil condition, hillslope stability, soil erosion, and rainfall runoff (Marston 2010). At broader scales, the hydrologic characteristics of hillslopes affect the volume of water stored in aquifers and river systems, and the chemistry and sediment loads of surface waters.

Among the systems of feedbacks affecting hillslope systems are the actions and responses of people. People alter drainage, vegetation, and surface characteristics of hillslopes through engineering, agriculture, trampling, and paving. In the processes of rainfall interception and transpiration, trees can use 40–80% of the precipitation that falls on a hillslope. Therefore, removing trees from a hillslope creates, in the short term, a much wetter hillslope, and planting trees on hillslopes is a well-known strategy for removing moisture. By altering the water budget through deforestation or afforestation, people affect the stability of a hillslope. Sometimes this is deliberate, as when trees are planted to dewater a slope to increase stability; at other times, the consequences are unintended, as when deforestation, without regard to hillslope hydrology, is followed by landslides.

Research on hillslopes

Recent research on hillslopes by geographers and others focuses on multiple themes: (i) better understanding hillslope hydrology and linking it to broader-scale patterns of water and sediment movement, (ii) improving the ability to predict slope instability and mitigate hazardous situations, (iii) understanding hillslope-scale change to improve models of landscape evolution, (iv) using hillslopes as examples of systems in broader studies of the organization and feedbacks of complex systems (e.g., Marston 2010; Poulos et al. 2012), and (v) deducing characteristics of environments and materials on other planetary bodies from imagery of hillslope form. New techniques have stimulated new avenues of research. High-resolution imagery and greater computing capacity have enabled researchers to link spatial scales and numerically model complex systems, and stable isotope analyses have provided new views of the pathways and residence times of water on hillslopes.

Conclusion

Hillslopes are important units of study. From a theoretical perspective, hillslopes are landscape subsystems in which organisms (plant, animal, microbial, human) interact with their environments and physical and hydrological processes interact with materials to alter landforms. From a practical perspective, the dynamic nature of hillslopes will continue to pose challenges to societies that expect permanence in landscapes and invest in rigid infrastructure. As places that integrate abiotic, hydrologic, and biotic (including anthropogenic) processes and feedbacks, hillslopes are essential building blocks of landscapes and landscape analyses at all scales.

Historical geography

Akihiro Kinda
Kyoto University, Japan

Historical geography studies phenomena occurring over time while simultaneously analyzing the spatial matrix of those phenomena. It maintains an attitude to research that embraces both time and space, for the most part focusing on various spatial phenomena that have undergone changes over the passage of time. If we think of it as a subdiscipline that brings time and space into its purview at the same time, it is the study of geography into which time is incorporated; it can also be, as exemplified in the French Annales school, the study of history that incorporates space, but this entry centers on historical geography from the vantage point of geography. In 1975 the first issue of the Journal of Historical Geography proposed a widened discipline: “The writings of scholars of any disciplinary provenance who have something to say about matters of geographical interest relating to past time.”

The questions that historical geography asks reveal curiosity about places of the past. Think of the Histories of Herodotus, written in the fifth century BCE, with their abundant geographical information on ancient Greece and much of the ancient Oriental world. Many people of later generations – not only historians but also those interested in the eastern Mediterranean region of ancient times – were eager to identify where those places were that Herodotus described in his description of historical occurrences. A geographical work called Shui jing [Water Classic] had the same effect in China. This account of China’s waterways is thought to have been completed during the Early Han dynasty (second and first centuries BCE). Such information, relating to water control and use, was extremely important in China, where flood control was vital for rivers like the Huanghe (Yellow River), which regularly overflowed, and where from time to time the courses of rivers were changed by flooding and by the building of artificial levees or dikes. This treatise was considered highly valuable, and in the early sixth century 40 volumes of commentary were completed, called the Shui jing zhu [Commentary on the Water Classic]. By around the tenth century, however, a part of the commentary was lost and some of it was said to have been mixed in with the original work, which jeopardized its integrity. During the Ming and Qing dynasties (fourteenth to early twentieth century), specialists in historical artifacts and documents struggled to replicate the whole commentary. The Shui jing zhushu [Annotation of the Commentary on the Water Classic], completed in 1615, is one of the most famous of these attempts, and in the eighteenth century the entire 40 volumes of the original commentary were restored and republished. These are just two examples, but a desire for knowledge about places linked with bygone phenomena in politics, history, geography, or literature was the wellspring of a general interest in the themes of historical geography, the chief aim of which was to identify the present-day location of places named in the past.

In his lectures on physical geography, Immanuel Kant (1724–1804) articulated the idea that there is a causal relationship between human phenomena and natural phenomena, and that the concept of the whole derives from
various phenomena within the framework of space. Space-oriented accounts are geography, he proposed, and time-oriented accounts are history. History, therefore, deals with phenomena in temporal sequence (zeitliche Nacheinander), while geography considers phenomena in their spatial proximity to one another (räumliche Nebeneinander). That is to say, Kant’s categories make geography the study of space without the time dimension, and history the study of time without the space dimension. Alfred Hettner (1859–1941) carried on Kant’s basic ideas in the substantive works he published on topography. Hettner’s topography (Länderkunde) argued that places big and small should be studied in conformity with their essence and that should be the core of geography. Richard Hartshorne (1899–1992), continuing in the direction taken by Hettner and other German scholars, made efforts to organize the subjects and approaches of regional geography and posited time and space as separate entities with no logical mutual involvement nor any direct link between them. He argued that geography is the study of changes occurring in the same space, not of the process of change itself; geography investigates only what is related to the present region.

Theoretically, space and time can certainly be separated, but looking at all kinds of real human activity, they are clearly intertwined, if not inseparable. Time geography, for example, examines the patterns of movement and activity that individuals undertake over the course of a day; it looks at the simultaneous consumption of time and space by human movement and activity as people move through time and act in space. The behavioral approach deals with human movement in units of days and months; social geography, using longer units of time than behavioral geography, looks for tendencies in social groups. What all these approaches have in common is the concept of the passage of time. Often historical geography looks at far longer units of time, but the research approach that takes into account both time and space in studying how humans live and act is the same.

Henry Clifford Darby (1909–1992), a giant in the field, who organized the subjects and approaches of historical geography, set out four categories of research that are generally accepted as basic to the underlying ideas of historical geography: past geographies, changing landscapes, past in the present, and geographical change (Darby 1962).

Hugh C. Prince (1971) also accepted the four-category paradigm, but he moved in somewhat new directions by developing a phenomenological and perceptual approach, on the basis of which he proposed three spheres in the world of the past that historical geography should address. Prince called them the “real,” “imagined,” and “abstract” worlds. He says that (i) “real” worlds of the past are close to Darby’s four subjects of historical geography and researchers find them useful, but this approach is not entirely successful in explaining the process of change or the reasons for change. (ii) Different people at different times all have their own ways of imagining past worlds; their intent and ways of thinking, prodded by cultural preferences and biases, are reflected in the images they form. When historical geographers living in the present seek to get closer to a past world, they do so positioned within a given cultural milieu. Thus the testimony to past times and places that they are trying to make sense of is itself colored by present necessity and present-day critical awareness. The task of understanding the past, therefore, is far from easy, but at the very least, argues Prince, it demands impartial comparisons of different observers. (iii) For historical geographers, it is important to look for order and regularity, and to construct logically consistent models for diachronic change.
Alan R. Baker (1972) basically agreed with Prince's ideas, but adjusted them in certain ways. Baker reframed Prince's category of “imagined” realms as “perceived” realms, and labeled Prince's “abstract” approach “theoretical.” In Baker's view, historical geography is the study of (i) past geographies – horizontal cross-sections; (ii) changing landscapes – vertical themes of landscape transformation; (iii) past in the present – historical explanations of the present-day geography; and (iv) geographical change – investigation of the influence of geographical conditions, and the (a) real, (b) perceptual, and (c) theoretical approaches that make it possible to pursue those inquiries. Twelve discourses have become the “new orthodoxy” for historical geography as follows: past geographies in the real, perceptual, and theoretical realms, and past geographies, changing landscapes, and geographical changes in those three realms. Landscape continues to receive a great deal of attention, especially ongoing evolution of landscape and present-day remains of landscapes from the past.

Landscape studies emerged in Germany and became a particularly strong and somewhat idiosyncratic current. August Meitzen (1822–1910), in working out how villages and farmland were formed, developed a theory of origins of the different landscape patterns shaped by different folk or cultural groups. He proposed that the different types of rural community – Dorf (village), Platzdorf (green village), Weiler (hamlet), and so on – and patterns of agriculture observed in Germany and neighboring countries originated from the cultural traditions of German, Slav, Celtic, Roman, and Finnish peoples. Otto Schlüter (1872–1959) did a careful and detailed review of that theory and used it to study villages in Thuringia and other parts of central Germany. His research and theoretical work became the basis for the discipline of Landeskunde (landscape studies), which focuses geographical inquiry on regional landscape. Diverging from historical geography, where space and time are studied simultaneously, Schlüter endeavored rather to foreground spatial elements and discount the influence of elements of time, and he tried to explain surface phenomena by giving causality to geographical factors through time. His work had a strong impact on the direction taken by, and the growth of, landscape studies in Germany.

Carl Sauer (1889–1975), citing in particular the work of Siegfried Passarge (1866–1958), introduced German landscape theory to America. Sauer's doctrine of landscape morphology (Sauer 1925) bears some marks of anthropological/sociological theory of culture, but it includes the temporal dimension, change over time, and thus locates his approach basically at the same vantage point as that of historical geography. Both of Sauer's diagrams outlining the process of morphological change in the natural landscape and the cultural landscape (for the cultural landscape, see Figure 1) incorporate the passage of time. In his model, historical geography includes tracing changes in the landscape and interpreting changes in regions, and that necessitates the study of cultural landscapes: developments and movements within human communities, changes born of new relationships, and improvements occurring within culture and cultural landscapes have to be considered in order to account for change. Sauer’s model was pursued by his research groups through the investigation of indigenous societies in Mexico and California. Before long it was taken up at symposiums organized around geography, anthropology, and related disciplines, and a collection of papers derived from one such symposium (Thomas Jr 1956) showed that perspective expanding to its most inclusive scope. Then, cultural geography, with its focus on elements of anthropology and
culture, gradually became the center of interest in the field and moved away from the direction of historical geography. According to Richard Hartshorne, an orthodox scholar of regional geography, Sauer’s version of historical geography was already discredited as an area of geography. The German school of landscape studies that had so influenced Sauer itself changed course. One reason was that, like Georg Niemeier (1903–1984) who studied the origin of rural settlements in central Germany and asserted his *Eshkentheorie* (Esch core theory) to describe the prototype of the rural landscape in the region, German historical geographers were beginning to use new and different kinds of increasingly specific data to document historical change in village communities. Another reason was that academics were turning toward *Sozialgeographie* (social geography), which puts social groups—the main factors in the formation of landscape—front and center as research subjects. On the other hand, landscapes, especially landscapes of the past, are studied as much as ever in the field of historical geography, and present-day remains of past landscapes continue to furnish productive research materials.

The materials for historical geography are not simply landscapes per se. Henry Clifford Darby, who in 1962 set out four subjects of historical geography, earned his doctoral degree in 1932 after completing research in the Fenland region of eastern England. Relying on many different kinds of historical sources to reconstruct and describe the historical geography of a part of the Fens, he structured his thesis in six parts: (i) the prelude to the draining, 1500–1600; (ii) the Fen project, 1600–1663; (iii) the consequences of the draining; (iv) the eighteenth century; (v) the nineteenth century; and (vi) conditions after 1900 (Darby 1940). He dealt with the draining, the heath, the “changing arable,” windmills, town, industry, and other topics to reconstruct the geographical conditions of a past time, and he used successive cross-sections to analyze and describe the change. Considering his use of historical materials, we can describe this approach as the historical source method. The distinctive feature of Darby’s completed thesis is a strong ecological emphasis in his treatment of the changes resulting from draining and banking in the heath and

peat region, and the special characteristics of the Fenland’s natural environment.

Darby’s application of the historical source method is even more evident in his reconstruction of locations and distribution of various items making primary use of the Domesday Book, a comprehensive and detailed survey of population, land, livestock, and other assets ordered by William I of England and completed in 1085 and 1086. Darby collaborated with other scholars in the field to produce a series of studies called the “Domesday geographies,” the first of which appeared in 1952. Together they provide detailed reconstructions of geographical patterns found in several regions in Britain, accompanied by a rigorous critique of historical sources (Darby et al. 1952–1977). Darby took the lead in developing and using the historical source method, which prioritizes historical materials. Although other scholars have continued to use it in different ways, it has become a standard approach to research in historical geography.

Among the most widely used and indispensable primary source materials for scholars interested in space and time when following the historical source method are old maps. A map is, by its nature, a way of expressing space. If language is a mode of conveying some idea, relationship, or information, we can think of maps as the language of space. Maps vary greatly—from small-scale maps of the world, continents, and countries wherein the representative fraction is small, to large-scale, detailed maps of regions, cities, or villages, whose representative fraction is larger. What features are described on a map depend on the scale: in modern scientific maps, the most common small-scale maps show lines of longitude and latitude, landforms, locations of major cities, the main geographic features of the world, continents, and countries, whereas a thematic map contains abundant data of a particular kind. Large-scale maps showing survey results, land-use planning, the shape of land lots, or conditions of land use provide very useful data for analysis. Cartographic techniques and the types of features shown in maps have changed over time, but the study of maps is central to geography in general, certainly to historical geography, and cartography has become another subdiscipline of its own. What can be called “old maps” are basically premodern maps with some features that appear in early modern maps, but they differ from scientific modern maps. For example, some small-scale old maps of the world, continents, or countries show not only the way the world or a country was portrayed in the past but what it was actually like then. For historical geography, such a map can be an object of research itself as well as a source for research on something else. Also, old maps commonly reflect the enormous expansion of geographic knowledge acquired during periods of exploration of little-known places, and they clearly reflect the perception of space that pertained at the time when the map was made.

While old maps serve as prime sources for historical geography, there are other useful sources as well, such as historical and archaeological materials from that period (e.g., Baker and Butlin 1973). Many elements of physical geography, such as the climatological, floral, faunal, and topographical features of a place, and other elements like location and distance between prominent features and various conditions, including cultural and historical environments, are also important in historical geography. It is notable that historical geographical research often stressed the significance of the natural environment in the historical events of places (e.g., Hassinger 1931; East 1967/1938).

Land allotment also provides valuable information for historical geographers. Patterns of land allotment generally take the form of partition into blocks, divisions, subdivisions,
parcels, sections, or lots for purposes of land-use planning, land ownership, and land utilization. Land ownership units are usually given the most weight. Allotment patterns can be ascertained by a variety of sources, but manorial and cadastral maps give the most information about the state of affairs when the map was made. When lots are identified by minor place name, number, or via some other identifier, it is often possible to reconstruct contemporaneous conditions even if subdivisions occurred after the numbers were designated. In addition to what is found in cadastral and other old maps, there is much to be learned from land division patterns visible in aerial photos. Maurice Beresford (1920–2005), who started out as an economic historian, developed an abiding interest in historical geography over the course of finding and exploring abandoned remains, especially of medieval villages in England, which led him also to become involved in archaeological excavations. Using aerial photography to look for correlations and contrasts between visible evidence in photos and information in old maps, he charted new pathways in research. Using that approach to study the interaction between the patterns of land allotment and documents including old maps, he was able to confirm the morphology of many long-forgotten villages and the layout of their fields. In 1957 he published a report, together with an aerial photographer, on the remains of 118 medieval villages in England (Beresford and St. Joseph 1958). Beresford was drawn to medieval cities as well. He applied the same technique of investigating remains on the ground and using aerial photos to establish or suggest, through analysis of land divisions and uses, the form, structure, and other data about the so-called new towns in medieval England, Wales, and Gascony (Beresford 1967). To this day Beresford’s technique of combining aerial photos with documentary or cartographical evidence remains a standard method in historical geography.

About the time when Beresford was working on medieval settlements, William George Hoskins (1908–1992), who also began as an economic historian and was an advocate of studies in local history, asserted the need for research methods focused especially on the effect of human activity on the history of landscape. He believed that the most effective research approach was to look first at landscape elements still remaining on the ground. He studied, for example, the remains of granite walls built by the Celts and by later groups, remains of Roman roads, traces of long strip fields, and the ridges running between fields deriving from medieval farming; he also examined field patterns and farmsteads that resulted from the onset of the enclosure movement, central greens of nucleated villages and meadows in the vicinity, and the type and structure of farmhouses in different periods. His purview of a landscape extended from the rural village to the factories and streets of the urban (Hoskins 1955). Both Beresford and Hoskins took a different approach from documentary historical research. They prioritized land division patterns seen on the ground, old maps, aerial photographs, and the present-day landscape – precisely the kinds of data central to historical geography studies.

Beresford, for one, had already been looking underground for evidence in archaeological remains and structures. Such remains, besides being immediately useful materials for historical geography, are effective in identifying the period of the object, and they enable a broader perspective. Karl W. Butzer (1934–) has done paleoanthropological and archaeological fieldwork in places on the northern edge of the steppe extending from North Africa to Europe and West Asia, where he also did a physiographical analysis of the geomorphology,
pedology, and climatology. He used the results to present a broad argument about the life of Paleolithic people and the origination and diffusion of farming, settlements, and towns (Butzer 1964). Since artifacts and structures lying underground can be analyzed together with sedimentary strata, archaeological remains and antiquarian materials have come to occupy an extremely significant role in research on culture, civilization, and environment. In Japan, Saneshige Komaki (1898–1990) cited Halford John MacKinder’s (1861–1947) unique concept of a cross-section to propose a relationship between shifts in desert sand dunes and the life of an essentially Stone Age people during the period 10 BCE to 4 BCE (Komaki 1937, in Kinda 1997). Kenjiro Fujioka (1914–1985) worked that concept of a cross-section into an archetypal thick cross-section (to reconstruct a landscape over a comparatively long time span, such as prehistory, ancient, medieval, early modern, and modern) that has stood the test of time up to the present. However, it might lead to another problem (as shown in Figure 3, below) (Kinda 1997).

In sum, historical geography research utilizes standard basic resources including landscape morphology, land divisions, old maps, and so on, but in many cases historical documents, structural remains, artifacts, and other archaeological sources of evidence are equally important. The three types of source – geographical, historical, and archaeological – overlap to some extent. As illustrated in Figure 2, from the viewpoint of historical geography, whatever is being studied from whatever angle, materials from all three – geography, history, and archaeology – will be relevant to part of it.

The methods of studying historical geography and producing an account of that study are inextricably bound to the type of source materials being used. Darby’s four types of research subjects mentioned earlier are related to the way the results of each are recorded. The first one, “past geographies,” is described by using horizontal cross-sections, and the second, “changing landscapes,” represents conclusions in successive cross-sections. A classic example of this method of description is found in An Historical Geography of England before 1800 (Darby 1936). The fourteen cross-sections in that book present various methods, such as views of England by a single individual at one given time, and views over longer spans of centuries or periods. For the revised edition (Darby 1973), in response to criticism that it lacked coherence, Darby rethought and reorganized the narrative description between the years of the cross-sections and the cross-sectional analysis of 1085 – the year of the Domesday Book – and created cross-sections for 1334, 1600, 1800, 1850, and 1900 (Box 1).

Darby’s successive cross-sections were methodologically adjusted so that thinner cross-sections covering narrow bands of time were integrated with narrative explaining the changes between
them. Among the more enthusiastic proponents of archaeological source materials, there were some who were working with well-defined thick cross-sections that covered broad swaths of time, and later in his life Darby reported that he, too, could have used thick cross-sections as an alternative (Darby 1983).

Since thin cross-sections are strongly dependent on what source materials could be used, they may tend to miss significant landscape elements within a given year, and if they are thick enough to contain landscape elements of different times, they may end up trying to explain a band of landscape elements that in fact belong to different periods. It is so easy to get trapped by problems of logic that some researchers have sought different methods. The one that Alan Baker and John B. Harley (1973) applied was to divide the diverse ways the landscape morphology had evolved from era by era into 16 themes, according to the special properties of the place, and to describe typical landscape or landscape elements for each theme. Their concept aimed less at methodological perfection than at providing more substantial explanation. This method, which approaches features separately, carries the risk of fragmentary treatment, whether of landscape or landscape elements, but this can be overcome to a certain degree by emphasizing the contextual approach. An actual landscape is made up of countless factors, both natural and cultural. Any element of the natural landscape, such as a forest, may become part of the cultural landscape. Those elements are established at different times, and while some of them remain the same over time, others change, and still others disappear. Furthermore, some elements, after disappearing, may be reconstructed. From time to time, an element will disappear, only to re-emerge later, but overall, new elements are continuously being added. It is an irrevocable process of change wherein social, economic, technological, ideological, and cultural factors have a certain impact at any given time. What determines whether they survive or not are government policies and planning, and the social value people give to them. When we study whole landscapes, we must trace as accurately as possible the appearance and disappearance of particular elements and identify the interactions between and among them, and at the same time we must expand our field of vision to encompass the whole context when examining and analyzing them (Figure 3; Kinda 2010).

Darby’s work on the Fenland and Carl Troll’s (1899–1975) perspective on landscape ecology (ökologische Bodenforschung), as well as Butzer’s aforementioned work, along with many other ecological approaches, have generally proceeded in that way.

**Box 1** Darby’s method in *A New Historical Geography of England* (1973).

1. (Before Domesday)

7. The ages of the improver: 1600–1800
8. England circa 1800
10. England circa 1850
11. The changing face of England: 1850–circa 1900
12. England circa 1900
Another type of research aims at identifying and describing the changes that have occurred over an entire region without using cross-sections but looking at a wide range of objects. Considerable work along these lines has been done, taking states, colonies, and countries as the unit, due to availability of historical sources and researchers’ interest in them. More work has been done in this way by states/provinces or colonies in North America and in Australia than by countries in Europe. In North America, a good example of this approach is the work by Andrew H. Clark on an island in the Maritime provinces in Canada, and another is the huge endeavor by Donald W. Meinig that culminated in four volumes of The Shaping of America (Meinig 1986–2004).

The practice of historical geography is contingent upon the availability of data and depth of analysis. Today, increasingly sophisticated ways to parse information in historical documents and techniques for component analysis are enabling ever more exact estimates of time and place, while global positioning systems give us fast and accurate specifications on localities, all of which raise the possibility of valid inference. Advances in the digital humanities and geographic information systems have brought greater diversity to analysis techniques, while making possible the storage and processing of huge amounts of data.
Historical geography, like other disciplines, is exploiting the possibilities these tools offer.

The vast amounts and greater specificity of data available today, along with ongoing progress in methods of sorting and examining it, are yielding improved research results, and at the same time facilitating the transmission of the results to the public. By digitizing their holdings, regional history archives, for example, anywhere in the world can be accessed by anyone with a computer connected to the Internet. Also, being able to bring more minute detail into large-scale maps and digitizing them will make it easier to enter and compare the location and configuration of archaeological remains, and this will bring more archaeological materials within easy reach of historical geography researchers.

Being able to integrate finer and more abundant detail and a wider assortment of data into reconstituted landscapes has already had a huge impact. In museums around the world it is common to find large-scale dioramas and assorted computer graphics showing the past of cities and explaining regional change and development. But with such dioramas and computer graphics we still come up against the same problem that Darby confronted as he grappled with (vertical) narrative and (horizontal) cross-section, and that is the problem of time in the cross-section of a reconstructed landscape: is it a fixed, specified time or does it represent a span of time? This question highlights the importance of dealing with cross-section in research.

Making thin cross-sections depends on whether there are adequate materials relating to the year in question that allow us to reconstruct the year and to make a description. Had the Domesday Book not existed, it would have been impossible to make a thin cross-section for the year 1085 or 1086 in England. When there are no adequate materials directly spotlighting the targeted year, the only recourse is to search around for some other sources and methods on which to base an estimate. Here, archaeological structures, with information coming from the strata where they are found, are invaluable. Steadily improving analysis techniques have made it easier to get more accurate chronological dating of those structures and to reconstruct the conditions of their natural environment; that allows one to examine different kinds of natural environment and to derive a picture of the way things were ecologically, thus facilitating an intersection with the focus of the historical geographical study. Once the year and character of structural remnants from the past estimated from aerial photos have been confirmed by archaeological methods, then aerial photos can be used to study such remnants in a much wider area. Further, when using large-scale old maps like cadastral maps to estimate conditions at a time before the map was made, archaeological and historical materials can also play a significant role in establishing the year and illuminating the state of the landscape.

With greater precision and richer substance, historical geography is contributing to a much more nuanced understanding of space in historical time.

Historical settlement

Jeffrey S. Smith  
Kansas State University, USA

Prior to the Neolithic age hunting and gathering were the primary means of securing food for early humans. Small bands of less than fifty people would stalk wild game and migrate between locations as dictated by growing seasons. Banding together offered mutual protection, but settlements remained small because larger groups could easily outstrip the food supply available within walking distance. Between 12,000 and 10,000 years ago the Neolithic revolution (also known as the agricultural revolution) began. Owing in large part to the ending of the ice age, over the course of thousands of years and at differing rates over disparate locations, humanity made the gradual transformation from a nomadic food gathering lifestyle to one based on food stuffs raised by a more sedentary populace.

The agricultural revolution brought about many changes for humanity. First, reliable sources of food made life more secure with fewer people dying of starvation. This led to a dramatic increase in the world’s total population. Second, as humans perfected irrigation techniques and larger scale agriculture, select people could be called upon to raise enough food to be distributed among the remaining population or stored for future use. Because not everyone was required to share in the food gathering duties, individuals could devote their time to other specialized activities. Some people focused on developing trade and commerce while others became governing leaders of the community. At the same time, arts, culture, and architectural diversity also emerged. This diversity led to a division of labor and social stratification within society. Third, as food supplies became more reliable and the capacity to store food ensured that it was available throughout the year, the previously small dispersed bands of humans slowly began to congregate into organized, sedentary population centers. As time passed, some of these settlements evolved into highly organized and noteworthy places.

Neolithic era settlements (10,000 BCE to ca. 1500 BCE)

Levant (near present-day Jericho, West Bank) is now considered to be the oldest organized human settlement. Marking the beginning of the Neolithic period at about 10,000 BCE, the diet of the local inhabitants became more dependent upon grains than wild game. As these people experimented with various agricultural techniques, the settlement’s population began to grow. Between 10,000 BCE and 8000 BCE, the farming techniques developed in the Levant area spread to Asia Minor (Turkey), Northeast Africa (Egypt) and Mesopotamia (Iraq, northeast Syria, and southeast Turkey). Two of the earliest settlements to adopt this new lifestyle include Çatalhöyük (present-day south-central Turkey) and Eridu (present-day Iraq). Archaeological evidence suggests that Çatalhöyük thrived between 7500 BCE and 5000 BCE with its heyday around 6000 BCE. Eridu first developed about 1500 years later around a ziggurat (temple and administrative building) that was surrounded by a residential space and a protective wall. As time
HISTORICAL SETTLEMENT

passed, concentrations of human settlements developed in four main areas. Most of the earliest settlements developed along river valleys because they afforded the local population a reliable supply of water, soils rich in nutrients, and efficient routes for trade and transportation. Cultural geographers refer to these locations as cultural hearths (or cradles of civilization).

Fertile Crescent/Mesopotamia

Believed to be among the oldest settlements in the world, Eridu (5400 BCE) and Ur (3800 BCE) were situated on the southern banks of the Euphrates River in southeastern Mesopotamia. The region was settled by three separate cultures (Sumer, Ubaidian, and Semitic) who all became integrated. As the local population honed their pastoral, fishing, and agricultural techniques, the ample food supply enabled the population to grow and to become denser. At the top of the division of labor was a strong ruling class who offered religious guidance. A merchant class traded surplus food and crafts with peoples in other parts of the Fertile Crescent and distant lands. Eridu and Ur entered a period of decay when the center of Mesopotamia’s population shifted north and the Euphrates River changed its course inundating many of the early settlements.

Around 2000 BCE the settlement of Babylon emerged farther upstream along the Euphrates River in a particularly fertile agricultural zone. What started out as a minor population center grew into a city-state eventually, becoming one of the most important cities in Mesopotamia. For a short time, it even served as the capital city of Babylonia, a center of learning and the arts that featured the Tower of Babel and the wondrous hanging gardens. Babylon was plundered and destroyed repeatedly with its ultimate demise coming at the hands of the Roman Empire.

Nile River valley

Within the Nile River valley two settlements are of noteworthy importance: Thebes and Memphis. Thebes was first established in ca. 3200 BCE on the eastern banks of the Nile River (in present-day Egypt). Not only was it an important religious and political settlement, but it became an important trade city. Merchants exchanged goods up and down the Nile River as well as across the Red Sea between various parts of the Fertile Crescent. Scholars believe that in 2000 BCE Thebes had 40,000 residents and by 1000 BCE its population had grown to 80,000 people. Its main rival along the Nile River was Memphis.

Pharaoh Menes established Memphis (ca. 3000 BCE) at the mouth of the Nile River delta. The site was ideally located not only because the surrounding fertile lands enabled farmers to raise an abundance of food, but its location facilitated an extensive trade and transportation network that extended throughout the Mediterranean region. Memphis became the capital of Egypt during the end of the First Egyptian Dynasty (ca. 2800 BCE) and grew in importance thereafter reaching its apogee during the Sixth Egyptian Dynasty in 2300 BCE. The waning of Memphis coincides with the rise of Alexandria (Egypt) which remained an important political center during the First Persian (550 BCE), Greek (323 BCE), and Roman (31 BCE) empires.

Indus River valley

Early humans began concentrating in settlements in a third cultural hearth located along the Indus River in present-day Pakistan. The Indus River valley attracted a mix of people including hunters, gatherers, and herders who traded among themselves. Over time the various populations concentrated in settlements along most of the Indus River valley with the two most noteworthy being Mohenjo-Daro and Harappa. Both
were established just after 3000 BCE and despite the considerable distance separating the two places, they were constructed of similar earthen building materials, giving scholars confidence to assert that they were ruled by a strong central government whose jurisdiction stretched up and down the river valley. Mohenjo-Daro, located at the mouth of the Indus River, was the most prominent settlement in the region and the local culture invested considerable effort into developing a system of irrigation, animal husbandry, and civil engineering. Around 1800 BCE the Indus civilization entered a period of protracted decline due to changes in the local environment and many of the early settlements including Mohenjo-Daro and Harappa were abandoned.

Wei/Huang He (Yellow) River valley

The fourth cultural hearth is found along the Huang He River valley and its tributary the Wei River. Located in present-day central China, humans first inhabited the region before 5000 BCE and established settlements around 2200 BCE in areas with highly structured irrigated farming. Over centuries the population grew and spread throughout the river lowlands. By 1750 BCE the Shang Dynasty consolidated power and the Huang He River valley emerged as the cradle of Chinese civilization. Key settlements in the region include Zhengzhou, Anyang, and Lanzhou. Each served as important administrative and cultural centers and the area surrounding these settlements has been continuously inhabited ever since. Over time city-states emerged and by 221 BCE the Qin Dynasty unified the independent principalities into a centralized empire focused on the Huang He River region.

Western Hemisphere

As settlements were being formed in the Eastern Hemisphere, humans began clustering together in various parts of the Western Hemisphere as well. Approximately 16 000 years ago the Earth’s climate began to warm and the glaciers ringing the Arctic Circle retreated creating passageways for one of humanity’s greatest diasporas. Early humans migrated across the Bering Strait and moved into parts of the Western Hemisphere. Although most of the hemisphere was thinly populated, humans became concentrated in two main areas (Mesoamerica and the Andes).

Mesoamerica encompasses much of present-day central and southern Mexico, the Yucatan Peninsula, and most of northern Central America. Within central Mexico the Aztecs built upon previous settlements first established by the Olmec, Toltec, and Teotihuacan cultures. They founded Tenochtitlan (present-day Mexico City) as their capital city on an island in the middle of Lake Texcoco. Tenochtitlan fell to the Spanish when Hernando Cortez invaded and founded Mexico City on the same site.

The Maya established numerous religious and political settlements throughout the Yucatan Peninsula and extending into northern Central America (especially Belize and Guatemala). Some of the most noteworthy include Uxmal, Chichen Itza, Tikal, and Copan. All of these high-density settlements were abandoned when the Maya population diffused into smaller, low-density settlements spread throughout the greater Yucatan region where they still live today.

Farther to the south were the ancient settlements of the Inca. Unlike most other Neolithic settlements, the Inca built many of their population centers high in the Andes Mountains. Cuzco (3352 m (11 000 ft) above sea level) became the Inca’s most important administrative settlement. An extensive series of roads (highland and coastal) connected a vast empire that extended from present-day southern Colombia to central Chile. Descendants of the Inca still inhabit the mountainous region of South America.
HISTORICAL SETTLEMENT

Humanity spread from each of these four cultural hearths, establishing settlements over much of the Earth’s surface. As settlements in these four regions continued to grow in size and population density, there were numerous challenges that never seemed to be properly addressed including reliable supplies of potable water, the management of waste (trash and fecal material), efficient transportation systems, and security from invading forces. If leaders were going to address these chronic issues the form and land-use functions of settlements would have to change. Spontaneous growth based on agriculture and trade needed to give way to planned cities. The next major era of human settlement was the Iron Age where Greek and Roman settlements became most noteworthy.

Ancient era settlements (1500 BCE to 476 CE)

As the fifteenth century BCE came to a close, the centers of human settlement began to shift. The hearths of civilization in Mesopotamia and along the Nile and Indus River valleys entered a period of decline. In their place the sun began rising on a new empire. The Greeks emerged from the Dark Ages around 800 BCE and over the course of 950 years the civilization expanded its influence throughout the Mediterranean and Black Sea regions. During the reign of Alexander the Great (356–323 BCE), the Hellenic Empire covered a vast territory from the Indus River valley and the foothills of the Himalayan Mountains on the east, through the Fertile Crescent and Nile River valley to present-day Greece on the west.

The Greek authorities founded an untold number of small settlements (polis, aka city-state) throughout their domain. A typical polis was comprised of a walled settlement surrounded by agricultural lands. Within the city walls was the acropolis – an area reserved for religious worship as well as a defensive site. Near the center of the settlement was the agora (a space for the public to gather to exchange goods and merchandise). In larger settlements (e.g., Athens and Sparta) the agora became a dedicated market place and entertainment district. Most of the residential space in early Greek settlements (especially on the western frontier in France and Spain) lacked formal planning and featured irregular, curvy streets with narrow walkways. Over time, however, Greek authorities imposed city planning mandates that redesigned the transportation network and improved the flow of traffic through the settlements. Streets then adhered to a rigid grid pattern and land use became specialized among different professions within the larger population (e.g., artists and craftsmen, farmers, military).

In 146 BCE Greek society fell under Roman rule and settlements began taking on a different character. Over the next 600 years, the Romans expanded their zone of influence to include all shores around the Mediterranean Sea and as far north and west as present-day Western Europe (including parts of the British Isles). A network of trade routes between the far-flung settlements combined with security and protection provided by the Roman Legions were key to holding the vast empire together.

In the early years Roman settlements adapted and built upon the foundations left by the Greeks. Under Roman authority however, water, sewer and sanitation, and transportation systems were all improved (including aqueducts and paved roads). Gradually, settlements evolved to reflect the rigid social stratification that characterized Roman society. For example, special administrative and religious complexes were set aside and segregated from space afforded to common citizens.

Most Roman settlements were laid out around a large central square or rectangular space with
its focal point being the forum. The forum was similar to the agora found in Greek settlements in that it provided a space for public gatherings and a market where merchants could sell their wares. The Roman forum also hosted political functions, sporting events, state funerals, and other public interest activities. In settlements that grew to become central places for trade (e.g., Rome, which had a population between 300,000 and 500,000 people), the Roman authorities built a basilica (a permanent, covered structure where vendors could sell their merchandise). On the frontier of the Roman Empire settlements took on a more specialized form serving as either administrative centers or military outposts. Yet, in all cases the layout, design, and function of Roman settlements reflected the empire’s strong sense of order and rigid social stratification. When the Western Roman Empire fell in 476 CE, the Roman Legions no longer provided safe passage for trade caravans. People were left to their own devices and many of them abandoned the larger settlements in favor of new, more secure places to live. Urbanized settlements were transformed once again.

Feudal era settlements (476 CE to 1492 CE)

Following the collapse of the Roman Empire, Western civilization entered the Middle Ages (aka Medieval period) where Europe made the transformation from being an exploited region on the margins of the Roman Empire to the center of population growth and innovative thinking. For the better part of those 600 years, however, the Middle Ages were more commonly characterized as a time of social unrest and civil war with countless invasions by marauding barbarians (e.g., Vikings, Germanics, Huns) from northern lands. In the absence of a central government, regional kings constructed walled settlements that surrounded a fortified castle. Seeing the obvious benefit of living within a secure settlement, residents in the region pledged loyalty to the king in exchange for protection. By the ninth century a feudalistic society emerged with an entrenched social hierarchy whereby everyone ultimately fell under the jurisdiction of the king. Serfs and landed peasants worked plots of land giving a portion of their annual harvest to the landlords. Knights served as the regional army providing protection throughout the kingdom. Lords, nobles, and barons (with their own smaller fortified castles) provided loyalty and tax support to the king, which in turn funded the activities of the knights.

In the eleventh century identifiable regions began to emerge based on specialized agricultural practices. For example, the lowland countries (present-day Belgium and Netherlands) became known for sheep production and a strong weaving industry developed. Slowly trade between these specialized regions expanded with some settlements assuming a primary role in hosting trade fairs. As the reputation of these important regional settlements spread, merchants, craftsmen, and laborers gravitated toward them (e.g., Ghent, Belgium and Vienna, Austria). What started out as small, walled settlements evolved into major European urban centers with sizable populations. Although religious conflict (e.g., Protestant Reformation) and economic stagnation limited urban growth in other parts of Europe, merchant activity throughout Italy (e.g., Venice, Genoa, Florence) continued to grow and expand. The Medieval Period came to an end with the rise of the Italian Renaissance and the Age of Discovery in 1492 CE.

Laying a foundation for modern settlements

The founding of settlements in the Americas did not occur in a vacuum. The general design of
human settlements can be traced back centuries to Greek, Roman, and Medieval influences. Europe’s discovery of the New World was largely the culmination of a series of fortuitous events both within and outside Europe. First, as the spirit of the Renaissance and the Age of Discovery swept across the European continent, royal leaders funded explorations to uncharted lands hoping to find abundant riches. As a handful of European monarchs gradually consolidated authority from local feudal lords and modern nation-states emerged, a new economic mindset developed in Europe. Mercantilism (a political economic system based on the principles of accumulating bullion, creating a merchant marine, establishing colonies, and exploiting natural resources to attain a favorable balance of trade) became the guiding force that steered the decisions of Europe’s rulers. As life under the modern nation-states became more secure, landed elites also looked to expand their wealth by investing their riches in joint-stock companies (precursors to modern-day corporations) which they hoped would return handsome dividends.

Geographers James Vance Jr (1970) and Donald Meinig (1986) explain that European settlement of the New World progressed in three main stages. Stage I (exploration) involved establishing settlements that served as a base from which the search for information and new knowledge could proceed. The explorations of Christopher Columbus (1492–1506) are an excellent example of this stage. Each voyage funded by European governments to the New World produced an increasing awareness of what the region had to offer. Stage II (fixation) refers to the establishment of a coastal settlement (entrepôt) where imports and exports are brought for collection and redistribution. In the third stage (colonial expansion), European governments began populating the Americas. A variety of settlement types radiated out from the port-of-entry along trade or transportation routes. During colonial expansion distinct differences became apparent in how the European governments settled the New World.

By the second decade of the sixteenth century, Spain established anchor settlements in strategic locations throughout the Caribbean, central Mexico, and the highlands of South America. From these administrative outposts Spain explored their newly claimed lands and searched for new sources of wealth. For example, from Mexico City and Cuba various Spanish explorers headed north to what is now the American Southwest (New Mexico, Texas, Arizona, and California) and Florida. With the aim of securing these lands for the Spanish crown, the Spanish established permanent settlements in coastal Florida, along the upper and lower reaches of the Rio Grande, and along coastal California. Some of the most noteworthy settlements include St Augustine (1565), Santa Fe (1609), Albuquerque (1706), San Antonio de Bexar (1718), San Diego (1769), San Francisco (1776), Santa Barbara (1786), and San Jose (1797). Most Spanish settlements followed the guiding spirit of the Laws of the Indies, but there were three main types: mission (settlements that focused on religious services), plaza (civil and administrative settlements), and presidio (fortress/military complexes). Nearly all of the major settlements were linked to Mexico City via various branches of the Camino Real (royal road). The multipronged “road” served as the principle trade and transportation corridors similar to the trade network that existed during the height of the Roman Empire. The best example of the ribbon settlements established along the Camino Real was located in coastal California where the Spanish built 21 settlements (primarily Franciscan missions) that stretched over 800 km from San Diego to San Francisco. Like the Spanish, the French colonial government’s primary concern with respect to
the New World was resource extraction and wealth accumulation. Therefore, most of the settlements France established were port or trade route communities. Quebec (1608), Trois Rivieres (1642), and Montreal (1642) were three of the earliest and most successful. Although each served its immediate hinterland, their main focus was to facilitate the shipping of precious goods (especially furs) back to France. As France’s influence in the New World expanded into the interior, additional settlements were established along water transportation routes (e.g., the Great Lakes, Mississippi River). These settlements (e.g., Niagara (1678), Detroit (1701), Memphis (1739), and Pittsburgh (1754)) tended to be fortified outposts where goods could be traded and stored for shipment to the larger coastal port facilities including Quebec, Montreal, and New Orleans (founded 1718). Most French settlements in the New World were little more than thinly populated outposts and did not move far beyond the fixation stage. Because France was more committed to the acquisition of wealth than establishing permanent settlements, other than in the Province of Quebec, it had a fleeting impact on settlement patterns in the New World.

British settlement in the New World was dramatically different. Instead of focusing on finding stores of wealth, their primary objective was to establish permanent settlements (e.g., Boston (1628), Hartford (1635), New York (1664), Philadelphia (1681)) that would relieve some of the population pressure and patterns of religious persecution in England. Over time coastal America became divided into three main regions (northern, middle, and southern colonies), yet the settlement pattern was remarkably similar following the three major stages explained above. After immigrants established an initial port colony, the population grew and expanded into the interior along trade and transportation routes. British frontier settlements were self-supportive but maintained well-developed trade connections with the coastal settlements. Most of the early settlers originated from Britain, yet thousands of people also came from other parts of Europe including Holland, Germany, Switzerland, and Sweden. Each brought with them cultural baggage that would have an influence on the form and function of New World settlements.

HISTORICAL SETTLEMENT

The oldest settlements in Asia in the sense of permanently inhabited sites may have appeared around 12,000 years ago, before the development of agriculture. These settlements were created by people who depended on wild sources of food obtained from aquatic environments, which provided dependable sources of sustenance throughout the year. The number of people in these early settlements probably totaled 30 or 40. Eventually some of these sedentary hunters and gatherers began to domesticate plants and animals. Population grew, and some settlements reached a total of approximately 400 people. This number seems to represent the limit of population size that societies can sustain without some mechanism of dispute resolution. Once new forms of government were developed, the size of the largest settlements expanded by to perhaps 5000 people.

In English-language terms, these three settlement types can be equated with villages, towns, and cities. These words, however, have implications for the types of activities carried out in settlements of each type, which are commonly found in Europe but not in all other regions of the world. Historians and archaeologists prefer to think in terms of hierarchies of settlement. A region with settlements of one size ("villages") would be termed a region with a single-tiered settlement hierarchy. A region with settlements of two sizes ("villages" and "towns") would be termed a two-tiered hierarchy. The number of tiers in a regional settlement hierarchy is, in theory, unlimited. The use of this system enables scholars to compare the historical development of settlements in different parts of the world while avoiding culturally specific terminology.

Settlement patterns can also be studied from the perspective of the number of settlements of different levels of a hierarchy. In some regions, the proportion of settlements in the third level of a hierarchy ("cities") relative to the number of first- and second-level settlements may be higher than in other areas. Differences between regions in terms of the proportion of settlements of different sizes may be seen by plotting them on a log-normal graph. This method has been used in Mesopotamia to compare different trajectories of settlement formation (Adams 1981). Settlement patterns can be correlated with economic and political institutions.

In southwest Asia, important prehistoric settlements include Catal Huyuk and Jericho. At the beginning of the historic period approximately 5000 years ago, the largest settlements were Eridug, Ur, Uruk, Girshu, Lagash, Nina, and Umma, all located near modern Baghdad. Research on these sites has focused on a search for the factors which led to their appearance. Among the most popular are water management, formation of religious cult centers, warfare, and trade. Scholars differ on the relative importance of these factors and the sequence in which they became significant. The same types of arguments developed for Mesopotamia recur in the study of historic settlements in other parts of Asia.

The concept of the “Islamic city” is another subject of debate, which arose in southwest Asia and spread to other Islamic areas. Not all scholars agree that Islam can be correlated with
HISTORICAL SETTLEMENT: ASIA

the formation of a type of settlement (Eldem, Goffman, and Masters 1999). The phenomenon of urbanization was widespread in the countries where Islam spread, from the Near East to North Africa, South Asia, and Southeast Asia. During a period when most Europeans lived in agrarian villages and only a few cities in Europe boasted 100,000 people, Cairo and Constantinople each had a population of several hundred thousands. The most prominent centers of activity in Muslim Asia and Africa, as well as the Arab countries, were the palaces, markets, and mosques. Cities were divided into quarters according to occupation and ethnicity. Whether Islam was the main independent variable in this development or one of a number of interrelated variables is a subject of complex debate.

In Central Asia, the area between the Caspian Sea and China, important settlements of the historic period began to form around 2000 years ago, when the Roman and Han empires provided two large and sophisticated markets for exotic commodities. Oases and caravan resting places such as Bukhara and Samarkand (now in Uzbekistan) existed as early as 300 BCE. Many of them became centers of Buddhism and later Islam.

In East Asia, important early settlements include Zhengzhou, Anyang, and Loyang in northern China. These appeared around 3500 years ago, when the first Chinese historical sources become available. Wheatley (1971) argued that the earliest large settlements in China coalesced around ceremonial centers, and that the same factor was responsible for the formation of settlement hierarchies elsewhere in Asia.

An important feature of early Chinese capitals is that they consisted of clusters of discrete activities, separated by open space. Administration, religious activity, various crafts, and settlements were conducted at separate locations.

In South Asia, the oldest large settlements appeared in the Indus Valley region of Pakistan and northwest India around 4500 years ago. The major sites of this period are Harappa and Mohenjo-daro. The Indus Valley phase came to an end around 3700 years ago; it was followed by a gap of about 1000 years until a second phase of large-scale settlement formation began, with sites such as Taxila and Ujjain. This phase too ended in a period of urban “decay.” In the subsequent phase, between 600 and 1300, important cities arose in places like Tanjavur in south India (Champakalakshmi 1996) and in Bengal.

Around 2000 years ago, important settlements appeared at seaports along the southern coast of Asia, from the Persian Gulf through the Indian Ocean to the South China Sea. The settlements of the Asian littoral were quite different from those of the agricultural hinterlands. The hinterland settlements were characterized by an emphasis on monument building, warfare, irrigation, and rigid social stratification. In coastal societies, it was easier to improve one’s status through becoming wealthy. Few resources were invested in large monuments or fortifications (Miksic 2013). Hinterland empires seem to have been well disposed to the development of autonomous ports on their fringes; they provided exotic status symbols desired by the elite and acted as a buffer against foreign cultural influences (Fox 1971). As long as taxes and tribute were paid, hinterland capitals did not concern themselves greatly with the administration of the ports. By the beginning of the Common Era, Greek and Latin authors became aware that a standard system of international trade linked ports in the Red Sea with those in the Malay Peninsula.

The growth of maritime trade provided a major stimulus to the growth of settlements in Southeast Asia, which lies at the midpoint of the Asian coastal sea routes. The oldest large Southeast Asian settlement, Oc-èo, in
the Mekong Delta of Vietnam, was probably known to the Alexandrian Greek cosmographer Klaudios Ptolemaeus. By 1450, Southeast Asia had become one of the most highly urbanized parts of the world. This maritime trade linking the Indian Ocean, South China Sea, and Java Sea also encouraged the growth of cities along the southeast coast of China. Cities such as Melaka in the Malay Peninsula and Bantam on the island of Java formed during the Islamic period, which some scholars classify as “Islamic cities.”

Southeast Asian lowland settlements are difficult to study. Many were built over water, both on stilt houses and rafts, and as a result their remains are submerged beneath water and sediment. Archaeologists have been unable to recover much data from important early settlements such as Palembang in Sumatra. That they were impressive is clear from the reports of the first Europeans who visited them in the sixteenth and seventeenth centuries.

Much more archaeological research is necessary to enable scholars to verify and expand on the historical descriptions of historical Asian settlements. The subject of settlement archaeology has only recently been introduced to Asian research. Most attention has been focused on the largest settlements and the most impressive buildings within them. Attention is now shifting toward the study of settlements of different sizes, and to the areas where people of the lower classes lived and worked. More research is being designed to recover patterns of settlement rather than concentrating only on individual settlements. This development will eventually make it possible to apply more sophisticated tools of geographical analysis to examine such subjects as demographic and economic change.

Writing on “Extraordinary Cities: Early ‘City-ness’ and the Origins of Agriculture and States,” Taylor (2012), supports Jane Jacob’s controversial thesis, which used Sahlin’s “stone age economics” of cities inventing agriculture. Using Mesopotamian studies, Taylor contends that states were invented in cities, and argues for “central flow theory” as an alternative to traditional central place theory. In identifying 12 possible early cities beyond western Asia, Taylor lists Great Zimbabwe (1250–1450 CE) and the Middle Niger urban complexes (first millennium CE, possibly earlier) as African examples. Taylor further identifies Upper Egypt (3200 BCE) and the Guinea and Sahel riverine areas of West Africa (900–1800 CE) as two of the six cities and city-states in the main “civilization” zones (the other regions being the Indus Valley, China (Erlitou culture and Shang empire), Mesoamerica (pre-Maya to Aztec), and “Greater Peru” (coastal and Andes)). The Upper Egypt cities included Hierakonpolis, Nagada, and This (or Thinite, near Abydos), while the West African Hausaland city-states were based on seven cities: Kano, Katsina, Zaria, Biram, Daura, Rano, and Gobir. In short, Taylor draws attention to some of the earliest African settlements.

This entry focuses on selected early African settlements in the following areas: Egypt; south central Africa (ca. 500 to 1450 BCE); the Pre-Aksumite and Aksumite settlements of northeast Tigrai (Ethiopia) (800 BCE–700 CE); the Iron Age (Early and Later) settlements in South Africa (third to nineteenth century CE); early medieval North Africa (Morocco, Libya, and Tunisia) (650–800 CE); and West Africa (the Hausaland city-state of Kano) (post-twelfth century CE) (Figure 1).
Figure 1  Historical settlements in Africa (courtesy of Dr Rajendra Pillay and Ms Susan Abraham).
sporadic, and not well integrated, and there was a lack of reciprocal Egyptian influence on Uruk sites or in the intervening regions; by the Terminal Predynastic period (ca. 3300–3050 BCE), however, there was an extensive network of contacts between these two regions, but it dissipated very quickly thereafter.

Savage contends that in the Early Predynastic period (ca. 5000–3900 BCE) the settlements in the Hierakonpolis region (from Hierakonpolis to Asyut in the Upper Nile) appeared concentrated close to the river, and showed evidence of remnant foraging, hunting, and industry (e.g., ceramic manufacturing). By the middle of the Late Predynastic period (ca. 3650–3300 BCE), settlements were found on the Nile levees, wadi fans, and the low desert terraces at the edge of the floodplain, and were more than 4–5 km apart in the most densely populated areas. This pattern contrasted with the early settlements in the Nagada and Thin(ite) regions (downstream from Hierakonpolis), with small sites at Nagada (3 ha or less) on low terraces overlooking the floodplain and about 2 km apart, while those in Thin on the east bank of the Nile were 1–2 km apart; however, during the Late Predynastic (ca. 3650–3300 BCE) and the Terminal Predynastic (ca. 3300–3050 BCE) periods the settlements in Thin – especially at Naga-ed-Der and the Abydos villages – were more nucleated, with fewer than 100 people each. In consequence, affiliated settlements contracted, and were curtailed or abandoned.

Smaller outlying sites of various functions in the Hierakonpolis area flanked the larger, more nucleated regional centers, and included clustered agricultural settlements of simple structures with hearths and pits. Agricultural production during the Late Predynastic period in Hierakonpolis and Nagada involved the cultivation of wheat and barley, and the raising of cattle, sheep, goats, and pigs, and fishing in Nagada. Surplus production in Hierakonpolis helped facilitate trade with Lower Egypt and the Southern Levant.

The Hierakonpolis villages seemed to have developed organically, with the spaces between houses irregular in shape and size, and with larger industrial-scale production facilities up the wadis. In the regional centers of Hierakonpolis, there were larger structures that probably fulfilled religious and administrative functions. Savage (2001) notes that the houses were circular and small; or slightly larger, rectangular, and semisubterranean. In contrast, the houses in the Nagada region often contained hearths and storage pits, and sometimes subfloor burials. The sites in Nagada, which were sometimes occupied for several generations, housed 50 to 250 persons, and trash pits and animal pens were scattered among the dwellings. Furthermore, the larger communities in the Nagada region seemed to have been planned, and Nagada South Town had rectangular, mudbrick buildings inside a 2 m wall thought to be a fortification system.

**Early settlements in south central Africa (ca. 500–1450 CE)**

Kathryn de Luna (2012) writes on the early settlement in south central Africa with reference to linguistic and archaeological records that go back some three millennia, using these records to produce a regional settlement chronology in south central Africa. Her work focuses on the Botatwe language in the Kafue–Machili–Zambezi–Linyanti river basins. She argues that the Proto-Botatwe-speaking communities diverged from the ancestral Bantu-speaking societies located to the north and east of the extant Botatwe languages. Moreover, the archaeological records and linguistic evidence correspond to identify the Greater Kafue region and the area immediately to the north as the homeland.
HISTORICAL SETTLEMENT: AFRICA

of the Proto-Botatwe speech communities for about 15 centuries. Over time the speakers of Proto-Botatwe slowly shifted from their original location to establish new settlements to the west and east of the Kafue River basin (ca. 500–1700 CE).

The archaeological and linguistic records show that several activities were undertaken in these early African settlements, including shifts in settlement patterns and developments in hunting, cattle keeping, cereal agriculture, and metal work. With the spread of food production and developments in the food economy in the Greater Kafue and Batoka Plateau, smaller localized changes and sometimes delays accompanied the adoption of cereals and livestock. While the Early Iron Age settlement in the Kafue region only occurred in the good agricultural lands of the grasslands, during the Middle Iron Age (i.e., from the last quarter of the first millennium through the early second millennium) settlements were extended into new ecological niches along the rivers and in the woodlands. Also, during the Middle Iron Age the Kafue settlements extended into a greater diversity of microenvironments. For example, the Botatwe settlers in the Batoka and Falls regions experimented with farming in previously untried ecological zones.

The Botatwe community engaged in hunting, and their hunting styles changed over time. The adoption of spears (and spearcraft) (eighth to thirteenth centuries) marked a change from archery to large-enterprise communal spear hunting involving the entrapment and encirclement of the hunt. Later (during the first few centuries of the second millennium), communal hunting gave way to group hunting, especially among the Proto-Kafue group. Proto-Kafue societies had adopted a largely sedentary lifestyle and hunted antelope and wetland antelope species in the Kafue floodplain. De Luna (2012) notes, however, the high mortality rates of species (e.g., buffalo, hippopotamus, elephant, zebra, and antelope) typically hunted by communal spear-hunting groups within the Botatwe communities. Hunting was accompanied by iron tool-making, particularly in spear parts and arrow forms in the Kafue region and the Batoka Plateau.

Cattle keeping was important among the Botatwe communities in an area now known as the Central Cattle Complex (de Luna 2012). The earliest evidence of cattle in the region dates back to the last two or three centuries before the Common Era. Cattle keeping was gradually adopted into the Botatwe subsistence economy. While small numbers of cattle were kept at most settlements in south central Africa by the close of the first millennium, cattle keeping had intensified across the western and southern regions during the second half of the first millennium – thereby becoming an important element of the economy as in the emergence of intensive pastoralism in the grasslands of western Uganda in the early second millennium.

Pre-Aksumite and Aksumite settlements of northeast Tigrai (Ethiopia) (800 BCE–700 CE)

D’Andrea et al. (2008) and Fattovich (2009) present windows on the world of the early settlements in Ethiopia with special reference to the Pre-Aksumite and Aksumite settlements of Northeast Tigrai, and of Yeha (northern Tigrai), respectively. D’Andrea et al. report on 17 settlements in the Gulo-Makeda region 15 km north of the present-day town of Adigrat, while Fattovich’s work is on Yeha (west of Gulo-Makeda). The Tigrai province of Ethiopia shares a common border with Eritrea to the north, while the Pre-Aksumite and the Aksumite periods extended from 800 BCE to 400 CE and
HISTORICAL SETTLEMENT: AFRICA

400 BCE to 700 CE, respectively, with the period 450–400 BCE identified as the Proto-Aksumite. Fattovich’s focus on Yeha coincides with the Pre-Aksumite period (although he suggests that a “Pre-Aksumite culture” did not exist). D’Andrea et al. contend that, while western Tigrai (e.g., Aksum and Yeha) has been extensively researched, the eastern Tigrai had not, prior to their study, been systematically surveyed. Thus, within the context of developments at the urban center of Aksum, their principal objective was to examine the nature and role of rural economies in the development of ancient Ethiopian complex societies. The focus here, however, is on the settlements in ancient Ethiopia.

D’Andrea et al. (2008) note that the Pre-Aksumite peoples were largely an endogenous community with cultural links limited to the Gash Delta region near Kassala in the Sudan, and to the Tihama region along the South Arabian coast. Politically, the Pre-Aksumite period reflects a peripheral role for Gulo-Makeda. Fattovich (2009) contends that it was during the eighth or seventh centuries BCE that contacts between the people of central Tigrai, Agame, and Akkele Guzay with the populations of southwestern South Arabia may have existed. In contrast, the Aksumite period was characterized by a dynamic empire that dominated the southern Red Sea region, had economic and political contacts with Egypt (fourth to second millennia BCE) and South Arabia (first millennium BCE), and links via Adulis on the Red Sea to the expansion of Roman commercial interests into the Indian Ocean during the early first millennium CE. In addition, the town of Aksum had developed a monopoly of trade routes leading to central Africa, from where various products (e.g., ivory, rhinoceros horn, hippopotamus teeth, gold, and incense) were sourced for export via Adulis. Products imported into the Aksum sphere of influence in Africa included iron, glass, ceramics, textiles, wine, aromatic substances, and spices, with several settlements serving as important transfer points in the salt trade. In light of the trading patterns, settlements were mainly located along the Adulis–Aksum belt and along the North–South trade route from Kohaito to Mekelle. The Aksumite period was therefore characterized by strong cultural, social, and economic influences along several fronts, with the settlement at Gulo-Makeda serving as an important regional center that connected the Aksum–Yeha region to the Red Sea and beyond.

D’Andrea et al. (2008) note that the settlements in eastern Tigrai were more numerous, but smaller, than those in western Tigrai, and that pastoralists and farmers occupied Gulo-Makeda for at least 3000 years. Also, the inhabitants of Gulo-Makeda experienced and participated in the trade and movement of persons from Yeha and Aksum in the west, across Akkele Guzai in Eritrea, and via the port of Adulis, with South Arabia. Gulo-Makeda was characterized by continuous occupation of the larger settlements throughout the Pre-Aksumite and Aksumite periods. In addition, water availability, irrigation, and agriculturally favorable locations were critical factors in the establishment and growth of settlements. Gulo-Makeda was marked by an increasing number of settlements over time, and with a long-term trend toward increasing population density. The larger settlements in Gulo-Makeda also had monumental buildings and sometimes tombs, as was the case, according to Fattovich (2009), in Yeha (ca. seventh and sixth centuries BCE) – thereby marking the existence of a social hierarchy at the time. Also, D’Andrea et al. (2008) note that workshops and factories for the production of primitive tools (e.g., scrapers), pottery, and beads were situated close to the town centers and not near raw material sources.

In Gulo-Makeda, smaller settlements were in close proximity to the big centers to
facilitate exchange of household goods and produce. Some rural settlements were located on hillslopes, so that grazing and vegetable cultivation based on water from wells and small dams occurred in the valleys. Elsewhere, dryland cultivation took place in areas where runoff naturally concentrated and where water diversion enabled cultivation on terraced land and sediment slopes. At the same time, Fattovich (2009) notes that cattle herders who were migrating across central Tigrai, Agame and Akkele Guzay, and Hamasien in the early first millennium BCE contributed to the development of an exchange network among these people, and between the communities on the highlands and those in the lowlands and coastal regions.

Settlement in post-Byzantine (early medieval) North Africa (650–800 CE)

The political hold of the Roman empire over North Africa (i.e., classical Africa) ended with the fall of Byzantine Carthage (Roman Africa) toward the end of the seventh century (ca. 698 CE). North Africa (Tunisia, Libya, Algeria, and Morocco), according to Fenwick (2013), officially became the Umayyad province of Ifriqiya, part of Dar al-Islam, under Arab control from the eighth to the nineteenth century. Fenwick contends that the major centers and settlements in North Africa during Arab control (medieval North Africa) (e.g., Kairouan, Beja (Roman Vaga), Sousse (Roman Hadrumentum), Tunis (Roman Thuna), and Tripoli (Roman Oea)) show instances of continuity (e.g., at Cyrenaica and inland Baqqa) and difference (e.g., the decline of Carthage) from the Roman period. In short, Byzantine towns were not necessarily destroyed or abandoned following the Arab conquests (with about 30% of them still occupied until the eleventh century), and pre-existing communication networks and trade routes linking towns to one another endured. Fenwick challenges the earlier traditional model that the transition from Byzantine Carthage to Arab North Africa was catastrophic and a moment of crisis for North Africa. He adds that several cities gained new significance as administrative, military, or trade hubs, for example Beja (in northern Tunisia), Tunis, Tripolis (Libya), and Kairouan (the new inland capital of Ifriqiya). In the next section, the focus shifts to the settlements of medieval North Africa.

Fenwick (2013) notes a decline in the number of rural settlements (e.g., at Jerba on the Tunisia–Libyan border) in the Late Antique II period (500–700 CE), followed by an increase during the Early Medieval I period (700–1050 CE). During Arab dominance, rural settlements became increasingly egalitarian and nucleated in several areas, as at Kasserine during the sixth century, and in Tripolitania and central Tunisia. This phase marked the progressive abandonment of farms, villas, and estates of the Roman period; however, hierarchical differences emerged between persons living in fortified structures, and those in simple huts and buildings. Elsewhere, settlement differences persisted. For example, in northern Tunisia small and large farms, villages, and towns continued to exist (e.g., around Carthage), representing continuity from the Roman era, while in the eighth century there were also large landed estates in the north as a result of land grants to the Arab conquerors and their Berber allies. Over time (700–1050 CE), the number and density of rural settlements increased, especially in Tripolitania and along the coastal areas near Leptis Magna, while further west at Jerba there emerged fortified villages and tower–granaries. Fenwick (2013) argued that the prevalence of large estates in North Africa probably represented a throwback from the Roman times where the church, state, and local elites
owned such property. The Arabs confiscated this property as conquest booty. In general, the nature of the rural landscape in North Africa during the early medieval period was indicative of agrarian wealth.

Following the Arab conquest of Byzantium, urban settlements were not abandoned, with urban diversity an important feature during the early medieval period. Fenwick (2013) notes that in Tocra (Taucheira) – a coastal Cyrenaican town with an irregular street plan – houses of the eighth to tenth centuries were humble structures comprising mudbrick walls and earthen floors, with rectangular rooms organized around courtyards that were also used for commercial activities. Sbeitla (Sufetula) in central Tunisia had been reduced by the seventh century to a series of small, thriving settlement clusters with single-storied fortified complexes, each with an internal well, cistern, and stabling, a church, and a production site – a pattern that survived to the ninth century. In some instances, former religious and public spaces gave way to residential or industrial uses. In contrast, the urban settlement of Volubilis (renamed Walila) (in Morocco) had a Roman settlement on the western third of the city, and within the sixth century wall to the east were Christian burial and industrial (e.g., pottery kilns) zones, while further east and south were Muslim graves. Volubilis was a thriving city and had an Arab quarter with a central tower built out of spoliated Roman blocks, an area of dense housing, a public building (probably a mosque), and an eighth- to ninth-century complex comprising a bathhouse, a granary, and three large – presumably public and administrative – buildings.

Fenwick (2013) contends that, in general, a defining characteristic of the early medieval townscapes in North Africa were fortifications and intramural fortresses – with the Arab army building new forts in the Byzantine style. In addition, there were monumental buildings that served as mosques and for civic purposes, while in some areas churches remained a feature of the townscape with some new ones built (e.g., at Kairouan). Elsewhere churches were repurposed for other uses including olive oil pressing, residences, and light industry (kilns and artisan workshops), while housing became simpler (and smaller) from the mid-sixth century. The port cities also engaged in trade with the Middle East and Spain, exporting oil and wine. In general, urban settlements showed continuity and differences from the Roman to the Arab-controlled periods, while rural settlements increasingly became nucleated.

Early Iron Age settlements in south Africa

Feely and Bell-Cross (2011) and Maggs (1976; 1980) have written on the (Early) Iron Age settlements in south Africa, including the Eastern Cape region, the southern Highveld, and the area to the south of the Vaal and the Pongola rivers, respectively, with the southern Highveld corresponding largely with present-day (i.e., postapartheid) Free State province.

The Iron Age settlements in the southern Highveld were built mainly of stone in the northeast, and of reed and mud huts in the south, and occurred in large numbers. The settlements varied in size from a few units to over 100, and comprised a primary circular structure. Each settlement consisted of a number of units that included huts and livestock pens. The large primary enclosures – built as stock pens – formed the nucleus of the settlement unit, though often several smaller enclosures were clustered at the center. The huts and other domestic structures were built in a ring around the nucleus, highlighting the economic
importance of stock, especially cattle, among the southern Bantu societies. Secondary enclosures were built against and around the primary structures, and separated the living areas from the cattle pens; however, in the southwest the nucleus of the settlements comprised a group of large primary enclosures, usually three to eight in number, with thickened walls on either side of their entrances and arranged in a loose circle around the stock pens.

The settlements to the northeast of the southern Highveld date back to the fifteenth century CE, although Maggs (1976) contends that settlements dating back to the Early Iron Age – some 1000 years earlier – could have existed in the area. These settlements were generally located on the tops or slopes of volcanic (dolerite) intrusions which were quarried on-site to produce the stone for dry wall construction. The settlements along the ridge or scarp crest were not contiguous, with cultivation and grazing in the valleys and along the slopes. Settlement density increased over time as new settlements were built in between older ones. Also, the drier conditions in the western part of the southern Highveld favored stock farming rather than cultivation.

Maggs (1980) contends that the earliest “expression” of inhabitants in the area to the south of the Vaal and Pongola rivers in southern Africa dates back to the Early Iron Age (EIA) (third to fourth centuries CE). The inhabitants were farmers, and excavated pottery in these areas was similar to those found in Matola, near Maputo in Mozambique, in eastern Kenya and Tanzania. Expressions of occupation south of the Vaal and Pongola rivers are lacking from 400 CE to 600 CE, however, suggesting a break in occupation during these years. Settlements reappear in the post-600 CE period, with patterns in the Late Iron Age (LIA) (tenth century onward) suggesting the presence of a different type of community in the area.

The settlements found in the area to the south of the Pongola River exhibit expressions of livestock farming, hunting, food gathering, and iron smelting in the EIA period. Evidence of cultivation is scattered and drawn from expressions of large, semipermanent villages with pits that served as storage for grain. Crops cultivated included millet, sorghum, cow peas, and cucurbits. EIA settlements were confined to sites below 1000 m, especially along the narrow coastline and further inland along the incised river valleys, and in areas of high rainfall (>1000 mm per annum). Inland settlements were also confined to the deeply incised river valleys with deep alluvial or colluvial soils, moderate rainfall (700–800 mm per annum), sweet grazing, and the availability of forests (for firewood and timber). Maggs (1980) notes that valley settlements during the EIA comprised large villages, often around 8 ha in extent, while those along the coast were smaller and more dispersed.

The Eastern Cape EIA farmers also visited the coastal areas to harvest marine shellfish.

Settlements during the LIA were located on hilltops and in the valley slopes in southern Africa, were small and dispersed, and comprised small groups of people who engaged in hunting and gathering. Later (1400 CE onward), settlement expanded into the grassland areas of the southern Highveld, western Lesotho, and KwaZulu-Natal province to secure livestock grazing opportunities, with transhumance a feature of the time. Given the absence of timber in
Settlements in West Africa (ca. 1500 CE)

Nast’s (1996) article, grounded in Foucault’s notion of archaeology, focuses on Islam, gender, and slavery in West Africa around 1500, with particular reference to Kano palace in northern Nigeria. Nast incorporates important elements on settlements in pre-Islamic and Islamic West Africa. Kano City is located in the southern part of Hausaland in present-day northern Nigeria and southern Niger, with radiocarbon dating of iron-smelting furnaces in the Dalla Hills region highlighting that the area was used in the seventh century CE. While Kano palace represented, perhaps, the oldest, largest, and most important palace ever built in sub-Saharan Africa, Kano city ranked with Fez and Cairo among the most important commercial centers of Africa around 1500. The prominence of Kano (formerly Dalla; renamed in the late fifteenth century) as a major economic, political, and cultural center was attributed to its Islamization, the rise of long-distance trade across the Sahara and North and West Africa, and the capture and consolidation of new territories.

The Kano city region was in the Late Stone Age part of a settlement cluster associated with six hills to the north of the Challawa River, with farming, hunting, and fishing the principal human activities. The Fangwai and Santolo settlement groups (located some 25 km to the southeast) initially controlled the Dalla Hill settlements, but were later defeated and scattered by the Dalla Hill groups. Subsequently, the walled city-state of Kano was established, with its Muslim cavalry-based aristocracy and merchant class, and slaves drawn from conquered territories (e.g., Nupe in the south). The establishment of Kano city was also linked to the introduction of a (grain) tax system of one-eighth of production during the reign of King Naguji at the end of the twelfth century, the development of a large and intricate state bureaucracy, and the strengthening of territorial alliances through marriages as a political tool in the 1400s.

Unlike the rest of Africa, matters of production within Kano’s sphere of influence were largely gendered, cultural, and class-based, with distinct separation of responsibilities between the royal household, men, women, eunuchs, and slaves; between adherents to the Islamic faith and those who were non-Muslims (pagan or Maguzawa); and on the basis of age. For example, while Muslim women were largely secluded and engaged their prepuberty daughters as trade intermediaries hawking their crafts, Maguzawa women undertook agricultural production on family and private fields; engaged in spinning, weaving, and beer brewing; were less stringently restrained in their sexuality and daily movements; and intermingled spatially with men both within and outside the household. Essentially, the Islamization of West Africa – especially during the reign of Muhammadu Rumfa (1463–1499) – affected gender relations along sociospatial lines in all spheres of life.

Rumfa’s reign also marked the construction of Kano’s central (Kurmi) market and the massive Kano palace. The palace was built in a separate walled suburb outside the walled city and, for the first time, it rooted the state in one place. The suburb and the palace – as in (Muslim) North Africa and Europe at the time – were rectangular in shape, with the southern portions of the palace aligned to point to Mecca, the Muslim holy city. The palace was also characterized by a strict spatial division along gender and class lines that included royal wife seclusion and massive concubinage, the formal exclusion of women from matters of state, the rise of a state slave
bureaucracy, eunuchs performing state treasury functions, and a special cadre of underclass slave women who tended to the needs of a leisure class of royal women in the inner palace and undertook other menial chores (e.g., laundry). In sum, Kano emerged as a major economic and cultural center, and became a political force that dominated the surrounding hill settlement systems. In addition, Kano exerted considerable influence over northern Nigeria, southern Niger, and West Africa. The Islamic dominance over West (and North) Africa from about the fifteenth century continued somewhat unabated until European states (Holland, England, and France) pursued their separate colonial interests in West (and North) Africa in the seventeenth and eighteenth centuries (Newton 2013).

Conclusion

From North Africa (Tunisia, Libya, Algeria, and Morocco) (650–800 CE), through the Nile Region in Egypt, across the Pre-Aksumite and Aksumite settlements of northeast Tigray (Ethiopia) (800 BCE–700 CE), into West Africa (Kano city), and then southward into south central Africa (the Kafue region), and south Africa, the nature, designs, structures, layouts, locations, functions, and the socio-politico-economic and cultural attributes of the historic settlements of Africa reflect the rich diversity and multifaceted characteristics of the different communities that settled these areas in earlier times.

Acknowledgments

The author thanks Dr Rajendra Pillay of the Department of Geography and Environmental Science, University of Fort Hare (UFH), South Africa, and Ms Susan Abraham for their kind assistance in producing the figure for this entry; and Mr Z. Ntaka, graduate student at UFH in 2014, for his kind assistance with the research for this entry.

The Holocene is the most recent geological epoch and is still ongoing. Charles Lyell introduced the term “Holocene” in 1839 to describe strata in Sicily that had all their molluscan fauna still alive today. This distinguished it from the older Pleistocene epoch with the deposits containing about 30% of extinct molluscan taxa. Lyell constructed the name Holocene (“wholly new” or “entirely new”) from the Greek ὅλος, hólos, “whole,” and καινός, kainós (latinized as cænus). Both tradition and widespread current usage have accorded the Holocene a high geochronological rank of epoch, as is also the case with the Pleistocene. Together they are placed within the Quaternary period, the most recent interval of the Cenozoic era.

The first classification of the climatic phases of the Holocene was based on the study of peat bogs in northern Europe. In 1876 Axel Blytt (Norway) hypothesized that the darker oxidized peat layers with buried pine stumps were deposited in drier conditions, while the lighter layers accumulated in moister conditions. Blytt applied his term “Boreal” to drier (continental) times and “Atlantic” to wetter (oceanic) times. In 1908 Rutger Sernander (Sweden) further developed Blytt’s classification, taking into consideration changes in temperature. He also defined Subboreal and Subatlantic periods within the Holocene and added the subdivisions of the Late Glacial (the Older Dryas, Allerød, and the Younger Dryas) to the sequence. The classification was later incorporated into a sequence of regional pollen zones defined by Lenart von Post (Sweden), one of the founders of palynology. Other paleobotanists, palynologists, and Quaternary geologists have since added information to further develop and improve the Blytt–Sernander climatostratigraphic periodization of the Holocene.

At the beginning of the twentieth century Gerard Jacob De Geer (Sweden) worked out the first timescale for the Holocene and the preceding Late Glacial based on the studies of varve (annual laminated) deposits in southeastern Sweden. The lower boundary of the Holocene was then placed at approximately 8700 years ago, at the time when the retreating Scandinavian ice sheet separated into two parts. Later the Blytt–Sernander sequence has been substantiated by a wide variety of dating methods, first of all, by radiocarbon dates obtained from organic remains and sediments. Although the climatic fluctuations during the Holocene were more complex than Blytt–Sernander classification can identify, it still has been widely used until lately as a temporal framework for the large-scale interregional correlations and comparisons. The Holocene is currently subdivided, in chronological order, into Preboreal, Boreal, Atlantic, Subboreal, and Subatlantic stages of the Blytt–Sernander scheme. According to the modern view, the lower boundary of the Holocene corresponds to the beginning of the rapid warming at about 11700 years before 2000 CE, which corresponds to approximately 10.3$^{14}$C kyr BP (Walker et al. 2009).

Worldwide practical application of radiocarbon dating of organic remains made it
possible to determine the age of the major climatic events and boundaries within the Holocene and provided an opportunity for spatial climatic reconstructions of definite time intervals (so-called time slices) for large areas, up to a hemispheric or global scale. The use of the accelerator mass spectrometry (AMS) further expanded the capabilities of the radiocarbon method and has significantly clarified the Holocene chronology, as AMS $^{14}$C dating can be used for such deposits and regions where the use of conventional radiocarbon analysis was not possible due to low organic contents. Apart from the radiocarbon analysis, a broad variety of methods is currently used for creating the timescale for the paleogeographic reconstructions of the Holocene, including varve counting, calculations of annual ice layers, measurements of cosmogenic isotopes accumulation, tephra- and dendrochronology, lichenometric analysis, and archaeological and historical data. For a correct comparison of the dates obtained with the radiocarbon method and chronologies in calendar (astronomical) years built using other methods, calibration of the radiocarbon dates is required, that is, making corrections for changes in $^{14}$C content in the atmosphere with time.

The Holocene is perhaps the most intensively studied interval of recent geological time. The paleogeographical records of the Holocene contain a wealth of detail on such diverse phenomena as climate change, geomorphological processes, glaciers and permafrost dynamics, sea level changes, vegetation developments, faunal migrations, and human evolution. Studies of peat, lake and marine deposits, soil and loess profiles, speleothems, ice cores, and so forth by a broad variety of methods show a general correspondence of the major landscape and climatic changes during the Holocene across Eurasia and North America and to some extent also globally. At the regional level, changes in the water balance are estimated from variations in the lake levels, in the morphology of meandering river channels, in frontal positions of mountain glaciers, and other natural “archives.” In addition to a variety of high-precision analyses of ice isotopic composition and that of inclusions in the ice, ice cores drilled on the Greenland and Antarctic ice sheets provide a high-resolution timescale for the Holocene, which is widely used as a basis for the interregional correlations of the Holocene landscape and climate reconstructions.

The present-day research of the Holocene is characterized by growing interest in quantitative reconstructions of climate, increasing their accuracy and time resolution, improving methods of reconstruction based on pollen data, broadening the variety of the paleoclimate indicators, and comparing the reconstructions obtained by independent methods. A large variety of proxy data is applied to the reconstructions of the climatic and environmental changes during the Holocene on the continents, including the detailed studies of the sediment’s grain size, chemical, mineral, and isotopic composition, magnetic properties, and so forth. Changes in the composition and geographical distribution of various groups of organisms, for example, large and small mammals, mollusks, and insects (especially Coleoptera), are also widely used for paleoecological reconstructions. In the studies of marine and lacustrine deposits paleoclimatic information is derived from changes in the composition of various groups of aquatic organisms (Foraminifera, Ostracoda, Diatomeae, Chironomidae) as well as from the isotopic composition of foraminifera tests and mollusk shells, and so forth.

Despite a relatively short duration of the Holocene, significant changes in climate and landscape occurred during this interglacial epoch. A rapid warming developed at the transition from the Late Glacial to the Holocene in all latitudinal zones of both hemispheres.
Data on the vertical growth of corals indicate that sea level rise caused by the melting of continental ice sheets continued with variable speed up to about 6 \(^{14}\)C kyr BP (\(\approx 7000\) cal year ago). In the early Holocene (11 700–8000 cal year ago) the sea level rise slowed down, which reflects a reduction of the meltwater discharge from the Antarctic and Laurentide ice sheets.

A large number of reconstructions of the climatic changes during the Holocene were based on various proxy data from specific terrestrial or marine sites. Based on such reconstructions, generalized paleotemperature curves were created to show the mean changes in time for large regions and, ultimately, for the global scale. Among the earliest generalizations of the kind, one can mention the paleotemperature curve worked out by N.-A. Mörner on the basis of changes in the isotopic composition of lacustrine carbonates in southern Sweden, the reconstruction of paleotemperatures in the eastern Mediterranean made by Nesteroff with co-authors, and the curve of the mean July temperature compiled by Borzenkova on the basis of palynological data for the latitudinal belt of 60–75\(^\circ\)N in Europe. These reconstructions showed the approximate synchronism of the most significant warming and cooling phases in different regions and latitudinal zones of Europe during the Holocene.

Based on pollen data from northern Eurasia, N.A. Khotinsky reconstructed three main thermal maxima within the Holocene: Boreal (8.9–8.3 \(^{14}\)C kyr BP), Atlantic (6–4.7 \(^{14}\)C kyr BP), and Subboreal (4.2–3.2 \(^{14}\)C kyr BP). The Boreal maximum was most clearly manifested in Siberia and the Russian far east, while the Atlantic and Subboreal ones were more conspicuous on the Russian Plain. Despite these regional differences, only the Late Atlantic phase marked by an optimal ratio of heat and moisture supplies can be considered the Holocene Climatic Optimum (HCO) across the whole of northern Eurasia. According to the reconstruction by I.I. Borzenkova, in mid-latitudes of the Northern Hemisphere (NH) the most significant warming phases corresponded to the early Boreal (9.0–8.6 \(^{14}\)C kyr BP) and early and Late Atlantic (7.9–7.5 and 6.2–5.3 \(^{14}\)C kyr BP). The Late Atlantic’s warming corresponded to the greatest sea level rise during the Holocene (\(\approx 2\) m higher than at present) and to the maximum expansion of coral habitats in the Pacific Ocean, which required the surface water temperature to be not lower than 20.5\(^\circ\)C. The peak of this warming (about 6–5.5 \(^{14}\)C kyr BP) is considered the HCO in a global context.

Spatial reconstructions of the main climatic indexes, based mainly on palynological data, were conducted for the HCO (6–5.5 \(^{14}\)C kyr BP) in the Northern Hemisphere by A.A. Velichko and colleagues. The reconstructions indicate a general decrease in positive temperature deviations from present-day values from high to mid-latitudes. South of approximately 40\(^\circ\)N the mean annual temperatures at the HCO were close to the present-day values. North of approximately 65\(^\circ\)N annual precipitation exceeded present-day values by 50–100 mm. In Eurasia, within the latitudinal belt between 60\(^\circ\) and 40\(^\circ\)N the rainfall was similar to present-day one, except for the areas with small negative deviations (\(-25\) mm per year) in the Russian and West Siberian plains. A substantial reduction of precipitation (over \(-100\) mm per year) occurred within the same latitudinal belt in eastern North America. The greatest positive precipitation anomalies (+100 mm per year and more) were reconstructed for Central Asia and North Africa on the basis of paleobotanic and archaeological data, as well as the data on the lake levels.

During the last decade several research papers provided reconstructions of macro-regional or global temperature anomalies for the entire
Holocene or for a large part of it, derived from comparative analyses of proxy-based reconstructions from various sites (e.g., Marcott et al. 2013; Mayewski et al. 2004; Wanner et al. 2008). In these studies, the preference was given to the longest and continuous data series of the Holocene with the highest time resolution. Based on the data from 73 globally distributed records for the past 11,300 years, Marcott et al. (2013) showed that the early Holocene (10,000 to 5,000 years ago) warming was followed by approximately 0.7°C cooling through the Middle to Late Holocene (after 5,000 years ago), culminating in the coolest temperatures of the Holocene during the Little Ice Age about 200 years ago.

Although the Holocene climate is conventionally thought to have been relatively stable, evidence from North Atlantic deep sea cores revealed that it was punctuated with episodes when cool, ice-bearing waters from north of Iceland penetrated as far south as the latitude of Britain and the atmospheric circulation above Greenland changed abruptly. These abrupt shifts (so-called Bond cycles) appear to be the most recent manifestation of a pervasive millennial-scale climate cycle operating independently of the glacial–interglacial climate state, apparently due to solar variability and the response of the global climate system to these oscillations.

Mayewski et al. (2004) compared about 50 globally distributed high-resolution climate proxy records to estimate the degree of climate variability in the Holocene. This study revealed six periods of rapid climate change (RCC) during the time periods 9000–8000, 6000–5000, 4200–3800, 3500–2500, 1200–1000, and 600–150 cal year ago. Most of these RCCs were characterized by polar cooling, tropical aridity, and major atmospheric circulation changes, although in the most recent interval (600–150 cal year ago) polar cooling was accompanied by increased moisture in some parts of the tropics. Comparison of paleoclimatic records with climate forcing time series suggests that changes in insolation related both to orbital variations of the Earth and to solar variability played a central role in the global-scale changes in the climate of the Holocene.

Bradley (2003) examined the role of the main forcing factors in the Holocene climate change. These factors operate on different timescales: lower frequency (millennial-scale) climate changes associated with orbital variations, century-scale variability associated with solar activity, and annual- to decadal-scale variability associated with volcanic forcing. Feedbacks within the climate system may involve nonlinear responses to forcing, especially if critical thresholds are exceeded. In addition, there may be distinct regional climate anomaly patterns that result from certain types of forcing. Some anomalies that appear in Holocene paleoclimatic records may be unrelated to external forcing factors, but reflect conditions entirely within the climate system.

Wanner et al. (2008) used selected proxy-based reconstructions of different climate variables together with time series of natural forcings (orbital and solar variations, large tropical volcanic eruptions, land cover, and greenhouse gases) to explain the climate changes from the mid-Holocene (≈6000 years ago) to preindustrial time. Their comparison showed that the redistribution of solar energy, due to orbital forcing on a millennial timescale, was the cause of a progressive southward shift of the summer position of the Intertropical Convergence Zone in the Northern Hemisphere, accompanied by weakening of the monsoon systems in Africa and Asia and increasing dryness on both continents. The shift was associated with summer cooling of the NH, combined with changing temperature gradients.
in the oceans. Although Wanner et al. (2008) did not find a worldwide coincidence between solar irradiance minima, tropical volcanic eruptions, and decadal to multi-century cooling events, they showed that such cooling events, accompanied by advances of mountain glaciers, occurred in the NH (e.g., in Scandinavia and the European Alps) during the Late Holocene. The most significant of them, the Little Ice Age, occurred between 1350 and 1850 CE when the lower summer insolation in the NH due to orbital forcing coincided with solar activity minimum and several strong tropical volcanic eruptions.

Nevertheless, it is impossible to explain some of the abrupt climate fluctuations that occurred during the Holocene by the influence of the forces external to the global ecosystem. The most abrupt and widespread of such events occurred between 8400 and 8000 cal year ago, when the temperature dropped by 4–8°C in central Greenland and 1.5–3°C at marine and terrestrial sites around the North Atlantic Ocean. It also appears to have been generally cool over much of the Northern Hemisphere throughout this interval, as evidenced by increased amounts of ice rafted debris, strengthened atmospheric circulation over the North Atlantic and Siberia, and mountain glacier advances in northwestern North America and Scandinavia (Mayewski et al. 2004). D.C. Barber and colleagues hypothesized that the so-called 8.2-kyr cold event was forced by a massive outflow of fresh water from glacial lakes, originally dammed by a remnant of the Laurentide ice sheet, into the Labrador Sea. A sudden increase in freshwater flux reduced sea surface salinity and altered ocean thermohaline circulation, resulting in dramatic reduction of heat transfer from the ocean to the atmosphere in the North Atlantic and adjacent regions. Thus, the 8.2-kyr event is likely to be similar in its origin to the younger Dryas cold stage and other abrupt climate fluctuations of the Late Glacial linked to changes in thermohaline circulation of the ocean.

A detailed global temperature reconstruction for the past 1500 years carried out by Marcott et al. (2013) shows a cooling trend from a warm interval from approximately 1500 to 1000 years ago (so-called Medieval Climatic Optimum) to a cold interval (≈500 to 100 years ago) that is approximately equivalent to the Little Ice Age. Global temperatures of the past decade have not yet exceeded peak interglacial (that is, the Holocene optimum) values but are warmer than during approximately 75% of the Holocene temperature history. Therefore, the mean global temperature has risen from near the coldest to the warmest level of the Holocene within the past century, reversing the long-term cooling trend that began after the HCO, about 5000 years ago.

Recently, the Global Stratotype Section and Point (GSSP) for the base of the Holocene Series/Epoch has been ratified by the International Union of Geological Sciences. The base of the Holocene is defined in the North Greenland Ice Core Project’s ice core drilled in the year 2003 in the central Greenland ice sheet at 75°06’N and 42°18’W (Walker et al. 2009). In the NorthGRIP ice core record, the horizon at a depth of 1492.45 m shows the clearest signal of rapid climatic warming, an event that marks the end of the last cold episode (Younger Dryas Stadial/Greenland Stadial 1) of the Pleistocene and the beginning of the Holocene. This climatic event is most clearly reflected in an abrupt shift in deuterium excess values, followed by more gradual changes in δ¹⁸O, dust concentration, and annual layer thickness. A timescale based on multi-parameter annual layer counting and constrained by bracketing tephra layers provides an age of 11 700 year before 2000 CE for the base of the Holocene.

Home

Alison Blunt
Queen Mary University of London, UK

From the domestic scale to broader ideas about belonging, privacy, and security, the home is a rich and diverse subject for geographical research. Often connected to, but distinct from, work on housing, household, and family, geographical research on home investigates imaginative and material spaces of home and the relationships between them, the significance of home from the domestic dwelling to the nation and beyond, and the ways in which home is bound up with identity, power, place, and mobility. For Blunt and Dowling (2006, 10): “home is a series of feelings and attachments, some of which, some of the time, and in some places, become connected to a physical structure that provides shelter. Conversely, one can live in a house and yet not feel ‘at home.’”

Humanistic geographers writing in the 1970s and 1980s provided the first sustained geographical engagement with ideas about home. In contrast to the abstractions of spatial science and structural Marxism, humanistic geographers valued the relationships between people and place, often expressed most eloquently through a love of home. For many humanistic geographers, home was the central anchoring point for human life, the heart and hearth of human creativity and self-expression. Home was a unique place – and a uniquely human place – to be celebrated as authentic and meaningful. Humanistic geographers trace the poetics of home in relation to both intimate and wider worlds, writing evocative accounts that bind individuals and their dwellings to a sense of home in the wider cosmos. Other geographers have studied the home as a “more-than-human” place, whether through the entanglements of nature and culture within and beyond the built fabric of a dwelling or in the space of the domestic garden.

The positive meanings of home celebrated by many humanistic geographers have been subject to significant critique by feminist geographers for ignoring the power relations and inequalities that shape experiences of home, particularly for women. As many feminists working in geography and beyond have shown, the home is a gendered place and is often a site of fear and violence rather than security and belonging (Brickell 2012). The home is an important and yet contested site in feminist debates about power and identity, often articulated through life stories in a variety of forms (Varley 2008). Some feminists have written about the political limits of home, implying a bounded and stable identity, underpinned by the exclusion of difference and a nostalgic appeal to unity and privilege. Others, in contrast, explore the political possibilities of home and critique ideas about home as a necessarily oppressive and apolitical space, including bell hooks’s (1991) influential work on “homeplace as a site of resistance” for black women.

Inspired by such research, Blunt and Dowling (2006) developed a “critical geography of home,” which argues that material and imaginative geographies of home are closely intertwined; that home, power, and identity are intimately linked; and that geographies of home are multi-scalar. Home takes material form in a wide range of ways, including through domestic architecture, interior design, domestic material culture, and homemaking practices. And yet, as Blunt
and Dowling argue, the materialities of home are closely shaped by and understood in relation to imaginative geographies of home. As they write, “the material form of home is dependent on what home is imagined to be, and imaginaries of home are influenced by the physical forms of dwelling” (2006, 22).

The relationships between home, power, and identity are also closely tied to the ways in which “[w]hat home means and how it is materially manifest are continually created and re-created through everyday home-making practices, which are themselves tied to spatial imaginaries of home” (Blunt and Dowling 2006, 254). The home is an important site for studying the politics of identity in relation to inclusion, exclusion, belonging, and inequality, particularly in terms of gender, class, age, sexuality, race, and religion. Feminist and postcolonial research on home as a site of both power and resistance has been important in this context, as shown by work on the relationships between home, nation, and empire; the inclusions and exclusions that underpin the geopolitics of home and homeland; and the politics of dwelling and belonging in relation to indigeneity, migration, and diaspora.

Connected to this interest in home within but also beyond a domestic dwelling, the third part of Blunt and Dowling’s “critical geography of home” concerns the multiscalarity of home, whereby “[T]he relations of domesticity, intimacy and belonging that construct home not only extend beyond, but also help to produce scales far beyond the household” (2006, 257). Research in this context spans the political mobilization of home in imperial politics, anti-imperial nationalism, and the contemporary politics of homeland (in)security; the transnational built form of domestic dwellings such as the bungalow and high-rise; the transnational and/or diasporic importance of homemaking practices and domestic cultures alongside wider ideas of home, belonging, and attachment; and the employment of domestic workers in the global economy.

Geographical research on home therefore spans past and present homes, home on domestic to global scales, and positive meanings of home alongside the home as a site of violence, fear, and oppression. Such research is part of a wider focus on home across the humanities and social sciences, and has made a distinctive contribution through its focus on the spatiality of home, the relationships between home and place, and home across multiple and coexisting scales. Examples of the wider cross-disciplinary interest in home include the journal *Home Cultures*, which was launched in 2004 and is dedicated “to the critical understanding of the domestic sphere, its artifacts, spaces and relations, across timeframes and cultures;” and the Centre for Studies of Home, a partnership between Queen Mary University of London and The Geffrye Museum of the Home, which spans “research on the home and domesticity (including everyday domestic life, domestic architecture, interior design, and domestic material cultures) to the significance of home beyond the domestic (including broader ideas about dwelling, belonging, and security).”

Homelessness

Erin DeMuynck

University of Wisconsin–Fox Valley, USA

The notion of home is associated not only with housing or a material structure but also with social relations and feelings of security and attachment. From this perspective, it is possible to be homeless but not unhoused or, perhaps, to be unhoused but not homeless. Homelessness is a complex concept that can be understood as composed of a number of experiences that lie along a continuum. At one end of this continuum, the visible homeless sleep and carry out most of their daily activities in public. At the other end of the spectrum, the hidden homeless have access to shelter but may live in unsafe or highly insecure conditions. The visible homeless tend to be more easily identified visually, while those who are part of the hidden homeless population may blend in to varying degrees with the nonhomeless population. During a lifetime, individuals may move back and forth along the continuum between visible and hidden homelessness. They may also move in and out of homelessness one or multiple times over the course of their lives.

Across types, homelessness can be understood as both an effect of severe social and economic marginalization and subsequently as a cause of further marginalization. While homelessness has been a feature of many societies throughout space and time, it tends to broaden and deepen or to diminish depending on social, economic, and political factors. Contemporary homelessness can be understood as an enduring outcome of the deepening poverty and inequality that have accompanied globalization, economic restructuring, and the dismantling of social safety nets. Deindustrialization and the increased mobility of companies initiated an increasingly asymmetrical system of income distribution in which many stable middle-class jobs have been replaced with contractual and part-time precarious employment opportunities at a lower pay scale and without employment benefits such as health insurance. This trend led to a growth in poverty, which was met by a retreat of the state at the national scale. The obligation for human service and welfare provision was then transferred to state and municipal levels. Neither state and local government nor the private sector has been able (or willing?) to meet the growing demand for human services. Today there continue to be calls for cutbacks in welfare spending, tightened eligibility requirements, and renewed efforts at welfare state reorganization at all levels of government.

As the numbers of people in need increased and national funding for human services was severely retrenched, local governments acted. However, rather than addressing causes of the growing social need or confronting it directly, municipal policy responses served to further marginalize people who are homeless and those who are vulnerable to homelessness. As a mode of adaptation to severe federal funding reductions and a postindustrial reality, available resources were redirected away from human welfare and toward pro-growth and pro-business strategies such as corporate tax breaks, privatization of public services, the creation of public–private ventures, and cultural development and image-building projects. The goal was to attract

an economically active population back to the city at a time when funds for services and infrastructure had been drastically reduced, unemployment was rising, and social need was high. As a result, cities have been reimaged as cleaned up, safe, and welcoming places for business owners, developers, and wealthy tourists and residents. This urban policy focus remains ascendant today.

People experiencing homelessness have no place in this kind of city. Revanchism – taking back the spaces of the city from those who make them undesirable to capital – is achieved through surveillance, policing measures, and regulations aimed at unwanted populations, and it keeps revitalized parts of the city free from the homeless and poor. These efforts criminalize homelessness and prevent individuals who are homeless from entering and staying in public spaces, where they are regarded as out of place. Their rights to the city are subordinated in the name of making spaces more attractive to middle- and upper-class residents and consumers. The results of this policy approach can be visibly seen in cities in the form of a deeply uneven landscape in which vibrant, highly designed, and maintained spaces are produced in showcase urban districts while the poor are shunted into increasingly neglected and deprived parts of cities. This kind of gentrification in privileged areas and the concomitant concentration of poverty elsewhere put pressure on housing markets and have the effect of driving up prices, most intensely at the low end of the market.

In the midst of converging challenges involving reduced wages, reduced resources for the poor, increased housing costs, and revanchist policies, people are actively blamed for their homelessness. Moreover, they are blamed for broader urban problems of unemployment, underemployment, and poverty. In this neoliberal era of hyperindividualism, all problems are considered the responsibility of the very individuals who are victimized by larger systemic and structural forces. As a result, people experiencing homelessness are constructed as not only out of place but also undeserving of assistance or care. In this climate of exclusion and disdain for the other, the impacts of homelessness on the physical and psychological health of individuals can be particularly harsh. While physical and mental health conditions may have predated the homelessness of some, this is not necessarily the case for all. Homelessness itself and its logic of exclusion are often the causes of illness and pain rather than homelessness being an outcome of pre-existing physical or mental illness.

The intensification of inequality and exclusion has also served to broaden the reach of homelessness and extend it to new spaces and populations. Young African American men were hardest hit by deindustrialization and became homeless at high rates during the 1980s, and racial inequality continues to be a factor in access to jobs and compensation today. Women and children have also joined the homeless population at higher rates as a result of deepening inequality and poverty, and decreased access to services and affordable housing. Gender identity and immigrant status are two additional factors associated with homelessness. LGBTQ youth are disproportionately represented among the homeless. Like homeless youth in general, LGBTQ youth may run away or be forced out of the home as a consequence of severe family conflict, abuse, or neglect; for LGBTQ youth, this happens at a higher rate. Immigrant youth are another overrepresented population. Those who arrive in the United States without a place to go or family to take care of them are at risk of becoming homeless.

Personal factors can increase vulnerability to homelessness for anyone. For example, limited access to education or training, mental or physical disability, lack of family to rely on, and
alcohol or drug addiction increase vulnerability. Yet, it should be noted that, while structural constraints compounded by individual vulnerabilities impact the everyday realities of people who are homeless on a deep level, individuals experiencing homelessness also exercise agency every day in their actions and decisions. They actively establish social networks, develop complex relations with people and places in the city, find moments of enjoyment, and create a life for themselves. These kinds of adaptive survival patterns may or may not make it easier to move out of homelessness in the long term; however, they do make it clear that individuals who are homeless should not be seen only as victims but also as people who have the power to develop alternative ways of understanding and being in urban space.

Housing

Daniel J. Hammel
University of Toledo, USA

Housing is an extraordinarily broad topic that touches on a vast range of human activities. It is also a topic that spreads across numerous subfields in geography and has significant cultural, economic, and environmental dimensions. Despite the breadth of the topic, there are relatively few geographers who claim a research specialization in housing. Yet, many geographers focus on related areas that draw from and contribute to a larger literature on housing in the social sciences.

The meaning of housing

Housing has both economic and cultural significance. In addition to fulfilling a basic human need for shelter (included in Article 27 of the Universal Declaration of Human Rights), housing also has legal and political ramifications, including the right to privacy.

The economic component of housing is perhaps the most commonly discussed and studied, particularly in the more industrialized world. Housing, like any economic good, has both use- and exchange-values. The use-value relates to the role of housing as a basic human right and also as a provision that structures people’s quality of life. The exchange-value of a house, referencing its economic worth, has become substantially more complex in advanced capitalist economies. Intricate procedures and laws have been developed that allow houses to be bought and sold with relative ease. Housing markets, which are often specific to individual cities, have developed with particular sets of characteristics relating to the processes of exchange. This formalization of the market allows housing to be treated as an investment. There is some argument that the investment component of housing is as important as the shelter component, especially for middle- and upper-class homeowners (Adams 1984). The investment component has enabled wealthier homebuyers in strong markets to purchase houses, extract a use-value from them for years, sell their houses, and realize substantially more than the original purchase price even when adjusted for inflation. The investment potential of housing is unevenly distributed at the global and national scales, and even within submarkets at the metropolitan scale. In general, moderate- and lower-income homebuyers and renters do not often receive a positive return on investment in their houses. Housing markets are closely linked to the finance industry through mortgages and a wide array of investment instruments brought about after deregulation in the financial and housing finance industries. These issues will be discussed in more detail in the “Housing Finance” section.

The cultural and social components of housing have also been the subject of significant attention by scholars. Housing can be understood in a number of different ways. One of the most important aspects of purchasing or renting a home is that it provides individuals with a physical space in which they may claim a level of privacy for conducting intimate human activities. Housing has also been an instrument of personal expression and identity formation, and some of these functions have been expressed...
in larger society shifts. David Ley (1980) suggests that cultural shifts throughout the 1970s created a new class of urban dwellers who defined themselves through the consumption of architecturally appropriate inner-city houses, which he claims became a driving force of gentrification. Housing has also been understood as a site of consumption. In Marxian thought consumption is a key facet of capitalist economies and the private residence is an important locus of consumption activities. While houses clearly have an exchange-value, the culture of consumption located in the home is an essential part of the capitalist economy.

The importance of the economic and cultural value of housing clearly varies over time and space, but it also varies across class. A traditional neoclassical view of housing has implicitly suggested that middle- and upper-class homeowners place a greater emphasis on the exchange-value and the investment potential of housing than lower-income individuals. This emphasis guides decisions about which house to purchase and what improvements to make to the house. These assumptions, even if once true, have not held up well since the 1990s. Housing is increasingly marketed and sold as an investment, despite the fact that gains in housing value adjusted for inflation appear to be short-lived and are only substantial in a few locales. In addition, most working-class individuals have very limited housing choices, confined to areas where price increases lag well behind those in wealthier areas.

The geography of housing

Geographers have paid a great deal of attention to the location and distribution of housing in cities. While the classic models of urban structure were not specifically housing-based models, they clearly identified strong patterns of housing. The earliest of these, the concentric ring model, used the terms “housing,” “house,” or “home” frequently, but not consistently, in the description of the ecological areas in Chicago. The sector model focused on neighborhoods and housing (Homer Hoyt trained as a real estate economist). While later models included other activities and some focused on commercial land uses, housing has always been seen as a key component of the geography of cities.

The theoretical basis of the models, particularly the social ecology of the Chicago School, has long been the subject of substantial critique. Yet the models, or at least the classic three – Burgess’s concentric ring model, Hoyt’s sector model, and Harris and Ullman’s multiple nuclei model – almost always appear in human geography and urban geography textbooks. Their inclusion is in part because these models are historically important, but also because they identify empirical regularities that are present in many American cities (and the American cities of nearly a century ago). There is a general pattern of lower-income housing around the central business district, despite decades of gentrification in many cities, and high-income housing in far-flung suburbs; although there are certainly poor and declining suburbs as well. The sectoral pattern of wealth and poverty that Hoyt observed is remarkably consistent in eastern and Midwestern American cities, although the complicated geographies of large metropolises resist simple description.

In the latter decades of the twentieth century several models were created that attempted to describe the structures of Latin American cities and Asian port cities, and clearly showed that the classic American models did not fit the rest of the world. Historical patterns of development, politics, culture, and a range of other forces help determine the geography of housing described
in these models, but this entry will turn first to the housing market to help understand the basics of housing geography.

The geography of housing depends a great deal on the workings of housing markets. There is frequent reference in the popular press and even in some economics literature to a housing market. Markets operate at the national level and are linked tightly to the performance of the national economy. While there are clearly national policies that influence and enable housing markets, in a country of any size there are no real national housing markets. A house in Amsterdam, for example, is not in the same market as a house in Rotterdam. Even though there are national-level forces that affect house prices and house sales in both cities, an individual wishing to purchase or rent a house will focus his or her search on a small area and rarely consider looking for a house “somewhere in the Netherlands.”

Housing economists frequently focus their analyses on a metropolitan housing market, and there are substantial differences between metropolitan markets. Part of this difference is explainable by the size of the metropolitan area, areas with larger populations often being more expensive. In 2012, for example, all but one of the five most expensive housing markets in the United States were part of the New York, Los Angeles, or San Francisco Bay metropolitan areas. Honolulu, the most expensive market in the United States, is a special case and provides clear evidence that population is not the only factor in determining house prices (NAR 2014). Detroit, perhaps another special case, had median house prices of about 9% of Honolulu. The general conditions of the metropolitan economy play a role in determining house prices, but so do the level of amenities present and factors that can physically limit the size of the built-up area. Finally, political factors can have a substantial effect on house prices.

There are also substantial variations within metropolitan areas that geographers have termed “housing submarkets.” The idea that metropolitan areas had submarkets that were interrelated but that functioned with some independence has a long history. This principle was implicit in some early urban models, such as the sector model, but it was formalized by geographers in the 1970s doing work on urban mobility (e.g., Adams 1969).

There is some disagreement as to why these submarkets existed and what they looked like. At the most basic level, geographers have pointed to the sheer size of some metropolitan areas and the tendency for the agglomeration of different kinds of economic activities in different parts of the city. Others have suggested that the patterns of industrial activities identified by Hoyt in many American cities guided daily activity patterns in such a way that strong housing sectoral patterns developed. Even a basic understanding of housing patterns in some US cities, particularly in the Midwest, would suggest that such patterns exist; however, there are also clearly divisions between submarkets created by race, ethnicity, and class. In the United States the early studies on filtering and vacancy chains identified clear sectoral patterns, but also strong inner city/suburban divisions driven by race. David Harvey and Lata Chatterjee’s work in Baltimore identified strong divisions of this sort. Harvey and Chatterjee (1974) focused on the workings of the capitalist housing market but, empirically, the existence of class and race divisions had been implicitly understood for years. The clearly inscribed borders of the Black Belt on the South Side of Chicago are perhaps the best example, and were identified in the early 1900s at the very beginning of the Great Migration.

Although the discussion of submarkets is set in the US context, they are present in every city and are particularly easy to see in large
HOUSING

cities. They are often long-standing and slow to change, although change in the characteristic of the markets does occur (the East End/West End divide in London in an excellent example). Although limits to human mobility and the sheer size of many cities create submarkets, many, perhaps most, submarkets are also features of race or class divisions present in the society.

Housing and economic rent

Different land uses have different location or site and situation preferences. They also produce different economic rents, with commercial land uses (office space and retail) producing the highest rents. The ability to produce high rents enables commercial developments to pay a higher price for land. Residential land uses are generally unable to pay as much for land as commercial uses. Of course, high-rise or high-income apartment buildings represent a high intensity of land use and enable very high rents to be paid for land; however, commercial uses at the same intensity will usually pay higher rents.

William Alonso suggested a bid rent function to determine land use, where the land most desirable for particular uses was put to the use that could pay (or bid) the most for it. Thus, areas of high accessibility, whether in the central business district or at a suburban crossroads, will be dominated by commercial uses. Residential uses will typically be found in areas surrounding the commercial uses on somewhat less accessible and cheaper land. This general pattern holds at several scales. Main thoroughfares in suburban areas are often lined with commercial land uses with high-intensity residential uses just beyond the commercial areas, and then lower-density uses beyond the higher-density ones.

The bid rent function becomes more complicated when different land uses are seen to have different attributes beyond accessibility, or when accessibility is more complex. Retail activities, for example, are often highly sensitive to accessibility at various scales from availability to large population centers to easy access to building entrances. Residential land uses, however, typically have lower accessibility requirements. Various physical and cultural amenities play a more significant role than access in the geography of housing. Rolling landscapes, water fronts, and public open space all attract higher-income residential development while heavy transit corridors, industrial development, and areas of high pollution discourage it. In short, the bid rent function suggests that the wealthy will be able to outbid the poor for residential land and typically will choose accessible locations with high amenities and a lack of disamenities.

While economic factors play a significant role in the geography of housing, social and political factors are just as important, especially in political systems with a high degree of local control and variation in the provision of public services, particularly public education. In the United States, sociopolitical factors are so important that they overwhelm or substantially alter the economic influences. In most countries, the central city is home to the wealthiest residents because of a high degree of accessibility to employment, and substantial amenities in shopping and entertainment. In many US cities, this situation is reversed. While some US cities do have significant numbers of wealthy residents in the core, in many others even the middle class has substantially abandoned the city. The pattern is most evident in the United States, but occurs to an extent in other countries.

In the United States, local governments are largely reliant on their own tax bases, typically property tax bases, to fund city services and, most crucially, public education. In most suburbs, these services can be supported at a substantially higher level than in the central
city through higher property taxes, which have the added effect of raising the actual cost of homeownership to a level that is unaffordable to potential moderate-income homebuyers. Higher taxes also raise contract rents to levels high enough to be a barrier to renting – if there are even rental properties available.

In addition, some local governments have established blatantly exclusionary policies through land-use planning. Requirements for lots of a particular size or houses of a particular size effectively prohibit moderate-income people from living in the area. This type of exclusionary zoning has been regulated for nearly 40 years, beginning with a series of legal cases involving the Philadelphia suburb of Mount Laurel, New Jersey. The Mount Laurel cases created a generally accepted “fair-share” doctrine, which noted that any municipality allowing for growth must provide housing for moderate- and low-income residents. This doctrine, however, is easily circumvented, in part because municipalities can actually buy out of it, by subsidizing housing in other municipalities. More recently, the pre-2007 housing bubble significantly inflated prices, pushing upward the price of “moderate-income” housing, which has thereby become unaffordable for even middle-class buyers.

While income and wealth are important variables in creating the geography of housing, in the United States race is the underlying factor in understanding much of the geography of housing. Through a variety of means, African Americans have been excluded from white areas. During a massive suburbanization in the postwar era, race, either openly or in latent form, was a driving factor, and in some areas it was the deciding factor in the decision by white families to move to the suburbs. The hypersegregation of many American cities was maintained through the housing market and a variety of other means, sometimes aggressive and violent, and was perhaps the most striking feature of the geography of housing in American cities. It remains so despite 40 years of legislation and policy prescriptions. Most recently, racial and ethnic segregation in US cities has been maintained through mortgage lending practices that will be discussed further in the “Housing Policy” and “Housing Finance” sections.

Much of the research on race and segregation has focused on the United States, where there are long-standing issues of racial discrimination and racial and ethnic segregation. Other traditional immigration-based countries (e.g., Canada, Australia, New Zealand, South Africa, and some South American countries) share some of these issues, particularly as they relate to indigenous residents, and Canada has some issues similar to the United States given its recent immigration history. With the exception of South Africa, discrimination and segregation are not as intensive and extensive in cities in these countries as they are in US cities. Many of these countries are large federal states, and the fragmentation of local government does make segregation easier to create and maintain, but it is certainly present in countries with centralized governments as well.

The United Kingdom was among the first European countries to experience high levels of immigrant segregation. Large numbers of South Asian and Afro-Caribbean immigrants began to arrive in the 1950s, and by the early 1980s a significant literature on segregation in the immigrant experience in the United Kingdom had begun to develop (see Peach 1996 for an overview). While there were clearly some similarities to the US experience, there were also significant differences – in particular, the experience of Muslim and non-Muslim South Asian immigrants – with a significantly higher and enduring level of segregation among Muslims, pointed to a religious dimension that was not
present in the United States. Despite some very high levels of segregation among ethnic and racial groups in UK cities, segregation is still not at the level of most US cities.

Other European countries have increasing issues of segregation and discrimination, perhaps most evident in the uprisings in Paris and other French cities in the fall of 2005. The geography of European segregation is profoundly different from that in the United States, and even the United Kingdom, with most immigrants segregated in housing projects outside the center of the city and in the suburbs.

Housing and the economy

The connections between housing and the economy are important at a much more theoretical level, and are developed most clearly in a Marxist analysis of housing and uneven development. As a significant portion of the built environment, housing plays a key role in the circuits of capital. Traditionally, the primary circuit, made up of investments in production of all types, is the most important area for capital investment. But, in times of crisis, defined as periods when a glut of capital occurs and rates of profit fall, the secondary circuit becomes an outlet for the excess capital and a target for increased capital investment.

The secondary circuit of capital is composed of investment in the built environment. While capital always flows into this circuit, when it receives comparably greater investment capital flows to areas that have the highest return on investment. These are often areas of traditionally lower capital investment with lower levels of development (Harvey 1978; 1985). In US cities, the suburban fringes or declining areas of the inner city are often the areas of investment. Not all of the investment is in housing (some is in commercial development), but much is.

This theory has been used to explain both suburbanization (Walker 1981) and gentrification (Smith 1982), and at its most essential level it suggests that such phenomena are the result of the need for capital to find a higher rate of return. Cultural factors, consumer preference, transportation innovations, all of which are often seen as important drivers of suburbanization, are thus moved to the role of enabling factors, but they are not the root cause. This view of housing expands on its economic importance as an exchangeable good, and makes it a key facet of the maintenance of global capitalism.

Housing policy

Because of the basic importance of housing and its important role in national economies, it is the focus of significant policy. Most housing policy is created at the national level, but some cities have policies that play a significant role in local housing provision. Thus, policy has profound impacts on the provision of housing and on how people acquire and use it.

Public and private housing provision

The most basic division in housing policy relates to homeownership and the provision of housing. At the two extremes are countries where almost all housing is owned by the government and all new construction is contracted by the government and often built by government laborers, and countries where almost all housing is provided through the private market, construction is carried out privately, and all housing is privately owned, although much of it may then be rented.

Public housing has been a hallmark of socialist countries. As late as the early 1990s, the vast majority of the world’s population lived in public
housing, or in housing highly regulated by the government. In China and the USSR all housing was public. In urban areas in India housing was highly regulated. Significant percentages of the populations of many European countries lived in public housing. One of the few areas of the world with significant amounts of privately owned housing was North America. Historically, in the United States, homeownership was not the norm in cities, but all housing was owned by private firms or individuals and much of it rented to residents.

It is difficult to generalize about the characteristics of these two systems, but typically public housing provision has been faulted for chronic housing shortages. Shortages are often attributed to poor central planning on the supply side, but they also have some roots in the demand for housing when it carries no specific cost. Private housing systems often create housing affordability issues, particularly in high-growth areas, and also have the potential to create high private debt levels for those attempting to buy housing. Some economists have argued that high housing costs can drain investment from other key growth areas of the economy and, certainly in poorer countries, limit the capital available to young people who might want to develop their own businesses.

Traditionally many capitalist countries have adopted a mix of housing provision, attempting to meet basic housing needs for lower- and moderate-income residents by providing the option of public housing, while higher-income people chose private housing. The mix of public and private housing has varied greatly. For example, since 1970 the homeownership rate in the United States has been reasonably consistent at around 63% to 65%. In the United Kingdom the rate increased from 55% to 67% in 2012 (currently higher than in the United States), and in Sweden the rate has gone from around 35% to over 70% during the same time period. While not all renters lived in publicly owned housing in the United Kingdom and Sweden, many did. In the United States in 1970 about 1.7% of all households lived in public housing. By 2010 fewer than 1% of all households lived in public housing, and about 4% received housing assistance (discounting the mortgage interest deduction).

In some countries the balance of public and private housing has changed dramatically. Of course, the fall of the USSR and the conversion of China to a market-based economy had the greatest effect on the global balance of public and private housing, but shifts were also evident in a number of other countries.

The neoliberalization of housing policy

Neoliberalism, the recent worldwide political movement that reduces government size and prioritizes market strength over government responsibility, is often thought of in two phases, rollback and rollout. These two phases affected housing in very different ways. Rollback neoliberalism refers to the movement to privatize the provision of goods and services that were traditionally publicly provided, and housing is clearly one of these goods. Rollout neoliberalism refers to government policies that, in one form or another, augment the free market in such a way as to provide significant advantages to particular private concerns. Although rollout neoliberalism has had some direct effect on housing policy, its most significant effect has been through housing finance (which will be discussed in the next section – the focus here is on neoliberalism and the privatization of housing).

The shift toward private housing can create some advantages. In good market conditions, it can aid in individual wealth creation through the appreciation of house prices, but just as often...
it results in substantial housing affordability and personal debt issues. It also exposes individuals, families, communities, and ultimately cities directly to the vagaries of the global capital that controls housing finance.

The United States is often thought as one of the central points of origin for neoliberal policy, but in larger housing policy, rollback neoliberalism wrought only minor changes in the United States. To a great extent, this is due to the lack of a coherent national housing policy, but primarily it is a function of the already dominant private provision of housing in the United States. Nonetheless, the very little housing in the United States that was government-owned was dramatically changed—principally through the HOPE VI program. HOPE VI worked to push local public housing agencies to become self-supporting, largely by encouraging them to develop market-rate housing in projects that had advantageous locations.

Neoliberal policies contributed to the substantial decrease in publicly provided housing in European countries (particularly the United Kingdom and Sweden), across sub-Saharan African (Jones 2012), and in Latin American countries, with Chile being one the starkest examples anywhere (Posner 2012). It is difficult to categorize Chinese housing policy as neoliberal, with its limitations on permanent residence (hukou) and the still substantial amount of corporate worker housing (danwei), but the dramatic shift toward market-based housing solutions in most Chinese cities has had a similar effect to neoliberal policies in other nations.

Subnational housing policy

It is common for special housing policies and programs to be developed for particular regions of countries, most commonly for large cities. Some of the funding for such programs comes from the national level, but there are significant housing affordability programs that are essentially completely local. Housing affordability is a major issue in global cities and many of them, particularly in Europe, have policies that attempt to provide housing at affordable rates. Most commonly, many cities control development rights and require the creation of a certain number of affordable units when they permit large residential developments. While such schemes can be helpful, there are a number of issues. In some cases, developers are allowed to buy out the requirements for affordable units—presumably with these funds going to construct affordable units elsewhere. In addition, given the extraordinary cost of housing in global cities, the definition of affordable is often quite malleable. In the United States, for example, the affordability definition is often set (by legal principle) at a percentage of the area median income (AMI). In many cities, the rate is set at 30% of the AMI, but in places with a particularly strong market, the rate is 60% of the AMI and there is a chronic shortage of housing even at this rate.

Rent control is a somewhat less common but perhaps more effective way of providing affordable housing. New York City provides an interesting example. Although it was initially a World War II era federal program, the program was taken over and continued by New York State in 1950. The program includes a complex mix of regulations that attempt to keep rents somewhat affordable. Actual rent control is the most stringent requirement and less than 2% of all units in the city are formally controlled; however, a series of rent stabilization programs limit rent increases in moderate-priced units (currently those with rent under $2500 per month). An increasing percentage of units in the city are not regulated at all. In 2011 the amount had risen to about 40%. Some municipalities have downpayment assistance programs...
for moderate-income buyers that are funded through various local fees and housing taxes, but even the most aggressive of these programs is limited in its effect in strong housing markets.

Many housing affordability programs are at the subnational level because, particularly in large countries, there are often many areas where housing is quite affordable. As of yet, there has been little attempt to restrict these programs at the national level akin to the efforts to weaken local predatory lending laws by passing superseding legislation at the state or national level. So, while local affordable housing efforts have not been helped much by national-level legislation, national governments have not acted to restrict local efforts.

**Housing finance**

Because few people can afford to buy a house outright, complicated financial systems have been developed to allow people to borrow money to purchase houses. These systems vary greatly from one country to the next, even in advanced capitalist countries with similar urban systems and homeownership cultures (e.g., the United States and Canada); however, government involvement in these systems is a constant. Almost all systems have or have had a fair degree of government regulation, and many governments have taken a proactive role to advocate for different types of finance instruments or to make financing more available to a wider spectrum of citizens. In the most extreme cases, government agencies often guarantee loans or even make mortgage loans themselves. The US housing finance system was one of the first systems to make homeownership available to a broad swath of the public. Many of its qualities, both positive and negative, have been emulated in other countries. And its failings helped trigger one of the largest global recessions in recent history, starting in 2007.

The birth of modern US housing finance dates back to the Great Depression and the series of acts passed by Congress in the 1930s. The creation of the Federal Housing Administration (FHA) in 1934 was a key moment. While the FHA involved itself in the provision of housing, its most important activities involved creating the means for Americans to be able to buy homes, and in a real sense it was a housing finance agency. The FHA began to guarantee long-term, fixed interest loans from private lenders, which allowed those without significant collateral to gain access to mortgages at reasonable rates with affordable payments. These types of mortgages had been in existence in the US housing market for some time and were becoming more common, but, in the midst of the economic downturn, the willingness of the federal government to guarantee loans spurred lending by many financial institutions and the long-term fixed interest mortgage loan became the backbone of American housing policy, and the key mechanism to provide US workers of modest means with the ability to own homes.

The creation of the Federal National Mortgage Association (FNMA) in 1938 also accelerated this trend. The FNMA created a secondary market to purchase mortgage loans from private institutions which allowed those institutions to escape the long-term commitment of a 20- or 30-year mortgage and to make more capital available for funding more new loans. The creation of a secondary market was a fundamental component of the long-term, fixed interest loan. It meant that private institutions were able to rid themselves of the perceived risk of these loans by selling them on the secondary market. It could have also broadened the range of people to whom financial institutions would be willing to lend, and probably did encourage lending to
HOUSING

middle- and working-class whites. In the Great Depression, when money was tight, it also increased the capital available for lending. In the 1930s, the FNMA only purchased FHA products. Its role gradually increased after World War II. FNMA, of course, is now officially known by an expansion of its acronym, as Fannie Mae.

In general, the federal programs in the United States were successful in expanding access to home loans for white families. Both institutional and individual racism worked to deny African Americans and other minorities access to the same mortgage finance. While strides were made throughout the 1980s and early 1990s, continued racism, coupled with several decades of deregulation of the housing finance industry, led to the targeting of poor and minority borrowers for high-interest loans. Through a complex series of financialization schemes, these risky loans eventually triggered the Great Recession in 2007.

Housing, development, human rights, and the environment

Housing is the space in which a number of significant human activities occur. It is also a tremendously important and emotionally charged subject in many societies. The exchange-value of housing links it to global economic systems. There are few issues that housing does not touch on; the following brief discussion highlights the most significant ones.

Housing is often a key component of the economies of both developing and highly developed countries. Decent, safe housing is a significant concern almost everywhere and is often used as one measure to gauge a country’s level of development. Housing is also a significant avenue for wealth creation. In developed countries, long-term mortgage lending is thought to allow people to purchase housing, pay off the mortgage, and own a house that has appreciated and will continue to appreciate in value. Take the example of a home purchased in 1965. If it was purchased at an average interest rate on a mainstream mortgage and located in a stable neighborhood, even accounting for the cost of basic repairs and upkeep and the real cost of property taxes (after accounting for the value of the tax deduction), the house could have been sold at a price in 1990 that would have likely covered most of the associated costs. Thus, a person could have lived in the home for 35 years and walked away with a cash payment that covered all the costs of living in the home during that time. This scenario typically would only be the case for white homebuyers in certain suburban areas, however; in other areas, homeowners may still walk away with a cash payment, but the costs of interest, upkeep, and so on would probably exceed the sale price. In purely economic terms, it would have been better for these homeowners to have used some of the money they paid for the home on rent, and saved or invested the rest. Despite these issues, however, homeownership is still advocated by many in the housing industry and by many government policies as an effective means of wealth creation.

In countries with highly unstable economic situations, housing can also be a safe investment for those with few resources. An additional room or a stronger roof always has use-value and provides a good option to saving when the currency is inflating. In addition, quite a lot of work is done by the homeowner and many materials involved can be purchased in small quantities and stored. Many houses in the developing world are in a constant state of construction, which is an effective use of spare capital, assuming the homeowners can stake a reliable legal claim to ownership.

The question of ownership is an important one in many developing countries. Significant portions of housing in cities in Latin America,
Africa, and South Asia have been and continue to be built on land that residents had no legal right to occupy. The living conditions in these squatter settlements are often deplorable, but policies toward the settlements are highly variable. Often, squatters are viewed as a nuisance and significant private and public efforts are made to move them and demolish the houses. People must then move and repeat the process of constructing some sort of shelter. In situations where eviction and demolition are common, individuals will not expend much effort on improving their houses, and in many situations they have little time and no resources to make improvements. There are examples of somewhat more enlightened policies toward squatter settlements. One of the more effective government policies has been to recognize their existence; provide water, sewer, and electrical services; and grant residents the legal right to the land. In such instances, which are rare, homeownership has been a path to modest wealth creation.

Housing also has significant legal and civil rights components. Claiming a right to privacy or a right to control the space within the home can be a key facet of developing broader human and civil rights. Conversely, in highly patriarchal societies, the home can also be the site of abuse and violence toward family members that is tacitly or even explicitly sanctioned by the state.

In countries with well-established human rights, housing is still a point of contention and sometimes a key indicator of civil rights. Chester Hartman (1984) proffered the idea of the “right to stay put” in the context of the urban renewal and highway building programs of the 1960s and 1970s. The significant slum clearance for highway construction throughout the postwar era in the United States destroyed neighborhoods, particularly poor and predominately black areas. Hartman suggested that the right to stay put should act as a significant counterbalance to market forces and the state’s power of eminent domain. Eminent domain, stemming from English common law, provides the state with the right to take land (and housing) if it needs to be acquired for a community’s health, safety, and welfare. Large public works projects may have come under these principles, but later eminent domain was used (often by quasi-public economic development entities) in contexts where the need to increase property tax revenues was couched in terms of a health, safety and public welfare issue.

The right to stay put is not an issue only in English common law countries, nor only in democracies; it is also an ongoing concern in rapidly developing countries such as China, where extraordinary levels of development in urban areas have created a crisis of displacement. For example, land rights protests are reasonably common and have given rise to the term “nail houses” to describe the houses and owners who would not sell out to development concerns. Often the house stays while the new development proceeds around it. In some ways this is less an issue in both China and India because of the huge gulf in wealth between the average urban dweller and the developers. Developers can often easily afford to pay the residents to be displaced a sum of money that seems extraordinarily high to the residents, but the issue still arises. The Chinese central government has recognized, in a manner, the right to stay put, while pressuring local governments to increase revenues through development. When the displaced appeal to the central government, it simply notes that the issue of displacement is a local one.

Although “sustainability” is a nebulous term, it is clear that there has been a long-term concern on the part of geographers about human impacts on the local and global environment and
HOUSING

the effects these may have on longer-term health of life on the planet. In this sense, housing is a key issue for anyone concerned with environmental issues from habitat protection to global climate change. There are three basic concerns with housing: where it is located, how large it is, and how it is made.

The location of housing is an important component of its environmental impact. Is the housing located near other locations to which household members need to travel? Is it located near effective mass transit with lower environmental impacts? Commuting long distances to work or other daily activities in a private automobile represents one of the most significant environmental impacts in many highly developed economies. It burns significant amounts of fossil fuel, contributing to global carbon output and is a significant contributor to local air pollution problems.

House sizes in much of the world have increased dramatically over the past century, even as family sizes have declined in many places. In 2009 Australia had the largest average new house size at 2303 ft² (214 m²) followed by the United States, at 2164 ft² (201 m²), which was down slightly from 2006 when new house sizes in the United States reached their peak. In the United Kingdom the average size of a new house was 818 ft² (76 m²), which was among the smallest in Europe. China’s new housing units averaged 616 ft² (60 m²).

House sizes matter for several reasons. Most new construction uses significant resources, few of which are renewable or environmentally benign. In the United States in 2005, half of all the wood cut domestically or imported went into housing construction. Even in countries where high-rise or higher-density houses are the norm, concrete, steel, aluminum, and glass all require significant natural resources to produce, and the larger the unit the greater the impact.

The size of a house also determines the amount of fuel used to heat or cool it, and single-family detached homes are the least efficient. Finally, there is also a correlation between larger houses and greater consumption of consumer goods, even when accounting for the influence of wealth and income.

Construction practices can also have an impact on the level of resource use for new housing units. There is a movement in some countries to use green methods for new construction by utilizing renewable resources and low carbon emission products. In the United States, the Green Building Certification Institute established and certifies green construction standards through the Leadership in Energy and Environmental Design (LEED) program. While these standards can also be applied to homes, they are most commonly seen in larger commercial projects. Green construction also emphasizes reducing other toxins that are common in the production of building materials. Highly insulated houses with efficient means of climate control are also important. Of course, renovation and reuse are typically much more environmentally sound and can substantially reduce the carbon footprint of older homes.

Directions for future research

Much research on housing and housing-related topics in a wide variety of disciplines precludes a comprehensive discussion of future research, but several areas do seem to be of importance and of interest to geographers. Urban policy in neoliberal market-based economies has increasingly been reduced to encouraging private homeownership. It has also served as a substitute for the lack of other government policies concerning broad issues of health, safety, and community welfare. The drive to homeownership has long
been a facet of US urban policy, and, while the emphasis has not been as strong in other industrialized countries, the rates of homeownership have still risen dramatically.

Homeownership certainly has benefits, but it also poses significant risks, as the most recent recession has shown. For many years, academics concerned with housing have questioned the benefits of ownership, particularly for moderate-income people, and the legitimacy of renting has been gaining more credibility. Renting, however, faces numerous institutional challenges, which are highlighted by Donald Krueckeberg in his aptly titled paper “The Grapes of Rent” (1999). Many attitudes about renting versus ownership are highly spatial in nature and include issues of place attachment and place-making as well as a range of other community development-based questions.

Geographers have also begun to investigate alternative forms of homeownership, including some that are intended to provide community members with a greater stake in the governance and management of communities. Community land trusts are one example of this kind of arrangement. They are more common in rural areas but are increasingly used in cities to mitigate some of the risks of homeownership while providing residents with a greater stake in their communities and an increased voice in neighborhood governance. They are also used to provide “perpetual affordability,” which guarantees that, even in the most overheated housing markets, affordable housing can be provided. While community land trusts have been used for over half a century, there are still significant questions about their effect on homeownership, governance, and affordability that become more significant as the instrument is more widely used.

Segregation has also received much attention from urban scholars. Yet this issue is still insufficiently understood as the nature of segregation evolves. The United States has been primarily concerned with racial and ethnic segregation, while the larger issue of sociospatial segregation has been the focus of less racially diverse countries such as China. In multicultural countries, however, there has been little change in levels of racial segregation since the 1950s. Even in postapartheid South Africa there has been little change in levels of residential segregation (Christopher 2005), despite often strong rhetoric from the national government (Turok 2001). This is not to say that changes in policies and laws have had no effect in cities across the globe; they have, and racial segregation levels have dropped in many places. Many US cities, however, are still hypersegregated, which suggests that the topic needs further attention. Politically, there have been calls from both the far left and the far right to allow segregation and to work toward (at least from the left’s perspective) a separate but equal society. There is sophisticated research ongoing about the effect of segregation on children – their worldview, their access to a range of opportunities – and geographers could play a larger role in bringing these discussions to the fore.

Inequality is currently a buzzword in discussions of socioeconomic conditions across the developed world, and much empirical evidence suggests increasing rates of inequality in North America, Europe, and East Asia. Inequality is deeply related to housing and homeownership policies, and is perhaps the strongest challenge to date to the use of homeownership as a wealth creation vehicle, particularly in a neoliberal society. Inequality is also inherently geographical. In the larger social science community there has, as yet, been little discussion of the spatial effects of inequality, which are related strongly to a range of housing issues. More importantly there is no discussion of the spatial origins of inequality by policymakers largely working out
of a tradition of neoclassical economics. These two broad topics have been the focus of a large body of research by geographers. The increasing importance of socioeconomic inequality provides geographers with an opportunity to highlight what is already known on these issues and to work to increase our understanding. Housing-related research is one important avenue for achieving these goals.

Broadly defined, human capital refers to useful skills, knowledge, competencies, and other attributes that enhance an individual’s productivity in the labor market and facilitate other forms of personal and social wellbeing. This capital arises from investments in areas such as formal and informal education, health, on-the-job training, and migration. Notions of what constitutes human capital have evolved over time. While earlier definitions more narrowly focused on the skills and knowledge that increase the economic productivity of individuals as workers, more recent understandings also include the sociopolitical and personal benefits that may arise from higher levels of personal development. Other elements, such as the ability of individuals to access labor markets or benefit from enabling institutional environments, have also been incorporated into more recent definitions of human capital. Measures of human capital have also become more sophisticated in capturing the complexity of personal development and valuable attributes. The characteristics now understood to comprise human capital are acknowledged to have both instrumental value in bringing about certain outcomes (e.g., economic growth, higher wages) as well as intrinsic value to individuals (e.g., enhanced self-respect, greater job satisfaction). As such, higher levels of human capital can be viewed as both a means to and a goal of human development.

Early theorizations of the economic production process considered three basic factors in the creation of economically valuable goods and services: land, labor, and capital (i.e., fixed non-financial assets used as components in the creation of goods or services that do not get significantly depleted in the production process). However, the view that not all laborers contribute equally to the production process and that workers can also have fixed assets has a long history. The notion that workers’ abilities (i.e., what is now referred to as human capital) shape economic productivity is grounded in the early work of classical economics, particularly the writings of Adam Smith and John Stuart Mill. For example, Smith (1981) wrote that workers acquire talents through education and experience that brings them and their society economic benefits via higher profits both in terms of personal wages and enhanced efficiency in the production process.

In the 1950s and 1960s, Jacob Mincer, T.C. Schultz, and Gary Becker pioneered the theoretical and empirical articulation of human capital as an important component in production within neoclassical economics, emphasizing that investments in people lead to individual and national economic growth. In particular, differences in human capital investments were theorized as the result of individual free choice in regards to the time allocated to education and training (Mincer 1958). Education as a human capital investment is predicted to incur near-term costs but the resulting knowledge base of individuals is projected to bring substantial
returns to these investments in the future. In the US context, economic returns to investments in human capital were found to be higher than those of physical capital (Schultz 1961). Moreover, human capital was shown not only to increase the productivity of both time and goods used in the production process but also to produce additional human capital (Becker 1993). Thus, human capital theory suggests that individuals and their respective societies derive economic benefits from investments in people, particularly with regards to formal education and on-the-job training. The long-term benefits of human capital investment are predicted to accrue to individuals and societies rather than to particular firms because human capital is not owned by the firm which employs it, but rather resides in individual workers who can change their place of employment.

The early theorists acknowledged non-economic benefits of human capital, including higher rates of voter participation, increased awareness of family planning options, and greater appreciation of classical music and literature (see Becker 1993, 21). However, their empirical studies and theoretical formulations focused on the relationship between human capital and monetary outcomes such as income inequality, economic growth, unemployment, and competitiveness in international trade. The traditional proxy for human capital was, and largely remains, measures of educational attainment, although health, nutrition, and ability to migrate have long been identified as important in improving worker productivity (Schultz 1961). Early concepts of human capital were generally one-dimensional, viewing human labor as a commodity in the production process and human capital as assets which increase worker quality and lead to greater economic output.

**Key critiques of neoclassical theories of human capital**

The neoclassical theory of human capital has been critiqued on a number of grounds. Within Marxian perspectives, critiques have centered on the failure of human capital theory to acknowledge the relevance of power, class, and class conflict in explaining labor market phenomena. Marxists and other heterodox economists often explicitly reject the view that earnings reflect the market rate of return on human capital (Bowles and Gintis 1974; Folbre 2012). Rather they present the theory as a problematic extension of neoclassical economic thought which promotes the commodification of people according to their knowledge base while ignoring structural imbalances of power that distort returns to education. Marxists reject the theory’s almost exclusive focus on attributes of human capital that arise from individual choice and investments while neglecting to account for unchosen attributes, such as race or gender, which lower returns to schooling for particular individuals. Some Marxists also maintain that the theory lacks explanatory power because it only considers the beneficial aspects of schooling for individuals and does not account for the role of educational institutions in legitimizing structural inequities of power (and wealth) that they argue are inherent in and produced by capitalist labor markets. However, some Marxist economists have also praised human capital theory for rejecting simplistic notions of a homogenous labor force and calling attention to the importance of basic social institutions – schools and the family – in economic analysis.

Within the development literatures, the human capital approach to promoting economic development in less advanced economies has also received substantial criticism. For example, the World Bank’s lending programs have been
heavily influenced by human capital theory since the early 1970s, and financing education remains a key component in the majority of its poverty alleviation initiatives. However, critics have argued that the World Bank’s application of the theory has overemphasized financing educational infrastructure and largely neglects the role of teacher training and the necessary incentives (e.g., salaries) to improve educational quality. Easterly (2002) notes that many teachers in rural areas of the developing world often fail to report to work or teach with very little oversight, often resulting in low quality education – and thus limited human capital production – for the poor. Other scholars and policymakers have noted that, in theory, human capital’s impact on wage outcomes and economic growth depend on assumptions of perfectly competitive labor markets and high levels of employment. However, the acquisition of human capital is unlikely to substantially improve economic wellbeing in areas where formal jobs are very scarce and excess labor capacity leads to downward pressure on wages (Mehrotra 2005).

Placing human capital within broader perspectives of human development

Contemporary concepts of human development view progress in improving the human condition not just in terms of increasing personal income or national economic growth, but as the creation of an enabling environment for people to enjoy long, healthy, and worthwhile lives. For example, Amartya Sen (1999) argues that economic growth is useful only in so far as it increases the opportunities and abilities of people to live lives they have reason to value. Development can thus be evaluated according to the opportunities people have to achieve personal development rather than by focusing on economic indicators. Within this view, human capital accumulation involves increasing intrinsically valuable elements of human wellbeing in addition to those having instrumental value in bringing about better economic outcomes. Thus Sen expands on previous notions of human capital’s value for people and societies.

Sen (1997) notes that the neoclassical view of human capital can easily fit into more inclusive conceptualizations of human development. For example, human capital, such as education and good health, can make workers more efficient in production processes, thus increasing the value of economic output and individual wages, while at the same time providing nonmonetary benefits to people that improve other dimensions of human wellbeing. Several influential studies of poverty find that many traditional components of human capital including literacy, numeracy, and freedom from disease are widely perceived by the poor as important in alleviating nonmonetary types of deprivation, such as social exclusion and the ability to appear in public without shame, even if they do not enhance income (cf., Narayan et al. 2000). Many international organizations and national governments now promote education, health, and mobility as important developmental outcomes independent of their potential contributions to economic growth.

Measuring human capital

Empirical studies of human capital’s influence on economic development commonly employ educational measures as proxies. However, the indicators used often differ in studies of developed countries (which tend to focus on human capital’s role in regional economic competitiveness and development) and less developed countries (which tend to focus on the ways in which human capital impacts poverty
HUMAN CAPITAL

alleviation). In developed countries, studies often employ measures of growth in university-level qualifications, graduation and enrolment rates, time invested in education, and education expenditures. Largely due to data constraints, studies of less developed countries tend to use more simplistic measures including school enrolment figures, years of schooling, literacy rates, and ratio of skilled adults to total adults. However, few of these measures account for possible barriers faced by individuals or groups in making human capital investments in education.

Some studies also include measures of human capital investments in health and nutrition. Common health indicators include health status and life expectancy (often broken down by socioeconomic groups), infant mortality rates, quality and accessibility of the health systems, and public infrastructure affecting health (e.g., sources of potable water, transportation networks, and sanitation systems). More recent work, particularly within advanced economies, has attempted to measure the complex cognitive and cultural characteristics of human capital. In addition, Richard Florida (2002) has argued for measures based on the occupational composition of regions, particularly employment in high skill sectors including science, finance, arts, and entertainment.

Perhaps the best illustration of the shift in viewing human capital accumulation as a goal of development rather than simply a means to expand production and economic growth is the Human Development Index (HDI), which was introduced by the United Nations Development Programme (UNDP) in 1990. Sen’s views on the intrinsic value of certain types of personal development, notably education and health, profoundly influenced the development of the HDI which replaced purely monetary measures of development, such as national gross domestic product (GDP), with a composite statistic comprised of indicators measuring educational attainment (i.e., mean years of schooling and expected years of schooling), life expectancy at birth, and gross national income at purchasing power parity per capita. Thus, traditional indicators of human capital take on enhanced significance as development outcomes when evaluating progress according to the HDI. In 2010, an inequality-adjusted HDI (IHDI) was introduced which accounts for the national-level distribution of health, education, and income measures, and thus better captures the potential costs to human development arising from structural inequities within societies. The HDI is now one of the most widely used measures of international quality of life comparisons and the IHDI is growing in popularity.

The growing realization that other indicators are necessary to more effectively capture the multidimensionality of human capital and its relationship to human wellbeing led to the recent development of the Human Capital Index (HCI), first published in 2013 (WEF 2013). The HCI includes multiple measures of human capital at the national level, as well as the social, physical, and economic characteristics of societies that shape the ability of individuals to benefit from personal development. Educational indicators incorporated into the HCI include both quantitative and qualitative aspects of learning. Health and wellness measures include aspects of physical wellbeing, cognitive functioning, and mental health. Workforce and employment indicators include measures of experience, talents, knowledge, and training for working age adults. The HCI also measures the extent to which human capital can be employed effectively (i.e., the degree to which an enabling environment exists) by incorporating indicators of the quality of legal frameworks, institutions, and infrastructure as well as the prospects of social mobility within a particular county. The index also takes a long-term approach to measuring human capital
by including measures on the differential access to education according to gender and the quality of early childhood development, both of which shape the potential human capital acquisition of individuals in the future.

**Current and emerging research themes**

Within economic geography, mainstream economics, and regional science, much of the theoretical and empirical work on human capital continues to focus on the effects of individual skill sets and knowledge in enhancing the economic competitiveness of firms, cities, regions, and countries. A general consensus exists on the importance of human capital to regional development, particularly with regards to employment growth, wages and income, entrepreneurship, and innovation. Migration, cultural diversity, and the presence of colleges and universities have been found to be a significant factor in the geographic distribution of human capital at the subnational level. For example, studies find that cities remain highly competitive even in theoretically mobile industries such as advanced business services, in part because urban areas attract highly skilled workers. Research also indicates that the level of human capital within localities positively effects the labor market participation of both men and women. However, a common theme in the literature is the need for better proxies that more effectively capture the full dimension of human capital including social skills and complex cognitive abilities such as analytical thinking.

The interest in human capital and its impacts on various elements of wellbeing has spread beyond the economic development literatures to a number of other academic disciplines and policymaking arenas. In particular, human capital has emerged as an increasingly important element in shaping differential vulnerability and adaptation to climate change and the processes driving violent conflict. Some recent research suggests greater human capital investments enhance climate change adaptation and improve risk management, especially among the most vulnerable to negative climate shocks. However, other studies have identified numerous channels through which climate change can actually diminish human capital formation, particularly among individuals living in poverty. For example, climate stresses and extreme weather can undermine health via contributing to food shortages and poor sanitary conditions, decreasing access to potable water, and destroying human shelters and other infrastructure. When they diminish income, climate-related disasters can also reduce the ability of families to send their children to school and intensify pressures on families to transfer children into labor markets. The relationship between human capital and violent conflict also appears to be multidirectional. Some studies find that higher levels of human capital enhance conflict resolution skills and participation in democratic processes. However, research also indicates that exposure to violent conflict negatively affects human capital accumulation by destabilizing educational and health care institutions, decreasing household assets, and contributing to involuntary migration. Taken together, the research to date suggests that exposure to violence, particularly in early childhood, has long-term consequences for educational attainment and human welfare.

**Important areas for future research**

A large body of theoretical and empirical work has produced detailed knowledge of the ways in which human capital investments and a skilled workforce can enhance economic growth, influence regional competitiveness, and contribute to the geographic clustering of
economic activity in advanced economies and China. However, much less is known about mechanisms that can promote and enhance human capital development in countries and regions where people face high barriers to both building and effectively using their human capital. Additional research on the characteristics and conditions that allow poor communities and individuals to accumulate and leverage their human capital to mitigate violent conflict or adapt to and recover from climate change also remain important areas for further study.

Researchers have also articulated many direct channels through which human capital can contribute to improvements in wellbeing; yet most empirical work, particularly within economic geography, has continued to view human capital in the traditional neoclassical sense as assets of workers that improve their economic performance and their leverage in the workforce. Other avenues of impact between human capital and human development, such as its potential role in bringing about social change and expanding the capabilities that allow people to live freer and more worthwhile lives, receive very limited attention in the literature. The potential social, political, and cultural benefits of human capital accumulation in both developed and developing world contexts merit further investigation.

Human ecology

Gregory Knapp
*University of Texas at Austin, USA*

Human ecology encompasses a variety of methods and theories for understanding the relationships between people and their environments at all scales, times, and places. The term has been used by various disciplines, including geography, but is usually understood today to be interdisciplinary. The reference to “ecology” implies that humans and their environment have mutual relationships. Although the term “human ecology” is historically new, dating from the early twentieth century, the underlying subject area, the study of human–environment relationships, is much older.

Every human society has studied and reflected on its relationship with its environment. The oral traditions of “ethnoscience” typically include empirical observations about natural resources, hazards, and management strategies. Spiritual and religious traditions, including shamanism, encompass stories and beliefs about the relationship between people, plants, animals, landscapes, water, and weather. As literacy has expanded in human societies, oral traditions have been incorporated into official discourses of knowledge and power. Although ethnoscience may be maligned in the contexts of colonialism and modernization, local knowledges have proven important and useful for understanding resource practices and even for identifying resource management options for the future.

In European civilization, the ancient Greeks and Romans wrote about agronomy, the impact of the environment on human health, and the relative habitability of various parts of the world, but had a limited grasp of the impact of humans on the environment. In medieval times, St Francis’s teachings urged the valuing nature as part of God’s creation. Many other cultural traditions suggested a close connection between human consciousness, society, and nature, including Taoism and Buddhism in Asia. However, the systematic empirical study of the relationship between people and the environment came later, especially with European exploration of the world and the development of modern science.

Beginning with Marco Polo and accelerating after the voyages of Columbus, European chroniclers published detailed descriptions of new landscapes, ways of life, and resource management practices; colonial and commercial authorities sponsored local studies which provided even more data about different coping strategies and challenges to health and livelihoods in different environments. Encounters with foragers and pastoralists prompted questions about the merits, drawbacks, and historical explanations of agriculture and civilization. By the late eighteenth century, Humboldt was mapping altitudinal zonation in the Andes, and Malthus was writing about the population–resource ratio and warning about the tendency of societies to outgrow their resource base.

Europeans also began to become aware of modernization itself as a new transformation in human history, comparable in significance to earlier transformations such as the rise of agrarian civilization. Modernization involved a shift toward promoting efficiency of production, through division of labor and increased mechanisms of oversight and control within
bureaucracies and firms; the process was facilitated by entrepreneurs in the marketplace and by managers in organizations, and was promoted or impeded by governments and popular movements. Initially, writers addressed (i) the desirability of the goal of increased efficiency of production; (ii) the degree to which this goal could be achieved by modernization methods such as free market institutions; and (iii) the degree to which human nature itself required specific institutional controls (checks and balances, competition) or, alternatively, could be trusted to undertake dramatic revolutionary changes in social structures (Sowell 1987). The ideological struggle over the degree to which human nature is constrained has continued to influence human ecology, separating sociobiologists and neo-Malthusians from political ecologists, for example.

During the nineteenth century, Darwin took up Humboldt’s challenge to perform fieldwork in South America; together with the work of Wallace, his field observations led to the formulation of a theory of natural selection in diverse environments to explain the origin and extinction of species. The theory suggested that humans, having evolved from primate ancestry, were also the products of natural selection. Humans have continued to evolve, developing such traits as lactose tolerance; plants, animals, and disease organisms have coevolved with human innovations in agriculture and civilization. Human cultural habits could also be viewed as subject to environmental selective pressures, based on their relative efficiency in survival and reproduction. The Darwinian tradition also includes sociobiology and its assertions that modern human behavior may be influenced by genetic traits that evolved in a foraging lifestyle in a savanna setting.

Karl Marx is important in the development of human ecology because of his focus on the central role of social arrangements for resource management and production in human history. He argued that the social arrangements for exploiting natural resources also had critical impacts on other aspects of society, and explained modernization as the product of the logic of capital accumulation as expressed by a capitalist class. The environmental implications of this perspective are still being worked out by political ecologists, and the spatial implications for the organization of the world-systems by scholars in development studies.

Many geographers in the late nineteenth and early twentieth centuries focused on potential environmental impacts on human affairs, a tendency that has been referred to as “environmental determinism.” Some of these writers attempted to explain the dominance of European civilization in ecological terms. Others, such as American geographer Ellen Churchill Semple, combined aspects of determinism with more careful empirical studies of human–environment relationships. In opposition to environmental determinism, the French geographer Vidal de la Blache helped develop the concept of “possibilism,” the assertion that the environment presents humans with possibilities and constraints, but that the ultimate outcomes reflect human agency. The work of his students focused on the careful study of ways of life (genres de vie) in particular landscapes (pays) that were also affected by long-distance processes. His students helped found the Annales School of history, which was devoted to the careful empirical study of environmental, demographic, economic, and other processual factors in the history of places and regions. In the United States, Berkeley geographer Carl Ortwin Sauer played a similar role to the Annales School in encouraging detailed long-term analyses of the relationship between people and places. He deployed the concept of ecology at times in his writings but
did not embrace a systems framework; instead he focused on cultural practices as affected by inventions and diffusions. In 1955 Sauer, along with the biologist Marston Bates and the urbanist Lewis Mumford, co-chaired an important symposium on “Man’s Role in Changing the Face of the Earth.” This helped launch the modern concern for human impacts on the planet and further reduced the importance of the determinist perspective.

The term “ecology” dates from the late nineteenth century, and there were a number of discussions of the relevance of biological relationships to human society, but the term “human ecology” was first used by geographers in the early twentieth century. Members of the department of geography at the University of Chicago, J. Paul Goode and Harlan Barrows, were pioneers in defining the term, and eventually argued for its deployment as synonymous with geography itself (Gross 2004). Barrows’s 1922 presidential address to the Association of American Geographers was titled “Geography as Human Ecology” (Barrows 1923). The Chicago geography program was important for the training of Carl Sauer and other influential scholars, including Gilbert F. White, who pioneered the systematic study of adaptation to natural hazards.

Sociologists at Chicago also embraced human ecological frameworks for field research on human society in urban environments. Chicago sociologists Robert E. Park and Ernest W. Burgess studied the concentric zonation of activities in cities, using analogies from biology including the ecological concept of community. By the 1940s and 1950s, sociology had turned away from ecological explanations toward more purely social explanations of social facts. In the late 1970s sociologists William R. Catton and Riley E. Dunlap were arguing for a “new human ecology” or environmental sociology, continuing the tradition of Park and Burgess (Gross 2004).

In Germany, the geographer Carl Troll coined the term “landscape ecology” in 1939 to describe detailed interactions of climate, soil, and plants (including crop plants) in particular places. He helped found the journal *Erdkunde*, which has published many important papers in human ecology, and influenced Karl Butzer, who built on Troll’s focus to include long-term analyses of demography, agriculture, and landscape impacts (Butzer 1982; Butzer and Endfield 2012).

Anthropologists also deployed ecological approaches for the study of cultures. British anthropologist C. Daryll Forde related cultures to habitats in the 1930s. In the 1940s Julian Steward deployed an environmental framework in editing a multidisciplinary handbook on South American Indians, and helped create the subfield of “cultural ecology,” defined by him as a study of the processes by which a society adapts to its environment. He urged careful study of the cultural “core,” practices directly related to making a living in a particular setting. By the 1960s and 1970s, cultural ecology was a flourishing paradigm in anthropology and archaeology and was influencing geography, particularly as deployed by William Denevan and his students at Wisconsin (B.L. Turner, Bernard Nietschmann, and others). Although some studies stressed environmental limitations, more commonly scholars placed an emphasis on the role of adaptation. Chicago-trained anthropologist John W. Bennett urged the study of human–environment relations in terms of adaptive dynamics, with full attention to questions of society, identity, and long-term change. Emilio Moran promoted the study of adaptations to the conditions of such environments as arid zones, high altitudes, grasslands, and the Arctic (Moran 2006).
As in biological ecology, systems approaches have been deployed in human ecology to organize data, guide research agendas, and integrate research teams. The Man and Biosphere Program (MAB) was launched by the United Nations in 1971 and initially attempted to include humans in systems analyses of energy flows, including feedback processes. More recently, the study of coupled human–environment systems has been promoted under the rubric of land change science. Although the human factor is considered to be a subsystem, actual human behaviors may pose challenges for systems analysis owing to their dynamism, local specificity, and the role of culture, governance, and politics. That said, certain regularities do seem to govern relationships between population, transportation, settlement patterns, and land use, and models of these relationships continue to be developed and tested using quantitative data (Turner, Lambin, and Reenberg 2007).

Since the 1980s, “political ecologists” have studied the roles of colonialism, globalization, and neoliberalism as leading to the disempowerment of local people and the despoilment of natural resources; some political ecologists have also deployed activist and/or participatory agendas to achieve emancipatory and conservationist goals (Robbins 2012). In addition, there has been a growing focus on the analysis of discourse and interpretive communities, with the aim of critiquing dominant narratives of progress and dominant depreciation of the validity of ethnoscience. The integration of political ecology, land change science, and cultural ecology approaches continues to be a challenge.

Ongoing research in human ecology across time and space has focused on the major transformations in human–environment relationships since the emergence of the human species, and on the resources, risks, and adaptive strategies deployed in varied environments (Bates 2005). Transformations and episodes which have been studied include the human revolution and emergence of humans as a species; the foraging way of life; domestication; the emergence of permanent settlements and agriculture; the rise of cities and civilization; and modernization.

Work on human origins has involved the investigation of early dietary and behavioral patterns and the geographical characteristics of early human habitats. Chimpanzees have been considered the closest living relatives, and their behavior has been examined for clues to early human behaviors. Recently, bonobos have received a great deal of attention as possibly being even more closely related to humans, and as possibly exhibiting less violence and more gender equality. Early bipedalism and nakedness have been considered hominin adaptations to conditions of emerging grassland and savanna environments (the “savanna hypothesis”). Management of fire enhanced hunting possibilities, and allowed for the cooking of food for more efficient acquisition of nutrients, especially to support large brains. Campfires could have been early centers of social life and sharing. Subsequent migrations to Australia and the Americas were made possible in part by the early use of watercraft.

Foraging (hunting and gathering) has been considered the earliest human adaptation. Studies of modern foragers such as the !Kung by Richard Lee and others have demonstrated that foraging can be labor-efficient; it usually involves gender specialization (women gather, men hunt), food sharing, and opportunistic migration by small bands. Specialization and sharing would make humans more efficient at using resources than other primates, but also required heightened communication skills for planning and coordinating, and mechanisms for rewarding cooperation and punishing cheating. Larger brains, language, and culture – the “human
revolution” – thus may have been driven more by the social than the technological aspects of the foraging adaptation. Forager mobility and perceived resource limitations probably helped place a limit on fertility and birth rates. There is an ongoing debate over the level of violence and warfare associated with foraging societies. Some such as Douglas Fry argue that warfare was rare, while others such as Richard Wrangham and Samuel Bowles argue that warfare was common. The debate depends in part on the definition of warfare, and in part on the inclusion or exclusion of sedentary foragers from the databases.

Since foraging seems an attractive lifestyle, the emergence of agriculture is something of a puzzle. Certain kinds of domestication (including dogs from wolves) are consistent with migratory foraging, and many early plant domesticates were probably cultivated in conjunction with a dominant foraging lifestyle. Jared Diamond has suggested that only some wild plants and animals were suitable for domestication, and their geographic distribution helps account for the subsequent competitive advantages of certain cultures and geographic regions. A shift to agriculture may have been spurred by “Pleistocene overkill” of large prey animals, by climate change at the end of the last glaciation, and perhaps by religious, funerary, and other cultural practices promoting sedentary settlements.

Early forms of farming could have included shifting cultivation in forested environments, which in modern times has been shown to be labor-efficient and consistent with sustainable productivity. However, Denevan has pointed out that shifting cultivation is much less efficient without metal tools, and has argued that intensive agriculture may have emerged much earlier than is sometimes thought. Much recent research has focused on “dark Earths,” modified soils high in organic matter, archaeologically found in such locales as the Amazon basin. Irrigation was probably also labor-efficient under early conditions, especially where the water was rich in nutrients (floodwater farming).

Sedentary life with agriculture encouraged higher birth rates, which resulted in population growth and, in some cases, conflict. Napoleon Chagnon documented high levels of violence among agricultural societies in the Amazon associated with struggles over resources and women. Robert Carneiro hypothesized that cities and state-level social organizations first emerged in areas of circumscribed resources (theory of environmental circumscription), and that conflict and war were the key to forcing members of chiefdoms to join larger civilizational units. Such circumscribed resources would be characteristic of deserts (Egypt, Mesopotamia, Indus river valley, coastal Peru) and mountains (central Mexico, Andes). In some regions, high population densities might create the “social circumscription” that was conducive to state formation (Maya lowlands). Other scholars have argued that large-scale states rely as much on ideological and religious means to gain and maintain power.

Jared Diamond’s popular books, including Collapse (Diamond 2005), have redirected attention to the many historical cases of population decline and societal simplification. Easter Island, the classic Maya, Viking settlements in Greenland, and others provide examples for analysis. His interpretations continue to stimulate critique and debate (Butzer and Endfield 2012). Ongoing research on climate change, volcano activity, earthquakes, hurricanes, and El Niño events contributes to these debates, as does continued archaeological and archival work on reconstructing population change, processes of colonialism, agricultural options and impacts, vegetation change, and soil erosion. A special case is the demographic catastrophe associated with the European conquest of the Americas; the
epidemiology of depopulation remains a topic of interest, as does the subsequent “Columbian exchange” of organisms and technology.

Modernization is the most recent transformative process studied by human ecologists. Involving the division of labor and maximization of efficiency for production of goods and services, modernization involves markets, firms, and organizations including state bureaucracies. Modernizing societies have tended to succeed through the same combination of improved efficiency, population growth, violence, and ideological appeal as marked the earlier triumphs of agricultural civilizations over chiefdoms and of agricultural villagers over foragers. Frameworks of analysis of modernization have varied: classical and neoclassical economics, Marxism (and Gramscian variants), Weberian sociology, and Foucauldian attention to discourse and power, for example.

The rise and development of the modern world has also been a topic of interest in human ecology. In addition to the Columbian exchange and other impacts of long-distance trade, environmental historian Gregory Cushman (2013) has called attention to the end of the ecological “old regime” as fertilization has been decoupled from local nutrient sources. First, guano and nitrate mines provided ready sources of transportable fertilizer, and, second, chemical fertilizers allowed for industrial agriculture. In addition to capitalists, international technocrats have been important in pushing this agenda. Innovations in technology, fertilization, pesticide and herbicide use, and genetically modified organisms (GMOs) have enabled increased agricultural productivity. Sometimes these have been managed by smallholders; Robert Netting (1990) argued that, even under conditions of modernization, family farms have certain advantages and can persist. Large-scale farms have become dominant in many areas, however, and the negative social and ecological impacts of the modern food system has attracted research attention.

Modernization has been associated with fossil fuel use, and increased food production (associated with meat eating) with deforestation; both have added greenhouse gases (carbon dioxide and methane) to the atmosphere, with impacts on climate change. Human ecologists have increasingly paid attention to the challenges of human-induced climate change, in terms of analyzing the impact of different practices, the array of alternatives for adapting, and policy alternatives to enhance resilience, adaptation, and the reduction of greenhouse gases (including sequestration and payments for ecosystem services). The social and environmental impacts of modernization have sometimes been analyzed in the context of Kuznets curves, suggesting that initial increased stresses and inequalities will eventually be followed by reductions in problematic variables. Kuznets himself looked at income inequality, but others have examined pollution, deforestation (forest transition theory), and other impacts.

Demography is another crucial variable in modernization. By improving public health, modernization initially triggered a population explosion even in regions far from the industrializing core. In the 1960s neo-Malthusian biologists were warning about the dire prospects of starvation (Paul Ehrlich) and overuse of common resources (Garrett Hardin). However, research has shown that most societies have possessed the knowledge and means to control their fertility. Research conducted at the School of Forestry at Yale, the Land Tenure Center at Wisconsin, and the International Association for the Study of Common Property has also demonstrated the widespread success of local groups in managing common resources.
In 1945 the demographer Frank W. Notestein suggested that, as the cost–benefit ratio of children goes up, birth rates tend to go down, leading to a “demographic transition” even in the absence of modern birth control or antinatalist policy. This theory has tended to be verified in almost every country experiencing modernization. The education and employment of women has increased the maintenance and opportunity costs of children, reducing birth rates to the point that even many poorer countries are now on a trajectory to population stability or even population reduction. The overcoming of the Malthusian dilemma is making possible new human ecological adaptations, although research on the implications of these trajectories is in its early stages. In theory, environmental impacts should decrease as populations decline, but much depends on consumption practices (per capita resource use), which in turn are connected to resource use.

Political ecologists have focused on power imbalances and resulting environmental impacts in colonial and modernizing contexts. Much effort has been devoted to critiquing official narratives of science, conservation, and progress. Some political ecologists have supported non-market forms of modernization as pursued by states and other institutions, while others have critiqued modernization itself, arguing for a postdevelopment world. Feminist political ecology has promoted research on gendered spaces, counter-mapping, and resistance to hegemonic discourses. Activist scholars engage with historically marginalized groups such as indigenous peoples or women to help them to organize to combat issues such as environmental racism. Others engage in ethnographic research, which sees local people as the keys to both understanding and solving environmental problems.

Much human ecological research has looked at particular regions and places in terms of their specific resources (including ecosystem services), hazards, and possibilities for adaptation. Many studies have combined ethnography, field research, and archival research in a process of “progressive contextualization” (Andrew Vayda), others have assembled teams to create and calibrate models using systems frameworks, while still others have focused on the role of political actors as implementing and resisting processes of colonialism and modernization.

Polar research has looked at arctic and subarctic adaptations to severe winters, short summers, and limited plant productivity. Climate change may lead to the enhanced importance of these lands. Arid land research continues to document the wide range of social and technological practices to tap, distribute, apply, and drain water supplies, as well as the actual and potential impacts of salinization, climate change, and conflict over water. Grassland research has focused on pastoralism and ranching, and also on changing patterns of grain and soybean production in the contexts of technological and climate change.

Mountain research has included detailed studies of management, including agricultural biodiversity, agricultural terracing, mountain irrigation practices, mountain wetland utilization, traditional rotational practices, adaptations to low air pressure, and use of multiple niches (verticality). Climate change, including glacier melt, may lead to upward movement of altitudinal temperature zones, impacts on pathogens including malaria, and changing patterns of precipitation.

Temperate forested areas have been the scene of a variety of agricultural technologies, including shifting cultivation, dairy farming, rice paddy agriculture, truck farming for cities, and animal raising, as well as efforts at forest conservation. These regions in North America, Europe, Japan, and elsewhere have been the scenes of experimentation in organic and other alternative
forms of agriculture. Tropical forests have a similarly wide range of agricultural possibilities; research has focused on traditional (dark Earth, raised field) and modern (ranching, soybean) cultivation practices.

Many other environments (coastal areas, oceans, Mediterranean climates) have attracted human ecological attention. Human ecologists are increasingly addressing concerns for sustainability in local contexts, where culture, demography, politics, economics, soils, climate, and water are involved in trajectories with unique characteristics. Maps, remote sensing, and geographic information systems (GIS), including participatory mapping and participatory action research, provide important tools for visualizing relationships. Fieldwork, including field ethnography, can document practices and alternatives, as well as all-important perceptions and narratives that influence adaptation and other behavior. Arenas of research and policy include land change studies, sustainability studies (combining human rights, poverty reduction, and environmental protection), up through and including education (including service learning and cooperative international education), geo-tourism, and activism. One ambition of human ecology has always been to suggest norms for behavior, including models, if not for some future equilibrium state, at least for institutional relationships and environmental practices that can promote adaptation for the future.

Since many disciplines have claimed proprietorship of the term “human ecology,” its usefulness as a common term for the study of human–environment relationships has been compromised (see Gross 2004). However, its use continues to be promoted by Human Ecology: An Interdisciplinary Journal, which began publication in March 1972. Other organizations promoting human ecology include the Society for Human Ecology (which publishes the Human Ecology Review) and various specialty groups such as the Cultural and Political Ecology Specialty Group of the Association of American Geographers.

Human geography

Audrey Kobayashi
Queen’s University, Canada

Human geography has ancient roots in many parts of the world. It became a formal discipline in Europe during the mid-eighteenth century. The term “geography” derives from the Greek geo (Earth) and graphia (writing), and is often defined in the broadest terms as Earth writing, creating a large scope for the Geographical imagination, which has not diminished since ancient times. Geographers’ imaginations, however, have always been guided by what is defined as knowledge of the world, as well as by the political, economic, and cultural interests embedded in human knowledge. Above all, therefore, human geography can be understood within the contexts of the interrelated processes – including imperialism and colonialism, capitalism, globalization, and recently neoliberalism – that have written the script of global development.

Geographers often bemoan the gap between public understanding of the discipline and what geographers actually do, yet among human geographers there is a very broad range of interests, methods, and approaches. Human geographers value the flexibility of interests and the lack of disciplinary dogma, however, and recognize that any approach that includes concepts of space, place, location, landscape, nature, or region is human geography. But all of these terms also represent concepts that are utilized in daily life. Their historical usage has varied, and they have been enthusiastically contested by geographers over time.

Geography in historical context

Most historians of geography locate Ancient geography in ancient Greek and Roman scholarship and even earlier (Burke and Lowenthal 2011; Mayhew 2011). It also has strong roots in early Chinese and Arab scholarship. It encompassed virtually everything that people knew about the Earth, from speculation about faraway places and how to get to them (often with the aim of conquering them), to understanding human interactions with their environments at a local scale. Arab and Chinese scholars had maps that informed flourishing trade networks long before the Europeans began their “age of exploration.” Human geography today, however, is closely associated with the process of Globalization, from its European roots in the fifteenth century up to the present. Early modern European geography was a practical affair which depended on exploration and cartography to support not only the geographical imagination, but also the projects of imperialism and colonialism. As the world became a vast trading network that allowed movement of commodities – and increasingly people – from one part of the world to another, relations between center and periphery became the foundation of uneven development centuries later. The scale of global expansion increased rapidly as a result of European exploration and colonialism, providing knowledge about lands distant from Europe, and about their flora and fauna. Geography as the study of the Earth became the basis not only for formal studies in universities, but also for the massive power of the European commercial network, attended by the movement not only of natural resources (gold, furs, timber) but also of people, including...
HUMAN GEOGRAPHY

colonists, slaves, indentured laborers, and in many cases unwanted humans such as convicts and religious outcasts. To obtain geographical knowledge by mapping the world was often quite literally to take possession of the world. Human geography is thus associated not only with imagination, innovation, and wonder but also with some of the most brutal practices, military and nonmilitary, of humans toward one another.

Geography as a formal discipline was established in European universities during the Enlightenment period of the mid-eighteenth century. At that time what we call geography today ranged across the fields of history, biology, zoology, geology, and more – anything that involved Earth writing. Immanuel Kant (1724–1804) held a chair at the University of Königsberg where he taught “physical geography.” Kant’s influence on the discipline is twofold and profound. First, the published notes from his lectures include wild speculations about racial differences, which reinforce the superiority of European culture and human bodies, and thus support the dominant discourse about colonial expansion (Kant 1997/1775). It is alleged that Kant garnered at least some of his knowledge by interviewing sailors returned from distant sea voyages. In any case, he began formal scholarship on the geography of races, based on an idea of the other as savage and inferior, which permeated human geography – and science as a whole – for two centuries thereafter (Livingstone 1992; 2003).

Kant’s second, and arguably more enduring, contribution was to write extensively on the concept of Space, which he viewed as a form of cognitive hardwiring that allowed the human mind to perceive and organize the external world. Understanding space for Kant was fundamental to ontology and epistemology. Spatiality, therefore, is not only a foundational concept in geography but is important for all disciplines.

Ironically, over the next two centuries geographers discussed extensively Kant’s notion of chorography, the spatial arrangement or clustering of things on the surface of the Earth, but his understanding of space was largely taken for granted. Only much later did it become a foundation of the discipline, and then with a very different ontology, based on the nature of space rather than on the human capacity for spatial experience.

During the nineteenth century, geography grew in stature as a scientific discipline. University offerings increased substantially, albeit still available only to an elite, almost completely male, student body. Especially in the United Kingdom and its Commonwealth system, the curriculum was strongly geared to Eurocentric colonialism. Geographical associations were devoted to collecting information about distant places brought gloriously into the imperial fold. Reports to these societies – in the case of the Royal Geographical Society (RGS) from the likes of Livingstone, Stanley, Scott, Shackleton, Hunt, and Hillary – became an important feature of public intellectual life. Publications, including eventually the National Geographic as the largest purveyor of popular geographical knowledge in the United States, had a significant impact on the anglophone worldview (Johnston 2011).

Meanwhile, scholarly developments in Germany and France were the most influential in establishing the formal discipline of human geography in the nineteenth century, as universities in Germany grew in conjunction with expansion of the imperial state. Carrying on the Kantian tradition of defining geography (along with history) as a foundational and overarching discipline, Alexander von Humboldt (1769–1859), Karl Ritter (1779–1859), and Friedrich Ratzel (1844–1904) were pre-eminent German geographers who most profoundly influenced the future of the discipline. Von
Humboldt traveled extensively, and his huge corpus of writing gave substance to a discipline that was seen as feeding not only imperial impulses but also a growing public and scientific interest in understanding all aspects of the world. Ritter “brought long-term depth to the explanation of human interaction with the various aspects of the Earth” (Berdoulay 2011, 76). Ratzel coined the term “anthropogeography,” which is close to the notion of human geography today, although many have identified Ratzel as inspiring, if not espousing, environmental determinism. In France, in contrast, Vidal de la Blache (1845–1918) and the French School practiced la geographie humaine as explicitly non-deterministic, focusing on human beings as agents of environmental change.

**Geography in the twentieth century**

By the twentieth century, according to Berdoulay’s review (2011), human geography had grown along five trajectories, all with deep Kantian roots: Environmental determinism, Regional geography, Landscape studies, methodological debates over the nomothetic–ideographic distinction, and the conflictual question of human geography’s political role.

The most overt environmental determinism is associated with American geographers such as Ellsworth Huntington (1876–1947), Griffith Taylor (1880–1963), and, in a much more moderate form, Ellen Churchill Semple (1863–1932), who as a student in Germany was influenced by Ratzel’s lectures. The question of environmental determinism – the belief that both human physical and mental traits and their capacity for civilization are determined by environmental conditions – generated vigorous debate. From the time of the Enlightenment, racial science, including the classification of separate “races,” was considered by most scholars to be a legitimate approach to understanding human difference. Geographers were an intellectual force in arguing, as had Kant, that racial characteristics were determined by climate, implying that one’s place on Earth was a significant measure of one’s place in the human hierarchy. Although no geographers challenged the existence of race on scientific grounds, much less addressed the process of racialization, determinism was gradually outweighed by possibilist ideas by mid-century. In the process, there developed a widening gulf between human and physical geography, mainly as a result of the process of scholarly specialization but also – and ironically – as a reaction to environmentalism. Physical geographers drew away from climatic determinism in order to study climate and its effects without reference to humans. Human geographers eschewed climatic determinism but continued to consider climate, and its classification, as an important aspect of regional geography.

By the mid-twentieth century, chorological thinking had given rise to the notion of the region and the landscape, as sections of the Earth’s surface where certain contiguities, or arrangements, of things and, of course, people are located. Controversy raged, however, over the processes at work and over what processes informed geographical science. For Carl Sauer (1889–1975), it was the process of culture that gave rise to the cultural landscape (Sauer 1925). Richard Hartshorne (1899–1992) named spatial variation, or Areal differentiation (or chorology), as the fundamental but taken-for-granted principle that justified his definition of geography as a taxonomic attempt to account for all differences across the surface of the Earth (Hartshorne 1939; 1959). The understanding of regions and of cultural landscapes represented fundamentally
different interpretations of geography’s subject matter and of the ontological status of sections of the Earth’s surface. According to Nicholas Howe (2011), Sauer and Hartshorne were influenced by different strains of German scholarship, the former by the antipositivist cultural approach of scholars such as Otto Schlüter (1872–1959) and Siegfried Passarge (1866–1958), and Hartshorne by the urging of scholars such as Alfred Hettner (1859–1941) to enshrine chorology as a scientific approach. For the landscape advocates, chorology represented a narrow classificatory approach to science rather than an understanding of process; for the chorologists, landscape was vague and failed to give geography a suitable, unique disciplinary base (see Mathewson 2011).

The ideographic–nomothetic distinction was just as hotly debated. Fred Schaefer (1953) caused a stir when he suggested that geography should abandon the ideographic approach (referring to regions or areas as unique) based on German idealism from Kant to Hettner and Humboldt, and instead should adopt a nomothetic approach, based on the positivist science of spatial laws. Hartshorne (1955), among others, responded vociferously that Schaefer’s work involved the “falsification” of science and facts about the discipline, and reiterated his long-standing belief in the concept of areal differentiation (the study of things in relationship to one another), rather than the study of particular phenomena, as the basis for the discipline (Hartshorne 1958). These were opening volleys in debates that continue today, but they are deeply rooted in the Eurocentric philosophies of the eighteenth century.

Geography flourished following World War II. Trained geographers, with their ability to create maps and their knowledge of different parts of the world, had been instrumental to the war effort in every country involved, and many of these geographers went on to productive and influential scholarly careers. Universities grew; cities grew; so too did gross national products, at least in the developed world. By the 1960s, human geography was becoming more specialized. Urban geography came into its own, especially in relation to the profession of planning, as cities with vast suburbs grew at unprecedented rates throughout North America and Europe. Economic geography also grew, animated by new methods of modeling economic systems, newly available datasets, and new developments in computers and regional science. Cultural and historical geography remained predominantly focused on landscapes and the methods of areal differentiation, but international areal studies had received a large boost as a result of the development of international expertise, especially in the United States, during wartime.

Barnes and Farish (2006, 807) argue that after World War II the “hallmark of change was an altered idea of science, made manifest in a different conception and treatment of ‘region,’ long a cornerstone of geographical inquiry.” According to this account, the heavily funded technoscience that developed during World War II and burgeoned during the Cold War was “formalized as a spatial science of society” (Barnes and Farish 2006, 808), founded on a political concept of region as a structural phenomenon deployed in the interests of political power. This interpretation takes the concept of region far from its seemingly innocent roots in cultural geography. Neil Smith (2003) also lays out the political implications of geographical scholarship in his sweeping analysis of the discipline based on the work of Isaiah Bowman (1878–1950), whom he depicts as “Roosevelt’s geographer” for his role in the redrawing of national boundaries after World War II. Bowman advocated a form of US-centered globalism and progress. He also caught the imagination of geographers with his notion of the frontier as being made up of those
diminishing sites still subject to the process of civilization.

The quantitative revolution

Whether the term “revolution” is apt could be debated, but from the 1960s geographers began to benefit from both the increasing power of technology and the sophistication of mathematical models. Major developments occurred, especially in urban and economic geography, which thrived at a few leading geography departments at the time, in particular at the University of Washington in the United States and at Bristol University in the United Kingdom. Perhaps at no other time has the discipline been invested with so much sheer intellectual power, leading not only to a proliferation of scholarship but also to scientific claims that offered disciplinary status as well as promise for geography’s contribution to knowledge.

To map spatial relationships between urban places, geographers turned to Central place theory, a conceptual model developed by the German geographer Walter Christaller to address optimum distances between cities and towns of different orders according to the goods and services they provided. During the 1960s and 1970s, central place theory was perhaps the single most heavily adopted concept in the discipline, not only applied by geographers to analyze spatial distributions but also utilized by planners and governments to address practical problems of urban growth. During this period of the most rapid urban and economic growth in world history, the emphasis was on rationality, optimalization, and an at times utopian assumption of universal progress.

The quantitative turn was more than sophisticated methodology. In the preface to *Explanation in Geography* (1969), arguably the most influential book to emerge from this period, David Harvey claimed that the quantitative revolution involved not only learning technical methods but also adopting a fundamental philosophical shift. It involved deep questions about the existence of a systematic, external structural order that could be discovered and through which scholars could interpret the world. The famous line “by our theories you shall know us” (Harvey 1969, 486) concludes the book that became required reading in most university human geography courses.

The Swedish geographer Torsten Hägerstrand (1916–2004) made a monumental contribution to the discipline, initially by developing the notion of diffusion as a quantifiable process of distribution of things over the Earth’s surface. Diffusion modeling became a standard classroom subject across all branches of geography. Hägerstrand was most interested in human behavior, however, and developed the field of Time geography and space–time prism, based on a concept of space and time as finite resources that people manage, thus creating patterns of daily movement. Notwithstanding later critiques that his theories likened human beings to physical particles, Hägerstrand influenced a vast number of detailed empirical studies based on a fascination with spatial pattern and process, which seem to be exhibited in all human life.

Quantitative approaches are often conflated with “positivism.” Geographers of the quantitative revolution tended to assume a number of aspects of positive science, including a belief in external, law-like structures, an assumption of neutrality (which discouraged overt ethical positions), faith in scientific method, and an assumption of a homologous relationship between empirical evidence and truth; but few adopted a more formal philosophy of logical positivism. These research tenets tended to discourage human geographers from engaging in or opining about politics, although, of course,
many scholars today would claim that their work was nonetheless implicitly political.

Methodologically, two historical precedents were especially important. The Chicago School had advanced the concept of urban ecology for modeling the spatial development of the city. Geographers took advantage of new quantitative methods to map and model what became known as the “internal structure of the city,” a term applied widely in both university courses and geographical publications (see Bourne 1971; Berry and Kasarda 1977). Urban ecology was inspired by the work of the Chicago School founder, Robert Park, who used biological, Darwinian metaphors to interpret the spatial arrangement of people, as well as what he called their “moral economy,” across the city. Urban ecology thus presented a powerful means of locating and describing the process of city formation.

The assumptions of quantitative geography shifted substantially over the years. Reg Golledge (1937–2009) pioneered the subdiscipline of Behavioral geography, focused on cognitive processes and spatial reasoning. Gilbert White and others established a new field of environmental perception studies. Such approaches pushed geographers to consider human beings as environmental actors. The geographical literature of the 1970s and 1980s also displays what Nayak and Jeffrey (2011, 54–57) term “extension,” early examples of mixed-method approaches that extend a quantitative analysis by adding qualitative methods to a quantitative foundation. Nayak and Jeffrey distinguish extension and revision, the latter referring to the complete rejection of external laws or structures. A hybrid approach derived from a philosophy of critical realism that received considerable attention starting in the 1980s was that of “structure and agency,” premised on the assumption that some things are structured while others are the result of human agency. There was considerable debate about what things are structured and what agential, and about the circumstances in which one or the other comes into play.

Quantitative methodologies remain a very important part of the discipline today, and have grown ever more sophisticated. The theoretical assumptions behind the methods that Harvey had valued most highly, however, came under increasing critique, starting in the 1970s. The positive science of space as an external category or a container has largely fallen away, although it is still not uncommon to read geographical studies that seem to assume an ontology of space. Many geographers felt, however, that the emphasis on space as a neutral and externally structured force was reductionist, and that it failed to capture the full meaning of humanity. Others questioned the ethical implications. Central place theory, for example, which had been the topic of Christaller’s PhD thesis in 1938, was a central tenet in the Nazi plan to repopulate the plains of central Europe after they were cleansed by the Holocaust. Christaller was actually hired by the Nazi regime to work on the plan (Minca and Barnes 2010). But for a discipline in which, at least on the surface, it was the veracity of the theory that counted rather than the ways in which it was applied, Christaller had contributed to what was hailed as the most important theory in human geography, and he was given the Association of American Geographers’ (AAG) Outstanding Achievement Award in 1964 (Kobayashi 2014).

Urban ecology does not have such infamous roots, but it represented a putatively neutral reading of the ways in which people are distributed throughout the city, treating such attributes as race, class, and gender as variables that could be mapped to reveal social geographical patterns. It did not address the processes by which race, class, and gender came to be the major factors
differentiating human beings; nor did it address the experiences of those who were racialized, classed, and gendered. Linked to Robert Park’s notion of a Darwinian process of survival of the fittest across urban terrain, urban ecology is therefore one example of the ways in which the assumptions of scientific process, and the uncritical use of scientific categories, can lead to and reinforce popular notions of difference.

Examined retrospectively, these two concepts, central place theory and urban ecology, are examples of some of the far from innocent ways in which human geographers have attempted to understand the human condition. The point that would be made by critical geographers today, however, is not that human geography was – at least in any simple way – unethical, but rather that it reflected both the overt ideologies and the implicit assumptions of its times, and that it has done so throughout its long history. Only occasionally can we identify a direct connection between geographical scholarship and political power, although Walter Christaller provides one example, and Isaiah Bowman another, of geographers who were literally men of particular places and times. It was in the context of the times that some of the brilliant geographers who had advanced the quantitative revolution began to shift their ideas again.

The rise of radical geography

While the roots of radical geographical opposition to the dominant political powers can be traced at least to the nineteenth century when, for example, Russian geographer Peter Kropotkin (1842–1921) advocated anarcho-communism, it was during the 1960s in North America that radical geography gained visibility. The 1960s were a period of turbulent social change. The world was caught up in the tensions of the Cold War, which mobilized governments and citizens alike to express or confront civil fears, entrenched ideologies, and the implications of global systems of power. Many geographers were part of the so-called student movement, and were concerned about the state of the world. They participated in movements to overthrow colonialism and in the antiwar movement, the Civil Rights Movement, the environmental movement, and a rapidly growing feminist movement. In 1969 the AAG was scheduled to hold its annual meeting in Chicago but, in response to police violence against demonstrators at the Democratic Convention in that city the year before, protests mounted within the discipline to the extent that the meeting was moved to Ann Arbor. There, a growing group of geographers opposed both to the dominant social trends and to the scholarly trajectory within geography began to coalesce around what would become known as Radical geography (Peake and Sheppard 2014).

The impetus behind radical geography was to change a world in which structural inequalities define human existence, and radical geographers undertook to rewrite spatial theory. At first, radical geography was broadly socialist, organized through a number of coalitions. The largest of these was the Union of Socialist Geographers, which met periodically through the 1970s and was made up of geographers from a range of national backgrounds studying or teaching at universities mainly in the United States and Canada. In 1969 Antipode: A Journal of Radical Geography was established at Clark University. At first the journal published a range of anti-establishment articles on issues such as poverty, war, colonialism, racism, and gender, many of them passionate about the need for social change and written by scholars who were activists in every sense of the word.
Some geographers pushed for a grassroots movement to bring about change, inspired by Bill Bunge’s work on the streets of Detroit through the Detroit Geographical Expedition and Institute, founded in 1968 with Gwendolyn Warren, an African American community leader. Several “expeditions” mounted in other cities by radical geographers connected academics and local activists in what is probably the first instance of Participatory action research (PAR) in the discipline (Heyman 2007).

According to Peake and Sheppard (2014; also Peet 1977), who interviewed many of the early proponents of radical geography, it took only a couple of years to coalesce into a Marxist undertaking. David Harvey published the first explicitly Marxist paper in anglophone geography in *Antipode* in 1972. Weighing in on an ongoing conversation over the segregation of African Americans, Harvey (1972) opined that it was not more empirical work documenting the geographical concentration of race and poverty that was needed, but a Marxist theory that would account for the production of inequality as a result of capitalism. The strong early interest in race, stemming from the Civil Rights Movement, therefore, was quickly occluded as interest shifted to questions of class.

Notwithstanding the activist passion of the 1960s and 1970s on the part of Bunge and others, the enduring contribution of radical geography during that era is theoretical. Throughout the 1970s, as theoretical debates became more sophisticated, radical thought was consolidated in a Marxist framework that viewed capitalism as the major engine of historical change, and class difference as the result in the spatial ordering of society. Some, such as David Harvey and Dick Peet, addressed the big questions of capital formation and power at a global scale, although Harvey also dedicated a great deal of writing to connecting the local and the global, a topic that became very important in radical geography by the 1990s. Geographers such as Milton Santos and James Blaut contributed to understanding colonial or imperialist relations between the developed and developing world as both economic and racialized. Still others focused on poverty at the local scale. Neil Smith’s (1984) *Uneven Development* became one of the most influential books of the twentieth century.

Marxist geography was heavily critiqued, however, by those who viewed the structuralist version that dominated (although by no means completely) as substituting one deterministic structure for another. The so-called relevance debate occurred through a disparate set of introspective publications through the 1970s, instigated by a 1974 presidential address to the AAG by Wilbur Zelinsky, in which he opined that the “demigod” of science, “In grappling with the complicated, abstracted, fluid, and intersubjective data of the social realm … has been applying a fatally inappropriate model to the world of human beings” (Zelinsky 1975, 139). Zelinsky was among a growing group of human geographers who shared the Marxist concern with issues such as alienation, but he advocated a nonstructuralist approach that could move beyond scientism – that is, belief in any system of causal, universal, final, or perfect knowledge – as an article of faith. Zelinsky was also one of the first in human geography to cite Michel Foucault (1926–1984), whose work would prove to be a dominant influence on human geography some two decades later, and would play a role in bridging the gap between Marxist and humanistic geography.

Humanistic geography

It is difficult to date the origins of Humanistic geography. The Enlightenment roots of the modern discipline were broadly humanist, and
HUMAN GEOGRAPHY

included a number of the German philosopher-geographers who addressed landscape change through human or cultural systems. Carl Sauer’s interest in cultural landscapes was certainly humanist in the broad definition of that term. Clarence Glacken’s (1967) *Traces on a Rhodian Shore*, with its emphasis on the human yearning to impose order on nature, epitomizes a humanist perspective and the power of human agency to transform the world. During the 1970s, many geographers who were disillusioned with positivist perspectives “humanized” quantitative geography by focusing on the psychological factors that influence human experience of their surroundings.

But the explicit use of the term was established in 1978 by David Ley and Marwyn Samuels whose edited collection, *Humanistic Geography: Prospects and Problems*, brought between two covers a range of authors loosely described as humanistic. The collection was informed by “a reawakened awareness of humanist principles and aims over and against a preoccupation with the techniques of scientific rationality” (Ley and Samuels 1978, 1). The influences here were from early twentieth-century philosophies, including American pragmatism, symbolic interactionism (which claimed a very different lineage from the Chicago School than the urban ecologists), and continental philosophies that included phenomenology and, in a limited way, existentialism. Humanistic geographers such as Ley and Samuels, Anne Buttimer, Donald Meinig, Edward Relph, and Yi-Fu Tuan opened up new and exciting avenues of study that linked geography to literature, to symbolic landscapes, and to the world of ideas, impressions, and representations that include the emotional, aesthetic, and generally experiential. Methodologically, humanistic geography shunned quantitative techniques for qualitative, ethnographic, and textual methods. Since that time, ethnogeographic methods have come to dominate field research in human geography.

For many radical geographers, however, humanistic geography, having arisen from within the relevance debate, was just as irrelevant as earlier regional and quantitative approaches. Radical geographers still sought an understanding of structural conditions, even if understanding of the exterior and a priori status of such structures was beginning to soften. Feminist geographers such as Doreen Massey and Linda McDowell emphasized that humanistic geography was still pretty much a male domain. Much of humanistic geography also came under scrutiny for its idealism, emphasizing geographies of the mind seemingly abstracted from its material surroundings. The abstraction of external structures and internal structures thus presented two sides of a single problematic coin.

The walls come down: poststructuralism as the new paradigm

In 1989, as the destruction of the Berlin Wall symbolized a new turn in world history, human geography underwent a significant paradigm shift. Many geographers who, through the 1980s, had identified themselves either as Marxist or humanist engaged one another much more under the general umbrella of poststructuralism, influenced mainly by the post-World War II convergence of those categories in continental philosophy (Kobayashi and Mackenzie 1989). Poststructuralism is a large umbrella of approaches with common roots in anti-essentialist historical materialism: a rejection of independent external structures in favor of recognizing all human history as socially constructed. During the 1990s, debates over structure versus agency, therefore, were largely superseded, and replaced with discussion of the relative power involved in the historical
structuration of human conditions. These influences were expressed across the subdisciplines of human geography, including in growing areas such as Health geography, Tourism and Recreation geography, Political geography, Social geography, and Urban geography.

The development of poststructuralism has led to the increasing use of the term Critical geography to describe geographies with radical roots and a strong influence of both nonstructural Marxism and a range of humanisms. The term “poststructuralism” has no inherent meaning, but generally reflects the growing interest in the humanistic Marxism that dominated post-World War II continental philosophy. Although geographers interacted with many social theorists across the social sciences and humanities, two stand out: Henri Lefebvre for his theories of the construction of “space”; and Michel Foucault for his illustration of the emergence of social institutions and the role of discourse as a form of power/ideology in institution building.

Postmodernity came to the attention of geographers during the 1990s as a collection of global characteristics that coalesced especially after the end of the Cold War and the demise of most socialist states. For some, it was an aesthetic movement that involved new forms of art, architecture, and fashion – and therefore new landscape features – and that rejected or mocked the more rigid and ideologically legible forms that characterized modernism. For others, it was a potentially emancipatory political movement that celebrated differences and emphasized the rights of minorities, including indigenous peoples, around the globe. For members of the Los Angeles School of urban geography, it was a set of characteristics that marked Los Angeles and other emerging world cities as a distinctive late twentieth-century form based on a shift from productive to postindustrial finance, an expansion of technological and creative industries, increasing inequalities in a highly differentiated labor market, as well as a certain style of living that Soja (1996) characterized as constituting a “thirstspace” of heterotopic lifestyles.

As with all “isms,” it is important to distinguish between postmodernist critique and a critique of postmodernism. David Harvey made this point clearly with The Condition of Postmodernity (1989), a direct response to Jean-François Lyotard’s The Postmodern Condition (based on a study commissioned by the government of the Canadian province of Quebec, which saw itself as an emerging postmodern society). Postmodernism as a theoretical perspective strongly associated with deconstructionist theory in the humanities has been widely critiqued by geographers as failing to provide a viable alternative political economy, and, with its wide open, anything-goes approach to methods, whose irreverence is often also irrelevant and, at worst, crosses over into disdain for the actual struggles to survive that face most of the Earth’s populations.

The turn to postmodernism also encouraged a Cultural turn in geography that flourished during the 1990s. Encompassing a wide range of perspectives and topics, the cultural turn refers to the recognition of the importance of cultural systems in influencing every aspect of human relations. Geographers have been less interested in the formal aspects of culture such as film, music, literature, and art – although certainly geographical studies of those formal activities have burgeoned as well since the 1990s – than in the cultural constructions of everyday life, including work, politics, the economy, and every aspect of human differentiation along lines of class, race, gender, or any culturally defined identity. Cultural geographers (e.g., Jackson 1989) were influenced by social theorists such as Stuart Hall, Paul Gilroy, and members of the Centre for Contemporary Cultural Studies (known as the Birmingham School), whose work explores the
ways in which contemporary life is structured through processes of representation, as well as by Michel Foucault, whose concept of discourse emphasizes the structured and power-laden ways in which human relations are forged and solidify into institutions. Geographers have been particularly concerned with Colonialism, decolonization, and neocolonialism as cultural processes of creating racialized difference and inequality at a global scale.

Poststructuralism profoundly influenced the emergence of Feminist geography and Antiracist geography, both of which depend on the anti-essentialist position that gender and race are historical constructions based on uneven social relations. In other words, gender is historically made and there is no essential sex; and race is a product of the historical process of racialization. Both of these perspectives therefore challenge uncritical assumptions of “race” and “gender” as variables that can be mapped without questioning the processes by which they are historically produced, and the lived conditions that result.

Although anti-essentialism is now overwhelmingly accepted throughout the social sciences and humanities, human geographers have been especially interested in its implications for understanding the spatial construction of human relations, the discursive construction of landscapes, and the meaning of distance and positionality in establishing difference, power, and social justice. In the process, interest has also widened to recognize that dominant identities are also socially constructed, with attention to the ways in which, for example, masculinity, whiteness, and heteronormativity came to represent normative human traits and values.

With its emphasis on the dialectical relationship of humans to the entire Earth, poststructuralism has also brought renewed focus on ethics as part of geography and indeed, for many, as a necessary part of geography. Certainly both feminist and antiracist geographies are by definition ethical, since they treat questions of social justice that result from unequal relations of power. This point extends to questions of environmental justice, relations between the human and the nonhuman, and the spatialities of political economy and geopolitics. Geographers addressing such questions continue, of course, to debate ethical needs and implications, but seldom do they deny that ethics underlie the geographical project.

The result has been a shift from the concept of space – even as relational – to spatiality, as the human condition. It is fair to say that there exists a great deal of confusion in the geographical literature today on the concept of space, and it is often used uncritically, thus unintentionally ontologizing external space. At the same time, however, the theoretical literature in human geography overwhelmingly supports an anti-essentialist perspective which, following Lefebvre’s influential book, *The Production of Space* (1991), emphasizes human interaction with and human production of environment, and the dialectical relationship that results. The active formulation of spatiality is the single most enduring legacy of poststructuralism in geography.

**Human geography in the twenty-first century**

Human geography has always been contested, never more so than in the twentieth century. If four decades ago human geographers were engaged in a relevance debate in the attempt to bring greater clarity to the ways in which geographers might contribute to make a better world, there is little question today that the majority of human geographers see relevance as their mandate. Of course, the question of
relevance to what remains at issue, as does the question of how to go about understanding the world and its potential. Geographers have always engaged in Earth writing, however, and, as the Earth has become more populated, more complex, more differentiated in some respects and more standardized in others, larger in its possibilities but smaller in the ease with which humans command distance; as the environment has been increasingly modified, not always in ways that are beneficial to humans, their progeny, or the Earth itself; and as technology has placed at our disposal increasingly powerful means of writing the Earth, the discipline of human geography has become more diverse, more interesting, and more challenging.

The new age of big data

Human geography has always involved a fascination with the technical, from the earliest maps, highly speculative over the extent of the Earth and its contents, to today’s techno-world where the volume of information at our disposal, and the means with which to portray that information, are far beyond the most speculative imaginations of our academic forebears. In no other discipline is there greater scope for harnessing technology to analysis. We have entered the era of Big data, and are mapping more and more of the Earth using the power of Geographic information science (GIScience) and the Global Positioning System (GPS), which open up immense possibilities of observing the Earth, using not only satellites and drones but also thousands and thousands of closed-circuit cameras. There is no corner of the Earth that is not potentially subject to intense scrutiny. Perhaps most powerfully of all, the vast Internet coagulates and channels information about everything, including individual people. Because they are so closely entwined with governance, military power, state regulation, and policing, new technologies are of interest to virtually every branch of human geography.

The age of big data has, of course, allowed much expanded observational and analytical power in areas where technical expertise is important, including observing climatic trends, modeling traffic and trade systems, disaster planning, and much more. It has also opened up new areas of geographical interest, such as the cultural impact of new forms of communication, especially through social media. Recent research addresses topics such as crowdsourcing, grassroots organizing, and changing consumer patterns. New forms of communication also mean new, or at least altered, forms of human relations, in which distance takes on new significance. At the same time, an increasing number of geographers have expressed ethical concerns about the range of ways in which data technology can be used by the state, enhancing its power to survey its citizens; by groups intent on bringing harm to others; and by private corporations which use information powerfully to advance the interests of capital and to intrude on the lives of consumers. All of these issues represent huge methodological scope and challenges for geographical understanding.

Methodological challenges

Technology has opened up huge vistas of geographical possibility, based on ever more sophisticated methods. But questions of methodology are much bigger, and involve tethering methodological techniques to questions of ontology and epistemology. Geographers have struggled for many decades over the critical task of going beyond the map to address just what it is they are mapping, how the mappable came to be, and what difference it makes that they choose certain things over others as the subjects of analysis.
Against the illusion of analytical power that attends big databases stand questions of what is assumed and what can be assumed.

Geographers have become more eclectic in their methodologies. Many studies use a mixed-methods approach of combining descriptive quantitative analysis with in-depth qualitative analysis. The legitimacy of mixed methods is seldom questioned, but questions do arise of representation, sample sizes, and the wisdom of making generalizable conclusions based either on large-scale numbers or on small-scale experiences. Issues of meaning rise to the surface in a context where discourse remains the dominant analytical concept for understanding both the production of the world and the production of the discipline.

A case in point is the extensive discussion over ontologies of Scale. While scale is a technical concept that represents the ratio of a map to the surface of the Earth, there is a debate whether scale itself, that is, the local, regional, national, or global, actually affects social, political, and economic processes. Antiscale theorists argue that ontologizing scale, giving it agency, has political as well as theoretical consequences. The same might be said of space, region, or any other product of the geographical imagination. Geographical concepts are not innocent. Their power is wielded to change the world.

The looming question is not only how geographers study what they do, but how they choose the objects of their concern, from people to all the other things that exist on Earth. Given the constant becoming of all things, perhaps the greatest methodological challenge is how to capture things in flux. Dynamic and interactive maps and other computer programs help but only go so far. If the world is ordered by vast, complex, fungible assemblages of things, how can the geographer present both the more durable things such as text, photographs, and numbers while still acknowledging that, although nothing is fixed, some things are more transient, harder to represent, but not thereby less important or powerful.

**Beyond – and around – the cultural turn**

The last decade of the twentieth century involved a new and theoretically sophisticated fascination with culture, discourse, and representation. The first decade of the twentieth century has seen increasing skepticism over the cultural turn. There has been a growing emphasis on things – commodities, buildings, bodies – and on the ways in which they are connected, drawn into webs of significance, given differential power to influence human experience and action, as well as on the inter-relationship between humans and things. Diverse theorists inform this trend, although it is often linked to the anti-dualist Dutch philosopher Baruch Spinoza (1632–1677). Gilles Deleuze (1925–1995) is often credited (among other things) with influencing a geography of difference that builds on geography’s legacy of understanding human relations. Bruno Latour has influenced geographers to think about the complex relationships between things (including people) on the Earth, especially in an age of advanced technology.

These influential intellectuals, along with a number of poststructuralists already mentioned, have in common a dialectical approach that emphasizes change, power, and the historical production of global circumstances. Within human geography, Actor-network theory, based on the thought of Latour and others, has been particularly well suited to analyzing the complexity of assemblages of things, the distribution of human actions and their results across a global landscape, and the systematic but often ineffable structure of those distributions.
Questions about ineffable structures have in large part underlain recent interest in Nonrepresentational theory (NRT) (e.g., Anderson and Harrison 2010) as a response to what many geographers see as the fascination with too fixed representations of geography’s cultural turn. Nonrepresentational theorists build on poststructuralist insights on the dialectical, always-becoming world to emphasize things in flux and flow, and the problems of attempting to fix meanings in place. Empirically, this approach has encouraged new research forays into such areas as dance, theater, and music, and into understanding affect as the emergent, immanent qualities between things in the landscape that influence embodied experience, but also lead interest toward the nonhuman or more-than-human world where affect is also produced.

Controversies over NRT include claims that it is universalistic and pays insufficient attention to questions of power (Tolia-Kelly 2006). Growing numbers of proponents of Emotional geographies emphasize the need to situate emotional experiences in a lived world where norms and habits are always and already structured as well as emergent, and in the same vein feminist geographers have warned of the dangers of moving beyond the everyday relations that regulate emotional lives (Thien 2005). Others, including Popke (2008) have expressed optimism over the potential of NRT for understanding embodied materialism, but skepticism over the ways in which its incorporation into geography has addressed questions of ethics. Two ethical issues arise. One is the tendency on the part of some NRT scholarship to refuse any distinction between the human and nonhuman, which both erases the power – and the responsibility – of the human to create the conditions of being, and privileges things that do not in themselves have any ethical intentions. The other issue concerns a tendency to cleave the affective from the political, with the attendant perils of failing to understand the potential for changing world conditions, for better or worse.

What human geographers do

There is a line, attributed to Peter Gould (1985) but repeated too many times to count, that “geography is what geographers do.” Recognizing that all boundaries Borders, boundaries, and borderlands are socially constructed, it may seem that geography has none. Certainly geography is an interdiscipline, but it is also increasingly interdisciplinary, as geographers engage with colleagues across the physical and social sciences and the humanities, as well as with a range of practitioners that may include policymakers, people in business, activists, or artists. Geographers also continue to import ideas from other disciplines, probably more so than the other way around. For many, the lack of discipline is a strength that allows a huge scope for the practice of Earth writing. It also creates institutional problems for many geography departments, however, as university administrations like to downsize or merge units, especially those they do not fully understand. There are increasing numbers of departments of “geography and …” (planning, environmental studies, development studies, etc.), which may be only the cutting edge of what will become the dominant institutional framework.

The question of what geographers do, therefore, is not one of simple capricious choice or of indulging an unfettered curiosity. It is a question of the geopolitics of knowledge. If at individual institutions that means negotiating administrative politics in an increasingly neoliberal environment, on the world stage it also means that anglophone geography has come to dominate
the field, a fact that has much to do with pro-
cesses that were set in motion (at least) from the
time of fifteenth-century European explorations.
Advances in communication technology mean
that it is now easier than ever before to commu-
nicate and collaborate across greater distances,
but it is also easier to impose epistemological
hegemony. The term “globalization” there-
fore needs to be understood in complex ways
(Derudder 2015), and it needs to be recognized
that epistemology and ethics are intertwined.

Questions of ethics range across the discipline
of human geography. Some of the concern has
been institutionally driven, as universities and
granting agencies apply a neoliberal lens through
which ethical precautions are strongly tied to
systems of audit and accounting, researcher/
institutional liabilities, and emerging definitions
of privacy. A broader set of ethical questions
continues the line of thinking of the relevance
debate to address issues of responsibility toward
communities and toward the Earth itself. Femi-
nist and antiracist geographies question the role,
identity, and positionality of the researcher, as
well as the difference that the scholar can make
in not only studying, but actually changing the
world (Castree et al. 2010).

Geography has seen a surge in both the number
and the analytical power of studies of Geopolitics
in the twenty-first century. The journal Political
Geography has become one of the most com-
pelling specialized journals in the discipline, as
the purview of political geography has expanded
from a much narrower focus on the spatial
patterns of formal politics to encompass the
range of discursive processes through which the
world is organized and power created, wielded,
and distributed. Political geographers have a full
slate addressing the geopolitics of world power,
warfare and violence, possibilities for peace, mass
migration, and the effects of climate change,
to name some of the most important areas of
concern. In the process, nearly every aspect of
human geography has also incorporated recogni-
tion of the political. Feminist geographers have
been instrumental in stressing that all human
relations, from the personal to the global, are
political. Antiracist geographers address the
geopolitics of colonialism and imperialism in
creating a world in which a putative science
of race was actually a means of constructing
racialized political hierarchies. Political economy
remains a powerful means of understanding the
relationship between formal political structures
and the globalization of resources. Cultural
and historical geographers today seldom fail to
recognize that all cultural systems are politically
forged and are fundamental to understanding
national, diasporic, or local identities.

Climate change, which has absorbed the
interests of more and more physical and environ-
mental geographers, is of immense importance
to human geographers, who are well positioned
to understand just what climate change means
for the quality of human life, in terms of health,
food production, and availability and in some
cases for the continued existence of places that
face inundation by rising water levels or sinking
land levels. Climate change has implications for
understanding shifting resources, human migra-
tion, changes in livelihoods, and the potential of
violent confrontations over resources and power.

Human migration has long been a main-
stay of geographical research. Going back to
the days of Chicago School influence and
urban ecology, migration – whether inter- or
intranational – was the process that underlay
urban development, as the residential spatial
patterns that ensued. In the twenty-first century
these processes continue, but geographers have
expanded their view. Questions of Race and
racism have never been more important as racial
violence, the racialization of poverty, and the
uneven distribution of the world’s resources
Human geography according to racialized patterns continues apace. Warfare has created millions of new refugees, whose circumstances cannot be separated from the geopolitics of border control. Larger and larger numbers of people are moving from one part of the world to another in search of a better life, or in some cases in search of bare life; and shifting economic activities are leading to shifting populations, causing some places to grow rapidly and others to decline. The treatment of migrants, including those subjected to human trafficking or to the bare life conditions of refugee camps, is of increasing ethical concern for human geographers.

Human geographers’ long history of speculation on the processes of spatial differentiation is evident in the abiding concentration of research on the diversification of humans living in a spatial relationship. Feminist geographers have addressed, among other things, the importance of studying gender relations in the home or the neighborhood. Geographers studying post-colonialism and decolonialism show that these processes have instigated significantly different human – economic, political, cultural – relations between core and periphery. Issues of multiculturalism as cities become more diverse encompass more than just cultural practices involving food, religion, and festivals; they also signal questions of labor markets, changing class divisions, and access to services such as health care – all of which are important ongoing challenges for human geography.

Climate change, human migration, ongoing urbanization, and the diversification of humans living in proximity to one another represent but three important research agendas for geographers in the twenty-first century, all with major geopolitical and ethical dimensions. Geographers have greater methodological power to address these issues, and greater capacity to write the Earth in ways that will make a difference.

Geographers continue to struggle to make their work known to the world, however, and perhaps that challenge is one of the most significant if geographers are to be known by the end of this century as the world changes. If the hallmark of human geography a half century ago was to be known by our theories, then perhaps an appropriate slogan for the twenty-first century is “By our actions you shall know us.”

Human rights

Mark Boyle
National University of Ireland, Maynooth

Human rights thought is based on the claim that human beings, precisely because they are members of the human family, are endowed with a number of rights which pertain to all, irrespective of race, age, nationality, gender, class, sexuality, disability, religion, and so on. While emerging and fermenting over a long time period, the idea of human rights arguably rose to particular prominence in 1948 with the ratification of the United Nations Universal Declaration of Human Rights (UDHR). Since then, states and peoples have consistently invoked, mobilized, and worked to enforce the UDHR, and in so doing have afforded it a degree of binding authority. This entry explores, first, the genesis of the idea of human rights and the substantive content with which the UDHR populated it; second, the various ways in which human geographical research has engaged human rights thought; and, third, recent neoconservative critiques on the one hand, and feminist and postcolonial critiques on the other, which call for declarations such as the UDHR to be historicized and provincialized.

The idea of human rights and the UDHR

Although the idea that human rights exist as a special or separate category of human entitlement has featured in many prior civilizations, a particular story about the historical and geographical emergence of this idea has settled into conventional wisdom (Nice 2014). According to this account, human rights thought began in earnest in Mesopotamia in the sixth century BCE under the progressive leadership of Cyrus, the first king of Persia. It then developed and persisted throughout the rise and fall of ancient Greece and then Rome. Strangely, and against all odds, it found life in Europe during the “dark” or middle ages (fifth to fifteenth century CE), evidenced most clearly in the English Magna Carta (1215). It re-emerged with renewed vigor with the rise of Renaissance humanism and the European Enlightenment (from the sixteenth century onward). It was developed and given shape in the thought of Enlightenment philosophers and political theorists such as Locke, Berkeley, and Hume in England; Montesquieu, Voltaire, and Rousseau in France; and Jefferson, Franklin, and Paine in the United States. It came to full fruition during the age of revolutions (1775–1848) when it served as a progenitor of the rise of constitutional republics. Here the two most oft-cited examples are the American and French revolutions and their attendant credos, the American Declaration of Independence (1776) and Bill of Rights (1791), and the French Declaration of the Rights of Man and of the Citizen (1789).

The horrors of the first half of the twentieth century, and in particular the traumas and violence of World War I and World War II, announced another pivotal moment in the history of the idea. Under the stewardship of Eleanor Roosevelt and French jurist René Cassin, and following only two short years of work, the United Nations Assembly drafted the
HUMAN RIGHTS

watershed United Nations Universal Declaration of Human Rights. The UDHR was endorsed by the General Assembly in 1948, with 48 of the then 58 member states voting for its acceptance. Fifteen of the signatories were Western states, the remaining 33 non-Western. Abstainers included Saudi Arabia, Soviet Bloc countries, and South Africa. The UDHR is not a treaty and cannot by itself impose legally enforceable obligations and sanctions on member states. Subsequently, and to give substantive effect to the declaration, the United Nations Commission on Human Rights issued two further covenants: the International Covenant on Civil and Political Rights and the International Covenant on Economic, Social and Cultural Rights, both of which were formally ratified in 1976. Together with the UDHR, these covenants comprise the International Bill of Human Rights. The UDHR and the covenants it bequeathed have inspired more than 80 international human rights treaties and declarations, a great number of regional human rights conventions, domestic human rights bills, and constitutional provisions, which together have worked to put in place a (yet to be completed) legally binding system for the protection of human rights.

The UDHR comprises a short preamble followed by 30 articles (United Nations 1948). The preamble confirms the importance of the violent twentieth-century backdrop and the aspiration never to return to a world where “disregard and contempt for human rights” results in “barbarous acts” which “outrage the conscience of mankind” and where violent “rebellion against tyranny and oppression” is mankind’s only and final option. “Recognition of the inherent dignity and of the equal and inalienable rights of all members of the human family,” the preamble continues, “is the foundation of freedom, justice and peace in the world.” The United Nations General Assembly, it declares, undertook to ensure “universal and effective recognition and observance” of the declaration, “both among the peoples of Member States themselves and among the peoples of territories under their jurisdiction.” Member states were asked to “pledge themselves” to the “promotion of universal respect for and observance of human rights and fundamental freedoms.”

Articles 1 and 2 assert that all human beings are born already endowed with basic human rights, irrespective of their race, age, nationality, gender, class, sexuality, disability, religion, and so on. These rights are both inalienable (they cannot be renounced) and indivisible (they cannot be parceled and passed on).

Articles 3 through 21 address civil and political rights. Article 3 confirms the “right to life, liberty and security of person,” article 4 prohibits “slavery and servitude,” and article 5 renders illegal “torture and cruel, inhuman or degrading treatment or punishment.” Articles 6 to 8 assert equal protection under the law, equal status in the eyes of the law, and the right to seek redress should these two prior rights be violated. Article 9 states that “no one shall be subjected to arbitrary arrest, detention or exile” and article 10 confirms the right to a “fair and public hearing by an independent and impartial tribunal,” while Article 11 declares that those charged with committing a crime should be “presumed innocent until proven guilty.” Article 12 outlaws “arbitrary interference with privacy, family, home or correspondence.” Article 13 confirms the right to mobility within states and the right to leave and return to one’s homeland at any time, while article 14 states that “everyone has the right to seek and to enjoy in other countries asylum from persecution.” Article 15 confirms the right to nationality, while Article 16 proclaims that “men and women of full age, without any limitation due to race, nationality or religion, have the right to marry and to
found a family.” Article 17 asserts the rights of people to own property, article 18 the right to “freedom of thought, conscience and religion,” and article 19 the right to “freedom of opinion and expression.” Article 20 upholds the right to “peaceful assembly and association” and article 21 the right to take part in the government of a country, “directly or through freely chosen representatives.”

Articles 22 through 27 set out a number of basic economic, social, and cultural rights. Article 22 asserts “the right to social security,” article 23 “the right to work, to free choice of employment, to just and favorable conditions of work, to protection against unemployment … to equal pay for equal work … to just and favorable remuneration and to form and to join trade unions.” Article 24 asserts the “right to rest and leisure, including reasonable limitation of working hours and periodic holidays with pay,” while Article 25 insists on the right to an adequate standard of living and states that “motherhood and childhood are entitled to special care and assistance. All children, whether born in or out of wedlock, shall enjoy the same social protection.” Article 26 upholds the right to education that supports the “full development of the human personality” and confirms parents’ “right to choose the kind of education that shall be given to their children.” Article 27 confirms the “right freely to participate in the cultural life of the community, to enjoy the arts and to share in scientific advancement and its benefits.”

Article 28 announces the conclusion to the declaration and asserts that “everyone is entitled to a social and international order in which the rights and freedoms set forth in this declaration can be fully realized.” Article 29 confirms that the rights and freedoms asserted in the UDHR may in no instance be exercised contrary to the purposes and principles of the United Nations. Finally, article 30 concludes: “nothing in this Declaration may be interpreted as implying for any state, group or person any right to engage in any activity or to perform any act aimed at the destruction of any of the rights and freedoms set forth herein.”

Human geography and human rights

Recently, the Association of American Geographers (AAG) engaged in a series of collaborative projects with the American Association for the Advancement of Science (AAAS) designed to promote the contributions that human geographical research and teaching might make to the protection of human rights around the world (Richardson and Bromley 2008). This collaboration has bequeathed the AAG with a “clearinghouse” for human geographical research with a human rights focus, otherwise known as the Geography & Human Rights Bibliographic Database (AAG n.d.); a Human Rights Coalition; and a joint project exploring “geospatial technologies and human rights.” The database lists over 700 human geographical research papers which, even if they do not deploy the lexicon of human rights explicitly, in one way or another place human rights concerns at their core. An examination of this dataset points to at least five ways in which human geographers have engaged with human rights thought: mapping and ruminating on the geographies of human rights law, enforcement, and enactment; tracking instances of human rights abuses; using geospatial technologies to document human rights abuses that might otherwise be concealed from the world; harnessing the idea of human rights to frame social movements concerned with human geographic topics; and working to uphold the human rights of human geographers and other scholars themselves.
HUMAN RIGHTS

To enforce the protection of human rights, the United Nations turns first to its own Committee on Economic, Social and Cultural Rights (CESCR), the Office of the United Nations High Commissioner for Human Rights (OHCHR), the Human Rights Council (HRC), and treaty-monitoring bodies like the Committee on the Elimination of Discrimination against Women (CEDAW) and the Committee on the Rights of the Child (CRC). Responsibility for responding to particularly heinous breaches of human rights (such as crimes against humanity, genocide, crimes of aggression, and war crimes) falls to the United Nations Security Council and to the International Criminal Court (ICC). Meanwhile, the work of translating the International Bill of Human Rights into law in particular jurisdictions is ongoing. As this bill has cascaded down through many geographical scales, it has become filtered, reworked, and transformed. Moreover, its “local” enforcement has given birth to many legal tensions, struggles, and contestations. Human geographers are interested in mapping these concrete groundings of human rights thought and in understanding the ways in which local context mediates and conditions supposedly universal rights. A good example can be seen in the European Convention on Human Rights (ECHR), drafted in 1950 as a European response to the UDHR, coming into force in 1953, binding on all member states of the European Union and overseen by the European Court of Human Rights. The ECHR has in turn given birth to human rights legislation in member states. For example, the Human Rights Act 1998 incorporates the convention into UK law. British citizens who claim human rights violations must first take their claim through the British judicial system; if this claim is rejected, they then have the option of taking their case to Europe for a determination. It is here that a politics of scale becomes important, as global, European, and British legal systems compete and jostle for sovereignty.

Human geographers are also interested in exploring geographies of human rights breaches and abuses. For example, on the basis of an analysis of the geography of 720 Amnesty International freedom writers’ letters, Selya (2012) tracked spatial and temporal variations in human rights abuses across the world between 1986 and 2006. The most common abuses cited were “prisoner of conscience,” “disappearances,” “detention without charge or trial,” “threats,” “torture,” “extrajudicial killing,” and “unfair trials.” Selya argues that, at best, the number of human rights abuses has remained stable over the period; certainly there is no sign that progress toward eliminating abuses has been made. Based on the total number of citations, the worst offenders were Syria, China, Myanmar, South Korea, Peru, Turkey, Colombia, Cuba, the Czech Republic, Sri Lanka, and India. Based on the highest abuse rates per 1 million of the population, the chief culprits over the period were Equatorial Guinea, Brunei, Western Sahara, Bahrain, Kuwait, Cyprus, Israel, Mauritania, Syria, and Bosnia and Herzegovina. Of course these geographies are dynamic and would look different again if the period from 2006 to the present were examined. Selya identifies 10 factors that together help to explain the lack of progress these data imply, including flawed conceptions of the democracy–development–respect for human rights cycle; the rise of authoritarian capitalism; the spread of neoliberalism; globalization and the demand for efficiencies; chaos and anarchy resulting from endeavors to democratize countries; deviant cultures and personalities that deem themselves to be above the law; the hypocrisy of Western democracies that cite human abuses inconsistently; the hypocrisy of signatories that promptly ignore their own commitments; the persistence of corruption and weak institutions
in new democracies; and the use of irregular paramilitaries in civil conflicts.

Geographers have also developed a raft of new geospatial technologies which enable new types of data to be collected, archived, scrutinized, stored, and visualized, and which organizations such as Amnesty International and Human Rights Watch are now finding useful when documenting human rights abuses in obscure, hidden, and difficult-to-reach places. Remote sensing and global positioning system (GPS) technologies are paving the way for a new era of big data. Big data comprise datasets that are huge in volume, consisting of terabytes or petabytes of data, and rapid in velocity, being produced in real time. Meanwhile the emerging field of geographical information science (GIScience), or geocomputation, is radically expanding the capacity of analysts to digest and to model big data. These new capacities allow evidence of past human rights abuses to be uncovered, evidence which might otherwise have gone unregistered and unrecorded. Moreover, because these developments allow for real-time data collection and analysis, it is now theoretically possible to monitor human rights abuses as they unfold, to forewarn at-risk groups and law enforcement agencies, and to prevent violations from taking place in the first instance. Geospatial technologies have been used, for example, to draw attention to attacks on civilians in Darfur, Burma, and the Ogaden region of Ethiopia; to support indigenous land rights in Guatemala; to document aerial defoliation in Colombia; to identify mass graves in Cambodia; to locate secret prisons in North Korea; and to document human right violations in Syria and track and anticipate Syrian refugee movements (Richardson and Bromley 2008).

Some critical and activist geographers are also drawing on human rights thought to inform and support the real-world political and legal struggles they themselves are actively engaged in or align with and contribute to. Framing topics as varied as climate change, housing, food security, access to public space, child protection, sexual equality, and refugee flows and asylum claims as human rights issues opens up powerful new possibilities for activist groups and social movements. Rights-based approaches have advantages over approaches that likewise seek to defend impoverished and excluded communities – for example, charity-based approaches (where powerful groups are asked to act benevolently for the sake of conscience) and needs-based approaches (where individuals are protected on the basis of what they lack) – because they insist that progressive interventions are mandated by juridical imperative and merely work to uphold basic inalienable rights. Human rights thought de facto pervaded the entire tradition of welfare geography, which came to the fore in the 1970s and 1980s and which sought to explore, as its practitioners put it, who gets what, where, why, and how. Welfare geography, in turn, has now been augmented by a potent new language which speaks of “spatial justice” and whose concern is the ways in which sociospatial processes conspire to render some social groups marginalized, impoverished, and minoritized. Political action to correct injustices may then follow. The “right to the city,” in particular, has enjoyed a meteoric rise to prominence within the human geographical activist community and has played a central role in social movements such as the Occupy movement (Harvey 2013).

Finally, human geographers are actively working today to protect their own rights as scholars. Higher education institutions worldwide are under attack, it seems, from political systems that value certain kinds of knowledge and pedagogy at the expense of others. Everywhere the concept of the public university is under threat, from fascist and despotic political regimes on the
one hand and from neoliberal funding models and interinstitutional competition for resources on the other. In this context academic freedom is being compromised and the health of all of basic, applied, critical, and public scholarship impaired (Burawoy 2011). In association with faculty from other disciplinary traditions, and in part through its learned societies, human geographers are actively confronting these threats and pressures. Given that many human geographers are interested in caring and taking responsibility for, and in acting ethically toward, others at a distance, human geographers are arguably themselves both especially vulnerable and especially well placed to contribute. For example, many geographers engage with the Scholars at Risk Network, an international network of higher education institutions established to protect scholars under attack by those in power who feel threatened by ideas that counter their own and who act to restrict academic freedom and to repress research, publication, teaching, and learning. The Scholars at Risk Network provides “positions of sanctuary” for scholars suffering serious threats to their lives, liberty, and wellbeing, and supports scholars who are effectively imprisoned in their home countries as a result of threats, restrictions, or wrongful imprisonment. This network also works to prevent more systemic attacks on higher education systems and sets standards and legal protocols to uphold academic freedoms.

The limits of human rights thought

While respecting the work of human rights thought in the world and while embracing, harnessing, and engaging the UDHR in various ways in their research and teaching, human geographers have also been at the forefront of recent calls for a critical discourse on the subject of human rights. The first section of the entry drew attention to the very particular history and geography of the idea of human rights. Critics claim that all formulations of human rights are spatially and temporally situated, embodying the cultures from which they originate, and that therefore claims to universality are questionable. Focusing on the politics of universality, as opposed to the fact of universality, critics question which institutions put the UDHR into the world, what work the declaration does in the world, who benefits from it, and how it survives and prospers over time. Such ruminations have led to at least two competing critical readings of the UDHR: a neoconservative reading which laments what it considers to be the appropriation of the idea of human rights by liberal and leftist camps; and a critical feminist and postcolonial reading that casts suspicion on the idea of human rights by dint of its imbrications in European colonial history and the work it is now being called to do as a “civilizing instrument” in our colonial present.

Neoconservative critics argue that, while the intention of human rights law is to protect and safeguard basic human rights, in reality it is being viewed by lawbreakers on the one hand, and by countercultures on the other, as a weapon to evade prosecution and/or to attack and relativize traditional and conservative values. Invoking the concept of “lawfare” (the use or abuse of law as a weapon of war), these critics argue that violent, despotic, and unsavory political regimes routinely exploit international human rights law with impunity, ensnaring lawyers in fruitless, endless, and spurious exchanges in a bid to delay, avoid, and frustrate justice. These claims take on a local hue too. In the British case, clashes between popular right politicians and ECHR law over, for example, the right of prisoners to vote and aspects of immigration, deportation, and extradition law and practice have fueled right-wing political commitments to temper the
ECHRI, to relegate it to a mere advisory body, and to reassert the sovereignty of the Supreme Court of the United Kingdom. Meanwhile the Christian right has criticized the (in its view) excessive extent to which human rights law has generated a climate of “political correctness,” which has resulted in the rights of secular groupings, Islamic militants, and LGBTQ peoples being privileged over the rights of those who hold “conservative,” “Christian,” and “British” values. Arguably, few human geographers support neoconservative critiques of the UDHR; certainly few declare their opposition publicly. But, as the far right gains a degree of popular authority in political systems across Europe and beyond, many are interested in studying the implications, especially for those who may be rendered more vulnerable should human rights legislation be repealed or reformed.

In contrast, recent writings in the field of critical legal geographies, and feminist, postcolonial, and subaltern geographies, contend that, in spite of its claims to embody timeless and universal concepts of justice, international human rights law, too betrays historical and geographical roots in the European Enlightenment and needs to be historicized and provincialized. The international legal system provides a critical infrastructure through which the international community seeks to care for (often distant) others by taking responsibility for their right to protection, justice, and legal redress in circumstances in which those rights are violated. But, given that it has been colonial and neocolonial powers that have conceived, authored, built, and now govern international law, it is pertinent to inquire into the limitations of routing caring (from a distance) through seemingly universal ethical, legal, and juridical frameworks. Specifically, critical scholars question the extent to which the UDHR has been appropriated by the West and put to work as the latest in a series of civilizing narratives that conceal Western geopolitical aggression. Some claim that the international legal system is systemically compromised because it is pro-Western by geopolitical fiat; for the West, the rule of human rights law has simply meant rule through human rights law (Boyle and Kobayashi 2015).

Meanwhile, deeper critiques again argue that international human rights law is systemically contaminated because it is conceptually Western and masculine. They point to the nexus between social power, epistemology, and human rights law. This critique has led feminist, postcolonial, and subaltern geographers to propose alternative ethical paradigms, care ethics being a case in point. Care ethics explicitly seeks to decenter established Enlightenment ethical frameworks, on the basis that these approaches to ethics are profoundly Cartesian, Western, masculinist, and limiting. Enlightenment ethics searches for justice based on universal principles that are capable of being articulated abstractly by autonomous subjects, prioritizes cool detachment, valorizes human reason, and advocates objective, neutral, and rational decision-making. The UDHR is viewed as embodying such justice through reason. In contrast, care ethics begins with a social ontology of connection, foregrounding social relationships of mutuality and trust rather than dependence, where ethical judgments need to be made in the context of caring relationships. Care ethics prompts reflection on the limitations of framing human rights discourse in and through Western ethical, legal, and juridical frameworks, and underscores the value of locating questions of justice in the context of complex and charged relationships.

Conclusion

Historically ingrained and tenacious power-laden and asymmetrical relationships and connectivities between peoples and places will ensure
that human rights thought remains of central importance in human geography. But recent feminist and postcolonial interventions in this literature insist that these very same power geometries also situate, condition, and color many endeavors (however well meaning) to frame and uphold the human rights of others (Noxolo, Raghuram, and Madge 2011). Supporters of the UDHR should not be overly disheartened by recent critical reflections on the origins of this particular declaration, the potential existence of different conceptions of human rights in differing cultural contexts, and the possibility or impossibility of ciphering and codifying a universal bill of human rights. The UDHR has served as a template and source of encouragement for progressive agendas for over 60 years, and it is essential to remember what has been achieved by international human rights law. But, to care that justice is served to others, it is necessary to question whether our justice is seen by others as a just justice and to entertain the possibility that potentially there exist other traditions of human rights thought.

Further reading

Most prominent in the 1970s and 1980s, humanistic geography is a conceptual perspective claiming that a comprehensive understanding of human–environment relationships must consider individual and group experiences and meanings of space, place, landscape, region, mobility, and related geographic phenomena. Partly propelled by 1960s research in behavioral geography and environmental perception, humanistic geography incorporated a wide range of philosophical approaches that included phenomenology, existentialism, idealism, pragmatism, grounded theory, and symbolic interactionism (Ley and Samuels 1978). Geographers most commonly associated with humanistic geography included Edmunds Bunkse, Anne Buttimer, James Duncan, J. Nicholas Entrikin, David Ley, David Lowenthal, Douglas C.D. Pocock, J. Douglas Porceous, Edward Relph, Graham Rowles, Robert David Sack, Marwyn Samuels, David Seamon, Yi-Fu Tuan, and John Western. The first geographer to describe humanistic geography formally as a disciplinary subfield was Yi-Fu Tuan (1976). He defined the approach as the geographic study of human beings’ experiences and understandings of space, place, and the natural world.

The development of humanistic geography

Though humanistic geography became an explicit subfield of the discipline only in the 1970s, there were several earlier geographers who, at least implicitly, pointed toward humanistic approaches, methods, and themes. Examples include Alexander von Humbolt’s interest in how landscape painting could contribute to the public’s awareness of the Earth’s interest in the Earth’s natural regions; Johannes Gabriel Granö’s efforts to develop an experientially grounded cartography that could map sensory and perceptual aspects of natural and human-made landscapes; and Paul Vidal de la Blache’s field studies of genre de vie, a term encompassing the idea that the “way of life” of a region reflected its inhabitants’ psychological, social, and economic identities imprinted on the landscape. Though not a geographer, another significant representative was French historian Eric Dardel, who examined geographicalité (géographicit), the experiential linkages that supported human worlds environmentally and geographically, including ties to places, landscapes, and regions.

In spite of these early researchers’ efforts, it was not until the mid-twentieth century that geographical thinking pointed toward a formal explication of humanistic geography. In a 1947
HUMANISTIC GEOGRAPHY

article in the *Annals of the Association of American Geographers*, J.K. Wright called for geographers to include a humanistic perspective in their studies. He advocated a subfield of geographical research that would study peoples’ subjective geographical understandings and values. He labeled this field of inquiry “geosophy,” which he defined as the examination of geographical knowledge in all manner of human forms. In a 1952 article in the *Indian Geographical Journal*, William Kirk, working independently from Wright, extended his call for study of geographical knowledge by developing the concept of behavioral environment, which Kirk defined as the environment not as it is known objectively but as it is perceived and understood by individuals and groups. Wright and Kirk’s efforts were significant for humanistic geography because both thinkers realized that geographers needed to expand their research horizon to incorporate human consciousness and cognition, since the ways in which individuals and groups structure and make sense of their world play a primary role in how they act in and make use of that world.

In the 1960s, Wright and Kirk’s ideas would help spawn a new disciplinary subfield of behavioral geography and environmental perception, which largely focused on the cognitive dimensions of environmental behavior. In the 1970s, the development of humanistic geography greatly benefited from this behavioral research, which had shifted the study focus from measurable aggregate analyses of spatial and environmental behaviors to individuals’ environmental images, attitudes, preferences, and worldviews. Though much of this research remained quantitative and focused on the consciously grounded dimensions of geographical actions, experiences, and meanings, this work was crucial for the development of humanistic geography because it helped to justify the study of human beings’ lived relationships with the places, spaces, and environments comprising their geographic worlds.

Why “humanistic geography”?

There are at least two reasons for the label of “humanistic geography” rather than “experiential geography,” “lived geography,” “existential geography,” or some similar term. First, the 1970s marked a time when psychology and sociology had already drawn on the “humanistic” label to identify new subfields in their disciplines. Unsettled by the behaviorist and Freudian perspectives that dominated psychology, Abraham Maslow advocated an alternative approach he called “humanistic psychology,” which emphasized free will, creativity, human potential, and self-exploration. Similarly, sociologist Peter Berger called for a humanistic approach in his discipline, suggesting that the societal dimensions of human life could be more thoroughly examined not primarily via social structures, networks, and institutions but via the experiences, actions, and understandings of the individuals and groups involved.

A second reason for the label “humanistic geography” related to links with “humanism,” a philosophical, ideological, and ethical perspective with a complex intellectual history often incorporating conflicting understandings (Relph 1981). Most broadly, humanism refers to a belief in the unity of humankind and in human beings’ potential to improve their own lives and worlds, making careful, critical use of accurate intellectual knowledge and relevant life experiences. Humanist hallmarks include reason, tolerance, individual responsibility, and understanding and action grounded in mature personal experience. “Humanist” originated from the fifteenth-century Italian umanista, a scholar of classical Greek and Latin literature. Originally,
these scholars used “humanism” to spotlight the core of the Italian Renaissance, which, in seeking to revive classical learning, emphasized that human beings themselves, rather than divine power, play an instrumental role in who they are and what they become. Over the centuries, many different modes of humanism arose, often contradictory philosophically and ideologically. In the twentieth century, humanism continued to incorporate a wide range of meanings, though one can argue that its primary philosophical and ethical tenets included: (i) the emancipatory potential of human reason; (ii) the significance of free, open inquiry; (iii) the understanding of things and events mostly as they offer value for human beings and human life; and (iv) the wish to make life better for all people, particularly the less able or less fortunate.

As it developed in the 1970s, humanistic geography generally hewed to these central humanist tenets but reinterpreted them in innovative ways that assimilated shifting philosophical and practical concerns, including Earth’s ecological crisis. Humanistic geographers accepted the constructive possibilities of human reason but contended that intellectual knowledge grounded only in scientific method too often misinterpreted phenomena and reduced them to inaccurate, piecemeal counterfeits. Humanistic geographers appreciated the possibilities of earnest, open-ended inquiry but looked toward conceptual perspectives like phenomenology and hermeneutics that respected the phenomena being studied and provided descriptive and interpretive methods whereby researchers could more accurately and comprehensively locate and understand those phenomena. Like social scientists, humanistic geographers were keen to use their knowledge to contribute to human betterment, but they emphasized that any practical plans or policies should be grounded in the experiences, needs, and wishes of affected parties rather than unilaterally dictated by outside governmental or corporate decisions and demands. In relation to environmental and ecological deterioration, humanistic geographers argued that, because humans are Earth’s most conscious and environmentally exploitive beings, their efforts at betterment must extend beyond the human world to protecting and strengthening the welfare of other sentient beings as well as ecosystems, places, landscapes, natural regions, and the planet as a living whole.

Key themes in humanistic geography

Broadly, one can identify four central conceptual and methodological themes relating to humanistic geography as it developed in the 1970s and 1980s.

1 Humanistic geographers understood human life and experience to be a dynamic, multivalent structure that incorporates bodily, sensory, emotional, attitudinal, cognitive, and transpersonal dimensions. Humanistic researchers argued that a comprehensive human geography must describe these many dimensions; understand what they contribute to environmental experience, action, and meaning; and seek out integrated frameworks identifying how these many dimensions relate and interact in supportive and undermining ways. For example, Edward Relph (1976) delineated a spectrum of spatial experience that ranged from the instinctive, bodily, and immediate to the cerebral, ideal, and intangible. He probed how the experience of space differs from the experience of place and contended that space becomes place when it gathers human meanings, actions, and identity environmentally and temporally. Similarly, Yi-Fu
Tuan (1974) delineated a conceptual structure of environmental attitudes and values by consolidating similarities and differences in the ways that human beings respond to their geographical worlds physiologically, psychologically, socially, and culturally. He concluded that every person is, simultaneously, a biological being, a social being, and a unique individual. He demonstrated how environmental perceptions, attitudes, and values arise from and contribute to all three aspects of human being.

Humanistic geographers emphasized that much of human experience is opaque, ineffable, or beyond taken-for-granted awareness. To identify and describe these less accessible aspects of human life, humanistic geographers largely turned away from conventional scientific method that required tangible, measurable phenomena explicated and correlated mathematically and statistically. Instead, humanistic geographers turned toward ontological perspectives that accepted a much wider range of experience and presence. They drew on epistemological perspectives that sought to be open to phenomena and to accept all aspects of their constitution. The aim was an empathetic, wider-ranging mode of discovery whereby the phenomenon was given time and space to present itself. The emphasis was on “methodologies of engagement” that allowed researchers to encounter and understand the worlds and experiences of their subjects carefully, accurately, and comprehensively. In working toward a more intimate encounter with the phenomenon under study, some humanistic geographers used directed intuition and self-reflective explication; others carefully studied real-world situations, for example, a specific urban neighborhood or a small number of individuals asked to describe their environmental experiences and actions as accurately and as thoroughly as possible.

Many humanistic geographers argued that, as much as possible, the evidence, general principles, and understandings of humanistic geography should arise from self-knowledge grounded in researchers’ firsthand experiences. Research should work toward a forthright engagement with the experiences of others, whether those “others” are people, places, landscapes, elements of nature, aspects of the human-made environment, or other sentient beings. Humanistic geographers called into question conventional empirical research that defined the topic of research in objectivist fashion as a thing or situation separate from and unrelated to the life or experience of the researcher. Humanistic geographers argued that, by understanding the significance of environmental and geographical experiences in their own lives, individuals might act more responsibly and generously toward other human beings and toward the places and environments that one inhabits or knows (Tuan 1976). In this regard, Edward Relph (1981) advocated for an environmental humility—a way of engaging with the world whereby things, places, landscapes, people, and other living beings are all respected just for being what they are and, therefore, are thoughtfully cared for and intentionally protected.

Broadly, humanistic geographers grounded their work in two complementary research models, the first of which can be identified as explications of experience; and the second, as interpretations of social worlds. Explications of experience were most often associated with “place studies” and represented
by such geographers as Anne Buttmer, Douglas C.D. Pocock, Edward Relph, David Seamon, and Yi-Fu Tuan. Much of this work was grounded in phenomenology and, for its place interpretations, drew on a wide range of descriptive sources that included first-person experience, philosophical argument, archival reports, accounts from imaginative literature, and experiential evidence from photography, film, and other artistic media. Typically, this work emphasized lived commonalities in relation to environmental and place experience, though these humanistic researchers also asked how those commonalities varied in terms of individual and group differences. In the 1980s and 1990s, this work would be criticized as *essentialist* – claiming generalizable, universal structures such as “place” and “home” and largely ignoring lived variations grounded in social, cultural, and historical factors (Cresswell 2013; see “criticisms” below).

The second research model for humanistic geography – interpretations of social worlds – was represented by the work of such geographers as James Duncan, David Ley, Marwyn Samuels, Susan Smith, Graham Rowles, and John Western. This work incorporated a wider range of philosophical traditions than experiential explication and included pragmatism, grounded theory, symbolic interactionism, poststructuralism, and Marxist perspectives. Typically, this research was grounded empirically in a specific place or social situation – for example, David Ley’s work on inner-city subcultures, housing, and gentrification; John Western’s documentation of the impact of apartheid on Cape Town, South Africa; or Graham Rowles’s research on the everyday environmental and place experiences of American elderly populations. These researchers interpreted place and related geographical phenomena as a “social construction” arising from purposeful actions of people-in-place. Place was interpreted as a negotiated reality via which people facilitated places, which in turn facilitated the lives of people associated with those places. In the 1980s and 1990s, this “social-constructionist” approach to place became one significant bridge to poststructuralist thinking and the “new cultural geography” (Adams, Hoelscher, and Till 2001; Cloke, Philo, and Sadler 1991).

Humanistic geography, 1970–1978

Though interest in humanistic geography still holds sway today, the most significant work was accomplished in the period 1970–1978. During this time, humanistic geographers produced important substantive research and explored broader conceptual and methodological concerns. Though humanistic research incorporated a wide range of philosophical traditions, phenomenology was most often used because it emphasized the elucidation of everyday human experience and could be readily applied to taken-for-granted geographic phenomena such as place, home, lived space, and environmental experience. The first explicit discussion of phenomenology and geography was a 1970 article in the *Canadian Geographer* by Edward Relph, who gave examples of how the phenomenological approach was appropriate for probing the relationships between human beings and their natural and fabricated environments. A year later in the same journal, Yi-Fu Tuan also considered the geographical value of phenomenology and concluded that the perspective was potentially helpful because it considered neither the world nor human beings in the abstract but, rather, emphasized “human-being-in-the-world” as it
incorporated environmental, geographical, and place aspects.

The next productive year in humanistic research was 1974, marked by four significant works. First, David Ley published *The Black Inner City as Frontier Outpost*, an ethnographic study examining an African American neighborhood in Philadelphia. Second, Anne Buttimer published *Values in Geography*, a work that considered how taken-for-granted personal and professional understandings and values ground scholarly knowledge, often in ways of which researchers were not self-consciously aware. Yi-Fu Tuan published two notable works in 1974, the first of which was an article in *Progress in Human Geography* in which Tuan described two different modes of place: public symbols, places of prominence, like New York City’s Time Square, that yield their meaning to the eye; and fields of care, places like a well-liked tavern or neighborhood only known through prolonged experience and typically undistinguished architecturally or visually. Tuan’s second significant work in 1974 was *Topophilia* (Tuan 1974), which delineated an outline for a phenomenology of environmental and place experience. This book became one of the best known humanistic-geographic works for researchers outside the discipline, partly because Tuan introduced the term “topophilia,” referring to attachment to and love of place.

The year 1976 marked a number of significant advances in humanistic research, including an explicit formulation of the subfield and two penetrating works that further clarified the relationship between humanistic geography and phenomenology. In a special June issue of the *Annals of the Association of American Geographers* devoted to the philosophy of geography, two important articles appeared, the first of which, by Anne Buttimer, examined how the phenomenological concept of *lifeworld* – the taken-for-granted world of everyday living – might offer insights for research on place, social space, and time–space rhythms. In the same *Annals* issue, Yi-Fu Tuan (1976) provided the first formal conceptualization of humanistic geography, which he described as a branch of the discipline that leads to a more thorough understanding of the human condition in relation to environmental and geographic concerns.

The most significant humanistic work in 1976 was Edward Relph’s *Place and Placelessness* (Relph 1976), a phenomenological study that interpreted place experience in terms of insideness and outsideness. Relph argued that the most intimate experience of place could be described by existential insideness, the lived situation in which a place is experienced and understood without self-conscious awareness yet is permeated with cognitive, sensory, and affective meaning usually unnoticed unless the place is changed in some way – for example, one’s home and neighborhood is destroyed by storm. Also in this work, Relph formulated the concept of *placelessness*, which he defined as the fragmentation and elimination of distinct places in the world. Of all the 1970s work in humanistic geography, *Place and Placelessness* perhaps had the most lasting impact because it provided a lucid, applicable presentation of why places are important in human life, what their constitution is experientially, and how they have been undermined in modernist and postmodernist times.

The year 1978 marked the high point of humanistic research in that David Ley and Marwyn Samuels (1978) published *Humanistic Geography: Prospects and Problems*, an edited collection illustrating the broad conceptual and thematic range that humanist perspectives could provide geography. In their introduction, the editors argued that the humanistic tradition was important for geographers because it offered one
conceptual and applied pathway for reconciling such dualisms as objectivity and subjectivity; materialism and idealism; agency and structure; and knowledge and wisdom. Chapters focused on such diverse topics as existential geography, alternative cartographies, a humanized economic geography, links between imaginative literature and geography, words for places, landscapes as experienced by tourists, and the phenomenological studies of the natural world produced by the eminent late eighteenth-century German poet and dramatist Johann Wolfgang von Goethe. In spite of their eclecticism, the 20 chapters of the volume effectively contributed to the editors’ main aim: to reconcile the “science and art of geography” (Ley and Samuels 1978, 10).

After 1978 and into the 2000s, important humanistic work continued to appear, including David Seamon’s *A Geography of the Lifeworld* (1979); Anne Buttimer and David Seamon’s *Human Experience of Space and Place* (1980); Douglas C.D. Pocock’s *Humanistic Geography and Literature* (1981); Edward Relph’s *Rational Landscapes and Humanistic Geography* (Relph 1981); Yi-Fu Tuan’s *Segmented Worlds and Self* (1982); David Seamon and Robert Mugerauer’s * Dwelling, Place and Environment* (1985); Edward Relph’s *The Modern Urban Landscape* (1987); J. Douglas Porteous’s *Planned to Death* (1989); J. Nicholas Entrikin’s *The Betweenness of Place* (1991); Robert David Sack’s *Place, Consumption and Modernity* (1992); Anne Buttimer’s * Geography and the Human Spirit* (1993); David Seamon’s *Dwelling, Seeing, and Designing* (1993); Paul Rodaway’s *Sensuous Geographies* (1994); Yi-Fu Tuan’s *Cosmos and Hearth* (1996); Robert David Sack’s *Homo Geographicus* (1997); David Seamon and Arthur Zajonc’s *Goethe’s Way of Science* (1998); Anne Buttimer’s *Sustainable Landscapes and Life-ways* (2001); Robert David Sack’s *A Geographical Guide to the Real and the Good* (2003); Edmunds Bunkse’s *Geography and the Art of Life* (2004); and Yi-Fu Tuan’s *Humanist Geography* (2012).

Most generally, however, the perspective of humanistic geography largely fell from sight or metamorphosed into the “new cultural geography” molded from poststructuralist, feminist, and critical perspectives. In this regard, many human geographers shifted their attention to the cutting-edge work of philosophers Michel Foucault, Jacques Derrida, Gilles Deleuze, Félix Guattari, Bruno Latour, and other poststructuralist, critical, and relationalist theorists (Cresswell 2013). One example of how humanistic themes shifted in the new millennium is *Textures of Place* (Adams, Hoelscher, and Till 2001), an edited collection dedicated to Yi-Fu Tuan and the humanistic tradition. Overall, the volume’s 27 chapters demonstrated how an engagement with critical social theory worked to transform earlier humanistic understandings of place, environmental experience, and geographical meaning. The editors of the volume called for a reconsideration of humanistic geography in the context of “revised assumptions about human subjectivity, the transparency of language, and the use of descriptive categories based upon Western traditions of understanding” (Adams, Hoelscher, and Till 2001, xvii).

**Criticisms of humanistic geography**

Beginning in the 1980s, humanistic research faced increasing criticism from quantitative-analytic geographers, on the one hand, and Marxist, feminist, and poststructural geographers, on the other hand (Cloke, Philo, and Sadler 1991; Cresswell 2013). Quantitative geographers largely criticized humanistic work in relation to research method: In turning away from deductive theory, predefined concepts, and measurable validation, how could humanistic
geographers be certain that their interpretive conclusions were accurate, comprehensive, and trustworthy? In response, humanistic geographers emphasized that their approach was generally inductive in that it drew on the richness and complexity of human situations and events to locate generalizable descriptions and theories. Humanistic geographers pointed out that the conclusions of any humanistic study were no more or no less than interpretive possibilities open to the public scrutiny of other interested parties. Humanistic geographers emphasized that their interpretive sources were wide-ranging and included field notes, focus groups, autobiographical descriptions, accounts from participant observation, and material texts like photographs, films, buildings, landscapes, imaginative literature, and archival documents. One methodological device used by humanistic geographers to better assure accuracy and trustworthiness was triangulation, whereby researchers drew on multiple modes of evidence-gathering methods to identify different lived perspectives and to corroborate different information sources.

The criticisms of feminist, Marxist, and post-structural geographers emphasized conceptual, ideological, and ethical concerns. Feminist geographers claimed that humanistic research was essentialist in uncritically assuming an unchanging, universal human condition that ignored individual and group diversity, including gender, social, cultural, and economic differences. These feminist geographers argued that humanistic work was authoritative in that it appeared to privilege the interpretive powers of scholarly experts who arbitrarily claimed the status to identify and describe the geographical situations of “more ordinary” people. Feminist critics contended that humanistic work presupposed an implicit masculinist bias that assumed academically trained men (mostly) could understand all others’ situations – for example, the experiences of women, the less able, gays and lesbians, ethnic and racial communities, and so forth. Marxist geographers criticized humanistic geography because they saw it as voluntarist in that it uncritically interpreted social life as a function of intentional, willed plans and actions of individuals. The Marxist claim was that humanistic thinking gave too much weight to autonomous human agency at the expense of entrenched, transparent social structures and power relations. Marxist critics pointed out that humanistic geographers gave little attention to the underlying economic and political dynamics shaping places and peoples’ everyday lives.

Humanistic geographers responded to the essentialist, authoritative, and masculinist charges by arguing that, in fact, humanistic work recognized human differences and sought conceptual and methodological ways for thoroughly engaging with the uniqueness of individuals and groups. They pointed to studies that used participant observation and other qualitative methods to understand particular geographical situations – for example, David Ley’s work on how African Americans negotiated their lives in the place context of Philadelphia’s inner city. In regard to the Marxist charge that they neglected the role of societal structures in constraining human freedom, humanistic geographers responded that their perspective could examine phenomena such as power, exclusion, resistance, and conflict, though little work was done in this direction, partly perhaps because most humanistic geographers instinctively favored freedom, creativity, and personal and group autonomy. Humanistic geographers accepted the Marxist claim that structural conditions are critical for the understanding of human action but, equally important, they argued, was the role of people’s values, beliefs, worldviews, intentions, and taken-for-granted ways of coping.
with the world. Humanistic geographers focusing on interpretations of social worlds probed the structural constraints of places and social worlds directly but gave equal weight to human agents being aware of and being able to change their lifeways in relation to limiting social and economic structures.

Poststructural geographers questioned humanistic work in yet other ways. Some poststructural critics claimed that humanistic geographers ethically favored place, insideness, and rootedness over non-place, outsideness, and mobility; place itself was assumed to be centered, static, bounded, and exclusionary. Instead, poststructural critics spoke of a “progressive sense of place” and focused on how places relate and respond to their wider social and environmental contexts. For these critics, places held their importance geographically, but the crucial theoretical and practical aim was finding ways whereby places could better incorporate diversity and partake in constructive interconnections and exchanges with other places. Another group of poststructural critics questioned whether “place” even existed in the postmodern world, claiming that real-world places were becoming marginal and obsolete because of trends toward globalization, non-places, and hyperspace. Some poststructural critics went so far as to suggest that, in our proliferating “hyper-real” world of digital environments and virtual realities, the lived distinctions between “real” and “imagined” places should be critically called into question. These critics challenged the rigid, unchanging stasis of physical places and environments that they claimed were encompassed by humanistic accounts. These critics spoke instead of provisional, shifting connections and flows among people, spaces, places, nation-states, information, worldviews, and digital representations. Key themes were mobility, flux, hybridity, relativity, relationality, discontinuities, rhizomes, assemblages, hyper-worlds, virtual places, and smooth and striated spaces.

Humanistic geographers responded to these poststructural criticisms by suggesting that, even as globalization eroded some places, it strengthened other places and contributed to new kinds of places. Humanistic geographers pointed out that, even with the growing importance of digital communication, hyperspace, and virtual realities, real places retain their importance because people are bodily beings who always unavoidably live a life in some physical place. This inescapable embodiment-in-place was often ignored by the poststructural critics who aimed for a more progressive sense of place grounded in a dynamic, ever-shifting network of intertwined, porous places. Humanistic geographers contended that a good portion of such dynamic exchange remains grounded in the habitual regularity of emplaced bodies. Humanistic geographers also emphasized that any dynamic interchange among places presupposes a robust integrity of each place itself; this robust integrity is at least partly founded in the habitual regularity of lived bodies inescapably bound to physical place (Seamon 2013).

Humanistic geography today

Though humanistic geography as an explicit subfield largely disappeared by the early 1990s, interest in humanistic themes continued inside and outside the discipline, particularly on the part of phenomenological philosophers concerned with the phenomenon of place. Humanistic geographers’ interpretations of place in the 1970s were largely subjectivist in that place was understood as a cognitive or affective representation inside the human being and ontologically separate from the objective environment outside. As phenomenological
philosophers Edward Casey (2009) and Jeff Malpas (1999) probed the topic in the 1990s and 2000s, they argued that place is a primary ontological structure that encompasses both human experience and the physical world in which that experience unfolds. This argument that a human being is always human-being-in-place highlighted an important new way of geographical thinking because it claimed that place is necessarily an integral, inescapable contributor to human existence and life. This understanding meant that places are not material environments existentially apart from the people associated with them but, rather, the holistic unit of human-beings-experiencing-place. Sometimes called *lived emplacement* or *embodied place*, this phenomenon was understood to be complex and dynamic, and to incorporate generative processes via which a place and its experiences and meanings shift or remain the same (Seamon 2013).

Partly because of Casey and Malpas’s writings, researchers inside and outside geography brought renewed scholarly attention to the lived qualities of place and to other topics associated with the humanistic tradition. For example, geographers Soren Larsen and Jay Johnson (2012) worked to link a place-grounded ontology with affinity politics, and geographer Sara Johansson (2013) developed a method of “rhythm analysis” to understand how the “lived body” encompasses and is encompassed by the urban environment as experienced. Echoing earlier claims on lived embodiment by French phenomenologist Maurice Merleau-Ponty, Johansson argued that the bodily dimensions of environmental experience are as meaningful and as important in understanding place as environmental cognition and intellectual geographic knowledge.

In research by non-geographers, one also finds a continuing body of work involving a humanistic approach to geographical and environmental topics. One example is philosopher Ingrid Stefanovic’s efforts (2000) toward a phenomenology of sustainability via an examination of how place and lived emplacement provide a foothold for grounding environmental responsibilities and actions in relation to particular individuals, groups, and localities. A second example is the research of literary scholar Anna Westerståhl Stenport (2004), who drew largely on Swedish writer August Strindberg’s works relating to Paris and Stockholm to examine how the nineteenth-century city shaped imaginative literature and how, in turn, that literature shaped perceptions of the nineteenth-century city. A third example is ethnographer Urzula Woźniak’s examination (2009) of at-homeness and placelessness in the context of current global migration. Drawing on Ukrainian, Turkish, and Vietnamese examples, she used the concept of community attachment to understand the contrasting degree of identification that different immigrant groups feel for their place of relocation; she demonstrated how mental associations with immigrants’ original home place play a significant role in their understanding of and feelings toward their new place of residence.

These studies and others exemplify a new generation of researchers who continue to be interested in such humanistic topics as place experience, at-homeness, community involvement and identity, out-of-placeness, environmental personhood, lived emplacement, mobility and place, supportive or undermining processes shaping place, and the lived similarities and differences between real places and virtual places (Seamon 2013). All of this work remains grounded in a central humanistic aim: to bring “human beings in all of their complexity to the centre-stage of human geography” (Cloke, Philo, and Sadler 1991, 58).

Description and purpose

The main purpose of the Magyar Földrajzi Társaság (Hungarian Geographical Society) is to generate more interest in geography by promoting and disseminating geographical knowledge and to encourage research, especially on the geography of Hungary. The society also serves as a forum for geography teachers active at all levels of the educational system.

The society builds good relationships with nonprofit associations operating in the field of geosciences. MFT organizes national and international conferences, lectures, study tours, exhibitions, educational competitions, and family programs. MFT also publishes two journals and has a website to further knowledge and arouse interest in geography.

Journals or major publication series

Földrajzi Közlemények (Geographical Review).

A Földgömb. www.afoldgomb.hu

Current activities or projects

Activities of the society includes co-organizing scientific conferences (e.g., http://eugeo2015.com) and lectures all around the country, while the annual meeting offers guided study tours in Hungary as well as abroad. The society is committed to assist talented pupils and university students interested in geography by offering them grants and co-organizing educational competitions nationwide. Journals published by the society target both scientific community and the general public. The society operates a library with the most significant geographical collection in Hungary.

Brief history

The MFT was founded in 1872 to promote the science of geography. Membership and interest grew, mainly because of the work of Lajos Lóczy, a determinative geographer who is credited with establishing modern geography in Hungary. The Földrajzi Közlemények, the scientific journal of the society, was first published in 1873. The Magyar Földrajzi Társaság Könyvtára book series had been published since 1880 and all 67 volumes became very popular due to its exclusive appearance and high quality scientific content.

Before World War II members of the society were accomplished researchers, some of them influential in politics, for example, Count Pál Teleki, who became prime minister between 1920–1921 and 1939–1941. This contributed to the abolishment of the society under communist rule between 1949 and 1952. The society gradually became more open towards geography education from 1952 onward when the membership mainly consisted of primary and
high school teachers and researchers. After the regime change and with the approaching twenty-first century and its challenges, the society renewed its efforts to recover its popularity and regain its scientific reputation.

Hybridity

Clemens Driessen
Wageningen University, Netherlands

Hybridity in the social sciences is the idea that the world does not consist of pure things. Hybrid entities are considered to be combinations of two or more types of substances, mechanisms, processes, and so forth. In everyday language one can think of hybrid cars that have both an electrical and a combustion engine, or hybrid fast food such as the cheeseburger pizza. In (human) geography and other social sciences the term is used to break down dualisms that structure our (Western) thinking and research. A dualism is a combination of two terms that are thought of as opposed and which are used to categorize and order the world into mutually exclusive domains. Examples of these dualisms are subject/object, mind/body, social/natural, material/symbolic, and human/nonhuman.

Hybridity involves an ontological claim that the world really is a much more heterogeneous and messy place than many of our common binary “either/or” conceptual schemes imply. In its strong form, a hybrid world is not to be thought of in terms of separate objects, spheres, or domains that interact or interface. Instead the world is to be understood in terms of relations and processes only. Objects or subjects “in themselves” in this view have no essential qualities such as being powerful or weak, active or passive. Everything is part of assemblages, networks, or mesh-works whose characteristics emerge depending on the ways in which elements are (inter)related.

This intricately connected world can be characterized using hyphenated terms like “nature–cultures” and “social–technical” (the term sociotechnical in fact no longer even requires a hyphen). Processes of change in these intertwined domains are analyzed in terms of mutual constitution, co-production, co-shaping, and co-evolution: notions that emphasize dynamic interaction without privileging a one-way directed causality between separate entities. Ultimately, hybridity generates an interest in processes of becoming rather than states of being as the primary mode in which things exist; a view that has been informed by the work of philosophers such as Whitehead, Heidegger, and Deleuze.

Symmetrical descriptions of science and technology

The main opposition that is analyzed in terms of hybridity is that between the natural and the social. The French philosopher/anthropologist Bruno Latour is a key author associated with “actor–network theory” in which a particular view of hybridity has been developed. His ethno-graphic fieldwork in a scientific research laboratory and his studies of the development of new technologies resulted in empirical claims on how science actually operates and how new technologies come to be successful. His description of the ways in which truth is constructed in laboratories highlight how both material and social operations are necessary for making facts emerge and stick. In order for facts to be true and scientific findings to be real, Latour outlined a process of purification and translation: in a lab phenomena...
are isolated and purified, after which—in order to be found true—the conditions of the lab need to be translated and spread out over the world, connected with various types of humans and nonhumans alike. For example, the microbes that Pasteur isolated in his lab only got accepted as real after a variety of sites such as farms and hospitals were changed in such a way to resemble the conditions of the laboratory in crucial respects.

In Latour’s account, the ways in which facts come to be held as true, and technologies come to adequately function, cannot be meaningfully explained in terms of these being true representations of nature or inherently feasible technologies. Only in hindsight may technical factors such as the quality of scientific instruments and the purity of substances be distinguished from social forces such as economic factors, powerful institutions, and the interests of important individuals. But even then trying to keep these factors apart is not the most interesting way of understanding efforts to find the facts of nature or to invent new technologies.

What is needed instead are “symmetrical” accounts of scientific and technological change, which means a failed technology or disproven scientific theory should be explained and described in the same terms as successful ones: so without referring to a nature that sooner or later had to be discovered or to a technology that had always been viable but merely needed to be invented. Technological, or rather “sociotechnical,” innovation in this view requires “heterogeneous engineering,” a process that in particular ways manages to link very diverse things—material artifacts, economic structures, political institutions, organisms, and groups—so as to “align” these with each other. Alignment is the term used for the activity of generating networks of humans and nonhumans that together produce a certain effect.

Latour expanded his early work on laboratories and technology into a wider theory of hybridity, according to which our world is increasingly populated by hybrids. Environmental crises, genetically modified organisms, and climate change are issues in which political and social debates are hard to disentangle from scientific and technological uncertainties. Trying to nevertheless separate society and nature means missing out on the mixed, constructed, and intertwined character of these issues. By continuing to try to sort out political decisions from scientific uncertainties, we actually muddle things further and allow for the unacknowledged proliferation of hybrids. Latour claims the “modern constitution,” which strictly separates society from nature, and values from facts, has always kept from view how science and technology actually thrive by connecting and mixing these. Therefore he argues “we have never been modern” (Latour 1993) in the way that we think we have.

In symmetrical accounts of science and technology, the material and natural sides of modernist dualisms are actively co-shaping our world, rather than merely being a mute and static background to human actions. Agency, the ability to act and to influence events, then cannot be accorded to human beings alone. Actors can only become powerful when they come to be aligned within networks of various kinds of beings, including material objects. Therefore, in Latour’s “flat ontology” there is no (a priori) distinction to be made between humans and “nonhumans,” so we can discern “nonhuman agency” just as well as “human agency.”

Biologist/science historian/philosopher/anthropologist Donna Haraway offers a similar symmetrical and relational take on science and technology. She combines this with ideas springing from ecofeminism in which feminist understandings of social justice and alternative
forms of knowing are linked to a critique of environmental exploitation and domination. She calls for accounts of the world conceived as coming with active “subjectivity,” rather than merely a passive resource to be mapped and appropriated.

In *Simians, Cyborgs, and Women* (Haraway 1991) she proposes a further set of dualisms to be broken down, including male/female, mind/body, organic/inorganic, and subject/object. This feminist-inspired understanding of science emphasizes embodied and immersive “situated knowledges” rather than an abstract universalist ideal of science as inherently timeless and placeless. It would of course be too simplistic and dualist to merely map all these dualisms onto each other: projecting an essentially feminine relation to the world that is embodied rather than distant, closer to nature instead of abstracting from it, subjective rather than objective. Instead, this whole array of binary hierarchies are all to be muddled as part of an emancipatory process that extends to and beyond women, people of different ethnicities, and a variety of animals.

Haraway’s cyborg is both organism and machine, though without constituting a merging of these two elements as if they were pure ingredients. Both already are infused with (information) technologies, desires, and projections, making it pointless to try and fully disentangle natural origins from social and cultural influences. This model figure of the cyborg is thus not merely the Robocop-like man-machine found in popular culture, but embodies the way that all of us are nowadays mixtures of chemicals and flesh, hooked up to gadgets and functioning as part of various technological systems.

Without claiming or seeking a perspective outside of hybridizing practices and situations, this theorizing of hybridity is affirmative and seems to welcome the liberating potential of “posthuman” futures. This promotes the idea of us “never having been human” in the first place, that is, human as in independent from our environments and sociomaterial relations.

An argument was extended in later work where Haraway (2008) proposed the “companion animal” as another model subjectivity to embody the breakdown of distinctions that structure (ideas of) the self and its relation to the world. She recounts how in practices such as dog agility training human selves are actively transformed in close interaction with animal counterparts as part of cross-species learning processes.

### Hybrid geographies

Geography can be considered to be conducive to appreciating hybridity due to its spatial and situated focus on practices such as food consumption and production, nature conservation, and resource extraction that are inherently both social and natural.

After discarding binary divisions such as natural/social that conventionally guide research practices, hybrid geographers aim to trace complexities that cannot or should not be dealt with by sorting out the elements of belonging to either nature or culture. They describe movements of goods and information, focusing also on the material practices and spatially situated character of an issue to help establish interconnections and discern multifaceted processes. Thereby, a seemingly mundane artifact such as a cup of coffee can be found to be part of global flows of substances as well as concepts, involving regional climates, water scarcity and distribution, migrant labor exploitation, free trade negotiations and their legal as well as economic ramifications, historical coffee house culture and early experiences of democracy, effects of coffee consumption on human bodies, moods, sleeping patterns, and organizational social dynamics as well as processes of urban gentrification around American coffee
HYBRIDITY

chain shops competing with local translations of Italian espresso culture. Hybrid research aims to unravel and foreground the intertwine ment of these variegated aspects, offering alternative ways of conceptualizing and understanding relations of humans and their environments.

The hybrid geographical mappings of processes and movements lead to topological rather than geometrical modes of analysis. This means that in a world defined by relations rather than more universalizing abstractions, such as conventional maps, understandings of space can be geared to the issue at hand. This involves analyzing how disparate places become closely connected through flows generated by industrial production and transportation as well as ecological migration and geological processes. Natural processes in turn may be inextricably bound up with human practices, for example, climate change, erosion, and deforestation.

Understanding hybridity involves embracing everyday knowledge-practices that are embodied, lived, active, and place bound. This form of knowing is explicitly partial and incomplete and challenges the conventional ideal of knowledge as universal, purely cognitive, formalized, distanced, and abstract. Understanding the world as hybrid means studying it is also a performative activity that involves enacting a particular reality rather than merely trying to represent one. Research then is intervening in the midst of things, ideally a lively and affective affair in which researchers develop and promote a sensibility for experiencing the fluid and relational character of the world (see e.g., Bennett 2009).

Mostly, research into hybridity is done by foregrounding the relations between humans and nature through cases in which these relations are unsettled or complicated. Thus hybrid geographers such as Sarah Whatmore have followed global linkages and the ways in which things like genetically modified soybeans travel across the globe – constantly changing in the process as they move between patent offices, corporate headquarters, research laboratories, and the fields of farmers (Whatmore 2002). Other poststructuralist theorizing tends to focus on agency and meaning coming solely from humans and mainly expressed in discourse. But hybridity has led researchers to move beyond a strict focus on language and symbolic meaning only, to analyze also material things and concrete places as sources of meaning and change. Understanding soy then means studying discursive practices that produce soy across texts of various kinds, including legal and policy documents as well as interpreting imagery such as advertisements. But tracing the movements and transformations of soy also means analyzing field sites that offer insights into the ways in which nongovernmental organization (NGO) campaigns, supermarket executives, national politicians, and EU bureaucrats come to define and “enact” particular types of soy and their production practices.

The fields of food consumption and agricultural production lend themselves well to hybrid analysis, being inherently mixings of nature and culture. Hybrid views of agriculture complicate analysis in terms of naturalness versus artificiality. Instead they offer detailed accounts of the ways in which modern high-tech agricultural production generates particular relations and experiences.

Relations with animals and nature comprise another topic on which the implications of hybridity have been widely noted. When nature and culture are not considered as distinct realms, conservation can no longer be guided by ideals
of pristine and untrammeled nature. Attention is drawn instead to how the practices of wildlife conservation may involve intricate breeding programs and close monitoring of genetic variety of remaining specimens, whereby animals and their genetics are taken up and translated into information systems. In relation to this development, the variety of motives of conservationists and associated ideals of wildness and authenticity can be scrutinized together with assumptions in conservation biology such as the concept of species and models of population viability.

Science and lay knowledge

Work under the banner of hybridity can be viewed as a particular response to an ongoing debate since at least the 1980s on how to deal with an apparent crisis in the public role of scientific expertise. In public contestations of (technological) risks in the face of pervasive uncertainties, science is deemed unable to provide clear and unambiguous descriptions of what is the matter in an issue. Controversies over nuclear energy and radioactivity, HIV/AIDS drug development, ecological and health effects of pesticides, farm animal disease outbreaks, and the genetic modification of food crops led to a mainstream questioning of existing institutional relations between science and society.

The risks and uncertainties embedded in these issues were no longer accepted to be dealt with in terms of an “information deficit model” via one-way efforts to educate a lay public to understand and accept scientific findings. Not only were the sciences found to be incapable of providing clear answers in response to public concerns, but these concerns were actually produced or attributed to technological risks emerging from within these scientific disciplines themselves, such as biochemistry, nuclear physics, and molecular biology. Moreover, the techno-scientific products of these fields of research and development – such as the cancer research animal “Oncomouse®” which is genetically engineered to develop tumors – often unsettle the basic dualisms in which the public used to make sense of these concerns: natural/artificial, living/nonliving.

Working to expose and detail hybridity tends to come with an implicit or explicit aim to embrace particular forms of knowing and involvement: as situated, local, embodied, and immersive. This is the type of knowledge that can be intimately related to communal practices, everyday language, and local environmental stewardship. At the same time, analyzing in terms of hybridity means opening up the workings of science in practice, to reveal how universal truth claims are in particular ways local too and consist of an array of translations and purifications. Some natural scientists have felt attacked by these hybrid analyses which questioned their privileged access to the truth. In what in the 1990s was called the “science wars” they responded by dismissing the hybrid accounts of their day-to-day practices as merely the fashionable product of ignorant philosophers and social scientists.

However, science and lay knowledge can often be found to be mixed, for example, where one is harnessed to inform the other: when biodiversity prospecting involves using local guides; when pharmaceutical companies try and utilize indigenous knowledge of medicinal herbs handed down over generations; or with nomadic herders adding GPS technology to guide their herding practices.

Projects have been set up to do flood modeling whereby the complex mathematical/computer models of a river system are developed and calibrated by input of local “lay” publics who have more direct experience with flooding in a particular catchment area (Lane et al. 2011). In
HYBRIDITY

this way the modeling exercise can be understood as integrating dispersed and informal ways of knowing a river with more formal, disembodied computer modeling to generate knowledge that transcends the lay/expert dichotomy. Hereby the natural (and social) science work itself also provides a platform for conflict resolution and dealing with uncertainties and risks. In debating the impacts of particular mitigation strategies in one site, these may be found to be connected to effects elsewhere. This can be considered an example of a variety of “hybrid fora” – that have sprung up or were explicitly created as such – in which various forms of expertise come together to deliberate knowledge controversies.

Geography seems uniquely positioned to engage and experiment with these hybrid modes of knowledge production and combinations of physical and social forms of representing and intervening; though this has not meant the split between human and physical geography is easily overcome. Most geographical forms of expertise, subdisciplinary institutional divisions, and research practices still seem firmly rooted in separate social and physical domains. It would be too simple to see the challenge of hybridity for geography solely in terms of an opposition between social theory oriented toward critique of power relations and spatial analysis aiming for objective representation. The point of what has come to be labeled as “more-than-human geography” is not merely to combine qualitative and quantitative and/or social and natural science methods and approaches in a single research project. Nor does it mean that there can be only one proper way of doing geography: an idealized integration of multiple approaches into a single coherent unified science. The aim rather is to interweave the reductions and translations of natural science approaches with other forms of knowing and of deliberating matters of concern.

This of course is difficult, as it involves practical, institutional, and theoretical challenges.

Methods and approaches of hybridity

Ethnography is an important method for producing hybrid accounts. Taking a cue from anthropology, researchers do not seek to discern a social world separate from its understanding of nature, but to describe a society and its nature as part of a single coherent (or conflict ridden) cosmology – thus studying how knowledge, social relations, and symbolic and material cultures interrelate in a web of practical meanings.

Hybrid research involves a tension between, on the one hand, an emphasis on lived everyday experience and, on the other, being informed by poststructuralist ideas on the subject as an effect of discourses and practices. Experience in posthumanist thought, however, does not occur in isolated bodies, but these are always immersed, emergent, and relational – thus building on, for example, Heidegger’s understanding of “being in the world,” in which the environment is thought not as something to deal with “from the outside” as a space “out there” from which humans can be considered separate.

Also, the affective character of hybrid research may be in tension with the impetus to chart and describe traces and patterns across the globe. The status of the knowledge claims produced in terms of hybridity can be questioned: who is doing the tracing of flows and patterns? Emulating ethnographic work by anthropologists, researchers often render themselves present in the “thick” accounts of situations they offer; this in order to prevent the hybrid view of the world becoming another “view from nowhere” that merely discerns processes of mixing, purification, and translation everywhere. Authors thereby self-consciously reflect on the type of
HYBRIDITY

intervention that particular methods of analyzing and reporting bring, meanwhile negotiating the question of who it is that is self-conscious here: the author him- or herself (or itself?), as an assemblage of methods, theories, biography, and cultural identities? This offers a way not to hide but to actually make present the partialities and situatedness of hybrid geographers, who of course bring their own positionalities while traversing multiple sites and getting themselves entangled in associated webs of meaning and material practices.

For instance, ethnogeomorphology is an approach to environmental research that incorporates the sentient and cultural relations of local inhabitants of an area. Thereby it reflects multiple ways of relating to a landscape that is conceptualized as emergent (see Wilcock, Brierley, and Howitt 2013). It will be interesting to learn whether it is possible to move beyond aboriginal types of indigenous people that have been the main focus of this type of research to probe other perhaps heterogeneous groups that after all “have never been modern” too.

The experience of a dissolving nature/culture divide also seems to motivate and inform new experimental modes of living with (formerly wild) animals and ecologies. This includes acknowledging “invasive species,” appreciating “novel ecosystems,” and developing modes of conservation involving “rewilding” and “dedomestication,” which in practice do not refer to pure wild nature as conventional conservation does. For these and other sites of human–animal interactions, “multispecies ethnography” has been proposed as a way to symmetrically study both human and animal (or even plant) behaviors and interactions as part of more-than-human nature–cultures.

Also, new combinations of science and the arts are explored as a mode of generating forms of knowing, intervening, debating, or otherwise engaging with the world as both a physical and social place. Visual as well as performed arts and creative design are not just inherently material and symbolic, but can involve experimenting with forms in which to integrate these dualisms.

Politics and ethics in a hybrid world

As opposed to common theorizations of politics that leave establishing “the facts” to science, work starting from hybridity has proposed alternative modes of doing politics. Hybridity has been found to be a productive way to look at all types of societal issues. Since scientific facts do not have to be assumed as neutral or given, what may seem natural conditions and factors can also be described as riddled with societal choices and interests, identities, and communal meanings. Likewise, technological change can be redescribed to be as much “social” as it is “physical” in character, with particular ways of thinking and idiosyncratic choices hidden in material devices and practices.

Seeing science as a material and social process can be thought of as democratizing or at least opening up scientific research to scrutiny by more lay publics. However, hybrid geographies tend not to be easily translated into policymaking, as policymaking is mostly still (formally) operating within modernist dualisms separating facts and values, science and politics, human decisions, and environmental impacts.

Annemarie Mol (2002) has described various ways of enacting a particular disease, by doctors, patients, and others, emphasizing how the body and its disease are “multiple.” She highlights how the messiness of, for instance, medical practices is not something that should be solved by rationalization, or be used to criticize medical professionals or policymakers, but is a sign of complexity that we need to live with. She
HYBRIDITY

proposes an “ontological politics” that promotes doubt and the cultivation of multiple modes of improving practices rather than arguments for optimization in terms of a singular understanding of what is the matter. Likewise, Isabelle Stengers (2010) has proposed a “cosmopolitics” that emphasizes contingency and diversity in the way sciences create particular truths as they shape practices of intervening and debate. This is contrasted with conventional ideals of “decision-making” based on facts and technological choices that already make for particular (self-)understandings of political subjects and the nature of the situation they find themselves in.

The hybrid understanding of subjects and agency has of course implications for how to conceive of politics and ethics. No longer can we assume or idealize the liberal subject as a rational, autonomous, atomistic individual. This means traditional understandings of morality as personal ethical dilemmas and calls of conscience to redirect our will are misguided. At best we can see relational characters immersed in practices or, as Whatmore identifies them, “intimate assemblages of corporeal becoming.” Approaches to ethics that start from a relational and fluid understanding of humans, animals, and technologies call for learning to be open, to tune in, and to seek to encounter “mindful others.” For instance, in relation to animals this means not extending humanist models of subjectivity and rights to a select group of higher mammals, but becoming aware of the various ways in which our language and material practices contain species hierarchies, make us overestimate our human specialness, and prevent us from more truly encountering and imaginatively responding to a variety of living beings.

Hybridity entails moving away from oppositional thinking when confronted with “risks” and uncontrollable processes. Risk can then be appreciated as not just a technical challenge but also a social and cultural challenge of acknowledging and appreciating that human intentions are not the sole source of agency. For instance, new designs of living with river flooding, wildlife, and bacteria are being experimented with that acknowledge the agency of nonhumans such as animals and even water. Viewing these processes in terms of hybridity suggests that agency is distributed across many sites, not located in one place or body; that we stop trying to command and control, but allow for nonhuman agency to partly shape how we live.

Critiques of hybridity

Hybridity as an ontological position and research agenda has drawn critique, especially for giving up valued terms. For instance, if hybrid approaches see pristine wild nature as merely a romantic dream and embrace how we are surrounded by successions of novel ecosystems, urban wilds, and formerly invasive species, there seems to be no way to conceptualize what we should still try and protect because we cannot separate out a “natural” state. When domesticated farm animals have no natural equivalent that could function as benchmarks of behavior and welfare, there seems to be no holds barred to their adaptation and industrial use. When genetic modification is seen as merely an extension of interweavings of the organic and the mechanical and of nature and society associated with ordinary breeding, it seems difficult to argue against more meddling in a gene base to further (particular) human interests.

So, although hybrid approaches may have noble anti-authoritarian and democratizing aims, hybrid theorizing and its joyful dissolution of boundaries may inadvertently leave things to powerful actors who get to strengthen their take on what is left of nature.
One way of dealing with this loss of critical capacity would be to take hybridity much further and purge it from the “residual humanism” it tends to retain as commonly only humans are considered central in the muddling of culture and nature. Lulka (2009) has proposed to symmetrically grant this hybridizing ability to nonhuman agents, too. For instance, beaver burrows can be the site and the expression of consecutive generations of beaver communities responding to a flooding river in a process of co-evolution of groups of beavers with particular material cultures and abiotic processes in their environment. Perhaps a truly hybrid mode of knowledge production and environmental management would then be to actively involve beaver communities in participatory flood modeling and flood control experiments.

Beyond hybridity?

The idea of hybridity seems to become more and more mainstream. For example, formerly “natural events” such as floods are increasingly blamed not only on bad weather but also on governmental authorities, shifts in land-use patterns, and climate change. Or obesity is viewed as not just the result of consumer choices, lack of exercise, or genetic disposition, but also associated with health policies, the invention of high-fructose corn syrup, fast-food culture, and the spread of “food deserts” in which affordable healthy food is difficult to come by.

Nowadays it is for many (human) geographers and other social scientists evident that all agency, human or otherwise, is the outcome of particular interweavings or assemblages of things that formerly may have been thought of as belonging to either a natural or a social order. However, it is one thing to state that we live in a hybrid world and that subject/object distinctions should be disbanded. But everything, from the grammar of writing to common ideas of doing scientific research, still seems predicated on this distinction, making it a stubborn idea in our minds (and bodies).

To emphasize the hybrid character of our world a hyphenated vocabulary has emerged. But after more than a decade of research into social-material (or sociomaterial) nature-cultures, eventually this may be perpetuating obsolete dualisms. In practice, dualisms can become so muddled that they lose meaning as a distinction or even as a gradual difference. One could think of virtual/real as no longer helpful to describe how our lives have become embedded in information technology networks.

While hybridity is ostensibly meant to oppose thinking in terms of purity, the notion can be seen as ill-chosen, since it (historically) actually presupposes two purified organisms with homogenous characteristics. Hybrid breeding of plants and animals is predicated on creating “pure lines” of breeding stock which carry particular hereditary traits. These are then to be combined into a single hybrid animal that comes with “hybrid vigor.” Since these entities before they are combined into a hybrid are first made more pure, beyond what can be found in freely procreating and germinating animals and plants, hybridity may implicitly promote thinking in terms of pure ingredients, substances, domains, and so forth. In view of Latour’s (1993) warning against conceiving hybrids as a mixture of two pure forms, it can be argued that for furthering hybrid geographies it would eventually be better to leave the notion of hybridity behind.

Hydroclimatology and hydrometeorology

Paul Houser
George Mason University, USA

The water cycle describes the circulation of water, a vital and dynamic substance, in its liquid, solid, and vapor phases as it moves through the atmosphere, oceans, and land. Water is an integrating component of the climate-energy-geochemical cycles, regulating biological and ecological activities at all spatial and temporal scales. There is an important nexus between water and energy, this being the relationship between how much water is evaporated to generate and transmit energy, and how much energy it takes to collect, clean, move, store, and dispose of water. Life in its many forms exists because of water, and modern civilization must continuously learn how to live within the constraints and extremes imposed by water availability.

North America is among the greatest consumers of water worldwide: “Americans use water even more wastefully than oil. The U.S. relies on non-renewable groundwater for 50 percent of its daily use, and 36 states now face serious water shortages, some verging on crisis” (Barlow 2008). The High Plains aquifer and Central Valley aquifers are being depleted, there is oversubscription of surface waters based on outdated hydrographs, and a lack of reservoir, snow, and soil moisture data observation coordination and centralization prevents informed management. Looming climate change complicates North America’s water balance, but projected increases in water demand from increasing population, industrial, energy, and agricultural needs may have four times the impact on the water supply–demand imbalance that climate change does (Kummu et al. 2010).

Problems that are directly associated with water can be simply classified as too much water, too little water, and/or poor water quality. This seemingly simplistic classification is key for resolving current water-related issues and challenges. The fact is we do not even know how much water is stored in North America’s lakes, reservoirs, streams, groundwater systems, or snowpacks (Famiglietti 2012), which is fundamental knowledge needed to manage any resource.

Reliable prediction of hydrologic change and extremes is of critical importance for policy- and decision-makers to adapt to future water challenges (Schiffer and Unninayar 2011). However, our water availability, flooding, and drought models are not up to the task of addressing our most pressing societal issues of food, energy, water, and national security. State-of-the-art, comprehensive computer models are not able to seamlessly ingest satellite observations and measurements to help monitor and forecast snowpack, river flow, soil water, and groundwater levels (Famiglietti 2012).

There are important gaps in knowledge of where water is stored, where it is going, and how fast it is moving. Our skill in predicting the water cycle is woefully inadequate to reliably inform critical societal decision-making. Figure 1 shows our low precipitation forecast skill in comparison to temperature. We need a decisive and coordinated effort to systematically quantify water storages and fluxes and improve water cycle prediction skill, and reliable
methodologies to translate those predictions into enlightened water resource management.

Definitions

Meteorology is the science that deals with the state of the atmosphere with respect to wind, temperature, cloudiness, precipitation, moisture, pressure, and so on. Meteorology describes the processes involved in atmospheric phenomena, and as such provides a basis for weather forecasting. Climate is simply the averaged weather conditions over a relatively long period of time as exhibited by temperature, wind, and precipitation. It follows then that hydrometeorology and hydroclimatology are branches of meteorology and climate that specifically deal with the hydrologic cycle: the study of the occurrence, motion, and changes of state of atmospheric, terrestrial, and ocean water (Figure 2). Hydrometeorologic and hydroclimatologic studies address questions regarding land use, precipitation, river flow, groundwater, snowpack, floods, droughts, and the long-term effects of climate change on water resources.

Hydroclimatology was first defined by Langbein (1967) as the “study of the influence of climate upon the waters of the land.” The boundaries of hydrometeorology and hydroclimatology are not clear cut and overlap with many other scientific disciplines (such as climatology, oceanography, hydrology, meteorology, geology, geography, civil engineering). There is an important and practical connection between hydroclimatology and engineering design that uses relationships between meteorological variables, precipitation intensity, and duration, and the resulting runoff dynamics, as the basis for the design of flood-control and water-use structures. Determining rainfall probabilities, the statistics of storm occurrence, snowmelt dynamics, and ocean tides, surges, and rise are critical to inform and mitigate natural disasters and adapt to climate changes. Water supply, sanitation, and environmental quality are also of growing importance as populations increase and concentrate in urban centers, and agricultural/industrial activities intensify.
As a basis for this discussion of hydrometeorology and hydroclimatology, we must introduce the concept of hydrologic balance based on a series of linked mass conservation equations between the land, ocean, and atmosphere. The water balance equation for the terrestrial branch of the hydrological cycle can be written at a point as equation 1, where $S$ is terrestrial water storage term, $P$ is precipitation, $E$ is evaporation, and $R$ is runoff. $S$ can include changes in groundwater, canopy interception, soil moisture, surface water storage, and snowpack; $R$ can include both surface and subsurface horizontal water flow; $P$ can include liquid or solid precipitation, condensation, and irrigation; and $E$ can include evaporation, transpiration, and sublimation.

\[
\frac{\partial S}{\partial t} = P - E - R \tag{1}
\]

The water balance equation for the oceanic branch of the water cycle is given by equation 2, where $B$ is the ocean water mass (storage), and $F$ is the horizontal input or removal of fresh water.
HYDROCLIMATOLOGY AND HYDROMETEOROLOGY

\[
\frac{\partial B}{\partial t} = F + P - E \tag{2}
\]

The atmospheric branch of the hydrological cycle can be expressed in the form of a simple equation of vertically integrated terms, as in equation 3, where \( W \) is the water vapor content in the atmosphere, which is defined as equation 4, where \( q \) is the specific humidity, \( p \) is pressure, \( P_s \) is surface pressure, and \( g \) is constant. In equation 3, \( C \) is the vertically integrated moisture convergence flux, defined in equation 5, where \( V \) is wind speed.

\[
\frac{\partial W}{\partial t} = C + E - P \tag{3}
\]

\[
W = \frac{1}{g} \int_{0}^{P_s} q dp \tag{4}
\]

\[
C = -\nabla \cdot \left( \frac{1}{g} \int_{0}^{P_s} q V \right) \tag{5}
\]

When equations 1–5 are evaluated over a long time or large area basis, some smaller terms can be dropped through a scale analysis.

Components of the hydroclimate system

Water is an essential for life; it is a critical resource for humans and ecosystems. Due to the abundance of water, Earth as viewed from space looks like a blue marble. Despite this appearance, only a small percentage is fresh and available for ready use. This small percentage of fresh water is also unevenly distributed across the Earth, with large populations living in relatively dry places. Water withdrawals to support food and energy production are outstripping available supplies all around the globe, resulting in significant groundwater and surface storage depletions. To understand these disparities between water supply and demand, we must investigate the underlying physical processes that account for these spatial and temporal differences. A combination of both natural and anthropogenic processes collectively recognized as the hydrologic cycle provides the mechanism for the natural redistribution of water among the land, oceans, and atmosphere. The major components of the hydrological cycle are summarized below (adapted from Shuttleworth 2012).

Atmosphere

Water occurs in solid, liquid, and gas form at the range of temperatures and pressures found in the Earth’s atmosphere. Atmospheric water can be visible when it is in the form of clouds and precipitation, while water vapor is transparent and serves as a critical greenhouse gas. Water plays a crucial role in weather and climate because its phase transitions absorb or release huge amounts of energy, and the formation of clouds greatly increases the albedo of the planet. Clouds are among the most complex and difficult phenomena in the Earth’s system to predict, but they also teach us a great deal about the movement of the atmosphere. The atmospheric water cycle interacts with the land and ocean water cycles principally through evaporation and precipitation, but also can have profound impacts on surface temperatures through the presence of clouds and atmospheric circulations. The atmosphere also circulates and is responsible for the general transport of water from the oceans into the continents, and from the tropics toward the poles.

It is important to recognize that the amount of water vapor the atmosphere can hold is strongly dependent on its temperature. According to the Clausius–Clapeyron equation, the vapor pressure of water increases significantly more rapidly than the temperature of the air (approximately logarithmic). Therefore, warmer air can hold more water. The atmospheric relative humidity
is the amount of water vapor in the air, expressed as a percentage of the maximum amount that the air could hold at a given temperature. This explains a large number of things that we observe about the behavior of water in the atmosphere. The most fundamental is that when the atmosphere cools it can become oversaturated with water vapor, causing condensation, clouds, and precipitation. Another common phenomenon we observe in the winter is when we take air from outside that is cold and heat it up in our homes; this causes a large drop in relative humidity resulting in very dry indoor air conditions.

Next, it is important to understand what drives atmospheric temperature changes. Pressure in the atmosphere decreases with height according to the hydrostatic equation, which describes the weight of the overlying fluid. Therefore, when a parcel of air moves higher in the atmosphere its pressure must decrease, and according to the ideal gas law, its temperature also decreases causing it to have less ability to hold water vapor. So when a parcel of air rises over a mountain, is elevated on a column of hot air (i.e., convective thunderstorm), or when two weather fronts collide causing one to rise over the other, air temperatures can decrease causing relative humidity increases and cloud formation.

We can extend these concepts to understand the effect of climate change on the water cycle; a warmer atmosphere would hold more water, and would be expected to lead to a general intensification of water cycling. However, an intensified water cycle would have both positive feedbacks on climate (water vapor is an important greenhouse gas) and negative feedbacks through increased cloudiness. Cloud feedbacks are the greatest uncertainty in modeling the general circulation of the atmosphere.

**Figure 3** The distribution of the Earth’s water. Numbers are rounded, so percentage summations may not add to 100. Gleick (1993). Reproduced by permission of Oxford University Press, New York.

**Hydrosphere**

Here the hydrosphere is defined as the liquid water component of the Earth, including the oceans, seas, lakes, ponds, rivers, streams, and groundwater. The hydrosphere covers over 70% of the Earth’s surface and accounts for over 97% of the total volume of the Earth’s water. The vast majority of the hydrosphere is encompassed by the oceans, with only a fraction of a percent on the land (Figure 3).

The ocean plays a central role in the Earth’s water cycle, and is the principle regulator of both water mass and energy flows. The ocean is also the primary reservoir for much of the energy and carbon that drives the Earth’s climate system. The flow of mass and energy between the ocean and atmosphere expands the ocean’s impact on global weather and climate. The ocean is also impacted by the atmosphere and land through precipitation, evaporation, and runoff exchanges. The ocean is divided by the land into basins which regulate ocean currents and heat balance.
Ocean circulation is the large-scale movement of waters in and between the ocean basins. Winds and rotational forces drive surface circulation, and the cooling and sinking of higher-density water in the polar regions drives deep thermohaline circulation. Surface circulation carries the warm upper waters poleward from the tropics, which warms the atmosphere along the way. At the poles, the water is further cooled during winter, sinks to the deep ocean, and gradually rises virtually everywhere else in the ocean. The Earth’s rotation deflects ocean currents proportional to their speed, a force also at play in the atmosphere known as the Coriolis force. Ocean circulation changes can lead to variations in heat transport and weather patterns. For example, the El Niño Southern Oscillation (ENSO) is a periodic ocean circulation anomaly that has a profound impact on global weather patterns. The North Atlantic Oscillation and the Indian Ocean Dipole are other well-known ocean circulation variations. Knowledge of these oscillations helps us to better predict seasonal to interannual weather, and mitigate potential hardships.

Fundamental thermodynamics and climate models suggest that the water cycle should intensify in response to a warmer climate. A clearly anticipated result of an intensified water cycle would be increases in evaporation, which over the ocean would result in saltier ocean water surfaces. The trend for increasing evaporation has been confirmed from enhanced balance between precipitation and runoff (Milly and Dunne 2001; Walter et al. 2004), sea temperature warming (Curry, Dickson, and Yashayaev 2003), increased freshwater discharge (Syed et al. 2010), and saltier ocean surface water (Durack, Wijffels, and Matear 2012). A recent study of observed global ocean surface salinity changes shows evidence of an intensified global water cycle at a rate of $8 \pm 5\%$ per degree of surface warming (Durack, Wijffels, and Matear 2012). This rate is double the response projected by current-generation climate models and suggests that a substantial (16–24%) intensification of the global water cycle will occur in a future 2–3°C warmer world.

Lakes, rivers, and groundwater make up the balance of the hydrosphere (see Figure 3). These water bodies can have significant influence on regional weather and climate, by such processes as lake-effect snow or land-water temperature breezes.

**Cryosphere**

Water stored in solid form, in particular in the Antarctic and Greenland ice sheets, accounts for 2% of total water on Earth, and about two-thirds of fresh water. Frozen water is also stored in snowpacks, glaciers, permafrost, seasonally frozen ground, and sea ice, all known as the Earth’s cryosphere. Large populations and agricultural areas rely on melt runoff from mountain glaciers and snowfields for their water supply.

The cryosphere has a profound impact on climate because of its very high reflectance. Snow can change the albedo significantly, thereby reflecting much more radiation back into space. This is why the melting ice sheets and seasonal snow cover changes are of significant concern; the lower albedo of ice/snow-free areas captures more solar radiation and increases heating. Another profound impact of cryospheric change is sea level rise, which can amplify the impact of storm surge, tides, and coastal flooding. It should be noted that changes in sea ice do not have a sea level impact, because it already displaces ocean water.

The cryosphere generally interacts with the atmosphere through both precipitation and evaporation, and with the hydrosphere through runoff. Freezing ocean water often rejects salt,
thereby increasing ocean salinity, whereas melting ice usually results in ocean salinity decreases through additions of fresh water. Both of these salinity changes can impact ocean circulations by changing seawater density.

As temperatures rise, the possibility of precipitation falling as rain rather than snow increases, especially in fall and spring at the beginning and end of the snow season, and in areas where temperatures are near freezing. Such changes are already observed in many places, especially over land in middle and high latitudes of the Northern Hemisphere, leading to increased rains but reduced snowpacks (Mote 2003; Knowles, Dettinger, and Cayan 2006).

Lithosphere

The Earth’s lithosphere includes the crust and the uppermost mantle, which constitute the hard and rigid outer layer of the Earth. The lithosphere can interact with the water cycle in a number of ways, including water vapor release through volcanic activity, subduction through plate tectonic activity, or chemical reactions with the atmosphere, hydrosphere, and biosphere through soil-forming processes. The Earth’s crust and mantle contain a vast but unknown amount of water. This water takes two forms: “free” water in cracks and pores, and chemically bound water – hydrated minerals formed in the presence of water and that contain hydrogen and oxygen. The lithosphere also largely determines the topography of the land and ocean, thereby resulting in critical boundary conditions that govern the movement of ocean and atmosphere circulation.

Biosphere

The Earth’s biosphere is defined as the regions of the surface, atmosphere, and hydrosphere of the Earth occupied by living organisms, and what supports them, including soil, groundwater, water bodies, and the atmosphere. The biosphere generally extends from the ocean depths to about 6 km above sea level. The biosphere has a profound impact on the water cycle, because water is used, stored, and regulated by living things. Plants can take water from the soils, and animals can drink water from rivers and lakes or eat plants. Even microbes deep in the ground live in tiny films of water surrounding rocks. The water will then stay in the biosphere until released through evaporation, transpiration, excretion, decay, respiration, and combustion and the whole process begins again.

Plants in particular have a significant impact on the water cycle through transpiration. Transpiration is the process by which moisture is carried through plants from roots to small pores on the underside of leaves, called stomata, where it changes to vapor and is released to the atmosphere. Transpiration is essentially evaporation of water from plant leaves, but it can be much more efficient because the plant can access deeper storages of water via its roots. Many plants can actually access groundwater reservoirs, providing another connection between disparate parts of the water cycle. About 10% of the atmospheric moisture is a result of transpiration, which is remarkable considering that plants cover less than 30% of the Earth’s surface.

There is a common myth that states that water in the Earth’s hydrologic cycle is never created or destroyed, and that we have roughly the same amount of water as we did when the Earth was formed (plus the water supplied by intercepted comets). In reality water is being constantly destroyed and re-created, and one very common mechanism is plant photosynthesis which liberates oxygen with the photolysis of water. There are many other similar chemical reactions that
consume or re-create water from its hydrogen and oxygen components.

**Anthroposphere**

The anthroposphere is a relatively new term that refers to the part of the environment that is made or modified by humans for use in human activities and human habitats. The anthroposphere is the sphere of the Earth system where human activities constitute a significant source of change through the use and subsequent transformation of natural resources, as well as through the deposition of waste and emissions.

Humans now occupy 8% of the global land surface with dwellings and agriculture, and 75% of the Earth’s land surfaces have been altered by people in some way. Humans have made profound changes to the water cycle, from diverting entire rivers for use in agriculture, to draining wetlands, depleting aquifers, and creating large lakes and reservoirs, and human activities have even resulted in the loss of inland seas. Excessive groundwater extraction has led to significant land subsidence and regional climate changes. Deforestation, agriculture, irrigation, hydropower production, and urbanization all have profound impacts on water pathways and storage. On larger scales, the burning of fossil fuels and large-scale agriculture are leading to climate changes that are melting ice sheets and glaciers, reducing snowpack, changing precipitation patterns, increasing evaporation demands, and raising sea levels.

**Challenges**

Water is an integrating component of the meteorological and climatological water–energy–geochemical cycles, regulating biological and ecological activities at all spatial and temporal scales. It is well recognized that human demands from a growing population for food, energy, shelter, and fiber has impacted the landscape (Foley et al. 2005) and threatens biodiversity and water security (Vörösmarty et al. 2010). Anthropogenic climate change can exacerbate these impacts and threats (Karl et al. 2009).

In order to deal with climate, population, and environmental change and its uncertainty, we must extend the current basis of the science with modern observations, and models and decision tools, to provide guidance to water planners and engineers. A decisive and coordinated effort to systematically quantify water storages and fluxes, improve water cycle prediction skill, and develop reliable methodologies to translate those predictions into enlightened, informed water resource management is needed. By entraining, integrating, and coordinating the vast array of interdisciplinary observational and prediction resources available, we can significantly advance skill in assessing, predicting, and managing variability and changes in water resources to meet ever-increasing demands and climate change complexities.

Outlined here are three hydroclimatology challenges that must be addressed to meet the water cycle demands of the future. The first deals with developing a scientific basis and tools for adapting to changes in the water supply–demand balance. Adaptation refers to our ability to anticipate and adjust to changes in water supply and demand, to take advantage of opportunities, and to cope with the consequences. The second challenge is benchmarking: to use incomplete and uncertain observations to assess water storage and quality dynamics, and to characterize the information content of water cycle predictions in a way that allows for model improvement. The third challenge is to establish clear pathways to inform water managers, practitioners, and
decision-makers about newly developed tools, observations, and research results.

Challenge 1: Adaptation

It is clear that human activities are modifying the Earth’s environment – this is usually referred to as “environmental change.” Anthropogenic climate change from increased greenhouse gases in the atmosphere is one driver of this change, whose effects are directly related to changes in climate system, and in particular to those affecting water and energy cycling. These changes, and projection of future change, have been documented in the Intergovernmental Panel on Climate Change (IPCC) reports, resulting in calls to mitigate future changes by reducing the release of carbon-based greenhouse gases. It is unclear that sufficient reductions will take place to mitigate the projected changes to the water cycle, or that other drivers of change (population increases, land conversion, reservoir construction, river modifications, urbanization, irrigated agriculture, and so forth) will significantly impact the mean and variability of the water cycle. The end result is that any performance evaluation of water resource systems must adapt to a wide variety of current and projected water cycle changes.

Hydrological time series are no longer stationary due to water cycling influences from a variety of sources (Milly et al. 2008) – changes brought about due to human activities to secure clean and reliable water supplies for drinking water, irrigated agriculture, energy production, and manufacturing as well as to climate change. Engineering hydrology is concerned with developing water resource designs that alleviate the situation of too much water (floodings), too little water (drought), and coping with natural hydrologic variability (reliable water supplies) – basically, extremes. Hydrologists use long-term data on which to base water resources designs, implying that hydrologic design by its nature is “risk-based design” and needs statistical models to represent the data. Are the underlying statistical distributions stationary or nonstationary? If the latter, how are the moments changing, can they be “predicted,” and what are the implications for the reliability of current and future water structures?

Subject to current and projected environmental, population, and climate changes, there is evidence that hydrologic and water cycle time series are becoming nonstationary. This is a significant challenge to the hydrology and water resources scientific and management community, and it is important to determine the best methods to model nonstationary processes and to develop procedures for incorporating nonstationarity into hydrological and water resources designs. The development of these new methods and tools needed for water resource systems to adapt to climate and environmental change in a nonstationary world is referred to as hydrologic adaptation science. Developing this science is a major challenge for hydrology.

Actions needed to develop a scientific basis and tools to adapt to climate and environmental change include not only addressing nonstationarity, but also establishing the scientific basis of water sustainability. This will require enhanced investments in hydroclimate process science, land change science, precipitation prediction, hydrologic ensemble generation, model building and calibration, Earth system model development, advancing land–atmosphere coupled models, including human dimensions in models, and developing risk-based uncertainty metrics.

In the water resources context, adaptation also involves achieving a balance between water supply and demand and easing water quality issues, thereby making more water available for human and environmental use. Improvements
HYDROCLIMATOLOGY AND HYDROMETEOROLOGY

in water supply or availability could take many forms, as in the following examples.

- Enhancing groundwater recharge by slowing runoff, using pervious paving methods, and so on.
- Reducing evaporation through proper forest management, improved irrigation practices, reductions in open water area, canal coverings, or land-use optimization. Reduced evaporation may also improve water quality.
- Rainwater harvesting from rooftops.
- Water treatment and reuse.
- Weather modification.
- Enhanced below- and aboveground water storage.
- Water conveyance from wet to dry areas.
- Desalination and water treatment science and technology.
- Alternative energy development that does not require thermal water cooling, such as wind, solar, and air-cooling.
- High-efficiency appliances, toilets, showers, and so on.
- Drought-tolerant landscaping and agriculture.
- Water pricing and economic incentives.
- Improved water distribution system efficiency (reduced pipe leaks and canal losses).

Challenge 2: Benchmarking

Benchmarking is the process of improving performance by identifying, understanding, adapting, and implementing best practices and processes. Benchmarking involves the creation of partnerships to exchange information on processes and measurements, bridging observational and prediction gaps, and setting realistic water cycle knowledge and prediction improvement goals. Effective benchmarking is a process framework within which indicators, best practices, and effective environmental management are continuously improved.

Models provide a key resource in our understanding of weather and climate, allowing/providing predictions that are used by national sectors on seasonal to climate timescales. Numerical simulation and prediction of water, in all its phases, presents challenges at many time and space scales. Improving model capabilities relies on consistent high-quality benchmark data and methods.

While there is a great need for analyzed precipitation to close water and energy budgets, it is a difficult parameter to predict, even on short timescales. Surface evaporation is not directly observed and relies on theory and calculations. There exist many similar gaps in our observational knowledge of the water cycle over North America. Higher spatial and temporal field studies can provide much-needed independent observations of these critical parameters, thereby exposing weaknesses in the numerical approaches that can be corrected to improve predictions. The current observing network has the capacity to provide certain measures of meteorology and climate, but the current lack of availability, integration, and quality control between disparate observational networks limits their usefulness for model benchmark investigations.

Single observations, even with uncertainty values, are often not a reliable benchmark. Multiple estimates from varying approaches can provide a range and better sense of the uncertainty for a parameter. However, it is unrealistic for a single organization to accurately develop multiple approaches to measuring all the water quantities needed, given the specialized knowledge required for each. As such, a community collaborative effort would be the most reliable
approach to gain success in reducing the uncertainties of the current analyzed regional water cycles and their prediction.

Actions needed to understand hydroclimate sensitivity and benchmark prediction models and decision tools include reanalyzing hydroclimate change and documenting its uncertainty, conducting field verification across regions and hydroclimate gradients, leading field campaigns focused on regions of high prediction uncertainty, developing prediction and operational support capabilities, and establishing water and energy budget closure methods across scales.

Challenge 3: Science informing decisions

Water cycle variability and extremes affect all aspects of society and the environment. Decisions are made every day to help communities, farmers, industries, and the environment effectively minimize (mitigate) and prepare for (adapt to) changing water availability and demand. The water science community has created a strong scientific foundation for informing decision-makers who need science to understand and envision a range of potential water-sector impacts, risks, vulnerabilities, opportunities, and tradeoffs. The challenge is to emphasize the decision-maker focus to better inform decisions — a focus that will conduct fundamental, user-inspired research while delivering credible, relevant, timely, and accessible information.

Central to the success of better-informing water decisions is strengthening the dialogue and engagement between the science and decision-making communities. This collaboration and coordination at the interface of science and decision-making requires new methods and a framework for multidirectional information exchange, including the following.

• Facilitating meaningful partnerships between science and decision-making to assess decision needs, science capabilities, and requirements; identifying knowledge gaps and inspiring a use-focused research agenda; and establishing sustained dialogues including development of communities of practice, training and outreach forums, and technology transfer.

• Providing easy access to science knowledge and operational practices through integrated water information, decision tools, and operational status; and developing simulators, libraries, and forums to make research available to the larger community.

• Guiding and coordinating water science efforts to ensure they are relevant to informing water management decisions; benchmarking uncertainties of the observational record, model predictions, and operational needs; developing new methods to transfer climate predictions into decision space (downscaling, application sector modeling); developing operational observation capacity to validate and improve operational products; and identifying and transitioning research products into operational applications.

In developing a strategy for informed decisions, it is recognized that scientific knowledge is only one part of a much broader decision process. For instance, information may be scientifically relevant without being decision relevant. Therefore, we must define a framework for informing decisions that connects to the broader decision process. We must develop processes that enable better “science-based” information that moves water management decision processes forward while also developing and transitioning science solutions. The desired framework will include approaches to assess the value of proposed decision support information, provide support for
understanding risk management options, and communicate uncertainties associated with data and projections. It is envisioned that science can inform decision-making, along with other critical information, in an adaptive management framework.

Water on Earth

The Earth system is unique in that water exists in all three phases, that is, water vapor, liquid water, and solid ice, compared to the situations on other planets. All organisms on the Earth, including humans, require water for their survival. The total volume of water on the Earth does not change on shorter than geological timescales (Oki 1999); it is estimated as approximately $1.4 \times 10^{18} \text{ m}^3$, which corresponds to a mass of $1.4 \times 10^{21} \text{ kg}$ (Figure 1).

The proportion of water in the ocean is large (96.5%). The global hydrologic cycle cannot be considered without including oceanic circulation. The ocean circulations carry large amounts of energy and water. The surface currents of oceans are driven by surface wind stress. The atmosphere itself is sensitive to the surface temperature of the sea. Temperature and salinity determine the density of ocean water, and both factors contribute to the turnover and general deep ocean circulation.

Other major reserves are the solid waters on land masses (glaciers and permanent snow cover) and groundwater. Glaciers are the accumulation of ice originating in the atmosphere, and they generally move slowly on land over a long period. Glaciers form discriminative U-shaped valleys over land and leave moraine deposits when they retreat. If a glacier “flows” into an ocean, its terminated end often forms an iceberg. Glaciers react over a comparatively longer timescale climatic change, and they also induce isostatic responses of continental-scale upheavals or subsidence over even longer timescales. Even though it is predicted that the thermal expansion of oceanic water will dominate the anticipated sea level rise due to global warming, glaciers over land are also a major concern as a cause of sea level rise associated with global warming.

Groundwater is the subsurface water occupying the saturated zone. It contributes to runoff in the low-flow regime between storm events, that is, during dry spells. Deep groundwater may also reflect the long-term climatological situation. The groundwater quantity shown in Figure 1 includes both gravitational and capillary water, but groundwater in the Antarctica (roughly estimated as $2 \times 10^6 \text{ km}^3$) is excluded. Gravitational water is the water in the unsaturated zone (vadose zone) that moves under the influence of gravity. Capillary water is water found in the soil above the water table by capillary diffusion, a phenomenon associated with the surface tension of water in soils acting as porous media. In terms of groundwater recharge, Döll and Fiedler (2008) estimated the global recharge flux to be $12,666 \text{ km}^3 \text{ year}^{-1}$ and approximately $1000 \text{ mm year}^{-1}$ in the Amazon region. They assumed the recharge flux is a fraction of total runoff. Koirala (2010) estimated groundwater recharge flux by coupling a land surface scheme with a macroscale groundwater representation. The global distribution of model-simulated groundwater recharge is illustrated in Figure 2a. Total groundwater recharge flux is estimated as $31,789 \text{ km}^3 \text{ year}^{-1}$ and the value is close to
The terrestrial water balance does not include Antarctica.

Figure 1 Global hydrological fluxes (1000 km³ year⁻¹) and storages (1000 km³) with natural and anthropogenic cycles are synthesized from various sources. Vertical arrows show annual precipitation and evapotranspiration over ocean and land with major landscapes (1000 km³ year⁻¹). Parentheses indicate the area (million km²). Modified from Oki and Kanae (2006).

the flux of subsurface runoff in Figure 1 (30,200 km³ year⁻¹).

Soil moisture is the water being held above the groundwater table. It influences the energy balance at the land surface in the way that a lack of available moisture suppresses evapotranspiration (which consists of soil evaporation, plant transpiration, and interception loss), and changes surface albedo. Soil moisture also alters the fraction of precipitation partitioned into direct runoff and infiltration. The precipitation water becoming direct runoff cannot be evaporated from the same place, while the water infiltrating into soil may be taken up by hydraulic suction and evaporated back into the atmosphere. The global distribution of model-estimated mean soil wetness index is shown in Figure 2b. Generally, the distribution is correlated with precipitation distribution (Figure 2c) as well as with runoff distribution (Figure 2d), but the global distribution of river discharge (Figure 2e) accumulates the total runoff generated in upper watersheds, and the shape of river channels can be seen in the distribution.

The atmosphere carries water vapor, which influences the heat budget via latent heat exchange processes. Condensation of water vapor releases latent heat, which warms the atmosphere and affects the general atmospheric
circulation. Liquid water in the atmosphere, such as cloud droplets and raindrops, is another result of condensation. Clouds significantly change the radiation in the atmosphere and at the Earth’s surface. However, the volume of liquid (and solid) water contained in the atmosphere is relatively small: most of the water in the atmosphere exists as water vapor. Water vapor is also the major absorber of both shortwave and longwave radiation in the atmosphere. Precipitable water is the total water vapor in the atmospheric column from the land surface to the top of the atmosphere.

The amount of water stored in rivers is rather tiny compared to other reserves at any time. However, the recycling speed of river water (river discharge), which can be estimated as the inverse of the mean residence time, is relatively high, which is important because most societal applications ultimately depend on river water as a renewable and sustainable resource.

The amount of water stored transiently in a soil layer, in the atmosphere, and in the river channels is relatively minute, and the time spent moving through these subsystems is relatively short. However, they play a dominant role in the global hydrological cycle.

The water cycle plays many important roles in the climate system. The various flow paths of water in the global hydrologic system are
HYDROLOGIC CYCLE

illustrated schematically in Figure 1 (Oki and Kanae 2006).

Fluxes

Precipitation is the water flux from atmosphere to land or ocean surface. It drives the hydrological cycle over the land surface; it also changes surface salinity (and temperature) over the ocean and affects its thermohaline circulation. Rainfall refers to the liquid phase of precipitation. Part of it is intercepted by the canopy over the vegetated area; the remaining part reaches the Earth surface as throughfall. The highly variable, intermittent, and concentrated behavior of precipitation in the time and space domain compared to other major hydrological fluxes mentioned below makes the observation of this quantity and the aggregation of the process complex and difficult. Global distribution of precipitation is presented in Figure 2c. Currently, satellite-based estimates merged with in situ observational data have been produced and are available to the public.

Snow has special characteristics compared to rainfall. When snow accumulates, the surface temperature will not rise above 0°C until the completion of snow melt. The albedo of new snow can be as high as cloud albedo and, being aged (dithered by dust), varies between 0.6 and 0.9. Consequently, the existence of snow changes the surface energy and water budget enormously. A snow surface typically reduces the aerodynamic roughness, so that it may also have a dynamical effect on the atmospheric circulation and hydrologic cycle.

Evaporation is the return flow of water from the surface to the atmosphere and the latent heat flux from the surface. The amount of evaporation is determined by both atmospheric and hydrological conditions. From an atmospheric point of view, the partition of incoming solar energy to the surface between latent and sensible heat flux is important. Wetness at the surface influences this partition significantly because the ratio of actual evapotranspiration to the potential evaporation is reduced due to drying stress. The stress is sometimes formulated as a resistance, under which evaporation is classified as hydrology-driven (soil-controlled). If the land surface is wet enough compared to the available energy for evaporation, the condition is classified as radiation-driven (atmosphere-controlled).

Transpiration is the evaporation of water through the stomata of leaves. It has two special characteristics different from evaporation from soil surfaces. One is that the resistance of stomata is related not only to the dryness of the soil but also to the physiological conditions of vegetation through the opening and closing of stomata. Another is that roots can transfer water from deeper soil layers than is the case of evaporation from bare soil. Vegetation also modifies the surface energy and water balance by altering surface albedo and by intercepting some precipitation and evaporating this rainwater. The global distribution of total evapotranspiration is shown in Figure 2f, estimated by a land surface model.

Runoff returns water from the land to the ocean; it may otherwise be transported in vapor phase by evaporation and atmospheric advection. The runoff into the ocean is also important for the freshwater balance and the salinity of the ocean. Rivers carry not only water mass but also sediment, chemicals, and various nutrient matter from continents to seas. Without rivers, global hydrologic cycles on the Earth are not closed. Runoff at a hillslope scale is a nonlinear and complex process. Surface runoff can be generated when the intensity of rainfall or snow melt exceeds the infiltration rate into the soil, or when precipitation falls on a saturated land surface. Saturation at the land surface can be
formed mostly by a topographic concentration mechanism along the hillslopes. Infiltrated water in the upper part of the hillslope flows down the slope and discharges at the bottom of the hillslope. Because of the highly variable heterogeneity of topography, soil properties (such as hydraulic conductivity and porosity), and precipitation, basic equations such as Richards’s equation, which can be fairly valid at a point scale or hillslope scale, cannot be directly applied on the macroscale because of the nonlinearity involved. The global distributions of runoff and river discharge are illustrated in Figure 2d and Figure 2e, respectively.

**Water balance**

In the field of hydrology, river basins have commonly been selected for study, and water balance has been estimated using ground observations, such as precipitation, runoff, and storage in lakes and/or groundwater. The water balance over the land is described as:

$$\frac{\partial S}{\partial t} = P - E - R_0 - R_u$$  \hspace{1cm} (1)

where $S$ represents the water storage within the area, $t$ is time, $(\partial S/\partial t)$ is the change of total water storage with time, $P$ is precipitation, $E$ is evapotranspiration, $R_0$ is surface runoff, and $R_u$ is groundwater movement (all fluxes above are given in the unit volume per time step). $S$ includes snow accumulation in addition to soil moisture, groundwater, and surface water storage, including retention water within the control volume. The control volume is defined by the area of interest over the land, with its base generally at the impermeable bedrock. These terms are shown in Figure 3a (Oki 1999). Equation 1 means water storage over land is increased by precipitation and decreased by evapotranspiration, surface runoff, and groundwater movement.

If the considered area of water balance is set within an arbitrary boundary, $R_0$ represents the net outflow of water from this area (i.e., the total outflow minus total inflow from surrounding areas). Although, in general, it is not easy to estimate groundwater movement $R_u$, the net flux per unit area within a large area is expected to be comparatively small. If all groundwater movement is considered to be that

![Figure 3](image-url)

HYDROLOGIC CYCLE

observed at the gauging point of a river \((R_u = 0)\), then equation 1 becomes:

\[
\frac{\partial S}{\partial t} = P - E - R_o \quad (2)
\]

This assumption is generally valid at the outlet of a catchment. In most cases, surface runoff \(R_o\) becomes river discharge through the river channel network. River discharge is an integrated quantity over the whole catchment and can be observed at a downstream point, in contrast to other fluxes, such as \(P\) and \(E\), which have to be spatially measured.

Atmospheric water vapor flux convergence contains water balance information that can complement the traditional hydrological elements such as precipitation, evapotranspiration, and discharge. The basic concepts, as well as the application of atmospheric data to estimate terrestrial water balance, were first presented by Starr and Peixoto (1958). The atmospheric water balance for a column of atmosphere from the bottom at the land surface to the top of the atmosphere is described by the equation:

\[
\frac{\partial W}{\partial t} = Q + (E - P) \quad (3)
\]

where \(W\) represents the precipitable water (i.e., the column storage of water vapor), \(Q\) is the convergence of water vapor flux in the atmosphere (all fluxes given in the unit volume per time-step). Since the atmospheric water content in both solid and liquid phases is generally small, only the water vapor is considered in equation 3. The balance is schematically illustrated in Figure 3b, which indicates that water storage in an atmospheric column is increased by the lateral convergence of water vapor and evapotranspiration through the bottom of the column (i.e., land surface) and decreases by the precipitation falling out from the bottom of the atmosphere column to the land.

Since there are common terms in equation 2 and equation 3, they can be combined:

\[
-Q + \frac{\partial W}{\partial t} + Q = (P - E) = \frac{\partial S}{\partial t} + R_o \quad (4)
\]

Figure 3c illustrates the balance in this equation, and that the difference between precipitation and evapotranspiration is equal to the sum of the decrease in atmospheric water vapor storage and lateral (horizontal) convergence, and also to the sum of the increase in water storage over the land and runoff. Theoretically, equation 4 can be applied for any control volume of land area combined with the atmosphere above, even though the practical applicability depends on the accuracy and availability of atmospheric and hydrologic information.

Further assumptions are often employed in annual water balance computations: the annual change of atmospheric water vapor storage is negligible \((\partial W/\partial t) = 0)\) and the annual change of water storage of the land is negligible \((\partial S/\partial t) = 0)\). With these assumptions, equation 4 simplifies to:

\[
Q = (P - E) = R_o \quad (5)
\]

If a river basin is considered as the water balance region, \(R_o\) is simply the discharge from the basin. The simplified equation 5 demands that the water vapor convergence, “precipitation minus evaporation,” and net runoff should balance over the annual period when the temporal change of all storage terms can be neglected.

Generally, it is not an easy task to obtain large-scale evapotranspiration \(E\) based on observations except for the annual timescale, where \(E\) can be estimated as the residual of \(P\) and \(R_o\). However, the combined water balance can help estimate \(E\) at a shorter timescale, for example, monthly. Note that equation 3 can be rewritten as:
which can be applicable over a period shorter than a year, unlike the assumption in equation 5. If atmospheric and precipitation data are available over a short timescale, such as a month or a day, evapotranspiration can be estimated at the corresponding timescales, but it is also subject to severe limitations imposed by the data accuracy. The region over which evapotranspiration is estimated is not limited to a river basin; rather it depends on the scale and the associated accuracy of the available atmospheric and precipitation data.

Total terrestrial water storage (TWS), as the sum of surface water (such as river water, snow water, and water in lakes), soil moisture, and groundwater, is generally difficult to estimate on the global scale. Combining equation 2 and equation 3 yields:

$$\frac{\partial S}{\partial t} = -\frac{\partial W}{\partial t} + Q - Ro$$  \hspace{1cm} (7)$$

which indicates that the change in water storage in the control volume over the land can, in principle, be estimated from the atmospheric and runoff data. Although an initial value is required to obtain the absolute value of storage, the atmospheric water balance can be useful in estimating the seasonal change in total water storage in large river basins.

The values quoted in Figure 1 were estimated based on various observations, with some assumptions in order to obtain global perspectives. These values are sometimes different in other references, probably because the source of observed data, methodology to estimate, and assumptions are different. In some cases, global water balances are estimated using the empirical relationship of evapotranspiration to precipitation in each latitude belt (Baumgartner and Reichel 1975).

Global distribution of hydrological quantities

A 35-year (1979–2013) land surface simulation (Kim and Oki 2014) was conducted to estimate global water and energy balances as a pilot study of an international research project. The physical quantities in this entry are mainly based on this simulation, and the project is the third phase of the global soil wetness project (GSPF). The original goal in the precedent phase (Dirmeyer et al. 2006) was to estimate global distribution of surface soil moisture, which is not easy to observe globally but is relevant for an understanding of the land–atmosphere interactions using multimodel ensemble simulations. In the third phase, a comprehensive global dataset of land surface fluxes, state variables, and related hydrologic quantities will be produced. It will extend the original science investigating long-term (1850–2100) interactions between energy, water, and carbon cycles over 0.5° terrestrial grids, excluding Antarctica. Three-hourly meteorological forcing data will be prepared as a hybrid product of a dynamically downscaled atmospheric reanalysis product and various observational data, based on in situ and satellite monitoring, to achieve further realistic representation with reduced bias in higher spatiotemporal resolution.

The advantage of using models to estimate global water balance is the capability to have more detailed insights than using observations. For example, snow over the land, excluding ice and glacier areas, is approximately 10% of total precipitation, and the ratio of surface runoff and subsurface runoff is approximately 1:2 in Figure 1. Even though, at present, it is difficult to assess the validity of these breakdowns due to the lack of global observations on the partitions between snow and rain or between surface and subsurface runoff, such model-based
HYDROLOGIC CYCLE

estimates will stimulate scientific interest to collect and compile global information on these important hydrological quantities in the future.

Kim et al. (2009) underscored the importance of the river component in TWS variation over global river basins. To reduce simulation uncertainty, ensemble simulations were performed with multiple precipitation data and a localized Bayesian model averaging technique was applied to the global river runoff simulation using a river routine model named TRIP (total runoff integrating pathways) (Oki and Sud 1998).

It was found that river storage not only explains different portions of total TWS variations, but also plays different roles in different climatic regions. It is the most dominant water storage component in wet basins (e.g., the Amazon) in terms of amplitude, and it acts as a “buffer” that smooths the seasonal variation of total TWS especially in snow-dominated basins (e.g., the Amur). It signifies that model simulation of TWS may not be able to properly reproduce the amplitude and seasonal pattern of observed TWS variation by GRACE (the gravity recovery and climate experiment) (Tapley et al. 2004) without an appropriate representation of the river storage component. The dominant role of river storage was already indicated in a pilot study that compared total TWS changes estimated by the atmospheric water balance method and a general circulation model (GCM) simulation coupled with TRIP in the Amazon River basin (Oki, Kanae, and, Musiake 1996). However, the message was not convincing until several years ago when satellite-observed GRACE data became available. Using a geodesy approach, Han et al. (2009) employed a fixed velocity version of TRIP in the Amazon River basin and its vicinity, and compared the model simulations to the residual of GRACE raw measurements derived from removing all the gravity-influencing factors except for the horizontally moving water. They demonstrated that the optimal flow velocity of TRIP in the Amazon varies between rising and falling water levels.

Water and climate

Based on observed precipitation (Xie and Arkin 1996) and river discharge records archived at the Global Runoff Data Centre, annual water balance for most river basins worldwide was estimated (Oki, Nishimura, and Dirmeyer 1999); this is presented in Figure 4. The ordinate in this figure is the residual of long-term mean annual precipitation and runoff; this annual loss should correspond to long-term mean annual evapotranspiration. Different symbols are used for plotting: red stars indicate the water balance of the river basins where gauging stations are located between 20°S and 20°N. The plus symbols indicate river basins where gauging stations are located between 20° and 40° in both hemispheres, and the blue circles are 40° or higher. Lines connect the mean precipitation and annual loss for each 5° latitudinal belt. As seen, even though the scatter is large, approximately 70% of precipitation undergoes evapotranspiration in high-latitude river basins. On the other hand, mean evapotranspiration in tropical river basins is approximately 1000 mm year−1 with less dependency on annual precipitation. Such analyses on the relationship between P and E have long been used for estimations of global water balance, for example, in Baumgartner and Reichel (1975). It is also clear from Figure 4 that river basins with an annual precipitation of less than 800 mm year−1 have a marginal amount of river runoff, as most precipitation is used for evapotranspiration. In these river basins, evapotranspiration
is mainly controlled by the availability of water (water-controlled); this is in contrast to tropical river basins with precipitation higher than 1000 mm year\(^{-1}\), where annual evapotranspiration is limited by the available energy (energy- or radiation-controlled).

Budyko (1974) proposed an equation:

\[
\frac{E}{P} = \left[ \zeta \left( \tanh \frac{1}{\zeta} \right) \left( 1 - \cosh \zeta + \sinh \zeta \right) \right]^{1/2}
\]

where \( E \) and \( P \) are annual evapotranspiration and precipitation, respectively, and Budyko’s dryness index \( \zeta \) is defined as:

\[
\zeta = \frac{Rn}{lP}
\]

where \( Rn \) and \( l \) are net radiation and the coefficient of latent heat, respectively. This equation is derived by considering that \( E/P \) should be asymptotic to 1.0 for dry regions (large \( \zeta \)) as \( E \) should be less than \( P \), and \( E/P \) should be asymptotic to \( Rn/IP \) for wet regions (small \( \zeta \)) as \( E \) should be less than \( Rn/IP \).
Budyko’s equation 8 is conceptual but can provide a realistic water balance, as shown in the inset in Figure 5a. Mean water balance averaged for each $0.2\zeta$ ($= Rn/IP$) bin estimated by a land surface model corresponds fairly well with the curve according to Budyko’s equation 8, even though large scatters are found in the plots of each $1^\circ$ longitudinal and latitudinal grid box. Yang et al. (2009) analyzed annual water balance in 99 river basins in China and concluded that this scatter can, at least partially, be explained by the vegetation cover in the river basin.

Annual water balances estimated by the pilot phase of GSWP3 were analyzed and each $1^\circ \times 1^\circ$ grid box was classified into one of six
The six classified regions are illustrated in Figure 5a along with the ice-covered region. The differentiation is difficult between the tropical humid region and the very humid region using only Budyko’s dryness index ζ. Therefore, annual precipitation is considered in the classification. It is interesting to see ζ is similar in both tropical and high-latitude regions in addition to the Asian monsoon region. Perhaps it is necessary to also consider the seasonal change of major water balance terms for better differentiation of these regions.

Long-term mean water balance for each climatic region classified by ζ is presented in Figure 5b. Separation of mean annual precipitation into evapotranspiration, surface runoff, and subsurface runoff is also illustrated. The sum of these corresponds to annual precipitation and the ratio of annual evapotranspiration to precipitation is close to the mean ζ of each region. Slightly negative evapotranspiration in the ice region indicates net sublimation in the region, that is, the land surface obtains energy from the atmosphere through sublimation.

Further, evapotranspiration can be divided into four components: bare soil evaporation (Es), evaporation from intercepted water on leaves (Ei), evaporation from open water (Eiw), and transpiration from vegetation (Et); these are illustrated in Figure 5c averaged over classified climatic regions. Transpiration and evaporation from intercepted water are proportional to the vegetation biomass in each region, and it is interesting to note that the magnitude of bare soil evaporation is more uniform globally than other components, except for arid, very humid, and ice regions.

Even though the values in Figure 5c are not definitive, it is interesting to see that bare soil evaporation and transpiration from vegetation compare closely, and interception loss is approximately 10% of the total evapotranspiration. It would be interesting if these estimates could be revised and validated by observation-based measures.

Hydrologic flow models

Douglas A. Howard
Georgetown University, USA

Hydrologic flow models are conceptual or mathematical representations or simulations of real-world physical hydrologic systems. Although this definition includes all of the hydrologic cycle, we will focus on the hydrologic flow of fluid on or beneath the surface of a planetary body. In general terms, a flow model is an accurate simulation of a process that cannot be directly observed, which applies to both surface water and subsurface, aquifer, flow regimes. Hydrologic flow models are used to understand why a flow system behaves in the observed way and to predict or forecast how it will behave in the future. They are also used to model hypothetical flow conditions. Typical hydrologic problems that models address are surface water flow (flood routing), groundwater flow (well-pumping and developing intersecting cones of depression), and solute transport (tracing chemical paths and their attenuation along pathways).

Types of hydrologic flow models

There are four basic types of hydrologic flow models, conceptual, physical, analog, and numerical, that can be used together or individually depending on a modeling approach.

Conceptual hydrologic flow models are broad general constructs of a hydrologic flow system. They are typically used for initial planning stages of more sophisticated hydrologic flow models. Conceptual models tend to be static and describe a specific condition at the highest level and do not fully describe the real-world hydrologic system.

Physical hydrologic flow models are commonly tangible large-scale representations of real-world hydrologic systems used to understand an engineering structure or natural formation utilizing simple hydrologic conditions. They are useful for understanding a specific hydrologic condition; however, they tend to be costly and inflexible in design. Henry Darcy created a physical sand-column model where he used dye-tracers to show flow paths and contaminant or pollutant distribution and subsequently established Darcy’s Law, the basis for modern groundwater analysis (Darcy 1856).

Analog models use the properties of one phenomenon to model another. One hydrologic example is the use of Ohm’s law governing the flow of electricity to model Darcy’s law of groundwater flow. It was found that the flow of electricity through circuits mimics the flow of water through a pipe. Although this particular example is useful, the disadvantage of analog models is that they tend to be very specific to hydrologic conditions and constraints, and are inflexible to adaptation for general hydrologic flow application.

Numerical or mathematical hydrologic flow models are now the preferred approach to hydrologic modeling due to their flexibility and wide range of applications. They are the basis for modern hydrologic modeling software programs. They are dynamic models that can be manipulated as needed to make predictions of future flow behavior. Numerical hydrologic flow models are generally sequences of equations that convert numerical inputs representing
HYDROLOGIC FLOW MODELS

Hydrologic parameters to numerical outputs such as flow velocity and discharge. These models are used when working with distributed parameters that vary across the modeled area, such as transmissivity and storativity, or when there are complex or moving boundary conditions. Numerical models recast partial differential equations that represent the flow conditions into an algebraic (matrix) form that is easily solved by digital computers. These numerical representations approximate the natural conditions to be modeled; as a result the output is also a close approximation of real-world conditions.

The most common numerical methods used in hydrologic modeling are finite difference and finite element techniques. These gridding techniques allow the modeled study area to be subdivided into smaller units where numerical analysis is accomplished more accurately.

The finite difference technique is the most commonly used for problems involving distributed parameters where algebraic difference approximations replace partial differential equations to compute, by discretization, approximate parameter solutions. These solutions represent the parameters at each cell node. Using the finite difference technique, parameters are not represented continuously across grid units but are represented at a node associated with each polygonal cell. Each cell has a node which is the location (reference point) of input or output parameters and can be either block-centered or mesh-centered. Block centered nodes are located at the center of the polygon while mesh-centered nodes are located at the corners of each polygon. Polygons can be either rectangular grids for two-dimensional (2D) models or prisms for three-dimensional (3D) models. The selection of the appropriate grid depends upon the boundary conditions of the modeled area.

The finite element technique uses a numerical approach to solve differential equations through integrals and, most commonly, the Galerkin interpolation method. This interpolation technique enables computation of output parameters that are obtained at any point within the problem area and not only at cell nodes as with the finite difference technique. The grid subdivisions are “elements” in the shape of triangles for 2D models and tetrahedrons for 3D models. The finite element technique is more accurate than finite difference for problems that have a moving boundary condition such as a transient water table.

Simplified forms of numerical models are known as analytical models. Analytical models are very often “back-of-the-envelope” first approximations of unknown parameters, typically in one dimension. Darcy’s law is based on an analytical flow model where the initial and boundary conditions are known.

With the use of desktop computers, hydrologists now have the ability to use or develop computer numerical hydrologic models to simulate more complex hydrologic systems than physical or analog models. These computer models are more flexible, dynamic, and reusable, and can mimic the field conditions more accurately, especially with the use of digital terrain models and geographic information systems (GIS).

Components of a hydrologic flow model

There are generally four key components of a hydrologic flow model process for developing reliable output parameters. The first is conceptualization of the problem. Although it is difficult to simulate the entire system accurately, this step sets up the problem to be modeled. The next step is to select or develop an appropriate model. As discussed, the numerical model has become the modeling method of choice; however, physical modeling is still used for understanding engineering structures. The third step is to
calibrate the model where iterative adjustments to the model parameters enable best-fit estimates to real-world parameters. Finally, the model is validated by historical matching of the model output to a long record of observed data.

The general approach to hydrologic modeling begins with building a conceptual model, followed by selecting a mathematical equation, or series of equations, that approximates the physical behavior of the hydrologic system. It is important that the hydrologic system, and how it pertains to the problem, is well understood. Additionally, selecting the appropriate equation relies on an appropriate set of simplifying assumptions – what does the equation require and assume to be true. For example, stable boundary conditions should be well defined for a finite difference numerical method; otherwise the finite element technique may be used. Simplifying assumptions can be tested to understand the tradeoffs for a less-than-optimal solution.

Model calibration is as important as any other modeling component and is accomplished by comparing computer model-generated predictions with measured known variables or parameters. The calibration processes is iterative, by trial and error, adjusting the model until it agrees with the real-world data within an acceptable margin of error or tolerance. For example, a groundwater model may compare its output to the known groundwater table or potentiometric surface condition. Another component of calibration is sensitivity analysis to determine the uncertainty of the output model parameters against known field values of the most sensitive parameters. The model is tested to determine which terms or parameters are most sensitive. For example, open channel flow may be very sensitive to Manning’s $n$, surface roughness coefficient. Therefore, this parameter may be adjusted within a range of roughness coefficients to test the uncertainty of the output of the model. Knowing the sensitivity of each parameter within the flow model enables a better understanding of the model outcome.

Model verification following calibration uses historical matching where the model output is compared to a long record of observations, which is typical of surface water flood predictions. The model may be considered validated if it consistently reproduces historical known output. If the model does not achieve the desired accuracy, model parameters may be changed to recalibrate the model.

An additional component of the modeling process to be aware of is the large amount of data required by the model (input) and the output of the model. Selection of the appropriate data to support and solve the problem is important. It is equally important to collect and compile the data into a database that the hydrologic model can readily use. As we have seen, each numerical flow model grid consists of a node where data are collected, computed, or interpolated. Each node may have many parameters assigned to it, such as flow velocity, discharge, transmissivity, storativity, or dispersion coefficients. Additional input data may consist of project-specific data (locational, temporal, or design characteristics) and existing data from external sources.

**Uses of hydrologic flow models**

Hydrologists use hydrologic flow models to better understand how changes in land use and climate will impact groundwater and surface water quantity and quality on a local to regional scale. Hydrologic flow models are also used to assist water-resource management and design approaches, for prediction and forecasting, and as tools to understand scientific questions. A thorough understanding of the physics of hydrologic processes allows the practitioner the foundation to develop and apply these hydrologic models.
HYDROLOGIC FLOW MODELS

There are many computer models for hydrologic modeling on the market today, many of which use existing computer programming code or application programming interfaces (API) due to well-validated and stable code, better quality control, and lower costs. Likewise, many hydrologists use published, well-established models because they have been validated and widely used and accepted as a standard, especially if used for regulatory processes or litigation. The most widely accepted and used hydrologic flow model is MODFLOW (McDonald and Harbaugh model; US Geological Survey 2013) and has been adopted by numerous commercial software packages.

With the wide use and accessibility of GIS, both hydrologic and hydrogeologic flow-modeling tools are included in or available as add-on modules to the software. The ease of use of GIS and its ability to visualize model output in 2D and 3D representations provides hydrologists a valuable tool for hydrologic flow modeling and presentation of results.

The abundance of hydrologic flow models and software from commercial vendors or freely available in the public domain makes the selection of the appropriate model difficult. The following are considerations when selecting a hydrologic flow model or software. First, does the model have the ability to solve the problem? What are the computer hardware requirements to run the software, data storage, and output? Is the user interface user-friendly based on the user’s abilities to input and visualize the data? Historically, many hydrologic models were based on command-line data entry requiring well-formatted databases or text files. In the modern age of computing, many, but not all, of these command-line models have been converted to user-friendly graphical user interfaces (GUI), increasing the usability to accommodate a larger audience. Another consideration is the acceptance of the model by the industry or institution in which it is to be used. Hydrologic models came into use mostly due to regulatory action, where a standard on which to measure hydrologic processes was needed. Subsequently, certain models have been accepted as standards by the industry. For example, standards for groundwater modeling were established by the American Society for Testing and Materials (ASTM). Finally, the availability and cost of the software can be a limiting factor for some users of hydrologic flow models. On the one hand, there are many highly robust hydrologic flow models free to the public, but they tend to be less user-friendly. On the other hand, there are many very user-friendly proprietary software products that are available at considerable cost. Two resources that provide access to hydrologic models and software are the Integrated GroundWater Modeling Center (IGWMC) clearinghouse for groundwater modeling software and the US Geological Survey.

Further reading

Hydrology is a relatively new science and a truly ancient one (Biswas 1970). It is fascinating to consider that the word hydrology, which refers to the study of water flows from precipitation to infiltration, groundwater, evapotranspiration, and runoff, only developed in the eighteenth century (Perrault and Perrault 1721). Even then it was regarded by some as the “wisdom of God,” as well as an empirical science (Tuan 1968). The scope of hydrologic science has been shaped by a combination of direct observation, remote sensing, practical action, and cultural beliefs. It is interesting to try to push the origins of hydrologic science back to include relationships between hydroclimatic phenomena and prehistoric human settlement (e.g., Magill, Ashley, and Freeman 2013). One may even wonder whether other species evolved sophisticated water finding, navigation, and regulatory capacities as hydrologic agents (Finlayson 2014). In each of these respects, the history of hydrology has far greater historical depth than is commonly perceived.

The benchmark study on this topic is Asit Biswas’s (1970) History of Hydrology which drew together a rich array of sources to survey the field. His volume begins with ancient archaeological and historical innovations from antiquity to 600 BCE and then proceeds to the classical world of Greece, Rome, and the Hellenistic empire. After an understandably short chapter on the medieval period (though see Magnusson 2001), the greater part of the volume moves chronologically from sixteenth-to nineteenth-century Europe. It offers brief descriptions of inventors, inventions, experiments, and scientific formulas.

Notwithstanding the fascinating contents of Biswas’s volume in 1970, a search of the literature indicates that it did not presage much advanced historical research, which remains limited in quantity, fragmented across subdisciplines, and muddied by terminology that sometimes conflates time series analysis with historical research. Recent assessments of hydrology rarely treat historical research as a source of insight for the field. For example, a 2012 US National Research Council report on Challenges and Opportunities in the Hydrologic Sciences discusses water processes over time, but it does not mention how historical scholarship can help interpret or explain them. Even so, the glass is also half full, as this entry hopes to show.

We may begin with a brief perspective on how the hydrologic sciences are currently envisioned. The United Nations International Hydrological Decade (1965–1975) and UNESCO International Hydrologic Programmes (1975–present) have included essays on the history of their programs and the topics they covered (see Linton 2010, 166–172). A key source for contemporary hydrologic thought is the International Association of the Hydrological Sciences (IAHS), established in 1922, which has nine commissions, four working groups, and a decadal vision statement (Table 1) (Montanari et al. 2013).

These topical groups indicate the diversity of the hydrological sciences and their association with water resources engineering (for a critical view see Klemes 1986). As Biswas noted in 1971, hydrology remains broadly distinct from
This approach is complicated by two factors. First, the sources cited still encompass a wide range of historiographies (i.e., modes of historical writing). The language of archaeological research differs from research based on archival documents, instrumental records, biographical archives, and ethnohistorical accounts. These historiographical approaches have developed more in parallel than in dialogue with one another (e.g., in Landa and Ince 1987; Patton 1987; and Rodda and Ubertini 2004). Second and more problematic is that much of the literature consists of perspectives by hydrologists who do not have training in historical theory or methods. While valuable in terms of firsthand knowledge, they rarely employ conceptual approaches that shed light on the social context of how and why the field developed in some directions rather than others, or what impact those trends have had on society and environment as well as science. Some social scientists interpret this neglect of history as part of a broader depoliticizing strategy in modern science and technology (e.g., Linton 2010; Schmidt 2014).

Before taking up these debates, it is useful to reflect upon how the field has developed since Biswas’s pioneering work. The History of Hydrology remains a valuable reference work, particularly for European hydrology in the sixteenth through nineteenth centuries. It strives for a global perspective through vignettes on ancient hydrologic sites, instruments, and records up to the sixth century BCE. Subsequent chapters are descriptive and largely chronological. Because these historical advances are not widely known among water scholars, the book has continuing value as a survey of innovations and inventors through the nineteenth century.

After the passage of over forty years, it is timely to revisit the history of hydrologic research, extend the account through the twentieth century, and consider the growing role of

national and international hydrologic research institutions such as the International Hydrological Programme. Proceedings of the American Geophysical Union also include historical topics (e.g., debates in paleoflood research by Landa and Ince 1987; Patton 1987; and others). A small but significant literature follows in Biswas’s footsteps with short essays that offer historical perspectives on the field at large, with increasing emphasis on the twentieth century (e.g., Back 1988; Dooge 2004; Nace 1974, 1975; Reilly 2004; Rodda 2006).

Ancient civilizations and their hydrologies – Mesopotamia, Indus, Rome, China, and beyond

One of the strengths of Biswas’s volume was its inclusion of water development in early civilizations. Over the past four decades several lines of water heritage have received detailed archaeological and historical attention. For example, Biswas’s brief discussion of Joseph Needham’s magisterial Science and Civilization in China invites consideration of the wealth of additional material in that source, as well as in subsequent research. In Egypt, Dooge (2004) has underscored the social as well as hydrological significance of Nilometers. Historian Terje Tvedt (2011) and colleagues have undertaken extensive historical studies of Nile River basin flows and management and have curated a multivolume History of Water series that includes papers on the history of hydrologic science. Ancient Mesopotamian irrigation systems have been the subject of archaeological surveys, excavations, dating methods, and remote sensing analyses that test hypotheses about the links between water systems, agricultural domestication, urbanization, environmental degradation, and decline. Research on ancient Roman water systems, hydraulics, and flooding continues to flourish, stimulating the formation of aqueduct studies groups and the Frontinus society named after the famous Roman curator aquarum.

Medieval Europe is not generally known for advances in hydrologic science, but locally adapted water technologies were developed in many places. Conversely, Islamic scholars of the ninth through twelfth centuries achieved scientific renown particularly for their contributions to hydraulic and agronomic sciences (vis-à-vis hydrology in the modern sense of the term; Hill 1994).

The transition to modern hydrology occurred in colonial regimes as well as European centers, which examined ancient water systems while generating new forms of water science and management. Gilmartin (1994) frames this shift as a dynamic tension between “imperial science” and the “science of empire.” Imperial science linked canal hydraulics with irrigation engineering, and developed a canal regime theory to maintain stable flows, channel banks, and sediment transport processes. The science of empire used water development to sedentarize the population, extract revenue, loyalty, and raw materials for European manufactures. D’Souza (2006) offers a similar critique of colonial hydrologic research and practice related to flood control in eastern India.

Histories of ideas about the hydrologic cycle, climatic water budget, and water molecule

Just before Biswas’s volume was published, geographer Yi-Fu Tuan (1968) wrote a fascinating monograph on The Hydrologic Cycle and the Wisdom of God, which reappraised the contributions of seventeenth- and eighteenth-century natural theologians. These were scientists such as John
HYDROLOGY: HISTORY

Ray (d. 1705 CE) and Thomas Burnet (d. 1717 CE) who strove in varying degrees to reason jointly from physical observation, experimentation, and theology. Tuan retraced their writings about the hydrologic cycle as a study in the history of ideas. They treated rainfall–runoff relationships, groundwater, springs, sea level, and natural disasters as matters of cosmological design as well as geophysical order.

The history of ideas approach has been eclipsed in recent decades by materialist and realist historical methods. The latter approaches also address the hydrologic cycle (Karterakis et al. 2007) and increasingly the hydrosocial cycle, which encompasses water use, degradation, and reuse (Schmidt 2014). Other scholars have reviewed the development of hydrology in specific regions and sectors, for example, arid hydrology, forest hydrology, and watershed hydrology (Gordon 1985; McCulloch and Robinson 1993; Todini 2011). Experimental watersheds established in the early twentieth century to test forest and grassland cover effects on streamflow, sediment, and erosion have become subjects of historical research (e.g., experimental watersheds at Wagon Wheel Gap, Colorado; Coweeta, North Carolina, and so forth; in Ice and Stednick 2004; Schumann and Herrmann 2010). A similar sequence is unfolding in urban hydrology in which early studies such as Wolman’s research on urban runoff and sedimentation in the 1960s have expanded to sustained urban hydrology research programs at the Long-Term Ecological Research (LTER) sites in Baltimore and Phoenix (Purcell 1998).

Water budget and water balance analysis have been sustained long enough to stimulate historical research, which includes a biographical focus on the work of Warren Thornthwaite, Russell Mather, and others (Mather and Sanderson 1996). Water budget analysis combines basic biophysical research with research on measurement, modeling, and socioeconomic application in irrigation, power, and other sectors (Wescoat 2014).

At the global scale, research on hydrologic processes has evolved from Soviet-led water budget estimates to research on the potential impacts and feedback effects of global climate change. Determining the relative importance of climate variability, extreme hydrologic events, channel change, social stratification, and conflict are central to these studies. As the field of climate history expands, so too will historical studies of hydrologic processes and interventions (e.g., Wigley, Ingram, and Farmer 1981). They are emulated in planetary studies of water evidence and landform evolution, particularly on Mars (Detay and Gaujous 2002). They will increasingly be linked with historical reconstructions at regional and local scales on Earth (e.g., Pastore et al. 2010).

At the smallest scale, several important papers are published every year on the physics of the water molecule in leading journals such as Nature and Science. Its properties and anomalies are endlessly fascinating. A recent monograph on the history and philosophy of water physics and chemistry offers a provocative argument for scientific pluralism, going so far as to suggest that even the long-rejected phlogiston concept may have continuing value for its way of thinking about water (Chang 2012). It is interesting to reflect upon the potential implications of these molecular scale studies for larger scale hydrologic processes, from topics in atmospheric physics to heat transfer, turbulence, sediment transport, and water chemistry.

Hydrologic processes and measurement

Historical research has concentrated on surface water hydrology and fluvial landforms
Ground water was the subject of ancient speculation about storage in a vast underground cavern. In a modern legal case, ground water was deemed, “so secret, occult, and concealed that an attempt to administer any set of legal rules in respect to them would be involved in hopeless uncertainty and would be, therefore, practically impossible” (Frazier v. Brown 1861). Karst hydrology is perhaps the most mysterious of all but has drawn attention of spelunkers as well as geologists (Clendenon 2009). Spring flows, formerly known as fountains, were one of the enigmatic phenomena to be scientifically explained as pluvial rather than subterranean in origin by Perrault in the eighteenth century, though this account has been shown to have modern rather than historic recognition in Perrault’s times (Linton 2010, 144–147). Histories of hot springs, mineral waters, and coastal and island aquifers have likewise drawn perennial attention (Epstein 1987; Weisz 2001).

In future histories, scientific research on groundwater dynamics will stand out as a major emphasis of late twentieth-century hydrology, due in part to rapid advances in groundwater pumping technologies, withdrawals, and contamination in all water use sectors. Contaminant hydrology is an ancient as well as modern topic. Historians have analyzed urban sewers from Roman to modern times. Reconstructing soil water contamination has become a forensic topic in environmental remediation research (Chapelle 1999; Colten 1985).

Historic contributions to fluvial geomorphology have been compiled in a four-volume collection, the first three volumes of which were organized around works leading up to and following from studies of landform evolution by William Morris Davis (Chorley, Dunn, and Beckinsale 2009). The field is much older, as Leonardo da Vinci’s studies of runoff, sedimentation, and channel change attest (Tokaty
HYDROLOGY: HISTORY

Indeed, floods constitute the most intensively studied hydrologic phenomenon in historical terms (Brazdil, Kundzewicz, and Benito 2006; Costa 1987; Cyberski et al. 2006). Their catastrophic effects, dramatic narratives of heroism and destruction, and generally well-recorded characteristics help account for the attention of both hydrologists and historians. Perhaps the largest research frontier concerns the history of global hydroclimatic change, which draws upon paleoclimatic, paleobotanical, and archaeological methods along with historical research.

Toward an historical sociohydrology?

Interestingly, late twentieth-century efforts to define hydrology as a distinct physical sciences discipline, in contrast to the caricature of “dillettantism” of applied water resources research (Klemes 1986), has been supplanted by renewed emphasis on scientific synthesis (National Research Council 2012). The extent to which the former view of hydrology as a reductionist science accurately characterizes modern water research has been debated (Linton 2010; Schmidt 2014). For example, Schmidt (2014) associates early modern social research on water with the vitalist philosophy of Henri Bergson. What seems clear is that there is renewed emphasis on linking social and hydrologic research in order to understand what Sivapalan, Savenije, and Blöschl (2012) present as the coevolution of social and hydrologic processes.

Historical sociohydrology is one of three main lines of research in this emerging field. Zlinszky and Timar (2013) have shown how historic maps can help reconstruct the history of both wetland hydrology and modification. Another recent study retraces the “duty of water” standards of water use from eighteenth-century steam engines in Britain to nineteenth-century canal irrigation in India, and twentieth-century water rights in the western United States (Wescot 2014). The development of a sociohydrology working group in the IAHS Panta Rhei (“Everything Flows”) decade may help coalesce individual studies into broader contributions.

Whatever the future of particular investigations, it seems clear from this review that the history of hydrology is an underdeveloped topic with considerable prospects. Ancient in its roots, fascinating in its modern developments, the history of hydrology includes many topics that beckon for future inquiry to better understand transformations of the field and better imagine its future paths.

**Further reading**

Remote sensing is the acquisition of information about an object or phenomenon without making physical contact with the object. In modern usage, the term generally refers to the use of aerial sensor technologies to detect and classify objects on Earth (both on the surface and in the atmosphere and oceans) by means of electromagnetic radiation. It may be split into active remote sensing (when a signal is first emitted from aircraft or satellites) or passive (when information is merely recorded) (Schowengerdt 2006).

As one special and effective way to acquire more information from a single observation, imaging spectrometry can simultaneously obtain a set of images in many relatively narrow, contiguous and/or noncontiguous spectral bands throughout different ranges of the electromagnetic spectrum (Chang 2003; Jensen 2005); this is also known as hyperspectral imaging. The concept originated in the 1980s, when A.E.H. Goetz and his colleagues at NASA’s (National Aeronautics and Space Administration) Jet Propulsion Laboratory began a revolution in remote sensing by developing new instruments such as the Airborne Imaging Spectrometer (AIS), then called AVIRIS, for Airborne Visible Infra-Red Imaging Spectrometers (Goetz et al. 1985). The basic workflow design of the image spectrometer has been vividly illustrated in detail (Shaw and Manolakis 2002). A sensor loaded in the satellite makes the acquisition from reflected sunlight passing through a spectrophotometer apparatus that splits the energy into different channels thus forming a continuous display of the spectrum of some material, such as soil, water, or vegetation, as shown in Figure 1. This kind of remote sensing activity using hyperspectral imaging equipment is called hyperspectral remote sensing (HSRS).

HSRS began a revolution in remote sensing by combining traditional two-dimensional imaging technology and spectroscopy, allowing for the synchronous acquisition of both images and spectra of objects (Tong et al. 2014). HSRS is able to describe the specific spectral characteristics of some materials in great detail. The reflective features of some materials can be extended to a continuous spectrum signature instead of several sample values, unlike single or multispectral remote sensing. As shown in Figure 1, data from multispectral sensors such as SPOT and Landsat can only acquire spectral signatures for several channels, which may not be able to best embody the spectral features of some similar materials, while HSRS sensors are greatly superior. For example, in bands 5 and 7, the grass with different water content cannot be separated in multispectral imageries. For material with extremely similar reflective spectral features, such as two subclasses of aspen leaf, they can be well separated using hyperspectral data.

Many commercial and government-funded hyperspectral imagers operate in the reflective range of the electromagnetic spectrum, from approximately 0.4 to 2.5 μm (400–2500 nm). This portion of the spectrum covers the visible through shortwave infrared (SWIR) wavelengths. Hyperspectral imaging systems designed...

for the emissive range, also called the thermal or longwave IR region, typically operate in the span from 7 to 14 μm. These sensors are less prevalent in commercial and academic research communities than in the government sector since they require more sensitive optics and more costly and complicated electronics. The AVIRIS system is able to cover the wavelength region from 0.4 to 2.5 μm, splitting it into more than 200 spectral channels, at nominal spectral resolution of 10 nm. Several other famous imaging spectrometers have been designed and put into practice, including the MODIS (Moderate Resolution Imaging Spectroradiometer) and the HIRIS (High Resolution Imaging Spectrometer). Since the initial development of hyperspectral sensors by NASA, data from these have been successfully applied to both qualitatively and quantitatively analyze various phenomena on the surface of the planet, prompting many other countries to start developing their own hyperspectral sensors. Canada, Australia, and China have all researched and developed their own image spectrometers, some of which are listed in Table 1.

Taking advantage of the unique capacity of HSRS to identify different materials, in the early 1970s, NASA established a preliminary Earth resources information system (ERSIS) gathering together more than 2000 kinds of reflectance laboratory spectrum data for vegetation, soil, mineral, and water bodies. In the process of creating this database for specific application, NASA also accumulated data and technology
for the rapid development of such spectrum databases. These include the Jet Propulsion Laboratory (JPL), United States Geological Survey (USGS), and Advanced Spaceborne Thermal Emission and Reflection Radiometer (ASTER) spectra databases as shown in Table 2.

Different ranges of wavelengths are supposed to excel at different application fields in HSRS. Development of advanced satellite platforms and sensor hardware was a boost to HSRS. Computer science, data storage, and information processing technology enable HSRS to play a significant role in promoting economic growth, environmental protection, and homeland security (Grahn and Geladi 2007). HSRS has been widely used in applications worldwide such as food safety, pharmaceutical process monitoring, and quality control in biomedical, industrial, biometric, and forensic processes at laboratory scale (Bioucas-Dias et al. 2013). A breakdown of common spectral data exploitation tasks and their correspondent spectrum regions are summarized in Farrell (2005).

HSRS applications meet Chinese demands for resource exploration and land utilization. Since the 1980s, the economy of China has grown rapidly; subsequently, exploration for mineral resources has become a vital concern. HSRS is also used in agriculture and forestry. Rapid economic growth has created serious problems; HSRS plays an important role in environmental management, in particular in monitoring water and atmospheric pollution and the effects of urban heat islands.

HSRS images have features that are different from those of traditional remotely sensed data. The data volume of a specific scene enormously increases with the refinements in the spectral channel. Information from adjacent bands, however, is analogous with great redundancy. Therefore, methods and algorithms such as PCA (principal component analysis), ML (maximum likelihood), and NDVI (normalized difference vegetation index) aimed at exploiting traditional remotely sensed data are no longer applicable. In

Hughes phenomenon of HSRS data.

HSRS image processing, scientists have identified some digital image processing methods that may be applied in a relatively straightforward sequence to extract useful information (Jensen 2005). The general steps are shown in Box 1.

The main processing techniques applicable to HSRS data cover dimensionality reduction, endmember extraction, unmixing, classification, target detection, change detection, and physical parameter retrieval. A brief introduction to these techniques is given in the following section.

**Dimensionality reduction**

HSRS data often have hundreds of bands. Enormous dimensionality will lead to high correlation among bands and therefore yield highly redundant information. HSRS data in their original form suffer from the Hughes phenomenon, the “curse of dimensionality,” referring to the loss of classification accuracy as data dimensionality increases, as shown in Figure 2. Data with higher dimensionality are not expected to yield a better classification accuracy. Moreover, data without dimensionality reduction are difficult to process without incurring huge computational costs, which impedes efficient image analysis.

The two dimensionality reduction methods for HSRS data are feature selection and feature extraction. Feature selection methods permit users to directly choose significant band subsets from the original bands according to their various needs, keeping the original information found in HSRS data in a partial form. Feature extraction methods are used to generate new features by transforming the original bands following certain rules. Once defined accuracy requirements are satisfied, feature extraction methods can save on the monetary and computational costs of measurement and calculation, with fewer feature observations and less analysis of the data.
Box 1 General steps used to extract information from hyperspectral data.

**State the nature of the information extraction problem**
Specify the geographic region of interest.
Define the classes or biophysical materials of interests.

**Acquire appropriate remote sensing and initial ground reference data**
Select remotely sensed data based on the following criteria
Remote sensing system considerations:
spatial, spectral, temporal, and radiometric resolution
Environmental considerations: atmospheric, soil moisture, phonological cycle, etc.
Obtain initial ground reference data based on: a priori knowledge of the study area

**Process hyperspectral data to extract thematic information**
Subset the study area from the hyperspectral data fight line(s).
Visual individual band examination
Visual examination of color composite images
Animation
Statistical individual band examination; signal-to-noise ratio
Radiometric correction:
Collect necessary *in situ* spectroradiometer data (if possible)
Collect *in situ* or environment data (e.g., using radiosondes)
Perform pixel-by-pixel correction (e.g., ACORN)
Perform band-by-band spectral polishing
Empirical line calibration
Geometric correction/rectification:
Use onboard navigation and engineering data (GPS and Inertial Navigation System information)
Nearest-neighbor resampling
Reduce the dimensionality of hyperspectral dataset:
Minimum Noise Fraction (MNF) transformation
End-member determination — locate pixels with relatively pure spectral characteristics
Pixel Purity Index (PPI) mapping
N-dimensional end-member visualization
Methods of mapping and matching using hyperspectral data:
Spectral Angle Mapper (SAM)
Subpixel classification (linear spectral unmixing)
Spectroscopic library matching techniques
Matched filter or mixture-tuned matched filter
Indices developed for use with hyperspectral data
Derivative spectroscopy

**Perform accuracy assessment**
Select method:
Qualitative confidence-building
Statistical measurement
Determine number of observations required by class.
Select sampling scheme.

Unmixing

Three types of mixtures exist in HSRS images: (i) linear mixing on a checkerboard type surface, (ii) nonlinear (linear plus bilinear) mixing in a two-layer medium, and (iii) nonlinear mixing in an intimate (particulate) medium (Dobigeon et al. 2014). As a result of the complexity of pixels in HSRS images, when mixing occurs, it is not possible to determine what materials are present directly from the respective measured spectral vectors. The unmixing problem addresses how materials can be quantitatively separated in every mixing vector; the objective is to precisely identify materials contained in a pixel.

HSRS unmixing provides a comprehensive quantitative mapping of elementary materials present in the acquired data. More specifically, unmixing can identify the spectral signatures of these materials (usually called endmembers) and can estimate their relative contributions (known as abundances) to the measured spectra. The main steps of HSRS unmixing cover endmember number estimation, endmember extraction, and spectra abundance resolution.

After carefully determining the amount of endmembers existing on the image, there is an array of methods which can be applied to extract the pure endmember spectrum from the data. These methods can be classified into two categories: sequential endmember extraction algorithms (SQEEAs) and simultaneous endmember extraction algorithms (SMEEAs). SQEEAs acquire endmembers separately, one by one, after each iterative procedure, while SMEEAs obtain all the spectra of endmembers at one time after the processing. The former methods suffer from accumulative errors caused by the iterations, while the latter approaches suffer from high computational costs. Having obtained the number of endmembers and their corresponding spectral signatures, estimation of their abundance in every pixel still remains a challenge due to the ill-posed inverse problem because of model inaccuracies, observation noise, environmental conditions, endmember variability, and data set size making the unmixing results nonunique (Zare and Ho 2014). Researchers have devised and investigated many models searching for robust, stable, tractable, and accurate unmixing algorithms that are related to the signal-subspace model, the geometrical model, the statistical model, the sparsity-based model, and the spatial-contextual model.

Classification

The goal of classification is to assign a unique label to each pixel vector so that it is well defined by a given class. Different from the classification problem in other remotely sensed imageries, HSRS classification has its own pros and cons. The availability of HSRS data with high spectral resolution makes even similar materials display with different spectral signatures, both those with more abundant detailed information and those at a more precise wavelength range. Take the image shown in Figure 3 as an example; only HSRS data can precisely divide the whole farm area into dozens of kinds of crops. However, accurate classification demands a high level of data preprocessing for atmospheric correction, geometric correction, and spectral calibration. Moreover, the number of available training samples tends to be insufficient due to the extremely high dimensionality of HSRS data, which decreases classification accuracy.

HSRS data classification can be conducted by either unsupervised or supervised methods. In an unsupervised classification, the identities of land cover types within a scene to be specified as classes are not generally known a
priori because ground reference information is lacking or surface features within the scene are not well defined. The computer must group pixels with similar spectral characteristics into unique clusters according to some statistically determined criteria. Therefore the unsupervised classification is also called clustering in the pattern recognition field.

In a supervised classification, analysts utilize some area of known spectral characteristics to train the classifier for eventual land-cover mapping of the remainder of the image with limited training samples. In order to address the above issues, feature mining, subspace-based approaches, and semisupervised learning techniques have been developed. In feature mining and subspace approaches, the goal is to reduce the dimensionality of the input space in order to better exploit the limited training samples. In semisupervised learning, the idea is to exploit the information conveyed through additional unlabeled samples, which can complement the available labeled samples with a certain degree of confidence.

**Change detection**

Biophysical materials and human-made features on the surface of Earth are dynamic and frequently changing. It is important that such changes be inventoried accurately so that the physical and human processes behind such changes can be more fully understood. Change detection is the process of identifying differences in the state of an object or phenomenon by observing it at different times. Remote sensing technology can observe the surface of a research area periodically for a long time at larger scales. It has been widely applied in the monitoring of land-use/land-cover research, city expansion, wetland vegetation monitoring, ice detection,
protection zone management, and disaster prevention.

Sometimes, anomaly change detection is of more significance, as shown in Figure 4. This term refers in particular to real changes other than the normal changes (seasonal changes of vegetation) found in the scene. Change detection results from HSRS data are well suited to detect subtle changes and contain detailed information. HSRS can identify not only the changed area but also “from–to” analysis information (what features were there before and after the change).

Target detection

HSRS can provide crucial spectral details of similar materials due to the high spectral resolution and continuous spectral curve in these images; therefore, it has exceptional advantages when detecting certain materials. Target detection is one of the most important applications of HSRS image processing. Typical examples include: the detection of specific terrain features and vegetation, mineral, or soil types for resource management; detecting and characterizing materials, surfaces, or paints; the detection of man-made materials in natural backgrounds for the purposes of search and rescue; the detection of specific plant species for the purposes of countering narcotics; and the detection of military vehicles for the purposes of defense and intelligence (Manolakis et al. 2014). Target detection can be also considered a classification problem as it assigns each pixel to either a target class or a nontarget class. However, these two classes are always unbalanced in number, with nontarget class pixels superior to target pixels.

Figure 4  Generalized change detection and anomaly change detection.
The general criteria for minimizing total misclassification error rates are no longer suitable for target detection tasks, as shown in Figure 5. When a target detection task is being conducted, a projection method is required to maximally separate target class pixels from other classes. HSRS data are often mapped into a hyperplane where target pixels and nontarget pixels can be best separated according to certain rules. Then, a threshold mechanism is adopted to tear them apart as shown in Figure 5. This projection operation is called designing a target detector. The state-of-the-art target detectors include, but are not limited to: detectors based on spectra unmixing, which determines a pixel by the target endmember abundance it contains; detectors based on signal matching, which determines a pixel by the correspondence to a given target referential signal; detectors based on hypothesis testing, which determines a pixel by the probability it belongs to the two opposite hypotheses with different statistical features; detectors based on feature space projection, which maps the original data cloud into a new feature space, and determines a pixel by its distance to the a priori information in this new space.

Despite the success that has been enjoyed in different HSRS techniques described in the above section, there still remain a lot of problems and challenges in HSRS information extraction processing. This entry could not cover all the interesting and relevant aspects exhaustively; however, HSRS is a mature and promising field and contributes actively with frontier cross-disciplinary research activities.

HYPERSPECTRAL REMOTE SENSING

Island biogeography

Rosemary G. Gillespie  
*University of California, Berkeley, USA*

The flora and fauna of oceanic islands have inspired scientific interest from the moment explorers first began sailing the oceans. In the history of scientific understanding, islands played a fundamental role in providing insights into the operation of biological evolution. The Galápagos Islands played a key role in the development of Charles Darwin’s theory of evolution by means of natural selection. Likewise, Alfred Russell Wallace contemporaneously developed similar theories based on studies in the Spice Islands of Indonesia. More recently, the closed nature of insular systems, their relative simplicity, and often replicated pattern within a known temporal (geological or climatological) framework, has allowed them to serve as microcosms for understanding fundamental processes in both ecology and evolution. Thus, studies exploiting the discrete nature of islands have allowed the advancement of pervasive organizing theories of community ecology, particularly involving island biogeography and related ideas of species abundance and diversity. More recently, with the advent of accessible molecular genetic tools, research on islands has allowed unique insights into the processes that generate biotic diversity, especially the mechanisms of speciation.

Unfortunately, islands are also prime targets for biological invasions, mediated largely by anthropogenic disturbance. The severity of such impacts on island biotas may be the result of their evolution in isolation, but it is certainly compounded by their characteristically small population sizes. Moreover, while the extraordinary rates of extinction of vertebrates on islands have been well documented, extinction among arthropods is largely unknown. Indeed, the profound lack of knowledge of many arthropod groups on islands means that it is likely that whole radiations of species of insects, spiders, and likely other invertebrate groups will go extinct before they are ever even recognized.

What is an island?

An island is generally defined as a landmass, smaller than a continent, that is surrounded by water. However, from a biological perspective, it is more useful to consider an island as any area in which a set of biota is isolated as a result of being surrounded by a dramatically different habitat matrix (Figure 1). Thus, the feature that make islands biologically interesting is their isolation, and the barriers that impose isolation vary according to the organism in question. A lake in the middle of a continent may be isolated for a fish but not so much for a lizard; an oceanic island may be isolated for a gecko or an insect but not for a whale; and a rock in the middle of a forest may be isolated for an ant, though not for a pig. Thus, the level of isolation is dictated by the impermeability and extent of the isolating matrix relative to the organism in question. But, whatever the context, the well-defined nature of islands results in properties such as a microcosmal nature and a uniquely assembled biota. In essence, islands can be considered nature’s test tubes. Each island represents a trial in an
experiment and each new island is the repeat of one of these experiments.

**Types of insular environments**

Figure 1 shows a diversity of insular systems. (a) The thousands of mangrove islands in the Florida Keys have been used to test the equilibrium model of island biogeography. (b) The Hawaiian Islands, the most remote archipelago in the world, are home to numerous adaptive radiations of terrestrial organisms. (c) The Galápagos Islands off the coast of Ecuador provide textbook examples of adaptive radiation. (d) The Canary Islands have also provided many examples of adaptive radiation among plants and animals. (e) Multiple pairs of sticklebacks have been found in the glacial lakes on Texada Island, illustrating the early stages of adaptive radiation (Schluter 2000); and numerous islands in the Barkley Sound have formed the basis for many studies on island plants (Cody 2006). (f) The African Rift Lakes have provided isolated habitat for aquatic organisms, with particularly spectacular examples of adaptive radiation in cichlid fish. (g) Uluru (Ayers Rock), Australia, where inselbergs, or “island mountains,” provide isolated habitat for organisms that are limited to the unique environments provided by the higher-elevation habitats. (h) The summits of the ancient tepuis or table-top mountains in the Guiana Highlands of South America, especially in Venezuela and western Guyana, have been isolated for approximately 180 million years. (i) The Panama Canal, in which Lake Gatun was created by the building a dam across the Chagres River in 1913, with the subsequent formation of Barro Colorado Island, provides a system for many studies on the response of organisms to insularization. (j) Theories based on island biogeography have been applied to the management of fragmented forest “islands” in Sumatra, Indonesia.

“True” islands – surrounded by water

The traditional view of an island is of a landmass surrounded by water. However, a huge range of habitats can be considered within this context, from intermittent tidal islands such as Lindisfarne in the United Kingdom to the remote islands of Hawai’i, and tiny rocks and islets off Greenland, which itself is considered the largest island in the world. While the size and isolation of an island is integral to understanding its biogeography, so also is its geological history. Since the 1960s, geological understanding of islands has advanced enormously. In many oceanic archipelagoes, the age of each island is often known with some level of precision, and information of various levels of precision is generally available for changes in island size, elevation, and associated climatic factors over millennia (Gillespie and Clague 2009). At the same time, information on islands that have long since disappeared provides insights into historical patterns of connectedness, and work on the complexities of the splitting, sinking, and uplifting of the ancient landmass of Gondwana has highlighted the potential impact of the dynamic nature of island formation on patterns of biodiversity. This has given biologists a temporal framework with which to examine ecological and evolutionary processes and how biodiversity has formed over time.

Mountaintops – sky islands

The environments of mountaintops are often quite different from the surrounding slopes, and can include cloud forests, alpine grasslands, herbfields, and páramo; these sites tend to be relictual fragments of previously more widespread habitats, isolated by the changing climate. Perhaps the best-known sky islands, at least from a biological perspective, are the American Madrean “sky islands” of southeastern Arizona and New Mexico. Here, striking phenotypic divergence has been found among populations of the jumping spider Habronattus pugillis. Given that these habitats are only around 10,000 years old, diversification has been rapid.

Caves

Caves can be considered rock cavity islands, with the taxa adapted to these systems isolated both by the impenetrable rock surrounding them and by the surface environment. Among cave spiders, beta diversity tends to be higher for troglobiont assemblages, often with minimal gene flow between caves, while alpha diversity and phylogenetic and functional diversities tend to be lower. Cave-adapted species are found among multiple different kinds of organisms, and many cave species have evolved suites of morphological traits associated with cave life, including reduced or missing eyes, reduced or missing pigment, elaboration of appendages, and hypertrophy of extrasensory structures (Culver and Pipan 2009). Moreover, cave-modified species tend to show the recurrent evolution of similar forms, controlled by the same genetic pathways that can span many taxonomic levels; for example, adaptation to cave environments has been found to involve a similar mutation at the first step of melanin synthesis in both planthoppers (from Hawai’i and Croatia) and Mexican cavefish.

Habitat fragments

The process of fragmentation has resulted in insularization at many different scales across space and time. In the Australian landmass, refugial rainforests dating from the Miocene are found in small pockets along the eastern and southwestern coasts. The diversity of taxa that are confined to these habitats is extraordinarily high, with species often restricted to single mountains, deep divergence between mountains
being due to ancient fragmentation of forest habitats and subsequent diversification.

On a somewhat more recent timescale, ongoing volcanic activity on the young island of Hawai‘i has created a dynamic mosaic of habitats of different ages as large areas of forest are destroyed or fragmented when lava flows around them. Fragmentation on scales of hundreds of meters and over several hundred years can be sufficient for the genetic differentiation of arthropod populations, though – because of its transitory nature – this fragmentation is likely to be more important in maintaining genetic diversity than in the separation of populations.

Considering habitat islands that have been created within recorded history, many of the ideas originally developed for islands in the sea have been extended to these systems. Most such islands are fragments of habitats that were historically connected, such as remnant trees and forest patches. For habitat islands, as for islands in the sea, ecological and evolutionary processes are governed largely by isolation, time, and the nature of the matrix relative to the dispersal abilities of the organisms in question. Because of their discrete nature and ease of manipulation compared to islands in the sea, habitat islands have been exploited in the development of many ecological principles including those related to metapopulation dynamics and the physical design of nature reserves.

**Fragment versus de novo islands**

From a biological perspective, there are in general two types of islands (Figure 2), depending on whether they are formed by fragmentation or de novo emergence. *Fragments*, which include continental and most habitat islands, are formed by separation from a larger entity, and become fragments in which various habitats have usually been occupied prior to isolation; thus, the number of species, at least initially, will tend to decline as a result of stochastic events. *De novo islands*, which include oceanic islands and certain lakes within a terrestrial landmass, are formed without life, so colonization inevitably occurs from outside. If the islands are not extremely isolated, an equilibrium will be reached between the immigration of colonists and extinction. With greater isolation (and lower immigration rates), local endemism will increase. For a given species, there is a level of isolation at which the frequency of colonization is insufficient to allow for the occupation of available ecological niche space through migration, and which can provide the opportunity for adaptive radiation for individuals that can establish; this area has been called the “radiation zone.” Here, species diversity will arise through the formation of multiple new species adapted to exploit the available ecological space.
Neo-endemics typically form on isolated islands that have been created de novo, and have abundant empty ecological space into which those few colonists can diversify. Besides Hawai‘i, other volcanic archipelagoes, including the Marquesas, Societies, and Galápagos in the Pacific, the Canaries in the Atlantic, and the Mascarenes in the Indian Ocean, have formed de novo and provided conditions for the formation of neo-endemics. However, neo-endemics can also form on fragment islands including the Caribbean islands and the islands of New Zealand and Madagascar. After these islands formed, genetic connection with the source populations was reduced, and over time this allowed organisms to diverge genetically. Unlike islands that form de novo without any species and tend to accumulate species through time, fragment islands are usually ecologically saturated at the time of separation and tend to lose species through ecological time, a phenomenon termed relaxation. Over evolutionary time, the species on these islands may change through a process termed relictualization, with the formation of paleoendemics, usually without adaptive radiation.

Adaptive radiation can then accentuate this effect when multiple species arise from the few that successfully colonize, the result being very few families and genera compared to the overall diversity. This pattern, whereby the species diversity is represented by few higher taxonomic groups (genera, families) and disproportionate numbers of species within a few genera, has been noted in many remote islands.

Endemism

On islands formed de novo, the pattern of species accumulation will depend on the rate of formation of new species relative to the frequency of island colonization, the extreme cases leading to extensive adaptive radiation as a result of in situ evolution, with associated adaptation to occupy the available ecological space. On remote islands, the frequency of colonization becomes vanishingly rare. As a result, the biodiversity of remote islands is made up in large part by the diversification of the few initial colonists, and levels of endemism are consequently very high.

Loss of dispersal ability and flightlessness

Loss of dispersal ability is a common feature of organisms on more remote islands. The phenomenon was first documented by Darwin, who suggested that “powers of flight would be injurious to insects inhabiting a confined locality, and expose them to be blown to the sea” (Carlquist 2010). However, not all species lose their dispersal ability on islands. Indeed, loss of dispersal requires that (i) there be some dispersal behavior on which selection can act, and (ii) there be no opposing selection to maintain dispersal ability. Thus, some birds and strong flying insects can still maintain flightedness even on remote islands. Nevertheless, flightlessness in birds has evolved repeatedly on islands where
predators are absent; there are about 40 species of flightless birds known today, including the kiwi, moa, emu, cassowary, and dodo. Many of these species have been driven to extinction following the arrival of humans; notable extinctions include the dodo of Mauritius, the elephant bird of Madagascar, and the moa of New Zealand.

Innovations

The known disharmony of islands appears to stimulate the development of some unusual traits in island groups. For example, Hawaiian birds have developed a remarkable diversity of elongated and decurved bill shapes, presumably because of the availability of nectar resources. The Hawaiian silversword plant alliance includes trees, shrubs, subshrubs, rosette plants, cushion plants, and a vine that occur in some of the wettest sites recorded on Earth to extreme desert-like environments (Bramwell and Caujapé-Castells 2011). Among insects, the absence of native social insects in some of the more remote islands of the Pacific may have been largely responsible for the adaptive shift to predation in some terrestrial insect groups and the diversity of other predatory arthropods on these islands. One of the most striking innovations is the development of predatory behavior in a lineage of Hawaiian caterpillar moths in the genus *Eupithecia*. Another innovation in Hawai’i has been the development of odonates with terrestrial larvae, associated with the paucity of lakes in the upland yet moist forests of the islands. Similarly, the unusual habitat of cryptogram herbivory in beetles in the subantarctic islands is considered to be a result of the disharmony of the flora.

Size

Change in body size is also commonly observed on islands, with species showing a tendency toward size extremes, both gigantism and dwarfism, a phenomenon that has been called the “island rule” (Meiri 2009). For example, large mammal species that colonize more remote islands tend to get smaller, while small species tend to get larger. Thus, gigantism is well known among rodents, as well as many birds (often associated with flightlessness, as mentioned earlier). It has also been documented among lizards (e.g., giant tortoises of the Galápagos, Seychelles, and Mascarenes; Komodo dragon of Timor), though in some cases the effect of larger species on islands is likely due to the extinction of their mainland relatives. Among arthropods, gigantism is best known among crickets (e.g., wetas in New Zealand and tree crickets in the northwest Hawaiian Islands); however, it is also known among beetles (long-horned beetles in Fiji), earwigs (St Helena Island), stick insects (Lord Howe Island), millipedes (Madagascar), and spiders (giant sheet web spiders in Hawai’i and the Juan Fernández Islands).

Island dwarfism is best known among mammals, including elephants (e.g., different species from the islands of the Mediterranean), hippopotamids (e.g., Cyprus dwarf hippo), sloths, and hominins, as well as foxes (e.g., Channel Island fox in California), felids (e.g., the Javan tiger, the Zanzibar leopard), procyonids (the Cozumel raccoon) and bocids (e.g., Balearic Islands cave goat), and cervids (e.g., Corsican red deer). It has also been documented in various dinosaurs, with some additional examples from lizards, snakes, and birds.

Plant reproductive shifts and arborescence

In plants, reproductive changes are common and include the development of dioecy, monocarpy, developmental heterophyll, sexual dimorphism, asexual reproduction, and low rates of reproduction. Stem woodiness and related differences in growth form, habitat, and floral morphology are
also recurrent and well-known adaptations of island plants.

Species diversity and the equilibrium theory of island biogeography

Equilibrium theory of island biogeography

Larger islands contain more species. MacArthur and Wilson formalized this idea in the 1960s with the development of the equilibrium theory of island biogeography (ETIB) (MacArthur and Wilson 1967). This theory relates species and area by the formula, \( S = cA^z \), where \( S \) is species number, \( A \) is area, \( c \) is a constant measuring overall species richness, and \( z \) measures the extent to which increases in area have diminishing returns in terms of species number. Values of \( z \) tend to vary between 0.18 and 0.35; that is, doubling the species number requires increasing the area by a factor of between 7 and 100. The premise of the theory is that species diversity on an island is a balance between immigration and extinction. The rate of immigration decreases with increasing distance from a mainland source, whereas the rate of extinction decreases with increasing island size (Figure 3). As the number of resident species on an island increases, the chance of an unrepresented species arriving on that island decreases and the likelihood of extinction of any one resident species increases.

When the curve trajectories of immigration and extinction rates are plotted (as ordinates) against species richness, the species diversity of a given island can be assessed by projecting to the abscissa of the curves’ intersection point, while the rate of turnover is reflected by the projection to the ordinates. Thus, species richness, together with immigration, extinction, and turnover rates, are all island-specific parameters that change according to the area of the island and its isolation, with species richness remaining roughly constant over time, while species composition is continually changing (Fernández-Palacios 2009). Thus, the predictions of the model are that (i) the number of species on an island should change little once the equilibrium is reached; (ii) there should be continual turnover of species, with some becoming extinct and others immigrating; (iii) small islands should support fewer species than large islands; and (iv) species richness should decline with remoteness of the island because islands farther from the source will have lower rates of immigration.

Figure 3  MacArthur and Wilson’s equilibrium theory of island biogeography, showing how (i) immigration, which is dictated by distance from a source of propagules, declines with the number of species present; and (ii) extinction increases with the number of taxa present, the rate declining with island area. \( S \) (species number at equilibrium) is the point where immigration and extinction curves intersect. Species numbers for a small far island (\( S_1 \)) are lowest; those for a large near island (\( S_4 \)) are largest. The turnover of species (\( T \)) can be determined from the y-axis: the turnover is lowest for a large far island (\( T_1 \)) and highest for a small near island (\( T_4 \)).
The equilibrium theory marked a substantial turning point in biogeographic understanding in general, and has played a key role in many different aspects of ecology and evolutionary biology since its publication (Losos and Ricklefs 2010). While there is widespread support for the basic tenets of the theory, in some cases it has been found that species numbers are affected by both area and isolation, whereas others have shown that an equilibrium does not exist, or that parameters other than area per se may dictate species richness. Such factors include habitat diversity, climatic conditions, island age, and even the status of knowledge concerning the presence of resident species. However, the theory has proved to be remarkably useful and, although it was developed for islands, it has had relevance for the study of many kinds of ecological communities.

Island colonization in the context of the ETIB

Given a suitable abiotic environment, the success of any given colonization event will depend largely on the availability of ecological space. Detailed studies of immigration patterns have been conducted on mangrove islands in the Florida Keys following artificial sterilization. Species of insects and spiders accumulated to an equilibrium number, though turnover of species was not randomly distributed between species – particular types of species were more likely to colonize or to go extinct. These studies supported theoretical work showing that the initial successful set of colonists is somewhat predictable based on the niche space available, and reaches a noninteractive equilibrium; however, over time, continued immigration and extinction can produce sets of species that are increasingly co-adapted, reaching interactive equilibria, each successive equilibrium having more species because the more co-adapted the assemblage the more species can co-occur. Recently formed volcanic islands, such as Krakatau, following the 1883 eruption (Thornton 1997), and Surtsey in 1963, have been used to calculate immigration rates on ecological timescales.

Long-distance dispersal, which is well known to play a role in the colonization of remote islands, is more difficult to study because of its infrequent and unpredictable nature, and therefore precludes development of testable hypotheses (Gillespie and Baldwin 2009). However, while a single rare long-distance dispersal event may indeed be impossible to predict, an understanding of the mechanisms involved in long-distance dispersal over extended time periods can lend predictability to the process. In particular, assuming that the three primary vectors for long-distance dispersal are wind, birds, and ocean currents, the likelihood of a propagule to be vectored will depend on its mechanism of association with the vector, coupled with its ability to withstand the environment to which it is exposed during transit, attributes that impose strong filters to the kind of organisms involved.

Factors facilitating establishment

Features of the new environment that affect the ability to establish will impose additional filters, with successful colonization and establishment being more likely in environments that approximately match the source environment. For example, organisms from higher latitudes are most likely to become established at lower latitudes in higher-elevation habitats with climatic conditions matching their original environment. Similarly, lower elevations at low latitudes should be more easily colonized by taxa from tropical sites. In addition, for taxa that live inside other organisms or are associated with particular substrates, it seems likely that establishment will
occur more readily if they arrive with (or after the establishment of) their substrate, symbiont, or host. Surprisingly, even some highly specialized mutualisms are maintained (or recovered) following the independent colonization of remote islands by the different partners. An additional factor that may contribute to successful establishment is escape from predators, parasites, and competitors, a phenomenon well documented through studies of successful invasions where predators are lacking.

Niche pre-emption

In a given area, once a niche has been filled, it appears to be more difficult for ecologically similar individuals to enter (MacArthur and Wilson 1967). Lineages of plants that are diverse in the Canary Islands are monophyletic, while those that are less diverse have colonized the islands repeatedly, suggesting the possible importance of niche pre-emption. Niche pre-emption also may contribute to the “progression rule” of successive dispersal from older to younger islands in the Hawaiian Islands (Wagner and Funk 1995).

Ecological release

What happens to a population subsequent to successful colonization? Subsequent to the initial establishment of species in new habitats, a common outcome is ecological (or competitive) release, with colonizers expanding their range to fill the available ecological space. Clearly, the extent and duration of any ecological release will depend on the isolation of the habitat. On islands that are close to a source of colonists, the niche space will be filled quickly by diverse taxa; on isolated islands, the infrequency of colonization allows the initial colonists to “explore” the ecological space much more broadly.

Regular cycles of distributional change following colonization of islands have been proposed several times in the literature, starting with the idea suggested by E.O. Wilson for a “taxon cycle” in Melanesian ants in which widespread, dispersive populations give rise to many more restricted and specialized populations or species. While the tendency is for species to expand their range to fill the available ecological space on colonization of a new island, the consistency of subsequent distributional changes associated with the taxon cycle has been found to be less predictable.

Evolution and the ETIB

The role of evolution within the dynamic of the equilibrium theory has only recently been examined, and shows that larger islands tend to have higher diversification rates (i.e., in situ speciation minus extinction) compared to smaller islands, and species diversity changes in concert with the geological ontogeny of an island (Whittaker and Fernández-Palacios 2007). Following on from these concepts, theoretical expectations for phylogenetic diversity–area curves using data from ecological community assembly models, together with macroevolutionary models, have revealed strong relationships between regional phylogenetic diversity and area, provided that species were derived only from within-region speciation. Moreover, there is support for the notion of an equilibrium diversity over evolutionary time, as species richness has been shown to be determined by island-specific limits on total diversification (Moen and Morlon 2014). However, the nature of equilibrium diversity – how it differs between lineages, and how it is attained and maintained – is still not clear. Studies using island chronology to look at changes in diversity over the course of adaptive radiation have indicated that diversity on islands...
does not change linearly over time; indeed, some lineages appear to reach their highest diversity early during the course of adaptive radiation, while others accumulate species more slowly, the result being that the oldest islands have the highest diversity (Gillespie and Baldwin 2009).

Evolution on islands

Anagenesis versus cladogenesis

On islands that are within the geographic distance to which a species is likely to disperse, the genetic coherence between populations from the source and those on the island can be maintained. In such circumstances, new species will tend not to form on the island (unless there is very strong selection driving divergence). On islands that are beyond the range within which populations can maintain genetic contact with source populations, then the island population will diverge to form a new species through the process of anagenesis (Whittaker and Fernández-Palacios 2007).

Cladogenesis and adaptive radiation

Where islands are farther from a source of colonists, fewer representatives from the entire source community will establish within the same time period. As a result, there is sufficient time for diversification; thus, cladogenesis within the island can lead to the formation of new species. The phenomenon whereby single (or few) colonists, isolated genetically from their source population, give rise to a series of ecologically disparate species, often through a rapid burst of speciation, is termed adaptive radiation. Adaptive radiation tends to be limited to islands that are beyond the so-called radiation zone, or normal range of dispersal, of a given organism. Species that form through adaptive radiation are typically neo-endemics, as described above, formed in situ and found nowhere else.

Adaptive radiation tends to be associated with the formation de novo of extremely isolated habitats, with subsequent colonization being very infrequent, giving the few successful colonists sufficient time to “explore” the ecological space available, diverge, and diversify into multiple species. Well-known examples of adaptive radiation include that of finches in the Galápagos Islands, which was likely triggered by the appearance of land through volcanic activity over the last 3 million years. In the same way, adaptive radiations in the Hawaiian Islands are found to be mostly associated with the volcanic activity that resulted in the initial formation of the current high islands approximately 5 million years ago. And the origin of the adaptive radiation of the African rift lake cichlid fish approximately 5 million years ago coincided with a period when rivers in the area became increasingly swampy.

For less dispersive organisms, adaptive radiation can occur on island archipelagoes that are relatively large and not extremely remote. Spectacular radiations among mammals are known among primates in Madagascar and rodents in the islands of the Philippines; among frogs in the islands of Southeast Asia, Madagascar, and the Caribbean; and among lizards in the islands of the Caribbean (e.g., Losos 2009). Each of these lineages has provided impressive evidence of adaptive diversification. For example, cloud rats in the Philippines provide one of the most spectacular cases of adaptive radiation by mammals anywhere in the world, with species ranging in size from 2.6 kg to 15 kg (Heaney and Goodman 2009).

For more dispersive groups, such as many arthropods and birds, adaptive radiation is largely limited to the most isolated islands. The most thoroughly documented instance of adaptive radiation is that of the finches in the Galápagos.
However, the Hawaiian honeycreepers are another radiation of finches that shows a good deal more ecological diversity with an associated larger number of species, although many have already suffered extinction. For arthropods, particularly noted examples of adaptive radiation are found in the Hawaiian Islands and include *Drosophila* flies, which are well known for their diversity of mating behaviors; lineages of crickets that have diversified explosively in song repertoire; sap-feeding planthoppers and psyllids that have proliferated by tracking and switching between plant hosts; and beetles that have formed new species on different substrates. Diversification may follow a predictable pattern, at least in some groups; for example, among *Tetragenatha* spiders similar ecological sets of species have evolved over and over again on each of the different Hawaiian Islands.

Among plants, the largest known island radiation is that of the Hawaiian lobeliods (Campanulaceae), with the >100 species now thought to have arisen from a single colonization event (Stuessy and Ono 2007). The radiation exhibits extraordinary diversity in vegetative and flower morphology, with species inhabiting a huge array of habitats. The diversity is considered to have arisen in concert with that of the Hawaiian honeycreepers, the lobeliods displaying a suite of morphological characteristics associated with bird pollination, including deep, tubular, long-lived inflorescences, with an abundance of nectar and no odor. Another spectacular example of adaptive radiation in plants is the Hawaiian silversword alliance (Asteraceae–Madiinae), in which 28 species are known that display a huge diversity in life form, from trees to shrubs, mats, rosettes, cushions, and vines, occurring across habitats from rainforests and bogs to desert-like situations. An analogous radiation of 23 species in the genus *Argyranthemum* (Asteraceae–Anthemidioideae) has occurred in the Macaronesian islands, although the largest radiation of plants in the Canaries is that of the succulent, rosette-forming species of the genus *Aeonium* (Crassulaceae).

Some of these radiations provide spectacular examples of the rapidity of adaptive diversification. For example, the estimated rate of diversification for Hawaiian crickets in the genus *Laupala* is 4.17 species per million years; the rate estimated for cichlid fish, which have undergone adaptive radiation in the African rift lakes, is 2.02–2.09 species per million years in Lake Malawi and Lake Victoria.

Most island adaptive radiations occur within an archipelago setting, with allopatry between islands implicated in providing sufficient isolation for adaptive radiation. Interesting in this regard is a radiation of small flightless weevils in the genus *Miocalles* (Coleoptera: Curculionidae: Cryptorhynchinae) on the single small island of Rapa in the southern Australs of French Polynesia. Rapa is home to almost half of the 140 species that occur across the western Pacific and Australia. Here, the beetles collectively feed on 24 genera of native plants, and show varying degrees of host specificity, thus utilizing almost all genera of native plants found on Rapa.

Some radiations have been studied because they are readily accessible to scrutiny of the process of adaptive radiation, in part because they have occurred very recently. In this context, Dolph Schluter’s (2000) research has focused on stickleback fish of the deglaciated lakes of coastal British Columbia, Canada. These lakes harbor a number of sibling species of fish, and repeated co-occurrence of pairs of species has been attributed to novel ecological opportunity provided by deglaciation and recolonization. In particular, the threespine stickleback, *Gasterosteus aculeatus*, is a species complex which has diversified in each lake such that no more than two species occur in any one lake. Interestingly, it
appears that pairs of species in different lakes have evolved independently of other pairs, and species have diverged as a result of parallel episodes of selection for alternative feeding environments. Research in this system has highlighted the role of divergent natural selection as a mechanism underlying adaptive radiation.

Isolation, hybridization and admixture

In addition to rapid genetic and ecological differentiation, there are elements that have become increasingly associated with adaptive radiation – in particular, the potential role of multiple colonizations and admixture in enhancing variability. While a break in genetic connectance is necessary for adaptive differentiation, hybridization and genetic admixture are key in the generation of adaptive variation and functional novelty (Seehausen et al. 2014). There have been a number of studies demonstrating how the negative effects of genetic founder effects may be offset if different colonization events result in multiple genotypes within the introduced population, highlighting the potential role of admixture among successively introduced populations in providing the genetic variation to allow adaptive evolution.

Parallel evolution and convergence

Many of the best-known island radiations are characterized by repeated shifts in phenotype and speciation, which are often associated with marked morphological and ecological convergence. This phenomenon, in which similar sets of ecological forms have evolved largely independently, was first documented in Anolis lizards (Losos 2009), but has now been shown in a number of adaptive radiations, including the sticklebacks mentioned earlier, as well as spiders in the islands of Hawai’i (Figure 4). It has been suggested that such examples provide powerful evidence that Darwinian natural selection acting on organisms exposed to similar adaptive landscapes can sometimes overwhelm historical and ecological contingencies (Losos 2009). Therefore, diversification during adaptive radiation may occur along predictable ecological axes and in a predictable sequence.

Conservation

Although islands have long proven themselves as extraordinary laboratories for studying processes associated with the generation of diversity, they are now contributing to our understanding of processes leading to the loss of diversity. The vulnerability of islands to extinction is now widely recognized. Islands have suffered much higher rates of extinction than continents (Steadman 2006). Given the information on species diversification that scientists have been able to determine from oceanic islands, the question is whether we can also use the islands as tools to understand extinction. Extinction is clearly more gradual in continents than on many islands, but the trajectory is similar. Accordingly, understanding of the processes involved in species extinction in the islands, and the replacement of largely native environments by species from elsewhere, may allow the development of effective conservation strategies in mainland habitats.

Major issues in island conservation include the lack of knowledge of the biota, the generally small size of the populations making them more vulnerable to extinction, and the large numbers of invasive species on islands. These are basically the same conservation issues as confront continental biotas; they are simply more acute on islands because of their small size and microcosmal nature.
Figure 4  Ecomorphs for Hawaiian *Tetragnatha* spiders, illustrating the repeated evolution of ecomorphological similarity. (a) Three of four known ecomorphs of the spiny leg clade: species shown from different ecomorphs on the same island are more closely related to each other than to the same ecomorph on different islands. (b) Representatives of different web morphologies of the web-building lineage where different web types on the same island are more closely related than the same web type on different islands (inset photos show the species that build the webs). ISLAND BIOGEOGRAPHY

Taxonomic impediment

The biota of islands is often unique; for example, the islands of the Pacific have been designated a biodiversity hotspot. Assessing this diversity, particularly for arthropods, is problematic. The major impediment is a lack of taxonomic understanding of arthropods on many islands, particularly those that are more remote. New species are being collected at a remarkable rate in areas such as French Polynesia, Madagascar, and even the relatively well-studied Canary Islands, New Zealand, Hawai’i, and the Galápagos, yet the training of arthropod systematists has lagged behind.

Size of distribution and related impacts

Species on islands tend to have a limited geographic distribution, and the naturally small population sizes means that most of these populations will not suffer high levels of inbreeding depression. However, they are vulnerable to extinction as a result of demographic accidents. In the tropical islands of the Pacific, extinction has been much higher than on the islands of the North Atlantic, where ranges are much broader. Species with naturally small population sizes are similarly more vulnerable to habitat modification, simply because loss of even a small amount of habitat for a geographically restricted species could easily reduce numbers below sustainable levels.

Islands can also be highly climate-sensitive, and a major concern is that climate change will compress ranges further, leading to increased extinction rates of mountain species that have limited opportunities for migration: the high-elevation cloud forests that characterize many oceanic islands have a narrow geographical and climatological niche that may be eliminated with even a slight climatological change. Climate change may also effect declines in forests due to floods, droughts, or increased incidence of pests, pathogens, or fire. In addition, increases in the frequency or intensity of hurricanes may cause disturbance that favors invasive species. Sea level rise is also a concern for oceanic islands, resulting in coastal erosion and salt water intrusion into freshwater lenses. However, it is the low-lying islands and atolls that are the most vulnerable to these effects.

Invasive species

The isolation of islands has makes them more vulnerable to invasive species and other stresses, with extinctions attributed to alien species invasion having been noted in several archipelagoes. However, alien species in the Hawaiian Islands, perhaps because it is the most remote archipelago, appear to have taken a much greater toll on the native biota. The numbers now estimated for animals purposely or accidentally introduced into Hawai’i and established are 3046 arthropods, 20 reptiles, 46 land birds, 19 mammals, and 927 plants. Multiple parameters may interact to dictate invasion success. The most important of these are (i) species diversity itself, which can serve as an ecological barrier to invasion – this effect has been used to explain the higher frequency and impact of invasions on islands; (ii) disturbance, and the opening of ecological space; (iii) propagule pressure, in particular the relative abundance of native versus non-native propagules; (iv) characteristics of propagules (more generalist in habitat requirements); and (v) novelty of perturbations and the “naivety” of native biota.

It is widely known that the worst kind of introduction to an isolated archipelago is that of a generalist predator or competitor capable of exploiting a broad array of habitats and causing secondary impacts. This can sometimes result in an effect known as “invasional meltdown.” For example, the crazy ant Anoplolepis gracilipes has
invaded Christmas Island, resulting in a complete modification of the ecosystem in just two years.

Devastating introductions of generalist predators or competitors such as pigs and goats mostly happened before protocols were established to mitigate the introduction of non-native species. However, abundant, small human commensals, such as ants and mosquitoes, are continually expanding their range to oceanic islands.

Conclusion

Islands have long provided intriguing insights into almost every aspect of biogeography, and indeed have spawned foundational understanding of ecological and evolutionary principles. The current rapid change affecting these systems is of immediate relevance, alerting us to the need to develop a more complete understanding of the biodiversity within these systems, to make use of the opportunity for understanding the shifting dynamic, and, most critically, to explore ways of mitigating impacts and potentially restoring ecosystems before they go beyond a state from which they will no longer be able to return.

Description and purpose

Ha’Aguda Ha’Geographit Ha’Yisraelit (IGA) is the professional association for Israeli geographers. Members of the association deal with all areas of human and physical geography. The association has been operating since 1961 and its aims are as follows: to promote knowledge and research of geography in Israel, to increase awareness of the theoretic and practical achievements of geography in Israel, and to present these achievements to geographic organizations and bodies. The IGA aims to promote its activities through knowledge and research of geography; in addition, it strives to further the professional position of geographers and to increase public awareness of their professional contributions, to promote the study of geography in Israel, to strengthen the connections and exchange of knowledge between organizations that deal with geography, and to increase cooperation between geographic departments at universities in Israel and around the world. In addition, members of the organization present Israeli geography in international forums.

Journals or major publication series

Ofakim Be’Geographia (Horizons in Geography)
HaReshet Ha’Geographit (Geographic Network)

Current activities or projects

The IGA conducts professional seminars throughout the year which promote the discussion and study of theoretical issues regarding geographic space and the factors that affect it. The association holds an annual conference that is attended by geographers from across Israel and around the world. The conference is held at a different university every year and includes the conferring of awards for distinct contributions to geography and geographic education. The IGA also oversees two geographic journals and maintains a website and mailing list.

Brief history

The association was founded in 1961. Its first president was Professor David Amiran, who later received the Israel Prize for his contribution to research in Israeli geography.

Submitted by Oren Ackermann
Description and purpose

The AGeI aims to stimulate, promote, and coordinate geographical research, initiatives for the training of geographers, and for the reproduction of a culture of the territory in Italy. Its members are geographers who work or have worked in Italian universities.

The association achieves these goals through its journal *Geotema* and the organization of the Italian Geographical Congress, the Days of Geography, and the Interuniversity Geographical Excursion. The AGeI coordinates 16 national research groups and seven commissions and is a member of the Association of Geographical Societies in Europe (EUGEO).

Journals or major publication series

*Geotema.* www.associazionegeografitaliani.it/geotema.html

Current activities or projects

The AGeI sets research programs and promotes 16 research groups in collaboration with national and international institutions, coordinates Italian participation in the International Geographical Congress, supports the action of the other national associations engaged in spreading the culture of the territory, sustains the activities of the Italian professional geographers and the work of young researchers also through research grants and awards, improves the conditions of teaching geography in schools at all levels with special focus on universities, and publishes the directory of Italian geographers and the Italian Department of Geography.

Brief history

In 1978, under the leadership of the first President Giacomo Cora Pellegrini and faced with the growing need for skills and geographical knowledge, the association of the Italian academic geographers (AGeI) was founded in Rome. One of its first initiatives was the organization of the congress Geographic Research in Italy 1960–1980, a critical analysis of the contribution of Italian geographers in research.

The AGeI replaces the CoGeI which included only full professors in its membership. The new association fostered the spread of innovative theories and methodologies in Italian geography. Previous presidents of the AGeI included Adalberto Vallega, Berardo Cori, Marcello Zunica Luciano Lago, Alberto Di Blasi, and current president Franco Farinelli.

Italy: Società di Studi Geografici (Society for Geographical Studies)

Founded: 1895
Location of headquarters: Florence
Website: www.societastudigeografici.it
Membership: 500 (as of 2014)
President: Lidia Scarpelli
Contact: info@societastudigeografici.it

Description and purpose

The main aim of the Società di Studi Geografici is the promotion and support of initiatives which will serve the progress and spread of the geographical disciplines. To this end the society publishes Rivista Geografica Italiana (Italian Geographical Review) and Memorie Geografiche (Geographical Memoirs), organizes study meetings, and participates in national and international research programs. Most members are university lecturers and school teachers.

Journals or major publication series

Rivista Geografica Italiana (Italian Geographical Review). www.rivistageograficaitaliana.it
Memorie Geografiche (Geographical Memoirs) – 1907 to 1919, 1995 to present. www.societastudigeografici.it/italiano/pubblicazioni.html

Current activities or projects

The society organizes and participates in a range of meetings, seminars, and conferences in Italy and beyond. The society publishes Rivista Geografica Italiana (Italian Geographical Review) and Memorie Geografiche (Geographical Memoirs). The society has a library with more than 20,000 books, over 500 scientific reviews, and a rich selection of maps.

Brief history

The society’s origins go back to the establishment of the Florentine section of the Italian Africa Society in 1884 which encouraged research in regions of Africa, such as Ethiopia where a peaceful settlement movement was underway, subsequently transformed into military conquest. From 1885 to 1895 the Florentine section of the Italian Africa Society published a bulletin (Bullettino della Sezione Fiorentina della Società Africana d’Italia) dealing with questions regarding Africa, its geographical description, and the civil, political, and economic activities that Italy was called upon to carry out there.

The organization became the Società di Studi Geografici e Coloniali (Society for Geographical and Colonial Studies) in 1895 and the bulletin was replaced by the Rivista Geografica Italiana (Italian Geographical Review). The association’s name was changed to the Società di Studi Geografici (Society for Geographical Studies) in 1936. Between 1907 and 1919 the society published a series of extempore studies known as Memorie Geografiche (Geographical Memoirs). A new series started in 1995.

Italy: Società Geografica Italiana (Italian Geographical Society)

Founded: 12 May 1867  
Location of headquarters: Rome  
Website: www.societageografica.it  
Membership: 924 (as of 2014)  
President: Sergio Conti  
Contact: segreteria@societageografica.it

Description and purpose

The society is a nonprofit organization, protected and supervised by the state, whose fundamental purpose is the advancement of science and geographical knowledge. To this end, the Società Geografica Italiana promotes and favors the progress of geographical studies with particular focus on knowledge of the territory, scenery, and environment and the safeguard of cultural, environmental, and scenic heritage. Moreover, it promotes the advancement of geographic culture in Italy, initiating public meetings, conferences, excursions, educational trips, films, conventions, roundtables, and so forth.

Journals or major publication series

The society's house organ is the *Bollettino della Società Geografica Italiana*, the oldest Italian geographic periodical, published every three months since 1868.

In recent years, it has been issuing an annual report, *Rapporto annuale della Società Geografica Italiana*, which is an important event aimed at a wide and qualified spreading of geographic culture. The 2003 edition focused on migration; the 2004 edition on transport in Italy; the 2005 edition on relations between Italy and the Mediterranean region with an in-depth view of environmental, economic, and political topics; the 2007 edition on tourism, cultural tourism in particular; the 2008 edition on cities; the 2009 edition on landscapes; the 2010 edition on the "northern question"; the 2011 edition on the "southern question." The annual report is always presented to the Italian parliament.

The book *Riflessi Italiani* (Italian reflections), published for the 2004 International Congress of the International Geographical Union of Glasgow, has so far been published in three languages.

Other publications: *Memorie della Società Geografica Italiana*, *Ricerche e studi della Società Geografica Italiana*, and *Geo Italy*.

Current activities or projects

In 2007, to celebrate its 140th anniversary, the Società Geografica Italiana organized the opening edition of *Esplorazioni*, a film series on travel. The events in 2008 included an exhibition on Chinese items (February–May), in particular of the Miao minority group, hosted in the Rome venue of the Museum of Oriental Arts, owned by the society.

Several events were held in 2009, for example, the Travel Literature Festival, and many other initiatives in line with the focus of the association. In 2010, the events included the third annual event of the Travel Literature Festival and the fifth forum on geographical books about the Piedmont region. In 2011, the events were focused on the celebration of the 150th year of the Constitution of the Unification of Italy through displays, conferences, and shows. The fourth annual event of the Travel Literature Festival was dedicated to the theme of Italy and the
Italian travelers to foreign countries, while the sixth forum on geographical books was about the Latium region. In 2012, the fifth annual event of the Travel Literature Festival covered several countries, among which Afghanistan and Jordan, and the seventh forum on geographical books covered Tuscany. In 2013, the sixth annual event of the Travel Literature Festival covered the Americas, having as hosting countries Brazil and United States.

Activities have increased with five events held every month, while about 12 volumes are published annually.

**Brief history**

The society promotes and supports all studies aimed particularly at knowledge of the national territory and all other regions on Earth. The society maintains a highly specialized library, making it the most important in Italy and among the most prominent in Europe. At the moment it houses over 400,000 books, which include various ancient texts and numerous valuable printed works. The map collection is of considerable historic and scientific value and equally impressive. A complete reordering and computerized filing of all maps have recently been undertaken. Among the most valuable maps is the famous nautical map of the Genoese school, drawn up by Albino de Canepa in 1480.

The society’s archive, which contains original documents of considerable importance, also has an important photographic collection, which has recently been reorganized and currently numbers some 120,000 photographs divided into two sections, namely historic and contemporary.

Definition and terminology

According to the classification scheme of the United Nations Educational, Scientific and Cultural Organization (UNESCO), an ice cap is a dome-shaped ice mass with radial flow (UNESCO 1970). It covers the surface topography completely and is smaller than 50,000 km². In particular, an ice cap has to be distinguished from the much larger ice sheets in Greenland and Antarctica (ice masses of continental size) and so-called ice fields that might have a similar shape and size but neither show radial flow nor obscure surface topography completely (i.e., their (lateral) extent is limited by topography). Unfortunately, in nature we find a continuous transition between ice caps and ice fields, making a clear assignment sometimes difficult (Figure 1). Moreover, both types can have outlet glaciers that might not have a clearly defined accumulation area but are confined in their lower parts by surface topography (e.g., glaciers of the Southern Patagonian Icefield).

On a more semantic level, the terminology is confused with popular terms such as “polar ice caps,” which generally refers to the two ice sheets but sometimes also includes arctic sea ice cover and excludes the Greenland ice sheet. In this regard, the use of the term “glaciers and ice caps” for the related essential climate variable (ECV) by the Global Climate Observing System (GCOS 2003) to distinguish these ice masses from the two ice sheets caused confusion for those not familiar with the UNESCO classification and will be changed.

Ultimately, ice sheets also originate from compressed snow (i.e., consist of glacier ice), have outlet glaciers, and are surrounded by so-called local or peripheral glaciers and ice caps (GIC), which might merge with the ice sheet (in the accumulation region) or its outlet glaciers (in the ablation region) to a variable degree (Figure 2). As a consequence, the recently compiled inventory for all local GIC on Greenland (Rastner et al. 2012) introduced three different connectivity levels with the ice sheet (CL0: none, CL1: weak, and CL2: strong) to be used by the community for reference (e.g., to avoid double counting of calculated mass changes). Such a separation is not yet in place for the GIC in Antarctica (in particular those located on the Antarctic Peninsula) and the last Intergovernmental Panel on Climate Change (IPCC) report (Vaughan et al. 2013) only considered the completely disconnected ice masses on the surrounding islands (Bliss, Hock, and Cogley 2013). In order to avoid the confusion in terminology mentioned above, the most recent IPCC...
ICE CAPS

Figure 1  This satellite image shows an ice cap (cold ice) on Ellesmere Island (Canada) with a complex shape and several outlet glaciers. While the ice dome on the right is rather well defined, in the left part some topography is visible constraining the extent of the ice flow. The ASTER (Advanced Spaceborne Thermal Emission and Reflection Radiometer) sensor acquired the false color infrared image on July 29, 2000. Vegetation is red, bare terrain is brown, ice is grey, snow is white, water is dark blue, and water-saturated snow (slush zone) is light blue; the image extent is 40.4 by 27.4 km. National Aeronautics and Space Administration.

Figure 2  The Greenland ice sheet (in the background) with some of its outlet glaciers and various local ice caps of differing complexity that are connected to the ice sheet to a variable degree (the large ice cap in the foreground is not connected). Photo taken by the author on July 9, 2012.

assessment report (AR5) only distinguishes between glaciers (including ice caps, ice fields, and other glacier types) and the two ice sheets (Greenland and Antarctica). As ice caps are not yet indexed consistently in the global glacier inventory, they have not been counted and their global distribution cannot be shown on a map.
Forms and shapes

Ice caps can have nearly any form and size, from circular (Figure 3a) to completely irregular (Figure 3b), with sizes ranging between 0.01 and about 20,000 km². Thereby, the required radial flow sometimes allows discrimination of distinct ice domes that strictly speaking are individual ice caps despite merging. A well-known ice cap with at least three major separate domes is the Jostedalsbreen Ice Cap in southern Norway (Figure 3b). While most ice caps are rather flat, pancake-shaped ice masses with limited variability in surface slope, a considerable number also have distinct outlet glaciers that can be rather steep. In this case, the flat area of the ice cap provides a comparably huge accumulation area for the emerging outlet glaciers. Ice caps covering volcanoes are somewhat different in this regard, as the central dome-shaped part is often small (only filling a central crater) and the outlet glaciers covering the flanks of the volcano have their own accumulation areas (Figure 4). According to the UNESCO classification, small ice aprons and corniche-type structures can also be listed here as they might exhibit radial flow (with a nonflowing central part). Compared to the other shapes, they have generally steep surface slopes and might even exhibit calving ice cliffs. For the purpose of this overview, the above shapes are assigned the letters A (only flat, no outlet glaciers, circular shape), B (flat with steep outlet glaciers, irregular shape), C (covering volcanoes), and D (ice aprons).

At least one of the above four ice cap shapes can be found in all glacierized regions. While type D is present in all mountain ranges, types A and B are found in Arctic Canada (e.g., Devon, Barnes, and Penny ice caps), Greenland (e.g., Sukertoppen, Flade Isblink), Iceland (e.g., Vatnajökull), Svalbard (e.g., Austfonna and Vestfonna), the Russian Arctic (e.g., Novaya and Severnaja Zemlja, Franz Josef Land), the Tibetan Plateau (e.g., Purogangri), the tropical Andes (e.g., Quelcaya), Southern Patagonia (e.g., Gran Campo Nevado), and several sub-Antarctic (e.g., Kerguelen, Bouvet Island) and Antarctic islands (e.g., King George and James Ross islands). The volcano type C is common in the Rocky Mountains of North America (e.g., Cascade Range) and the Andes in South America, but can also be found in Iceland (e.g., Vatnajökull), New Zealand (e.g., Ruapehu), the Caucasus (e.g., Mt Elbrus), and on top of Kilimanjaro in Africa. The wide range of geographic locations also has an impact on thermal conditions of the ice. As for glaciers, ice caps in the high Arctic or at very high locations are cold (e.g., Flade Isblink, Devon, Colle Gnifetti Saddle), while at lower elevations or latitudes the ice could also be polythermal (e.g., Quelcaya) or temperate (e.g., Vatnajökull).

The example images shown in Figures 1 to 5 illustrate the above points and the various shape types. While the ice cap in Figure 3a (located southwest of Tsast Ula in Mongolia) shows a simple type A shape clearly revealing the radial flow pattern, the example from Liverpool Land (eastern Greenland) in Figure 5a also shows the radial flow pattern but has at least one distinct outlet glacier with its extent constrained by topography (type B). The examples in Figures 3b (Jostedalsbreen in Norway) and 5b (on Baffin Island) have a much more complex shape with several ice domes and outlet glaciers but also some topography (rock outcrops) visible. Both images also show several smaller and sometimes less complex shaped ice caps of type A. Separating these ice caps into distinct hydrologic drainage divides (as required for a glacier inventory) is rather challenging and might not even be appropriate for type A ice caps. The volcano in Figure 4, Cotopaxi, is topped by a typical type C ice cap with several steep outlet glaciers covering...
Figure 3  (a) A small ice cap (approximate diameter is 2.4 km) located to the southwest of Tsast Ula in the Altai Mountains (Mongolia) that is largely snow free thus revealing its radial flow pattern. The image is a screenshot from Google Maps and was acquired by the Quickbird satellite on August 5, 2006; (b) The southern and central domes of the Jostedalsbreen Ice Cap (Norway) with its several outlet glaciers and surrounding smaller ice caps. The image is 36 by 39 km in size and was acquired by the Landsat TM sensor on September 16, 2006. United States Geological Survey.

the flanks of the volcano. Very common to all ice caps and their outlet glaciers is the missing debris cover on the surface due to the missing ice-free rock walls that would provide debris when located above the ice cap.

Climate sensitivity

Ice caps (types A and B) have some special characteristics in a climatic sense, making them particularly vulnerable to melting when temperatures increase. The problem is that they receive accumulation in the form of snow only due to the elevation of their highest area rather than from much higher rock walls extracting extra amounts of snow when it falls. As the elevation range of ice caps (type A) is small, temperatures that are only slightly higher can remove the entire snowpack from the previous winter (and maybe further firn layers from previous years). The decreased albedo causes increased absorption of solar radiation and thus stronger melt. The resulting enhanced mass loss causes a further elevation reduction of the entire ice cap. The two ice caps shown in Figures 3a and 5a are in this situation, as well as the smaller ice caps shown in Figures 1, 3b, and 5b. With the melting of their highest points, a reinforcement feedback starts, as temperatures at lower elevations are higher causing stronger melt in summer and a reduction of solid precipitation in winter. At the same time, direct radiation is also melting more ice due to the lower albedo of bare ice compared to snow. As long as a complete loss of snow cover only occurs occasionally, the ice cap might still recover and persist. But once the reinforcement feedback is in effect, the ice cap will inevitably disappear. On Baffin Island in arctic Canada such an acceleration of mass loss might have already started for some ice caps (Gardner et al. 2012). The larger ice caps in Figures 3b and 5b are still snow covered at their highest elevations, so they will be more stable in the long term.

A further point to consider is the ice thickness distribution (Figure 6). Ice caps (type A) are very flat over large parts of their area, resulting in comparably thick ice, while for the steep outlet glaciers (type B) thickness is much lower. These outlet glaciers are thus reacting very strongly and quickly to small changes in climate (Winkler, Elverhøy, and Nesje 2009). On the other hand, the much thicker ice found at the central and highest parts of an ice cap will result in a limited change of ice cap extent during meltdown over decades (e.g., Giesen and Oerlemans 2010). Accordingly, the major contribution of ice caps (and also ice fields) to global sea level rise will come later than that of large valley glaciers, where most of the volume is concentrated in the thick flat tongues at comparably low elevations (Linsbauer, Paul, and Haeberli 2012). However, in a case where the ice cap was resting in a closed overdeepening (i.e., limiting the possibility for
Figure 5  (a) A small ice cap (diameter up to 2.5 km) on Liverpool Land (East Greenland) with only a few remaining snow and firn patches (white), clearly revealing the radial flow pattern. The ice cap has several outlet glaciers differing in development. The image is a screenshot from Google Earth and was acquired by the Quickbird satellite on July 19, 2005. The Landsat ETM+ satellite image (path-row 21-20) was acquired on July 30, 2002, and covers an area of 35 by 25 km. United States Geological Survey.
Figure 6  A schematic diagram illustrating the general ice thickness distribution for different glacier types. Most of the ice volume (grey) is found where the surface (black) is flat, that is, in the accumulation region of ice caps (i.e., they are “top heavy”) and in the ablation region of valley glaciers (“bottom heavy”). Mountain glaciers are comparably thin.

meltwater to leave), the ice would quickly melt away in a surrounding water body.

Paleoclimate

The radial flow of ice caps results in a point within the ice cap that should not flow, either at the surface, or at the ground. This is to a large extent also valid for ice masses of type D or those located at topographic saddle points (Haeberli et al. 2004). Such locations are ideal for retrieving ice cores (with annual layers undisturbed by ice flow) that reveal the climatic history at that location, given that the ice is cold (i.e., the snow metamorphosis is dry and not disturbed by liquid water). Nearly independent of the ice cap size, the missing flow at these locations results in potentially very old basal ice that can be found here (much older than in the largest glaciers). Accordingly, ice cores have been drilled into ice caps all around the world revealing the climatic history in the respective regions over the past millennia from the isotopic analysis of enclosed gases and particles. The variability derived from the respective components allows us to see currently observed changes (in climate and glaciers) from a much longer perspective, that is, to confirm evidence that current changes are extreme and exceptional over a timescale of 1000+ years (e.g., Fisher et al. 2012; Thompson et al. 2006).

Regarding the limited basal movement of the ice for the central part of an ice cap, it has also to be mentioned that human artifacts or even entire bodies can be preserved more or less unchanged for thousands of years at these locations, opening up a possibility for archaeological studies (e.g., Grosjean et al. 2007). The Ötztal Iceman (“Ötzi”) is likely the most prominent and well-known example, revealing that current ice mass loss is unprecedented for >5000 years in this region of the Alps (Baroni and Orombelli 1996).

Hazards

In several regions of the world, ice caps cover still active volcanoes. In the case of an eruption, parts of the ice cover can melt and cause enormous flood waves. For the ice-clad stratovolcanoes in North and South America, the mixture of melt water with the loose clastic material covering the surface of such volcanoes often results in huge and devastating debris flows called lahars (a Javanes term). They can reach velocities of more than 100 km$^{-1}$ (depending on the slope of the volcano) and travel over distances of >100 km. Their generally high sediment load results in characteristics similar to liquid concrete. While the well-known eruption of the Mount St Helens volcano in the Cascade mountain range caused a lahar that devastated large regions surrounding it, the 1985 eruption of the volcano Nevado del Ruiz in Colombia created a lahar that destroyed the town of Armero causing an estimated 25,000 fatalities. That lahar, known as the deadliest lahar in history, created an awareness that had long been missing of this widespread problem in the Andes. It has to be noted that lahars can
also be created on volcanoes without an ice cap and long after an eruption, for example due to high amounts of rain. However, an ice-capped volcano has an increased hazard potential.

For ice-capped shield volcanoes (or basaltic domes), such as the Grimsvötn volcano located under the Vatnajökull ice cap in Iceland, the situation is very different, as the ice covering the crater is much thicker and surrounding steep slopes of the bedrock are missing. This results in a possible accumulation of huge amounts of water underneath the ice that may after some days create sufficient pressure to lift the ice and break out catastrophically. The related event is called a jökulhlaup (an Icelandic term) and is also well known for its devastating nature affecting large areas. As these events are to some extent predictable, safety measures can be taken and fatalities are limited. This is not the case, however, for the also englacial but much smaller water pockets that can form inside any glacier and break out suddenly, thus creating catastrophic debris flows, sometimes with many fatalities (e.g., Vincent et al. 2010). Ice caps can also be related to a further destructive type of water release, so-called glacier lake outburst floods (GLOFs), which are related to a sudden drainage of a proglacial or supraglacial lake. The use of the terms jökulhlaup and GLOF in the literature is often interchangeable.

Inventory

In principle, a glacier inventory provides information on water resources for distinct hydrologic catchments. This often requires a separation of an ice cap into different parts according to the ice flow directions on the glacier surface (i.e., along drainage divides). Though this is in general possible using a digital elevation model and watershed calculations, it is unwanted for some glaciological calculations that require consideration of the respective ice cap in one part, for example for volume estimates (Grinsted 2013). The situation gets more difficult for ice caps with visible topographic undulations (Figures 1 and 2) or those with distinct outlet glaciers (Figure 3b). In these cases, there should be a possibility to analyse them separately (i.e., have drainage divides applied). When an ice cap has only one clear outlet glacier that can be separated by drainage divides, the other parts of the ice cap should also be separated. This is also the rule that has been applied for the inventory of the local GIC on Greenland (Rastner et al. 2012). The number of glaciers in an inventory and their size distribution varies depending on the decision whether or not to separate ice caps (Racoviteanu et al. 2009; Winsvold, Andreassen, and Kienholz 2014).

Conclusions

Despite the fact that ice caps are only a morphologically different type of glacier, they have some specific characteristics deserving of an in-depth description. The consequences of their generally flat topography with radial flow are their high climate sensitivity, the rather different ice thickness distribution (top heavy), the possibility to extract ice cores at their flow center and find undisturbed human or natural artifacts revealing paleoclimatic and archaeological information, and their association with natural hazards when they cover active volcanoes. They are also special in a more methodological sense as they can be difficult to distinguish from other glacier types (such as ice fields), and the separation along drainage divides that is required for a glacier inventory is limiting glaciological applications (e.g., volume calculation and change assessment). They are thus not (yet) properly indexed in glacier inventories and we do not exactly know how many ice caps we have on Earth or what area they cover.

Ice sheets

Marie-Françoise André
Blaise Pascal University, France

Definition and genesis

Ice sheets are huge dome-shaped continental glaciers up to several kilometers thick and covering at least 50,000 km². They form in vast areas where winter snow accumulation exceeds summer snow melting: over thousands of years, the layers of snow pile up into thick masses of ice. The growth and decay cycle of ice sheets is forced by orbital variations of the Earth around the sun. Ice sheets grow as a response to climate cooling and the lowering of equilibrium line altitudes. When they form, ice sheets store massive quantities of water as solid inland ice, inducing sea level lowering and continental crust subsidence. Conversely, ice sheet decay is accompanied and followed by rapid sea level rise and more gradual continental uplift called postglacial isostatic rebound. Two main models of ice sheet formation have been proposed: (i) highland origin, in which ice sheets start to form as alpine glaciers in mountain areas and flow out to lower regions before thickening; and (ii) instant glacierization, in which extensive flat areas become snow accumulation zones as a result of cold conditions and continue to grow as a result of high albedo and positive feedback processes. These two models should be considered as more complementary than antagonistic because most ice sheets develop or have developed in vast and flat shield areas fringed with mountains.

Current and past ice sheets

The two current ice sheets, which contain more than 99% of the freshwater ice on Earth, are located in Greenland and Antarctica. The Greenland ice sheet, which formed 3 million years ago, is up to 3 km thick, covers 1.7 million km², and displays on its margins mountain peaks called nunataks and outlet glaciers called ice streams. The Antarctic ice sheet, which started to form 35 million years ago, is more than 4 km thick and covers 14 million km². It is fringed by floating ice shelves that break into giant flat icebergs (e.g., the 11,000 km² B-15 iceberg which broke away from the Ross Ice Shelf in 2000). The Antarctic ice sheet is divided by the Transantarctic Mountains into two unequal sections: the East Antarctic Ice Sheet (EAIS) rests on a major landmass, retains 85% of the ice volume, and reaches almost 5 km in thickness; the West Antarctic Ice Sheet (WAIS) retains 15% of the Antarctic ice volume, is thinner (1–2 km), and is partly marine-based because it rests on an archipelago. During the Last Glacial Maximum (20,000 years ago), two additional ice masses existed: the Laurentide Ice Sheet which covered most of Canada and the northern part of the United States, and the Fennoscandian Ice Sheet which covered much of Europe from Scandinavia to the British Islands and the Germano-Polish Plain. At that time, ice sheets contained more than twice as much ice as the present ice sheets and sea level had dropped by 120 m.
Ice sheet motion and thermal regime

Ice sheets flow downhill and outward from their dome-like centers and much of ice flow terminates at the ocean as ice tongues or ice shelves. Ice sheet flow is a function of surface slope and ice thickness. In the central part of the ice sheets, where most of the glacier bed is subhorizontal, flow speeds are a few centimeters to a few meters per year, whereas along outlet ice streams, ice speeds can reach hundreds of meters or even kilometers per year. Comparison of landform patterns beneath the former Laurentide and Fennoscandian ice sheets to the flow organization beneath parts of the contemporary Antarctic ice sheet by Kleman and Glasser (2007) indicates a complex thermal regime of ice sheets associating frozen-bed patches, ice streams, and lateral shear zones. In some areas (e.g., near the ice divide in continental areas), frozen-bed zones are extensive, whereas in other areas they constitute isolated “islands” in regions dominated by thawed-bed conditions. Sharp lateral boundaries mark the location of shear zones between thawed-bed ice streams and intervening frozen-bed areas.

Ice sheet landforms

The classical zonation of ice sheet landforms identifies three landscape associations (Bennett and Glasser 2009): (i) interior tabular shield areas glacially scoured in a subdued “knob and basin” topography characterized by polished and striated roches moutonnées (e.g., the Ungava lowlands east of Hudson Bay); (ii) mountainous margins displaying glacial troughs and fjords dominated by alpine peaks and cirques (e.g., the Narvik region in Norway); and (iii) marginal southern plains with terminal moraines damming lakes (e.g., Lake Michigan). Beyond the sharp contrast between the glacial imprints of ice sheets in their inner and outer parts, the variations in space and time of the thermal regime of ice sheets have induced a complex landscape mosaic including widespread remnants of preglacial topographies and weathering mantles preserved during the Quaternary glaciations below cold-based ice. Low sedimentation rates inferred from the off-shore record indicate an overall limited erosional impact of ice sheets except in their mountainous margins where fast-flowing thawed-bed ice streams operate.

Ice sheet climate record

Ice sheets contain a unique record of Earth’s climate history, which is provided by the air bubbles trapped in the ice layers accumulated over thousands of years. Pioneer ice-coring operations were carried out by the Americans in the 1960s at Camp Century and Byrd stations in Greenland and Antarctica, respectively, and this allowed them to reconstruct the climate history for the last 80,000 years. In the 1980s and 1990s, the French–Russian Vostok ice cores provided a 420,000-year record of past temperatures and atmospheric carbon dioxide (CO$_2$). To date, the longest climate record is held by the European Project for Ice Coring in Antarctica (EPICA) team, which in the 2000s extracted an ice core from the Dome C area in East Antarctica. This 3300-meter-long ice core provides information on the natural climate variations over the last 800,000 years. It also confirms that the current level of atmospheric CO$_2$ is unprecedented and should therefore be partly attributed to human emissions (EPICA Community Members 2004). In the Arctic, the international North Greenland Ice Core Project (NorthGRIP) operation provided, in the 2000s, a high-resolution ice core covering the last 123,000 years.
Ice sheet mass balance

As complete melting of the Greenland and Antarctic ice sheets has the potential to raise the sea level dramatically, scientists try and measure the ice sheet mass balance, that is, the difference between ice gains and losses (Shepherd et al. 2012). These estimates are based on two approaches: (i) the component approach, which compares mass input by snowfall and mass output by meltwater runoff and iceberg calving; and (ii) the integrated approach, which measures changes in the surface height (hence volume) or gravitational attraction (hence mass) of the ice sheets using instruments mounted in satellites, including radar and laser altimeters and high-precision gravity-measuring systems (Rémy and Parouty 2009). Mass balance estimates for Greenland show thickening at high elevations, but this mass gain by winter snow accumulation is far exceeded by losses due to increased melting and iceberg discharge from fast-moving outlet glaciers (up to 14 km per year). Dynamic thinning (ice loss resulting from accelerated glacier flow) now reaches all latitudes in Greenland, and the mass balance of the whole ice sheet is clearly negative, resulting in a current contribution to a sea level rise of about 0.20 mm per year. In Antarctica, dynamic thinning has intensified at key areas of West Antarctica such as the Amundsen Sea sector, with special reference to the Pine Island Glacier (Flament and Rémy 2012). Recent breakups of the Larsen, Wordie, and Wilkins ice shelves in the Antarctic peninsula have also induced important ice losses. But, as most of the EAIS is gaining mass slightly as a result of increased winter snowfall, the mass balance might be close to 0, inducing a negligible sea level rise.

Projections and uncertainties

According to pessimistic mass balance estimations and emission scenarios, some models suggest that accelerated ice loss from Greenland and West Antarctica will continue and cause sea level rises of 12 cm and 5 cm respectively by 2100. But predictions are uncertain because of high natural variability that occurs on a range of timescales. Separating long-term trends from the effects of this variability requires observation over long time periods. Another open question deals with the significance of the current accelerated ice flow of outlet glaciers on the ice sheet margins (Figure 1): are they indicators of destabilization or normal modes of the dynamic readjustment of ice sheets? In any case, the improved knowledge of the subglacial thermal organization of ice sheets indicates that widespread frozen-bed

Figure 1  Map of ice velocities (m per year) derived from satellite radar altimetry data showing the numerous ice streams draining the Antarctic ice sheet. © Frédérique Rémy (Rémy and Parouty 2009, 1226, fig. 8).
patches contribute to the stability of ice sheets by laterally constraining and isolating peripheral drainage basins and their ice streams (Kleman and Glasser 2007). In Antarctica, if the future of the WAIS is uncertain, the long-term view indicates an overall stability of the EAIS, which is the main ice mass on Earth.

**Controversy over the long-term stability of the East Antarctic Ice Sheet**

The interpretation of the sediment marine record had long promoted the view of a stable Antarctic climate and ice sheet over the last 14 million years, but the discovery of puzzling deposits in the Transantarctic Mountains challenged this view and triggered a 10-year-long controversy (Sugden 1996). The Sirius till deposits contained fossil wood, indicating a glacial advance into a temperate forest, and marine diatoms entrained by glaciers from seabed dating back to the Pliocene warm period. It was inferred from this finding that the EAIS had experienced massive deglaciation and caused dramatic sea level rise 3 million years ago. This deglaciation hypothesis was contradicted by the preservation of fragile Miocene deposits on 30° slopes in the Dry Valleys area, which indicate that the landscape had been unmodified for the last 14 million years. But geomorphological evidence was not considered at that time and, as the instability theory had major implications for the potential risk of future ice sheet collapse in the context of global warming, it achieved some success until diatoms were found in cracks and surface layers at various places in Antarctica including the South Pole. It meant that the diatoms had been airborne instead of glacially entrained from the seabed and that the Pliocene dating of the Sirius deposits was wrong, which ruled out the hypothesis of a Pliocene collapse of the Antarctic ice sheet. The addition of geomorphological evidence, the marine sediment record, and glaciological modeling strongly supports the hypothesis of the 14-million-year stability of the EAIS, the main ice mass on Earth.

**The marine ice sheet instability hypothesis and the threat of collapse of the West Antarctic Ice Sheet**

The WAIS is the world’s most vulnerable ice sheet. This is because it is marine-based, and therefore prone to rapid melting due to the upwelling of warm, deep ocean water along the coast of Antarctica. This warm water has increased the melting of floating ice shelves at the edge of the WAIS. Ice streams draining the WAIS into the Amundsen Sea, which have a grounding line on a reverse bed slope (becoming deeper inland), have started to thin and accelerate. The marine ice sheet instability hypothesis is that atmospheric and oceanic warming could result in increased melting and recession at the grounding line on such a reverse slope gradient. This would activate flotation, basal melting, increased iceberg production, and further retreat within a positive feedback loop. Ultimately, it could result in the massive collapse of the WAIS, triggering rapid sea level rise. If the ice shelves that fringe the WAIS are known to have a stabilizing or buttressing effect on the ice sheet, the recent speedup of their outlets is spreading far inland, which is considered by some scientists as the start of marine ice sheet instability. Some numerical models suggest that a full-scale collapse of this sector of the WAIS may be inevitable, but leave a large uncertainty in the timing.

Ice shelf buttressing

Daniel N. Goldberg
University of Edinburgh, UK

The Antarctic and Greenland ice sheets are the most massive bodies of ice in the world, containing about 30 million and 3 million km$^3$ of ice, respectively. Input of mass to the ice sheets is exclusively through snowfall on the surface densifying into glacial ice. Mass is lost through melting, either at the surface or at the base of the sheets, and through icebergs calving off the margins of the ice sheets into the ocean. The two ice sheets differ greatly in the importance of these outputs, however: in Greenland, surface melting is quite important and a large part of the ice sheet margin is land-terminating. In Antarctica, surface melting is negligible and ice flows into the ocean around its entire perimeter. These inputs and outputs control the volume of ice in the sheets, a quantity of great societal importance because it affects global sea levels.

In Antarctica, snow accumulation has increased in recent decades, possibly due to warming air masses. Loss of ice by flow across the ice sheet margin, however, is poorly characterized and its future behavior is almost completely unknown. Around most of Antarctica, the ice sheet goes afloat in the form of large ice shelves, which vary in area from the size of Greater London to roughly that of France. Since the ice shelves are in hydrostatic balance with the ocean, their direct sea level contribution would be negligible were they to melt entirely. On the other hand, the indirect effect of such an occurrence would have far-reaching effects, and in some cases could threaten the stability of large parts of the Antarctic ice sheet. This is due to “ice shelf buttressing,” the term used to describe the resistive forces imparted to the ice sheet by its ice shelves.

Physical setting and theory

The transport of ice toward the ocean is not uniform around the continental margin; rather, it is concentrated in relatively narrow, fast-flowing ice streams. These ice streams empty into ice shelves, and the point at which the ice goes afloat is called the grounding line. The position of the grounding line is determined by a floatation condition: the weight of the ice column must equal the weight of the water column it displaces. In other words,

$$\rho g H = \rho_w g D$$

where $\rho$ and $\rho_w$ are average ice and ocean densities, respectively, $H$ is the ice thickness (distance from top to bottom), and $D$ is the bedrock depth. Thus the grounding line is dynamic; if ice thickness changes, the grounding line will adjust to a position where equation 1 is satisfied. As ice shelves do not contribute to sea level, any changes in grounding line position, or in the flux of ice across the grounding line, translate to sea level change.

To appreciate the role that ice shelves play in grounding line position and ice flux, one should first examine the dynamics of a grounding line with no ice shelf attached, that is, where there is simply an ice cliff at the grounding line, and all ice that crosses it calves off instantly as icebergs (Figure 1). In this case there is an imbalance between the pressure within the ice and the
ocean pressure along the ice face, and this results in a tensile stress acting at the grounding line in the seaward direction, pulling the ice forward. Averaged over the depth of the ice sheet this equals

\[ \sigma = \frac{1}{4} \Delta \rho g D \]  

(2)

where \( \Delta \rho = (\rho - \rho_w) \). (Note: some sources quote a \( \frac{1}{2} \) factor on the right-hand side; this is because they are discussing membrane stress, which in this context is twice the tensile stress.) This tensile stress induces a flow of ice across the grounding line; however, the relationship between equation 2 and ice velocity depends on a number of factors. Weertman (1974) derived an approximate relationship between the two, and deduced the result that ice flux across the grounding line increases quite strongly with depth. More recently, Schoof (2007) derived the analytical result that ice volumetric flux per unit width is proportional to \( \sigma^\alpha D^\beta \), where \( \alpha \) varies from approximately 1.5 to 2.25 and \( \beta \) from approximately 2 to 2.5, depending on the nature of the ice-bed interface.

That ice flux increases with grounding line depth has far-reaching implications for ice sheet behavior and stability. A large sector of Antarctica, the West Antarctic Ice Sheet, is a marine ice sheet: it rests on a bed that is far below sea level, in part due to the weight of the ice and in part due to millennia of erosion. Moreover, it is deeper, on average, toward the center than at the margins. For such an ice sheet to be in steady state, input from snow accumulation, which is roughly

---

ICE SHELF BUTTRESSING

proportional to its area, needs to be balanced by the flux of its ice streams across its grounding line. If stress and flux are related as described above, such an ice sheet cannot be stable.

To see this, consider a small inland retreat of part of its grounding line: this decreases the input to the sheet by decreasing its surface area. At the same time, the grounding line has retreated onto a deeper bed, increasing the flux. Thus, in this new configuration, less ice is delivered to the grounding line than moves across it, and ice thins at, and upstream of, the grounding line. Since total accumulation input has decreased, this imbalance will not correct itself; rather, ice at the grounding line will go afloat and subsequently calve into icebergs or melt. Similarly, a small advance of the grounding line would result in unchecked advance to the edge of the continental shelf. This instability is often referred to as marine ice sheet instability (MISI) (Mercer 1978). The instability has significant implications: if the entire West Antarctic Ice Sheet were to collapse, sea level would rise by 3–5 m globally.

An important point to make is that the above arguments hold not only for a grounding line with no ice shelf, but also for a grounding line with an ice shelf that is completely unconfined, that is, it does not exist in an embayment and there are no points of contact between the ice and the ocean bottom. However, such is rarely the case for Antarctic ice shelves. Most ice shelves are embayed, flanked by slow-moving grounded ice that limits the oceanward flow of the ice shelves; and the larger ice shelves – the Ross Ice Shelf and the Filchner-Ronne Ice Shelf – are pinned at large ice rises in their interior. These embayment walls and ice rises exert a resistive force on the ice shelf, which is carried through the ice shelf and exerted on the grounding line, lowering the tensile stress relative to equation 1, and in turn decreasing ice velocity relative to the unconfined case.

This ability of ice shelves to exert resistive force and decrease velocity of outlet streams is commonly known as buttressing: the ice shelf buttresses against the tendency of ice to flow under its own weight. Strictly speaking, the force is not originating from the ice shelf itself; the ice shelf is simply allowing forces along different parts of the grounding line to be felt nonlocally. If a part of the grounding line, for example a ridge along the side of the shelf, experiences strong friction at its base, the ice shelf allows this frictional force to slow other parts of the grounding line, such as the outlet of a fast-moving ice stream. In the following, different types of buttressing will be examined.

Buttressing by rigid sidewalls

Consider an ice shelf in a rectangular channel of width $W$ and length $L$; at one end ($x = 0$), an ice stream flows into the shelf; and the other end ($x = L$) is open to the ocean. On either side, the ice is slow-moving, and at every point along these rigid sidewalls a shear stress $\tau$ resists flow in the ice shelf. It can be shown (Thomas 1973) that the tensile stress felt at the grounding line at $x = 0$ is lessened by $F$, where $F$ is the total amount of force arising from this stress. If $\tau$ is assumed uniform, then tensile stress at $x = 0$ is given by

$$\sigma = \frac{1}{4} \Delta \rho g D - \tau \left( \frac{H_r}{H} \right) \left( \frac{L}{W} \right)$$  \hspace{1cm} (3)$$

where $H_r$ is a representative ice shelf thickness (in general smaller than $H$; see Figure 2). Let us consider how this might change grounding line velocity. If we consider a value of 750 m for $D$, and $10^5$ Pa for $\tau$, then $\sigma$ will decrease by a factor of approximately
ICE SHELF BUTTRESSING

![Diagram of ice shelf buttressing](image)

Figure 2 Two simplified cases of an unconfined and buttressed grounding line: (top) an unconfined shelf with depth \( D \) at the grounding line; (bottom) a confined ice shelf. There is stress \( \tau \) along the sides of the ice shelf which effectively slows ice velocity.

\[
0.5 \times \left( \frac{L}{W} \right) \times \left( \frac{H_s}{H} \right) \tag{4}
\]

relative to its unconfined state. From the arguments of Schoof (2007), this can be translated to velocity change. For instance, if the unconfined grounding line velocity (the velocity if \( \tau \) is zero) is 1000 m per year, an ice shelf of aspect 1 \( (L/W \approx 1) \) and thickness \( H_s/H \approx 0.5 \) will reduce this speed to approximately 600–650 meters per year. A narrower, longer, or thicker ice shelf will reduce this speed even more.

It should be pointed out, though, that the above analysis is oversimplified: equilibrium ice shelf thickness would change with width and length. Additionally, \( \tau \) would not be constant, but would decrease as the shelf widens, and \( \sigma \) is unlikely to drop to zero. To truly determine the effect of buttressing, the differential equations governing stresses within the ice must be solved.

In general, though, the narrower, longer, and thicker an ice shelf, the more effective it will be at buttressing the flow of the ice stream that feeds it.

This has implications concerning MISO: if a grounding line retreats, the length of its attached ice shelf will increase, unless its calving front retreats at the same rate (which is unlikely because of the different physics determining the positions of the two). Thus, grounding line tensile stress could actually decrease as grounding line moves inland, even though the bed deepens, and the grounding line may stabilize. It should be pointed out that whether or not grounding line retreat is unstable depends on a number of factors, including the specific geometry and mechanical properties of the bed, and any factors influencing the ice shelf, such as crevassing and melting by ocean currents.

**Buttressing by ice rises and ice rumbles**

Theoretical studies suggest that a relatively narrow ice shelf is capable of reversing MISO, but a wide ice shelf is not. The Ross and Filchner-Ronne ice shelves are 700–800 km wide at their calving fronts, and it is unlikely that these ice shelves could effectively restrain ice stream flow through sidewall buttressing alone. However, these ice shelves come in contact with the ocean bed in several places in the form of massive ice rises – regions of grounded ice that are not connected to the main ice sheet. Ice flows away from the rise in all directions, as if it were an isolated ice cap or ice sheet, implying a strong (likely frozen) bed. Ice rises influence ice shelves in much the same way as slow-moving ice at ice shelf boundaries, and in
ICE SHELF BUTTRESSING

doing so effectively narrow a wide ice shelf. In Ross Ice Shelf, Roosevelt Island and Steershead and Crary ice rises are spaced more closely than the width of the overall ice shelf, and so the sides of the rises exert a stronger buttressing force on the Siple Coast ice streams than the side margins of the ice shelf could. Roosevelt Island may have had a strong influence on the location of the grounding line of MacAyeal Ice Stream since the Last Glacial Maximum. Similarly, it has been suggested that ungrounding of these ice rises may have had a dramatic impact on the flow of Whillans and Kamb ice streams; See Figure 3.

Ice rumples are isolated regions of grounding as well, but ice slides over the contact; the ice shelf flow slows but does not stagnate. In general, the surface elevation contrast between rumples and the surrounding shelf is less than that of ice rises. Ice rumples provide buttressing as well, by transmitting frictional force from the bed back to the grounding line. While the bed is weaker than under ice rises, ice rumples can be as important as ice rises in providing buttressing. There are several locations in which ice rumples are thought to provide ice stream stability, or have in the recent past. As recently as a few decades ago, Pine Island Ice Shelf, West Antarctica, was in contact with an undersea ridge; ungrounding of the shelf from this ridge is thought to have led to acceleration of Pine Island Glacier (Jenkins et al. 2010). On the other hand, the adjacent Thwaites Ice Shelf is in contact with a seamount at its base, and while this local grounding has a noticeable effect on the flow of the ice shelf, recent studies indicate it does not play a strong role in the stability of Thwaites Glacier.

Buttressing by unconfined ice shelves

A frequently made statement is that an unconfined ice shelf does not exert any buttressing force on ice flow at the grounding line. This is not completely true, however. Ice shelf buttressing refers to any transfer of force across distances due to the presence of an ice shelf. If a section of the grounding line overlies a stronger bed than the rest, this stronger bed effectively provides a restraining force to weaker-bedded parts of the grounding line; the strong-bedded section is essentially pulled forward by the weaker-bedded sections. If the ice shelf were to be removed, the latter would accelerate (and the former would decelerate somewhat). In general, buttressing by unconfined ice shelves is likely less important than that of sidewalls and ice rises, but it may be of importance to short, narrow ice tongues, such as those in Greenland fjords whose margins are too crevassed and broken up to provide any support.

Climate impacts on ice shelf buttressing

As in the simple example of sidewall buttressing, thinning of an ice shelf will limit its buttressing ability. However, the cause of thinning is important. If the shelf thins because it is “starved” by the ice sheet, it may be due to changes in the ice sheet interior, such as long-term changes in precipitation. But if the thinning is due to melting at its lower surface by heat from the ocean, the impacts on the ice sheet can be very important. As the ice shelf thins due to melting, buttressing is lost and velocities at the grounding line increase. The thinning of grounded ice propagates inland because the lowering of the ice surface increases the basal slope, which increases velocities. If the ice sheet bed deepens inland, extensive grounding line retreat occurs as well. The velocity increase results in more mass being fed to the shelf; but if the ocean contains sufficient heat to remove this ice, the ice shelf does not thicken and the retreat does not reverse itself.

This process is currently occurring on several ice shelves in Antarctica, most notably in those of the Amundsen Sea Embayment in West Antarctica. Almost all of the ice shelves around Antarctica are exposed to some degree of melting in their deepest parts, since ocean waters can be no colder than the surface melting point (about $-2^\circ$C) due to sea ice formation, and the melting point decreases with depth. However, due to deep underwater troughs in the Amundsen Sea, along with the fact that waters tend to be warmer at depth at high latitudes, these ice shelves are exposed to waters of 1.2°C or greater (Jenkins et al. 2010). Exposure to these warm waters results in large thinning rates; ice shelf thinning of 6–8 m per year has been inferred, which has caused extensive speedup and thinning of the Pine Island, Thwaites, and Smith glaciers (Shepherd, Wingham, and Rignot 2004). On Pine Island, thinning and speedup are seen hundreds of kilometers upstream from the ice shelf (Wingham, Wallis, and Shepherd 2009; See Figure 4). This thinning could have far-reaching implications: these ice streams (Pine Island, Thwaites, and Smith) drain a portion of the ice sheet that could raise global sea level by 1.3 m, and they rest on inland-deepening beds, making them unstable.

Ice loss due to melting ice shelves is not limited to the Southern Hemisphere. The floating tongue of Jakobshavn Isbrae, a fast-flowing outlet glacier in southwest Greenland, rapidly thinned and broke up when a shift in large-scale ocean circulation brought relatively warm waters from the Atlantic into its fjord. The loss of this small ice shelf led to a doubling of the glacier speed (Holland et al. 2008). Elsewhere in Greenland, marine-terminating glaciers without floating extensions can be exposed to high melt rates along their calving cliffs. It is important to realize, however, that this is different from ice shelf melting: in the latter case, grounded ice is

![Figure 4](image-url)
affected through the loss of buttressing; in the former, melting affects grounded ice directly.

Loss of buttressing due to melting has been observed to be a slow process, operating over years to decades. However, far more rapid collapse of ice shelves has been observed. In the past two decades, several ice shelves along the Antarctic Peninsula have “disintegrated”: seemingly intact, they are transformed into a mass of small icebergs in a matter of days and then drift away. The process is thought to be due to melting at the upper surface by solar radiation and heat from the atmosphere, as the Peninsula lies farther north than the rest of Antarctica. Extensive melt ponds form, seeping into surface crevasses; the crevasses then quickly deepen, wedged open by the weight of the water. The breakups may have been preconditioned through the removal (by iceberg calving) of parts of the ice shelves vital to their structural stability. At any rate, after the disintegration of one of the largest of these ice shelves, Larsen B, large speedups were observed on the ice streams that fed it, indicating that the Larsen B provided buttressing for these streams (Scambos et al. 2004; see Figure 5).

Finally, it should be stated that the mechanisms through which the ocean and atmosphere affect ice shelves are still poorly characterized. An improved understanding of the processes involved is necessary before the effects of climate change on the Antarctic and Greenland ice sheets can be assessed.

Ice shelves

Adrian Jenkins

British Antarctic Survey, Natural Environment Research Council, UK

Ice shelves are the parts of an ice sheet that are afloat in the ocean, forming at the marine margins where the ice is no longer thick enough to maintain contact with a bed that lies below sea level. Although floating, they remain an integral part of the ice sheet, providing a critical control on the outflow of ice from inland and hence on the size of the grounded ice sheet. Understanding the behavior of ice shelves, and in particular how they interact with the ocean waters that circulate beneath them, is a prerequisite for understanding how the transport of ocean heat toward the Earth’s great ice sheets controls their size.

Ice shelves range in scale from the simple extension of a single tidewater glacier, rarely more than approximately 10–100 km long and often not accorded a geographical name distinct from that of the parent glacier, to vast amalgamations of many tributary glaciers that can extend approximately 1000 km from the grounding line, where the ice goes afloat, to the ice front, and individually cover areas of up to $5 \times 10^5$ km$^2$. They are nourished by the flow of ice across the grounding line and surface and, less commonly, basal accumulation, while they lose mass by calving of icebergs from the seaward edge and basal and, less commonly, surface ablation. Their state of free flotation on a frictionless substrate lends them a distinctive stress regime, in which vertical shear stresses are almost entirely absent. The dominant longitudinal stresses drive horizontal spreading and vertical thinning of the ice. Since the rate of thinning is strongly dependent on the ice thickness itself, the process acts to smooth variations in ice thickness. The resultant near absence of surface topography and crevassing made the larger Antarctic ice shelves important highways to the interior of the ice sheet for the early explorers of the continent.

The vast majority of currently extant ice shelves are to be found in Antarctica, especially west Antarctica, where they almost completely surround the marine-based West Antarctic ice sheet. Antarctic ice shelves range in thickness from several hundred meters at the calving face to one to two kilometers, or even more in a few places, at the grounding line. Although they represent only a small percentage of the Antarctic Ice Sheet by area ($\approx$11%) or volume ($\approx$2.5%), their coastal location means that they receive around 20% of the overall accumulation directly and around 80% of the remainder indirectly as drainage from the grounded ice sheet. Thus the majority of mass input to Antarctica is returned to the oceans via the ice shelves, from where about 50% is lost by iceberg calving and about 50% by basal melting (Rignot et al. 2013). In contrast, only a few Greenland outlet glaciers retain a floating tongue, while the few small ice shelves that historically fringed some of the smaller ice caps of the Arctic have all disintegrated.

Systematic scientific studies of the Antarctic ice shelves began in the second half of the twentieth century. Initial efforts involved mapping of ice thickness and underlying seabed topography, with measurements of the former being revolutionized in the 1960s with the development of ice-penetrating radar techniques. In the 1970s the simple stress regime
of ice shelves was exploited as they became large-scale samples on which to test flow laws for ice in a natural setting, while in the late 1970s and early 1980s major international campaigns were initiated to study the vast Ross and Filchner-Ronne ice shelves. In the latter half of the twentieth century, interest in ice shelves waned somewhat, but was reinvigorated as developments in satellite remote sensing allowed continent-wide monitoring of ice extent, surface elevation, and ice flow. It soon became apparent that dynamical changes were taking place in both the Greenland and Antarctic ice sheets on timescales that could be observed. The most rapid changes were taking place on the ice shelves and floating glacier tongues, from where the signals extended inland to the outlet glaciers that were feeding them. This was a major stimulus for recent research work focusing on the ice shelves and how they interact with the atmosphere and especially the ocean circulating beneath them.

The loss of ice shelf cover along the Antarctic Peninsula has been one of the more dramatic indicators of recent climate change in the polar regions. Ice shelves appear to be subject to a strict climatic threshold, in that once surface temperatures are high enough for significant melt to occur in the summer, they are no longer viable. The lack of significant surface topography means that surface melt does not run off, but accumulates in minor depressions and surface fractures. When meltwater fills a crevasse, the pressure within the crevasse exceeds that in the surrounding ice and the fracture can penetrate the full depth of the ice shelf. Opening an access route to the ocean beneath allows the meltwater to drain, but full-depth fracturing of the ice shelf eventually leads to its disintegration. Warming of the Antarctic Peninsula has driven the climatic threshold southward, leading to progressive loss of ice shelves along both coasts.

Below the climatic threshold, ice shelves show little sensitivity to surface temperature. Although the viscosity of ice, and hence its flow rate in response to a given stress, is a function of temperature, snow and ice are poor conductors of heat, so that the core of an ice shelf remains cold even as the surface warms. Thus for most ice shelves, the primary control on the mass balance is set by the ocean. Although the polar oceans freeze at the surface during winter, at depth they remain above the freezing point year round, and the enormous specific heat capacity of water means that even a small temperature increment above freezing represents a substantial reservoir of thermal energy. Furthermore, the lowering of the freezing point with depth means that even water at the surface freezing point has the potential to melt ice at depth. Technically the process is one of dissolution, rather than melting, since, because of the presence of salt in the water, the phase change occurs at temperatures below the melting point of pure ice. Thermodynamically the process is equivalent to that by which ice can be cleared from roadways by spreading salt over the surface. The resultant heat loss from water that is already at the surface freezing point results in a distinctive water mass that would be supercooled at atmospheric pressure and remains liquid only because of the elevated pressure. When such a water mass rises back toward the sea surface, the reduction in pressure results in supercooling and freezing. Thus, melting of thick ice near the ice shelf grounding line tends to be partially offset by freezing beneath thinner ice nearer the ice front, and the net melt rates of the ice shelves floating in such cold waters are relatively low.

Although the surface waters are cooled to freezing by heat loss to the atmosphere, warmer waters are found at depth within the polar oceans, and where these can reach the ice shelves
the basal melting rates can be much higher. The warm waters have their origins in the subtropics, from where they take a relatively direct route to high northern latitudes. There the surface layer is cooled by the atmosphere, a process that makes the water more dense, but surface freshening, particularly at the coasts where runoff supplements precipitation, lowers the density and keeps the cold layer at the surface. Thus the floating ice tongues that extend into the Greenland fjords experience a two-layer water column, with a near-freezing layer typically around 200 m thick overlying a warmer, saltier layer with temperatures up to four or five degrees above freezing. Nowhere does it appear that the surface layer is thick enough to block the access of the warm water to the ice, even where the inflow of the deeper layer is partially impeded by seafloor sills. Many of the recent changes in Greenland’s floating ice tongues appear to be linked with changes in the quantity and temperature of this warm water layer in the fjords.

In the centers of the subpolar seas to the east and west of Greenland, freshening of the subtropical waters is insufficient to offset the impact of cooling, and denser water formed at the surface sinks to great depths to form new deep water, which is subsequently carried at depth to southern high latitudes where it feeds into the Antarctic Circumpolar Current. Core temperatures are typically around 1–2 °C where the deep waters approach the continent. As in the north, cooling and freshening at the surface produces an overlying layer of near-freezing water that is typically a few hundred meters or more thick near the coast. Coastal runoff is practically nonexistent around Antarctica, so the density difference between the cold surface layer and the underlying warm water is not large. Consequently, deepening of the surface layer isolates most of the ice shelves from the warm waters, reducing the basal melt rates. However, along the Pacific coast of west Antarctica the warm layer of deep water reaches to the coast and basal melting of the ice shelves is one to two orders of magnitude greater than elsewhere around the continent. The temperature of both the surface layer and the deep water is relatively constant and largely unaffected by contemporary atmospheric temperatures. However, winds affect the ocean circulation and control the relative thickness of the two layers. Thus, changes in wind forcing can change the amount of warm water beneath the ice shelves and have a profound impact on the basal mass balance. Thinning of the ice shelves in west Antarctica that has led to acceleration of outflow glaciers and thinning in the interior of the ice sheet appears to be linked to wind-forced changes in the delivery of warm water to the ice shelves.

When ice shelves change in thickness or extent, they affect sea level in two ways. The direct impact is commonly, although mistakenly, considered to be zero. Since ice shelves are freely floating, they do displace their own weight in seawater. However, once they have melted the equivalent volume of freshwater is greater than that of the displaced seawater, because it is lower in density. As the freshwater mixes with seawater the total volume is conserved, because the equation of state for seawater is approximately linear in salinity. There is thus a small steric rise in sea level, equal to about 2.7% of the ice volume, resulting from the net dilution of the ocean, that occurs when floating ice shelves melt. The indirect effect, whereby changes in ice shelf geometry influence the flow of inland ice into the ocean, is more significant because changes initiated by ice shelf thinning and retreat can propagate far into the interior of an ice sheet. Current thinning of some of Antarctica’s major drainage basins has been initiated by either
ICE SHELVES

ocean-driven thinning or atmospheric-driven breakup of the ice shelves. Similarly, some of the most rapid thinning rates seen in Greenland have been linked to the thinning and breakup of floating ice tongues.

Idealism

Alex Jeffrey
University of Cambridge, UK

The concept of idealism is open to multiple interpretations. In general terms, idealism refers to a broad range of philosophical positions within the social sciences that have sought to understand how human interpretation shapes understandings of reality. These approaches can be roughly organized into two philosophical stances: a form of metaphysical idealism, where reality is understood to be primarily in the mind, to forms of epistemological idealism, where understanding is limited to perception of external objects. In this framework, idealism stands as an antonym for either materialism (where matter is privileged as the primary concern) or realism (which assumes an external and independent world operating beyond human beliefs or ideals).

In its philosophical traditions, idealism orientates attention to the systems of interpretation and categorization through which an external world is apprehended and understood.

Such general characteristics of idealism are both reflected, but also somewhat reworked, in the adoption of the term within geographical scholarship. While geographers had focused on issues of perception for much of the twentieth century, most significantly through the work of Richard Hartshorne, the challenges to logical positivism in the 1970s brought refreshed interest in the philosophical and methodological possibilities of idealism. Theoretical perspectives such as humanism, phenomenology, existentialism, and feminism each sought in turn to better incorporate the experiential elements of being human into geographical scholarship. Where logical positivism had sought to accentuate the objectivity and distance of geographical scientists, these diverse perspectives emphasized embodied practices of experience, thought, and practice.

At first glance idealism fits within this postpositivist mindset, and certainly its early adopters in the 1970s saw idealism as a means of challenging the supposed objectivity of logical positivism. This desire is apparent in the work of Leonard Guelke, who was one of the first geographers to adopt a language of idealism, if not its full philosophical implications. For Guelke (1974, 193), idealism offered a means of illuminating how human geography should be “largely concerned with rational actions and products of human minds.” In his wide-ranging explanation (from witchcraft through to the voyage of Columbus), Guelke views idealism as a means of explaining the wide range of human actions in different geographical environments. For Guelke, actions cannot be unified within a single theory, but rather the rational decisions of individuals can be understood within the frameworks of interpretation and meaning in a given context.

Guelke’s account was also a critique of emerging humanist and Marxist theoretical positions within geography. Where such accounts had sought to construct wide-ranging theoretical explanations for geographical phenomena, advocates of idealism were more circumspect on the possibility of grand theoretical propositions. By foregrounding the decisions and reflections of the individual, Guelke sought to posit an “atheoretical” account, since the character of human thought “precludes the possibility of
human geographers developing general theory capable of meeting minimum criteria of scientific criteria” (Guelke and Chappell 1976, 168). Thus for a geographical idealist, and in contrast to more structured accounts of human practice, an action was explained when the thought behind it had been understood (Guelke 1974).

Taken together, these attributes suggest a more ambiguous position toward logical positivism, Marxist geography, or humanist forms of theorization. In the intervening years these ambiguities have prompted scholarly criticisms, focusing in four main areas. First, scholars have questioned the extent to which Guelke grounded his conception of idealism in the appropriate philosophical canon. Reflecting on the relationship between cognition and the material world has its roots as far back as the seventeenth-century meditations of René Descartes and has been a constant feature of political and philosophical writings since. Immanuel Kant, for example, espoused a form of transcendental idealism which posited the unknowability of the “thing in itself,” pointing to the epistemological limitation that an individual cannot step outside his or her own mind (Guelke and Chappell 1976). Rather than contextualizing the term in this long intellectual tradition, scholars criticized geographical idealism in the 1970s for failing to employ standard conceptions of the term and therefore limiting the possibilities of interdisciplinary debate regarding idealism.

Second, commentators have questioned the extent to which the geographical interpretation of idealism represented a genuine break from the logical positivism which it sought to supersede. The continued attachment to the rationality of the individual suggested an enduring sense in which certain frameworks structure human behavior, even as individuals conceive of the world in different ways. In tandem, Guelke’s work does not refute the verification principle, since his accounts continue to espouse the necessity of grounding knowledge in experience, but through the reconstruction of the thoughts behind actions. Supporting this positivist attachment, Guelke was eager to distance his concept of idealism from more phenomenological and existential accounts, keen as he was to stress the focus on human rationality and lack of interest in psychological and emotional concerns. There is a sense, then, that idealist accounts wanted to break from positivism while retaining key elements that provided the possibility of verification and corroborations.

As a third criticism, the methodological possibilities of idealism were considered to be rather ambiguous. While Guelke sought to enter the mindset of the subjects of his research, he simultaneously advocated a form of theoretical detachment. Guelke’s assumption that one’s own theories could be “put to the back of one’s mind” within an atheoretical idealism seemed to reproduce the imagined detachment and neutrality of the positivist researcher. As Harrison and Livingston (1979, 78) suggest, this position imagines the researcher could simply “shake off the shackles of their own presuppositions in complete detachment from the matter under study.” There is a confusing construct here of an idealist scholar who understands the significance of human cognition, but only in those under investigation and not in themselves. Feminist work on positionality, psychoanalytic work on the subconscious, and postcolonial scholarship exploring the production of academic knowledge have subsequently challenged this enduring imagination of the privileged and neutral viewpoint of the social scientist.

Finally, idealism has been criticized for its avowedly humanist focus. Recent posthuman geography has sought to incorporate the agency of nonhuman actors and objects within
geographical theorizing. In doing so, this work orientates attention on the limits of an epistemology that focuses solely on human rationality, since it brackets the wide range of nonhuman forces and intentions that shape a given set of circumstances. This does not discount the significance of human cognition, but it does direct scholarly inquiries to the ways in which the material and discursive boundary between the human and the nonhuman is drawn, and with what political and intellectual consequences.

Taken together, these criticisms have limited the theoretical and methodological application of idealism within geography. But we must be clear that the fundamental claims of idealist philosophy – that human interpretations shape understandings of reality – are crucial to many strands of contemporary human geography. For example, the increased use of ethnographic methods and concerns of positionality have brought analysis of interpretation to the forefront of studying understandings of space and place. In these terms, we can perhaps say that idealist concerns have become a starting point for much scholarship within human geography, rather than a body of thought that marks a distinctive philosophical position.

Identity

Elaine Lynn-Ee Ho
National University of Singapore

Identity belongs to a realm of experience that is intimately felt at an individual and community level, yet it can be slippery to pin down conceptually. Identity refers to a person’s sense of self and how it shapes an individual’s interaction with others in the social world. Identity claims can be invoked to reinforce or challenge systems of domination; hence it is a powerful tool in the hands of social actors and the social structures they represent. Social constructivists, influenced by the poststructural and postmodern turn in the social sciences, do not view identity as a biologically determined condition or fixed across time. Rather identity is amenable to change in response to social processes, relationships, and culture. Geographers further argue that identity is spatially situated and in turn shapes space. Analyses of identity should also be situated in wider structural systems associated with globalization and transnational migration as well as macro-ideologies such as postcolonialism and cosmopolitanism.

Identity is usually categorized according to a person’s social and cultural affiliations, such as socioeconomic status (or class), “race” or ethnicity, religion, gender, sexuality, or nationality. On the one hand, such affiliations serve as a bonding mechanism that helps define social membership. On the other hand, they also serve as markers of difference that delineate social groups from one another. A person is likely to identify with more than a single social categorization at any one time, experiencing not only multiple identities but also intersectional identities. Intersectionality refers to the interrelationship of different axes of identity, such as gender with ethnicity, making the experiences of certain social groups distinct from others. For example, critical race feminists (e.g., Hooks 1983) argue that women of ethnic minority status experience an additional layer of oppression compared to white women, which in turn affects their social positioning, access to resources, and life opportunities.

The process of identity-making is known as subjectification, and identity is also sometimes referred to as subjectivity (or subjectivities in plural). Powerful social actors can forge identities through the use of discourse, ideology, social interaction, and material means. Political elites regularly deploy policies and discourses that promote ideologies corresponding to their political beliefs. Such policies in turn affect social relationships and resource allocation. Together, such mechanisms reify and reproduce the desired identity among the wider population. Notwithstanding the hegemonic practices of powerful social actors, individuals and the social groups to which they belong are also capable of enacting agency to contest and resist dominant ideologies and identities.

Research within the social sciences also foregrounds the emotional aspects of subjectification that contribute towards how identity is shaped. Studies on the way emotions guide identity-making are gaining traction, led by disciplines such as cultural studies, sociology, and geography. In these readings of identity, emotions act as a type of logic that guides decisions and actions, thus contributing to subjectification. But emotions are amenable to regulation
by individuals or other social actors, and emotions circulate in society to shape individual and collective human relations (Hochschild 1983; Ahmed 2009). Studying emotions reveals the emotional logics by which identities are formed intersubjectively and in turn constitute social structures (Ho 2009).

Although subjectification is often thought to be spontaneous, individuals and social groups regularly embody and perform the identities they aspire towards or wish to preserve (Butler 1988). Class identities, for instance, are differentiated in terms of access to income, educational levels, and occupational status. But class identities are also distinguished by way of moral and behavioral attributes associated with the “rough” working class compared to the “respectable” middle and upper classes. Such class identities are performed regularly to maintain class distinctions, but class identities are fluid in other ways. Class identities can be improved by engaging in consumption that represents upward social mobility or efforts to practice the mannerisms associated with a particular class status; equally, class identities can be degraded as a result of deskilling experiences. The fluidity of identity suggests that certain features of identity can be invoked situationally to assert or downplay social affiliations depending on the circumstances.

Geography and identity

Geographers have considered how identity marks out the body as a type of spatial representation. When markers of identity are inscribed onto bodies, these bodies become set apart from others. “Race” or ethnic identity is manifested on the body not only by phenotype but also by attire or comportment. Bodies bearing racial differences that are considered incompatible with the mainstream society become vulnerable to abjection and spatial exclusion in their everyday lives. Whereas earlier geographical research focused on mapping ethnic segregation in urban spaces, geographers today are more likely to be attentive to how identity-driven discrimination contributes to spatial exclusion and multiple layers of social disadvantage. “Race” also cuts across wider national, cosmopolitan, and postcolonial identities and spatial referents.

The politicization of identity by different social groups can result in place contestations as competing groups stake claims to material and immaterial spaces. Such spaces can bear symbolic meaning for the social groups in question or contain resources coveted by those groups. Geographical research further argues that identities are not only situated in space but also constituted through space. For example, divisions in gender identities maintain a public and private divide that entrenches women’s reproductive role in the home by relegating them to domestic spaces. Gendered ideologies are also more likely to associate the productive roles of men with public spaces. Such spatial differences privilege masculinity and the earning power of men whereas the work performed by women tends to be undervalued, thus reinforcing unequal social relations and positioning women’s identities as subordinate to men.

Other geographical concepts also contribute to identity-making or trigger identity change. Scale refers to levels of social organization, such as at the home, community, or nation-state. They influence social relations contributing to one’s personal or communal identity. An influential set of debates on identity from the late 1990s onwards concerns the scalar relationship between the local, national, and global. Economic and cultural globalization, particularly that representing “Western” values, are thought to transform and challenge “local” or national identities. Under siege, scalar units at
the local and national levels reassert themselves through community-based activism, ideologies promoted by the state, or claims to pan-regional identities.

Inasmuch as the global has a bearing on the national and local scales, identities at certain sub-national levels can also cut across scale to leverage resources transnationally. Transnational religious movements are an example of how locally based religious identity politics can escalate to the global scale in order to advance certain parochial visions of national identity (van de Veer 2002). Geographers are attentive to how globalization and transnational migration prompt greater awareness of global interconnectedness across spaces and relational identities (Massey 2004). As flows of people, information, and resources become concentrated in key nodes, greater interconnectivity between such nodes results in distinct networks taking shape. In this rendering, a topology of flows and networks characterizes the geography of globalization even as scale remains useful as an analytical tool to examine the power relations that mediate identity-making (Leitner, Sheppard, and Szairto 2008).

Identity and membership in citizenship spaces

Identity connotes a personal dimension that defines selfhood, but it also has wider implications for social and spatial inclusion or exclusion from community and national membership. Belonging or nonbelonging to a collective body is premised on perceptions of difference, which is in turn defined by axes of identity. Identities function as a reference point for the social location of attachment and belonging. This can act as both a centripetal and centrifugal force, simultaneously drawing in those considered as belonging to a community while expelling others that do not fulfill the criteria for belonging.

At the national level, identity is considered a key component in the institution of citizenship, which in turn defines the extent to which a person can claim the rights associated with citizenship as well as the type of citizenly responsibilities ascribed to that person. Citizenship delineates territorial nation-states externally while internally it determines belonging, membership, and rights. The social processes defining citizenship spaces can have symbolic and emotional effects on identity, as demonstrated by nationalism claims, and even material effects in terms of resource allocation. This raises critical questions about who defines identity and how identity is shaped in citizenship spaces.

“Race” or ethnicity, for example, is a controversial topic in immigration debates on identity, belonging, and citizenship. Criteria such as phenotype, language, and cultural practices are used to classify new immigrant arrivals and differentiate them from the citizen population. Racial categorizations can contribute to social prejudices that feed into perceptions of group membership or nonmembership. Rhetorical devices invoking emotional logics are used to advance the superiority of the self versus the abjection of the “Other,” portray immigrant cultures as a threat to national identity, and create binary framings delineating winners and losers. These representations are regularly mobilized for legitimizing policies that exclude or subordinate social groups considered different from the mainstream society.

National governments play a key role in setting the tone for the extent to which plural cultural identities receive official recognition and equal treatment. Multicultural policies, for example, represent the nation-state’s willingness to accommodate identity differences while stressing the need for harmonious intergroup relations within
the nation. The ideology of multiculturalism is advanced discursively through government pronouncements as well as socially and materially by way of policy guidelines over schooling, housing, or workplace relations. Such policies influence the degree of social interaction or segregation between plural cultural groups. While the model of multiculturalism encompasses diverse types of identity rights (e.g., gender or sexuality rights), it is more often used to refer to ethnic or religious difference associated with immigration. State-sponsored multiculturalism has been critiqued, however, for failing to cultivate immigrant integration fully. This gives rise to competing representations of the nation to be advanced by chauvinist agendas, oftentimes provoking emotional responses to promote indigene identity and limit ethnic minority groups to partial citizenship rights.

Nonetheless, intersecting axes of identities contribute to a variety of immigration and citizenship experiences. Markers of identity to do with class, gender, sexuality, or religion can contribute to multiple layers of abjection experienced by certain ethnic minority groups. Yet it can also privilege the social status of other groups and concentrate resources in their hands. Although identity experiences and negotiations are anchored in citizenship spaces they can also transcend the national to span wider referent points, particularly in postcolonial contexts.

Identity politics writ large in postcolonial nation-states

Identity negotiations at the personal, community, and national levels are inflected by wider structural systems and macro-ideological beliefs arising from past or present colonial relationships that exist alongside contemporary globalization and transnational migration trends. Postcolonial readings of identity underline the colonial histories of violence and dispossession that continue to shape people’s social worlds today, reworked through globalization processes and neoliberal market forces. Postcolonial identities are constituted by Anglo-Eurocentric cultures of the past as well as in the present. They remain significant in postcolonial nation-states that grapple with colonial legacies even as they aspire towards building a national identity and citizenship. Writing about postcolonial cities, Yeoh (2001) argues that they represent sites where claims of an identity different from the colonial past are expressed. Likewise, accounts of postcolonial identities in citizenship spaces are attentive to the colonial discourses and practices that constitute belonging and membership. But they also assert the agency of colonized peoples, especially when defining what citizenship means in postcolonial contexts.

Globalization and transnational migration accentuate old and new divisions of identity that are borne by the figure of the ex-colonial subject and in the postcolonial nation-state. Former colonies, often bearing migration histories, have become sites of new migration as the demands of global economic competition drive transnational migration (Fechter and Walsh 2010). In postcolonial immigration contexts this development could mean inflows of expatriates from former colonial metropolitan centers because they are seen to embody cosmopolitan dispositions and skills coveted by industry employers, policymakers, and political elites. Also converging in these postcolonial settings are other inflows of less privileged migrants from poorer former colonies. They undertake menial work considered undesirable to the local labor pool. This meeting of postcolonial migrations also crosscuts with other types of racialized, classed, and gendered identities. In the ensuing
Identity politics, some differences are bridged while other social divisions become exacerbated in postcolonial citizenship spaces.

On one level, markers of white Anglo-European identity associated with colonial metropolitan centers set apart “Western” expatriates from “nonwhite” migrants who come from former colonies. On another level, there are internal stratifications within both of these referents as well. The category of Western expatriates is characterized not only by nationality or gender distinctions but also by classed identities that span a range of occupational and skills profiles. In this respect, class identity is more likely to forge commonalities regardless of racial difference, differentiating the privileged transnational capitalist class from not only transnational labor migrants, but also less privileged citizens of postcolonial nation-states.

On another level, notwithstanding such bridging axes of identity, racialized social hierarchies still matter in how social groups make sense of their identity relationally. “Western” expatriates may mobilize the legacy of colonialism to portray the identity of ex-colonial subjects, even the citizen population of postcolonial nation-states, as inferior to self. But ex-colonial subjects are just as likely to invoke situational identities advantageously. In the popular imagination, Western norms have become associated with cosmopolitan attributes and modernity. At times, ex-colonial subjects perform what they perceive to be cosmopolitan identities in order to accumulate cultural and social capital for advancing their upward social mobility (Ho, 2011). Yet when confronted with aspects of Western identities that they resist, ex-colonial subjects lay claim to other place identities, such as pan-regional “Asian” or “African” values, to affirm their difference and claim their rightful place. The key point is globalization and transnational migration processes in postcolonial citizenship spaces complicate identity politics but also demonstrate sharply how place histories and representations matter in the making of relational and situational identities.

Identities have the power to enforce social and material inclusion or exclusion in the places that shape them. A person can embody multiple identities and perform certain identities situationally. Identities are thus fluid in nature and relationally formed or performed. Subjectification is also underpinned by the emotions and emotional logics that contribute towards shaping social relations, social structures, and intersubjectivity. The processes of identity-making are spatially situated and further constitute place meaning. Identity politics grow in complexity when people draw in wider social referents to make sense of their social worlds. Among them are structural systems and macro-ideologies that cut across the geographical spaces and scales in which identities are formed.

IDENTITY

Imaginative geographies are representations of peoples and places that express the perceptions, desires, fantasies, fears, and projections of their authors, who are generally external observers. Power is an integral part of imaginative geographies, which are both a tool and an outcome of colonialism and imperialism. Within these broad social fields and political histories, imaginative geographies are indicative of the power dialectic that exists between the observers and those who are observed, the colonizers and the colonized. Reification of self and other is an integral part of imaginative geographies and, as these systems of knowledge develop and become entrenched, the reification can go both ways.

The concept of imaginative geographies was formulated by the Palestinian American post-colonial critic Edward Said (1935–2003) in his analysis of Orientalism, originally published in 1978. A professor of English and comparative literature at Columbia University from 1963 to 2003, Said worked primarily with text, visual representations, and other cultural productions to build his critique of Orientalism, which, he stated, emerged in the Christian West in the fourteenth century as a field of learned study based on a geographical, cultural, linguistic, and ethnic unit called the Orient. Although his approach was rooted in discourse analysis, Said always emphasized the geographical underpinnings of his concept, presenting Orientalism as a “more or less total geographical position toward a wide variety of social, linguistic, political and historical realities” (Said 1978, 50). Therefore, as a structured field for the production, acquisition, and dissemination of knowledge about peoples and places, Orientalism is at its core an imaginative geography. One of its key characteristics is that it constructs and circulates a binary order of meaning where East and West function as opposite categories. Said’s notion of imaginative geographies is anchored in Michel Foucault’s (1970, 1977) analysis of the creation of truth regimes via discourse and episteme. As colonial truth regimes, imaginative geographies are profoundly polarizing, producing and solidifying self and other as inevitably separate and opposite rather than co-constitutive: because they render what is foreign familiar to the observer, the other — that is, the one who is being observed — can only derive his or her identity negatively (Said 1978, 64). Such ordering serves to secure a specific place for each thing so that it can be located again and again, “therefore giving things some role to play in the economy of objects and identities that make up an environment” (Said 1978, 360).

In the light of these elements, imaginative geographies can be understood as particular forms of power that are constituted not only through discursive formations but, more specifically, through the production of authority by way of discourse. As systems of knowledge, imaginative geographies facilitate the circulation, citation, reiteration, and performance of various meanings, with the result that these meanings become dominant, eventually acquiring the status of truth; this despite the fact that they are neither chosen nor shared by the people
to whom they refer. Thus, Said’s concept of imaginative geographies intersects with some aspects of behavioral geography, which posits that what individuals believe about a place or environment will largely determine their spatial behavior independently of (purported) factual data. One of the chief consequences of this iterative process is that objects that are made by the mind will end up appearing to exist as objective realities even though they have only a fictional identity (Said 1978, 54). Said gives the following example:

A group of people living on a few acres of land will set up boundaries between their land and its immediate surroundings and the territory beyond, which they call “the land of the barbarians.” In other words, this universal practice of designating in one’s mind a familiar space which is “ours” and an unfamiliar space beyond “ours” which is “theirs” is a way of making geographical distinctions that can be entirely arbitrary. (Said 1978, 54)

Again, the assignation of a people and their space to the negative side of the binary system does not require their acknowledgment for the colonial regime of truth to operate. Therefore, as a form of generalized ethnocentrism, imaginative geographies set up a universe of meaning and practice where the “subaltern cannot speak” (see Spivak 2010).

And, yet, the concept of imaginative geographies problematizes the relationship between knowledge and geography, showing that no simple dichotomy can exist between “real” and “perceived” worlds, and underscoring the ways in which discursive formations become geographical formations. Although Said elaborated his theory from literary and other cultural productions, the key point of Orientalism and its attendant imaginative geographies is that they enter fully into the creation of material worlds, dramatizing as they do the distance – cultural, political, epistemological – between what is close and what is far away, notably through notions of “home” and “abroad,” “our space” versus “their space” (Said 1978, 55). Said vividly captured this issue when he stated that “Racism is spatially as well as socially constituted” (1978, 3): from the Great Wall of China, to Native American reserves, or the South African apartheid system, worlds are built on the basis of ideas. Consequently, Said does not propose to rectify the error of ethnocentrism by countering its mistakes with another truth, that of the insider. Such an approach would contradict the Foucauldian notion of power that informs his theory, as well as the discourse–materialism dialectic on which his concept of imaginative geography is founded. The political scientist Timothy Mitchell (1989) has critically engaged this question in his own work: drawing on Said as well as on Walter Benjamin, he has referred to the play of colonial representations that enter into the constitution of the modern world as a “labyrinth without exits.”

In the early 1990s Derek Gregory enjoined geographers to engage more fully with Edward Said’s work and to chart the evolution of his theory from a discursive analysis of cultural productions to what Said termed “the struggle over geography,” to which his inquiry had led him (Gregory 1995, 447). Gregory’s chief interest was to develop more critical approaches to understand human geographies, approaches that allowed for more integrated analyses of cultural, historical, and political landscapes. As Gregory states, the effects of cultural imperialism and its geo-imaginings were not limited to epistemological violence, as is strongly indicated by the fact that Said’s analysis of Orientalism is “framed by a series of wars” (Gregory 2012, 151). Against that background, Gregory’s own book, The Colonial Present: Afghanistan, Palestine, and Iraq (2004), is a rigorous engagement with the material effects of the cultural-political performances of
imaginative geographies. In it, he traces one of Said’s key notions about geographical imaginations – namely the dramatization, and reification, of the distance between home and abroad – into the political geographies of the “war on terror.” Analyzing the cultural and political responses to September 11, 2001, Gregory underscores how, as they “circulate in material form,” imaginative geographies render some of the most extreme forms of violence onto the lives of ordinary people. Gregory’s use of the expression “colonial present” signals both the limits of and the continuing need for postcolonial studies. Offering a meticulous illustration of what Said meant by “the struggle over geography,” The Colonial Present traces the spatiotemporal reach of British colonial imaginings into the contemporary chaotic landscape of a particular Orient, namely the “Middle East” (Gregory 2012, 151). Through his engagement with Said, Gregory has contributed to revivifying the tools and approaches of historical geography, chiefly by building stronger bridges with the disciplines of critical geography and political geography. For him, the ordering of the Orient through a binary system of meaning translates into the political “disorder” of modern war, which he describes as a widening net of ocularcentric surveillance via increasingly sophisticated military means (Gregory 2012).

The question of how, through imaginative geographies, space relays and reproduces ethnocentrism has led to new avenues of inquiry in geopolitics, and brought closer attention to the ways in which the dialectics of violence produce their own geographies, thus deepening the interest in human geography for studying militarization (Cowen and Gilbert 2008) and geographies of violence (Gregory and Pred 2007; Barkawi and Stansky 2012). The dynamics of scale and globalization are key aspects of these analyses. In the current political context, the deep colonial roots of Orientalism’s imaginative geographies continue to activate different forms of polarization across global space, a process that was powerfully illustrated by George Bush’s unilateral placement of Iran, Iraq, and North Korea into an “axis of evil” in his 2002 State of the Union address. Against this background, critical geopolitics (Ó Tuathail 2003) and military studies in geography have analyzed how – on the international political stage – notions of “terror,” “security,” “homeland,” or “foreign land” are constituted within the paradigm of otherness and othering that is inherent to imaginative geographies. Interrogating how colonial histories of power continue to produce – and indeed multiply – violent geographies across the Earth, these conceptual developments have underscored how the ramifications of geographical imaginations across global space have a direct impact on peace and security, at home, abroad, and across the full spectrum of unevenly interlocking geographical scales.

With the overarching reach of the “war on terror” since the early 2000s, these debates have brought attention to the various technologies that are implicated in the production and circulation of imaginative geographies. In 1983 Benedict Anderson published an important book that resonated strongly with Edward Said’s concept of imaginative geographies, Imagined Communities: Reflections on the Origin and Spread of Nationalism, where he analyzed how print capitalism enabled the imagination of a shared “communion” between members of a nation, despite the fact that they will never meet each other face to face. As Anderson put it, “the members of even the smallest nation will never know most of their fellow-members, meet them, or even hear of them, yet in the minds of each lives the image of their communion” (Anderson 2006, 6). Through their sedimentation over time, imaginative geographies may
very well have produced the opposite effect where, as it were, the West will never meet the East and yet in the minds of each will live the image of their separation. Like Said, Anderson never lost sight of how the production of the imagined community of the nation simultaneously generates the outside of that political community: as the collective “us” of the nation is imagined, so is the “them” of those who do not belong to it. Imagined Communities was reprinted in 1991 to include chapters on the census and the map, which, in addition to mass media, also contributed to the construction of a shared national space. As it relates to geographical imaginings, Anderson’s development of his theory reminds us of the importance of technologies in sustaining and renewing colonial (dis)orderings of global space, and in relaying distanciation through means not only of the dramatization, but indeed the materialization, of distance. If segregation and exclusion (Sibley 1995) have always contributed to the shaping of human geographies, modern military technology has exacerbated the production of distance between self and other. From the armored ground vehicles and aircraft of World Wars I and II, to distance surveillance systems, unmanned air and ground combat vehicles, and the recent development of drones, the modernization of warfare can be interpreted as an attempt to increase the distance and, ultimately, to eliminate all forms of contact, between human combatants. Indubitably, this process contributes to the upsurge in the externalities of war and their increasing reach into the everyday spaces of civilian lives. While Edward Said stressed the importance of discourse in the production of imaginative geographies and its many forms of violence, geographers have contributed to outline and analyze the role of spatial tools and technologies in materializing these realms.

Lastly, imaginative geographies also reach into the politics of nature (Braun and Castree 1998; Castree and Braun 2001) and there is a growing body of work in political ecology and environmental history looking at the role of imaginative geographies in producing dominant understandings of nature and the environment. Colonialism produced various normative representations of nature, chiefly through representations of a “normal” — meaning temperate — nature, as opposed to an “unnatural” nature, generally referring to environments that correspond to tropical, desert, or polar regions of the Earth. In The Road to Botany Bay: An Essay in Spatial History (1987), Paul Carter brought together history, discourse analysis, and cultural geography to examine how mapping, narrative, urban planning, and aboriginal mythologies participated in the imperial conquest of Australia. As Carter demonstrated, spatial knowledge contributed to bring nature within the colonizers’ realm of intelligibility, a process he viewed as being key to colonial dispossession.

Stemming from the fine-grained analysis of culture that was the hallmark of Edward Said’s work, the concept of imaginative geography allows for a deeper understanding of the work of culture in bringing places, resources, and environments into view in and through the ontology of the state (Willems-Braun 1997), the market, the military, and the various extractive industries that are related to them. In Canada, Caroline Desbiens has examined how — during the rise of the Quebec nationalist movement in the 1970s — hydroelectric development in Northern Quebec relied on what could be described as “Norientalism” (2013, 12), that is, an imaginative geography of the north that denied its aboriginal histories and subjectivities to envision its development narrowly, according to the economic and political priorities of the south, in
this context the urbanized core of the province. The geographical coordinates of this Canadian dialectic between north and south are reversed in the international arena but the imaginative geographies that sustain it are similar: indeed, critical studies of development demonstrate how frequently peripheral spaces function like a “theatrical stage” (Said 1978, 363) that is seen to exist solely as an extension to the center, whatever and wherever that center may be, depending on scalar shifts and dynamics. Whether they are activated by racism, colonialism, terror wars, resource extraction, or performances of national sovereignty, imaginative geographies are ultimately power moves. As such, we cannot forget that they necessarily generate various forms of resistance and activism, which in turn aspire to the creation of alternative geographies that are hopefully built on more hybrid, dynamic, and relational versions of the world.

IMAGINATIVE GEOGRAPHIES

Further reading

The concept of imperialism and related ideas of empire were restored and rejuvenated by the United States’ invasion of Iraq in 2003. Previously, people had preferred the more neutral term “globalization.” Imperialism was avoided as outdated, pejorative, or left-wing, and its pre-World War I reference to investing capital in the colonies (Lenin 1964/1917) appeared to be especially outdated as transnational movements of capital are now mostly between advanced countries, with ex-colonies relatively neglected. When referring to the United States’ dominance over other countries, some geographers preferred the more consensual term “hegemony” (Agnew 2005, 12–36). It was often unclear what “empire” and “imperialism” could mean in today’s world, when they had apparently been superseded by national states and nationalism. Where it was discussed at all, imperialism was usually confined to an “age of empires” that was safely located in the past.

These views were either unnecessarily constraining or simply mistaken. The Iraq invasion showed that imperialism and empire were still very much alive (if not necessarily very well). Multiple publications appeared with these terms in the title (e.g., Harvey 2003; Smith 2003; Colás 2007; Münkler 2007), as supposedly left-wing terminology was “legitimized” by neoconservatives advising President Bush to invade. Vice-President Cheney, Secretary of Defense Rumsfeld, and Deputy Secretary of Defense Wolfowitz and others effectively declared that the United States was an empire – indeed, the empire – and should actively assert its global hegemony. A British neoconservative historian weighed in with the suggestion that global disorder was due to America not behaving like an empire (Ferguson 2004): it should learn from British hegemony and police an unruly world instead of being reluctant imperialists, castigating the British empire as the 1776 butt of their own anti-imperialist credentials (forgetting, it might be added, their own Manifest Destiny imperialism which created the continental United States on Indian territories).

For some the Iraq invasion signaled a “new imperialism,” although in truth it was a lot like the “old” historical imperialisms which stretch back to Sargon of Akkad, history’s earliest named person, who around 2300 BCE created the Sumerian empire in what is present-day Iraq (Mann 1986, 131–150). Imperialism traditionally meant a state taking over other people’s territories by force and theft; sometimes ruling more indirectly on the empire’s outer frontiers through puppet governments, local elites, or client states; establishing colonies, sometimes for economic reasons (oil loomed large in Iraq); and all typically with the moralistic self-justification of a “civilizing” mission (to democratize Iraq), for beyond the expanding frontiers of empire people have traditionally been seen as “barbarians,” with rival empires adding to the threat. Indeed, it was these historically familiar features of empire that quickly popularized the notion that imperialism had returned.

The reality was quite different but less obvious: imperialism had never gone away. When Europe’s overseas territorial empires were...
dismantled after World War II, supposedly ex-imperial powers were occasionally accused of neo-imperialism or neocolonialism in former colonies; imperialism continued in more hidden forms, pursuing similar objectives by different means. It was adapted to fit the new era of politically independent national states. Instead of occupying or annexing territory and making formal claims to rule, imperial powers switched to working more subtly and indirectly within and through independent states. It was now an informal and largely nonterritorial imperialism, shaping developments in its own interests by a “carrot and stick” approach, a variable mix of economic, cultural, and political inducements and pressures. Instead of formally claiming territory, it generally went along with the conventional assumption—or useful fiction—that all states have equal sovereign independence. This more indirect or informal type of dominance, and not the ill-fated Iraq adventure, was the real new imperialism.

Its better fit with independent national states—where nationalism can effectively mobilize against obvious “foreign interference”—was confirmed, ironically enough, by the costly debacle of the old-fashioned and unsubtle imperialism of the Iraq invasion; likewise by the failed Russian and US occupations of Afghanistan (1979–1989 and 2001–2014, respectively). Furthermore, informal imperialism is not really new, only much more generalized. It emerged with the rise of capitalism and, more specifically, in the late nineteenth century when the “gunboat diplomacy” of the British empire’s navy supported the profitable operations of private British capital in the already independent states of Latin America. The overseas empire of the United States, almost entirely informal, emerged shortly afterward (Smith 2003, 9–17).

We cannot do justice to imperialism’s complex history over several millennia. Instead, with contemporary relevance as the touchstone, the focus in this entry is on the general transformation of imperialism since the French and Industrial Revolutions. The first ushered in nationalism as a major force in politics; the second clearly transformed the material capacities and infrastructural (as distinct from despotic) power of states (Mann 1986, 27) and the logistics of ruling over extensive territories (e.g., using railways, telephonic communications, and modern bureaucracy). Less obviously, the spread of capitalism revolutionized the relations between political and economic power that made possible the transformation to the new imperialism.

While for some geographers imperialism is political and military, others recognize important political economy dimensions. Some emphasize the exploitation of less developed countries, but a broader view holds that imperialism and imperial rivalries constitute the global geopolitical-geoeconomic system (Callinicos 2009, 3–14). This entry first characterizes old imperialism and formal, territorial empires as an ideal type, contrasted with national states. But ideal-typical simplifications can mislead unless combined with more concrete analysis. Second, the entry turns briefly to how imperialism and nationalism have now been interacting for over two centuries, rather than imperialism being replaced by nationalism. Third, it argues that the partial separation or “contradictory unity” of political and economic forms of power, and their territorial implications, explain the eventual dominance of the new, informal, imperialism. Crucially, they allow foreign direct investment to escape being seen as foreign interference, and thus facilitate the coexistence of a single global economy with multiple independent states despite the apparent contradiction. However, new imperialism is not the whole story. Fourth and finally, there are also very significant continuities from
the old imperialism, especially the continuing importance of territoriality, theft, and physical force, particularly for the hegemony of leading powers. The invasion of Iraq was not entirely an aberration or a throwback. The indirect power of informal imperialism can mean less power, which occasionally calls for old-fashioned imperialist interventions despite the often costly consequences (especially if there is the subsequent aberration of prolonged occupation).

**Old imperialism and its heterogeneous territories**

Historically the quickest way to accumulate wealth was to steal other people’s possessions – “primitive (first) accumulation” or “accumulation by dispossession” (Harvey 2003, 137–182). For state elites (e.g., monarchs, aristocratic hangers-on) it meant stealing other people’s territories. Theft was central in the territorial formation of states and of empires: initially, the distinction was largely one of geographical scale, which changed through history, with early state formation effectively the imperialist expansion of empire (e.g., the continental United States; or “Wessex imperialism” amalgamating separate territories into the Anglo-Saxon kingdom of England). Interestingly, up to the mid-nineteenth century the term “British empire” meant amalgams of territory within the British Isles, while imperial possessions beyond the core UK state were referred to as “the British empire in North America,” “the British empire in India,” and so forth.

Imperialist accumulation used a diversity of violent and nonviolent means, including territorial invasion and military occupation, colonization and settlement, dynastic marriage, barter or purchase from other powers. Piecemeal expansions mostly resulted in a heterogeneous hodgepodge of territories, very different from each other and from the imperialist or metropolitan core state, in terms of ethnicity, culture, economy, and political rule (the multination United Kingdom of England, Scotland, Wales, and Northern Ireland is itself an example).

Giovanni Arrighi (1994, 33–36) identifies two logics behind imperial strategy. A territorial logic of accumulating wealth and power through accumulating territory – its natural resources and agricultural producers the main source of wealth – was the dominant logic historically. State elites also followed a capitalist logic, where merchant capitalists amassed wealth by economic trading. But trading was usually subordinated to the logic of territoriality associated with the ruling landowning classes: capital accumulation was a means of acquiring territory rather than a priority in its own right. In the merchant-led city-states of medieval Italy, however, the capitalist logic became more central, and it dominated in the city-empire of Venice. Here the priorities were reversed and territorial acquisition, rather than being an end in itself, was subordinate to accumulating wealth through trade. Venetian wealth and power were based on seaborne trade and determined a network form of empire, not extensive territories but trading posts and ports around the eastern Mediterranean, with the trade routes between them protected by the large Venetian navy. This system, however, was exceptional. Most empires were primarily territorial up to the mid-twentieth century, although the capitalist logic also featured strongly in the hegemonic empires of the Dutch in the seventeenth century, and even more the British in the nineteenth century – by which time territoriality was combined with the much more powerful logic of
industrial, as distinct from merchant, capital. And now the capitalist logic clearly predominates in the largely nonterritorial new imperialism.

The two logics are associated with the dual character of capital accumulation: through capitalist production and “a transaction between the capitalist and the wage laborer in apparent peace, property and equality,” but also through the “other aspect of accumulation” involving “force, fraud, oppression, looting … political violence” — in the words of Rosa Luxemburg (1968/1913), as quoted by David Harvey (2003, 137–149). The latter, overtly violent, aspect clearly predominated in the old imperialism, and very obviously so in its colonial contexts, but it still plays a role in contemporary imperialism.

Key features of the old imperialism’s territorial empire as an ideal type are highlighted by contrasts with the more familiar nation-state. Where the idealized space of the nation-state is uniform, at least theoretically homogeneous, with all parts of the state territory effectively the same (e.g., in citizenship rights), the territorial empire was heterogeneous, with multiple, differentiated spaces and diverse interrelations between them. The citizens of the nation–state belong directly to the nation and the state as individuals, whereas people belonged indirectly to the empire, by virtue of first belonging to one of its many constituent communities and territories. On the face of it, pragmatic territorial empire and nation–state could hardly be more different, the latter reflecting doctrinal principles of nationalism, its idealized objectives making it more than simply an analytical ideal type.

According to the doctrine, the nation and its territory should be culturally homogeneous within clear state borders; all nations have an equal democratic right to self-determination (self-expression, self-protection) in their own independent states; and the borders of nation and state should coincide geographically. Such a happy coincidence rarely, if ever, occurs in reality, however, and attempts to make reality fit the nation–state ideal typically result in serious ethno-national conflict.

In contrast, the old imperialism was arguably more grounded in reality. It was generally guided by pragmatic power politics and unburdened by (often unachievable) principles — its justificatory civilizing missions were perhaps the nearest it got to principle. Instead of attempting to culturally homogenize, it was generally more flexible, inclusive, and accepting of cultural and ethnic difference; however, it was often more overtly hierarchical and more likely to accentuate differences between ethnic groups in order to divide and rule diverse populations. With its typical commitment to expansion and to hierarchy (especially of the metropolitan core over the peripheries), imperialism did not presume any sovereign equality between separate national or other entities, and it was much less concerned with (even lip service to) democratic principles. It depended largely on the military and political power of the core state to capture and control peripheral regions, and it ruled or exerted influence within often fuzzy boundaries or indeterminate frontier zones rather than within precisely demarcated borders (Colás 2007, 62–63).

Toward the frontier, its rule generally became more indirect and informal, sometimes operating through client states, with central power declining in unstable spheres of influence, which often overlapped with the spheres of rival empires. Whereas state power and cultural identity tend to be relatively uniform throughout the territory of the modern national state (or so it is hoped), and usually end in a sharp inside/outside dichotomy at the border, power in territorial empires generally declined on a gradient with increasing distance from the metropolitan core, and petered out more gradually on the frontier. This was
often the case de jure and nearly always the case de facto. Even where the introduction of modern technological infrastructures (e.g., railways, telephones) greatly facilitated rule from a distance, the more peripheral territories furthest from the core were still more likely to have greater ethnic, cultural, ideological, or economic differences, and be more susceptible to influence from rival empires. The core–periphery/distance–decline power gradient is a key distinguishing feature of the old imperialism.

As a very oversimplified ideal type, territorial empires comprised three concentric circles: the inner core state; a broad middle zone of heterogeneous territories and colonies ruled from the core in a variety of more or less direct ways; and an outer frontier of more informal, indirect, and often unstable rule, or merely influence, through local elites or client states.

The transition from empires to national states

Ideal–typical contrasts initially enlighten but can mislead. There were complex interweavings and mutually supportive, as well as conflictual, relations between imperialism and nationalism. There was no simple opposition or linear replacement of imperialism, contrary to the perspective of some nationalists and academics who see nationalism as only “an anti-imperial ideology” (Münkler 2007, 123). History is a lot more complicated. Imperial powers fostered nationalism; they themselves adopted nationalist strategies; some nationalisms allied with rival imperialisms; and some developed their own imperial pretensions (Anderson and O’Dowd 2007).

Some of the earliest nationalisms developed in the core states of the imperial powers (e.g., in France and England), and they spread nationalist ideals at home and abroad, and not least to their own colonies. Links between the metropolitan core and cities in the peripheries were often crucial in the promotion of nationalist and democratic ideals of self-determination, obviously appealing to opponents of authoritarian colonial rule. Resistance usually intensified when the empires modernized and, to varying degrees, adopted nationalistic policies toward their subject peoples, essentially attempting to extend the nation-building of the empire’s core state, hoping thereby to enlarge the core and/or its control over peripheries. Initially, the combined forces of capitalism and nationalism probably boosted traditional imperial power as much or more than they boosted oppositional national movements. Capitalism, by transforming the logistics of rule from a distance, gave traditional empires a new lease of life, and central controls generally became more pervasive and effective. Compulsory state education from the late nineteenth century was an opportunity for some imperial powers to make schools in the periphery use the language of the core (e.g., German rather than the local Polish in parts of the Prussian empire; the attempted Russification of the czar’s Finnish territory). But such nationalistic policies were a significant departure from traditional pragmatic imperialism (contradicting its ideal type), and they would generally prove counterproductive, galvanizing nationalist opposition.

Ultimately, nationalist opposition would prove disastrous for the old imperialism. But it is important to grasp the latter’s resilience. Most of Europe’s territorial empires were still firmly in place up to World War I, and its overseas empires in Africa and Asia outlasted World War II. Their dismantling was often due to national anticolonial movements, but also to US opposition to territorial empires: the American empire was very largely of the new, informal type, and Europe’s formal empires had often marginalized or excluded US business interests.
IMPERIALISM

It has only been in the last 50 years or so that the very long era of territorial empires (such as the USSR up to 1989) eventually fizzled out and national states became the global norm, and only then that the new imperialism became fully and firmly established. Traditional empires incorporated and benefited from nationalism and capitalism before eventually being undone by them.

But imperialism adapted: the three concentric circles of the ideal-typical old territorial empire have effectively been reduced to two: the broad middle zone of heterogeneous territories ruled more or less directly from the core has been removed, leaving the inner core state and a greatly expanded surrounding zone of more informal, indirect, but now predominantly economic power over independent national states, sometimes with geopolitical influence exercised through client states (e.g., Israel for the United States, Cuba for the old USSR).

Politics and economics in capitalism and the new imperialism

Nationalism necessitated the transition to the new imperialism, while capitalism enabled it. Intercapitalist competition ensured the continuation of a multiplicity of states, while the contingent struggles of nationalism and imperialism decided which ones. There seem to be contradictions between the politics of multiple states and the economics of a single global market, between the independence of national states and the interdependencies of economic globalization. However, the new imperialism and inter-imperial rivalries now constitute a combined geopolitical-geoeconomic system unified by a predominant capitalist logic.

These related propositions are best explained by the theory of capitalism’s partial separation or “contradictory unity” of political and economic forms of power, their mostly separate institutionalizations, and the territorial consequences. Capitalism not only greatly increased state power, but it also revolutionized the nature of power. Economic power, now associated with the capitalist market, became more distinct from political, including military, power associated with the state; and capitalist economics are now arguably more important than national states as sources of social power. But the “new,” and to a large extent economic, imperialism is far from transparent, and theory is needed to reveal its inner workings.

As the late Ellen Wood (1995) explains, the partial separation of politics and economics arises uniquely from within the capitalist mode of production, from the way in which economic surplus is extracted from the producers. In pre-capitalist production systems the surpluses had typically been extracted by extra-economic or political means, often relying on the direct use of physical force at the point of production (e.g., armed overseers on slave plantations, the private armies of feudal landlord). In sharp contrast, surpluses in capitalism are mainly created by the “free” labor of waged and salaried workers through the economic operations of the free market. Here, however, the absence of force is more apparent than real. In the partial separation of politics and economics, physical force is only displaced from the economic sphere of production to the political sphere of the state, less obvious than in slavery or feudalism but still necessary. In capitalism, state force maintains property rights and the rule of law, without which production and the so-called free market could not operate. Ultimately, force is necessary to exclude workers from possessing or using the means of production (e.g., land, machinery, raw materials) to produce their own necessities of life, generally leaving them no alternative but to
sell their labor power to employers who possess the means of production.

The degree of partial separation varies and is politically contested. It is clearest in liberal or neoliberal regimes, where the market is clearly dominant. But even in the state capitalism of state-owned enterprises there is partial separation because these enterprises usually follow the dictates of the market more than political criteria. Furthermore, as in privately owned firms, the partial exclusion of politics not only applies to physical force, but it is also the exclusion of democracy from the major decisions about what to produce and where to invest — representative democracy stops at the gates of the workplace (points further developed in Anderson 2005).

The partial separation is expressed in the institutionalized division of labor between business people and state personnel, including politicians. It has several profound consequences for territoriality and is spatialized, as in the division between Wall Street, New York, and Washington, DC, or between the City of London and the City of Westminster. It transformed state–city relations, with cities generally becoming politically subordinated (de jure and de facto) within the more homogenized and centrally controlled space of the national state, and (with some exceptions) becoming more one-sidedly economic and cultural centers, where previously cities also had greater political roles or political autonomy. Crucially for the new imperialism, the separation transformed state territoriality, with borders differentiating more sharply between political and economic processes.

The extraction of economic surplus in precapitalist systems was inseparable from politics and often required force at the point of production; and hence extracting surplus in foreign territories readily called for direct political control through incorporation in formal territorial empire. For instance, Europe’s overseas empires combined slave labor with territorial possession: the Spanish operated mines in Spanish-held territories, the British sugar and cotton plantations were in British colonies, the Dutch plantations in Dutch colonies, the French in French, and so on (Rosenberg 1994). But such direct territorial possession was rendered unnecessary by capitalist production’s separation of politics and economics.

This separation enables foreign direct investment (FDI) to take place in politically independent sovereign territories; and, conversely, it enables states to make plausible claims to be independent, despite the interdependencies of economic globalization. The economic and political objectives are facilitated as two sides of the same coin: considerations of political sovereignty are in effect removed or forgotten where FDI is concerned; and considerations of economic interdependency are forgotten when political sovereignty is being claimed. The claims to sovereignty and national self-determination apply only in the sphere of politics, and they are usually recognized because economics is only marginally involved in this sphere and is treated as separate.

FDI, the bedrock of contemporary (mainly economic) imperialism, is generally accepted despite national states and populations being imbued with nationalist ideals of sovereign independence, because FDI is deemed to be economics rather than politics. Furthermore, democracy stops at the border as well as at the workplace gate, so in a sense FDI is doubly insulated from the sphere of politics. Market criteria could be enforced by independent states for foreign-owned as for indigenous capital, both having the same state-protected rights (at least in principle). Exploiting foreign labor could now be negotiated as a purely economic transaction between foreign employer and indigenous
worker – the foreignness of the exploiter being effectively depoliticized. Political control of the territory was no longer required. Hence, far from rejecting FDI as foreign interference, independent states fall over themselves trying to attract it – sovereignty is sacrosanct in politics, but financial investment is merely, well, economic. Political problems do arise from foreign decisions to disinvest, but the separation of politics and economics is crucial in defusing potentially explosive contradictions between sovereign states and economic imperialism, and it mostly ensures a relatively harmonious combination of many states and one global economy. Less benignly, and reminiscent of Lenin’s association of economic imperialism with colonies, it is also the basis of the “superexploitation” of very cheap labor in the Global South.

The global geopolitical-geoeconomic system is best seen as a single contradictory unity rather than as two ontologically separate systems which somehow “come together.” Following Arrighi’s (1994) formulation, the system is unified by a logic of capital accumulation, which now predominates over a territorial logic for state elites as well as it obviously does for business people. David Harvey (2003, 26–36, 183, 204), however, has reformulated this understanding, confining the capitalist logic to business people, with state elites allegedly following a different territorial logic of geopolitical competition to augment state power. The dualism of two different sorts of actors with two different motivations could, arguably, help to avoid an economic reductionist or functionalist approach to imperialism (Callinicos 2009, 15), but it is not necessary for avoiding reductionism and it has its own pitfalls and inconsistencies (see further Anderson 2005). Arrighi’s formulation of both logics as state strategies – alternative, complementary, or contradictory – seems clearly preferable. If the elites running the Venetian city-empire predominantly followed a capitalist logic, with capital accumulation as their main goal and state territory seen as only “a means and a by-product of the accumulation of capital” (Arrighi 1994, 33), that is surely at least equally, if not more, true of contemporary states in global capitalism. There is, however, more to the story.

Hegemony and continuities from the old imperialism

We have seen that capital accumulation has two aspects: violence-free economic production, backed at a distance by physical force, but also the fraud, theft, invasion, and violence of “accumulation by dispossession” (Harvey 2003, 137). The latter is now generally more muted or secondary than it was formerly in the old imperialism. It is not the dominant aspect, but it continues and surfaces strongly in questions of hegemony over the global system and whether states follow hegemonic powers voluntarily or are persuaded by economic coercion or by political violence (threatened or actual). John Agnew (2005) prefers “hegemony” to “empire” in analyzing the United States’ dominance, whereas Michael Mann (2013) sees the United States as the world’s “sole remaining empire.” But, while by far the leading military superpower and still hegemonic, the United States is far from being the only empire or practitioner of imperialism. Lesser powers also practice it (e.g., Serbia’s murderous aggression in the former Yugoslavia, Israel’s illegal colonial occupation of the West Bank and Gaza). Other major powers – Russia, the European Union, and rising powers such as India and Brazil – increasingly challenge the United States politically or economically, and China may potentially be a future contender for hegemony. Largely because of growing competition between imperialisms big and
small, US hegemony is starting to decline in an increasingly multipolar world. And all three concepts – imperialism, empire, and hegemony – are needed to make sense of the complexities.

The new imperialism can usefully be described as less territorial, less direct, more informal, and more economic than the old imperialism. But ideal types aside, real-world imperialism is now a mix of both. Territoriality and direct non-economic power and violence are still crucial, are sometimes used against independent states in the outer zone of informal empire, and are present in the empire’s inner core or all-important home territory. For instance, in the continental United States, the Russian Federation, or the Chinese Republic, power is still direct, territorial, and based on political sovereignty, whereas the rest of their empires are non-territorial and involve mainly economic power (e.g., China’s increasing economic involvement in Africa) – at least most of the time.

But core–periphery relations have a variety of aspects. First, operations in the periphery can produce problems of “blowback” in the core, such as the Home Rule struggle in Ireland which produced a constitutional crisis in Britain in 1912 (Anderson and O’Dowd 2007), while US support for Israel and military interventions in the Middle East arguably contributed to the terrorist attacks of 9/11. Second, success in the periphery depends on support in the core, at minimum its pacification, and here recruitment to the empire’s military forces played a key role, as did incorporating potential opponents in the periphery. Third, imperial success and leverage depend on the relative size and weight of the core state (e.g., Portugal was too small and weak to develop its vast and potentially rich territorial empire, so a self-serving British empire helped out by treating it as a junior partner). Fourth, the historical pattern has been for hegemony to require ever larger core states: the global hegemony of the small seventeenth-century Dutch Republic was followed by the hegemony of the medium-sized British national state in the nineteenth century, and it in turn was followed by the hegemony of the vastly larger United States in the twentieth century. Fifth, it can be inferred that the global hegemon or an eventual contender (perhaps China) now requires a home territory of continental proportions, partly because of the extra leverage needed to exercise hegemony in the more difficult conditions of informal empires and politically independent states. Sixth, practices of territoriality in the home territory are especially evident where the territory itself is being expanded and/or threatened. For example, China’s home territory in the far northwest, resource-rich, province of Xinjiang (meaning “new frontier” or “new territory”) is being threatened by the national separatist movement of Muslim Uyghurs, as China aggressively populates the region with Han Chinese settlers in an old-fashioned imperial expansion.

This process follows Arrighi’s “logic of capitalist rulers,” for whom territory is a secondary means toward accumulating capital, rather than an end in itself, but it nevertheless involves territoriality. Similarly, the eastward expansion of the European Union since the collapse of the USSR involves a different sort of capitalist empire enlarging its home territory and increasing its informal leverage. Here analysts mostly concentrated on the economic processes of securing former Soviet satellites as investment opportunities rather than treating them only as a source of cheap migrant labor, but typically they failed to see its military aspect (Armstrong and Anderson 2007, 125–141, for example), blinded by the partial but institutionalized separation of economics from politics, in this case the
European Union from the North Atlantic Treaty Organization (NATO). This failure was exposed in print by Perry Anderson (2007), who pointed out that all the former satellites admitted to the European Union had first been incorporated into NATO under US command (the Clinton administration reneging on US nonexpansionist undertakings given to the USSR’s reforming President Gorbachev). And it was exposed in practice in 2014 when EU/NATO expansion resulted in a confrontation with Russia and armed conflict in a Ukraine caught between the two. It looked very like classical territorial competition between empires in their overlapping spheres of influence. While the European Union’s external operations are typical of contemporary informal empires, the novel construction of its expanding home territory with a “ring of friends” on its complex outer frontiers (see Armstrong and Anderson 2007, 142–159) is paradoxically more like a traditional territorial empire combining heterogeneous units with a gradient of power declining toward the edges. Furthermore, the institutionalized division of labor between the “economic” European Union and the “political” NATO indicates that the European Union, rather than constituting itself a rival empire to the United States, is acting as its junior imperial partner – as advocated, for example, by Germany’s government adviser Herfried Münkler (2007).

Using military force against independent states is particularly problematic in outer zones where indirect power generally means less power – the Achilles’ heel of informal empire. Hegemony works best where states decide for themselves that following the hegemon’s lead is in their own best interests, or where economic carrots and sticks suffice to persuade them. But, for more recalcitrant states, imperial powers intervene with stronger measures, usually starting with economic sanctions, then threatening military force (recently dressed in the clothes of human rights or democracy), then actually using force with drones or conventional air strikes, and finally engaging in armed invasion as a last resort. Iraq was not an aberration because of invasion per se – after all, US forces have been bombing or invading other (mostly small) countries for decades. The problem was that invasion seemed a first resort rather than the last, and the prolonged occupation was an overambitious and failed attempt to prolong US hegemony (partly by controlling the oil supplies of rival powers; see Harvey 2003). That failure was unusually spectacular (as was Vietnam), but interventions against independent states usually bring substantial risks. In typically requiring interstate cooperation, they are vulnerable when that is withheld or is widely opposed, especially by leading imperialist rivals. Other vulnerabilities include client states acting in their own independent interests which may contradict those of the empire (some American analysts now see Israel as a wayward example).

US military power is unrivalled. Its spending in the military sphere exceeds the combined spending of the next seven or eight countries, accounts for about 40% of global arms expenditure, and is over five times greater than China’s. Its networks of surveillance and detention, and its military archipelago or “empire of bases” – territorial bases, mobile aircraft carriers, and nuclear submarines – is unparalleled. Yet even here there are challenges, and militarism brings its own problems.

Military power is the mailed fist in the velvet glove of foreign direct investments. Here the physical force is largely displaced to external network space, an extension of the displacement of armed force from the economic point of production to the political state, for the force is generally hidden outside the particular state that the United States deems is misbehaving. The United States
polices its own external interests, especially its FDI, and at the same time it inevitably protects the FDI of private capitalists from other imperial powers. This extended protection goes a long way to explain the appeal of US hegemony, but also the growing US complaints that other leading powers are not contributing enough to global security, for it is indeed an economic burden on a declining US economy (declining relative to its post-World War II zenith, and to the rise of China and of the European Union as rival economies of roughly similar size). While obviously greater in scale, the United States military archipelago is reminiscent of Britain’s global network of naval bases in the nineteenth century, but, whereas those were directly owned colonies of Britain, most of the United States territorial bases are within the sovereign territory of other independent states and are subject to formal contractual agreements which may circumscribe the purposes for which the bases can be used.

More problematically, military power is inappropriate or counterproductive for many hegemonic purposes, but there are nevertheless temptations to use it simply because the United States has an overwhelming lead in this sphere. Furthermore, to be credible, threats of force sometimes have to be carried out. If Arrighi’s (1994) historical analysis of past hegemonic transitions between the Dutch, British, and Americans is any guide to the future, the political turbulence in periods of hegemonic decline or transition was mainly due to belligerent attempts by the declining hegemon to prolong its dominance (and Bush’s Iraq adventure is easily seen as such). The United States might need to be saved from itself by its friends in the European Union showing some independence, rather than simply following along as junior partners.

In short, exercising and maintaining hegemony is more complicated in today’s new imperialism and in an unruly, multipolar world of independent states; and it is likely to become even more difficult. The Dutch and British arguably had an easier job policing the simpler world dominated by formal empires (which vitiates any British pretentions to give the Americans lessons in how the British did it). The relative economic decline of the United States, increasingly reliant on its dollar being the global reserve currency, has reduced its leverage on recalcitrant states. Even more challenging for the future, there is the global turbulence and recurring economic crisis tendencies of capitalism, and the looming threats of climate change, resource scarcity, and even resource wars. Believing that only “colonial possession” guaranteed control over raw materials, Lenin (1964/1916, 22, 260) warned that “The more capitalism is developed, the more strongly the shortage of raw materials is felt, the more intense the competition and the hunt for sources of raw materials throughout the whole world, the more desperate is the struggle for the acquisition of colonies.” Future territorial control may not literally take the form of colonies, but the likely logic could be very similar. The geopolitical and geoeconomic implications are unpredictable, but it is not too difficult to foresee more of the old imperialism reappearing.

Capitalism (and its partial separation of politics and economics) underpins the present nexus of a global economy, multiple national states, and the informal empires of the “new,” less territorial, imperialism. But territoriality, along with theft, force, and invasion, are still integral to the system. Imperialism now is a variable mix of old and new imperialisms.

Indexing

Changxiu Cheng
Beijing Normal University, China
Chinese Academy of Sciences

Indexing is the process of assigning and maintaining the organizational or storage structure of data to provide efficient data access. In most cases, indexing is a core database management system (DBMS) function that automatically updates and manages data indices.

Traditional indexing approaches (B+ trees, etc.) are often inadequate for spatial data handling because of distinctive characteristics of spatial data. Spatial data come in various forms, the most common being points, lines, and regions. In geographical information systems (GIS) applications, typical spatial queries are selection, join, and aggregation (Shekhar and Chawla 2003; Cheng, Song, and Zhou 2013). “Selection” queries include the spatial range query (“find all objects that lie within a given query region”) and the spatial point query (“find all objects that contain a given query point”). In addition, spatial relationship functions (e.g., overlap and disjoint) and operators (e.g., nearest neighbor) are essential to spatial data handling. Spatial relationships serve as the foundation for spatial join queries (e.g., “find all pairs of objects that intersect each other”) and nearest neighbor queries (e.g., “find the five objects nearest to a given query point”).

Several spatial data indexing approaches were developed over the years to accelerate spatial data access. In the early days, spatial data indexing focused on spatial ordering, such as the Z curve, Gray curve, and Hilbert curve. All of the indexing strategies map two-dimensional spatial data onto one-dimensional linear orders while preserving the relative locality of the data points. Once the data are sorted into one of the ordering schemes, spatial data can then utilize one-dimensional data indexing methods, such as B-trees, hash tables, and so on, to facilitate query and data access. Another multidimensional access example is the k-d tree (short for k-dimensional tree), which is a special type of binary space partitioning tree. Attempts to apply multidimensional indexing schemes proved challenging due to the lack of total ordering in a multidimensional space. Therefore, it was necessary to develop some specialized data structures for spatial data. Grid indexing, quad-tree indexing, and R-tree indexing are the three most common spatial indexing structures. These methods divide data space into several partitions and record the local relations between partitions and the minimum bounding rectangles (MBR) of spatial objects, while the actual spatial object is stored separately.

- **Grid index:** Grid-based spatial indexing registers objects to their position or positions in a grid then creates indices to relate object identifiers with grid cell identifiers for rapid access. Figure 1a shows an example of some features (F1–F3) and two levels of grid partitions: four quadrants of A, B, C, and D, and 16 cells (1–16). Figure 1b shows two grid index strategies corresponding to each of the two levels. Grid indexing is a space-driven or data-independent method; the procedures first create the index structure and then register data on an ongoing basis within the index structure. As a result, a common grid
indexing scheme can facilitate data merging from multiple sources or from individual data collections and indexing activities.

- **Quad-tree index**: The quad-tree was named by Finkel and Bentley (1974) and is now perhaps the most common indexing scheme for spatial data. Quad-tree indexing partitions a two-dimensional space by recursively subdividing it into four quadrants or regions. The regions may be squared, rectangular, or in arbitrary shapes. Figure 2a shows an example of some features, those features’
MBRs (F₁–F₁₉), and their recursive quad divisions. Figure 2b shows the corresponding quad-tree indices, in which each internal node has exactly four children quadrants: northeast, northwest, southeast, and southwest. In Figure 2b, a rectangle node symbolizes the MBR of a feature, whereas a circle node represents a quadrant divided by the quad-tree. Both the grid index and the quad-tree index are space partitioning indexing techniques; they divide the overall region using split operations. The difference is that the quad-tree index is a recursive quadrant division that is based on spatial distributions of data objects rather than seeking a height-balanced structure of the space partitions taken by the grid index approach. Thus the quad-tree indexing scheme is more efficient for spatially skewed data than the grid indexing scheme. In addition, the quad-tree index is a “data-driven” or data-dependent method. If the maximum capacity of a cell is reached as new data are coming, the cell should be further divided to register spatial objects at a finer resolution.

R-tree index: The R-tree was proposed by Guttman (1984). R-trees are commonly used to index multidimensional information, such as geographical coordinates, rectangles, or polygons. Central to the R-tree indexing scheme is the idea of grouping nearby objects and representing them with their MBR to form a node in the tree. Every nonleaf node in an R-tree contains a set of pointers to the corresponding child nodes and the MBRs of their child nodes. Furthermore, every leaf node contains a pointer to an actual spatial object and the object’s MBR. For example, the R-tree in Figure 3b has the “root” node that covers the maximal rectangle region in Figure 3a. The root node in Figure 3b has two child nodes that separately cover region I and II in Figure 3a, and leaf node 8 contains a pointer to a spatial object and the object’s MBR. Like quad-tree indexing, R-tree indexing is also a “data-driven” or data-dependent method. Being data-driven, quad-trees and R-trees are generally efficient for spatial data storage and spatial search. Many database management systems embed quad-tree or R-tree indexing schemes in

Figure 3 Example of R-tree indexing: (a) labeled rectangles in different levels and a dash-line query window; (b) R-tree index of (a).
INDEXING

their internal data structures to take full advantage of their efficient storage and searching capabilities. R*-tree, R+-tree, Hilbert R-tree, and X-tree are the different variants of R-tree indexing.

Data indexing helps sort candidates in response to spatial queries, especially for complex spatial queries. A spatial database management system (SDBMS) breaks down complex spatial queries into a series of basic spatial operations (such as spatial selection and spatial join) and executes these basic operations with efficient two-step query processing (Figure 4). First is the filter step that uses indices to locate possible candidate objects whose MBRs satisfy given query conditions. For example, a dash-line rectangle, as a window query, in Figure 3a will start with the entire extent (i.e., the root node of the tree). For each rectangle in a node, a decision needs to be made whether the rectangle intersects with the query window. If yes, the search process checks corresponding child nodes recursively until the search has traversed all intersecting nodes. The objects in leaf nodes, intersecting with the query window, will be put into a set of candidates, such as objects 4, 8, and 9. Then the refinement step performs exact comparisons among the candidate objects to select those that should be in the final query result. The filter step involves only an index search and is considered a low-cost step. In contrast, the refinement step is computationally expensive, but the computations are applied only to a smaller set of objects resolved from the filter step.

In recent years, spatial data have been collected from diverse sources and used as an ensemble to derive information referred to as big data (Dasgupta 2013). Volume, variety, and velocity are three characteristics of big data application. Big data are massive and can have a volume ranging from tera- to petabytes, even contiously increasing, and can come from multiple sources. Due to the large volume, big data repositories do not undergo rigorous preprocessing as commonly performed by operations via Structure Query Language (SQL) in a DBMS; instead, computational demands are shifted to data access and delivery. In addition to large volume and pronounced variety, big data come from multiple data streams at high velocity. An SQL DBMS quickly reaches its limits when handling the vast volume, velocity, and variety of big data. NoSQL databases play a very important role in spatial big data applications.

Geohash is an example of spatial indexing methods commonly adopted in NoSQL database systems. Geohash applies a hierarchical coding scheme and a Z ordering scheme for spatial indexing at multiple spatial resolutions. Geohash coding schemes map latitude and longitude coordinates into one single location index, namely geohash code. Furthermore, a geohash code comprises a hierarchical string that can be used to conveniently group objects at nearby locations. Hence, the geohash code serves as a key in a NoSQL database, such as Google Bigtable or MongoDB, to facilitate spatial search. For example, Bigtable, in a nutshell, is a NoSQL
massively parallel table indexed in a three-level B+ tree scheme. Bigtable employs a map (an associative array) that is indexed by a row key, a column family, and a timestamp. A common row key used by Google is reversed URL (such as com.google.ww) to facilitate webpage searches. Geohash codes can serve as a row key to support spatial search on web map applications. As semistructured or unstructured data indexing schemes adopted in NoSQL databases are widely used in geospatial semantic web applications, Geohash and other new spatial indexing schemes will continue to grow in popularity in spatial big data applications. Nevertheless, SQL database technology remains important to organize data and assure data integrity and quality in structured and long-transaction database applications (Dasgupta 2013).

India: National Association of Geographers, India (NAGI)

Founded: 1978
Location of headquarters: Delhi
Website: www.nagi.org.in
Membership: 2226 (as of January 20, 2015)
Secretary General: S.C. Rai
Contact: raisc1958@rediffmail.com

Description and purpose

The main objectives of the organization are to foster geographical research in the country; cooperate with professional organizations of cognate disciplines and to promote academic interaction within an interdisciplinary frame; cooperate with international organizations with similar objectives; improve the teaching of geography at all levels; foster cooperation between government and quasi-government organizations, research institutions and educational institutions for the advancement of geography; hold an Indian Geography Congress, ordinarily once a year; to take all such measures needed to secure geography's legitimate place in national life; and to strengthen among geographers a sense of national responsibility and professional efficiency.

Journals or major publication series

Annals of the National Association of Geographers, India. www.nagi.org.in/publications.html

Current activities or projects

The association runs various projects determined by a yearly schedule. The 36th Indian Geography Congress was held on November 17–19, 2014 in Jaipur, Rajasthan. The main theme was “urban systems, rural livelihoods security, and resource management”.

Brief history

Although the discipline of geography was institutionalized in India long before the establishment of the association, the organization came into existence only in 1978. Before that, individual universities and research institutes had their own geographical societies, but in 1978 an organization covering all of India was founded by eminent geographers to make the discipline more research oriented and interdisciplinary. The association played a significant role from its beginning in bringing young geographers and scholars together into a single organization and gave an opportunity to interact and discuss the emerging issues in geography. It has a long history of productive cooperation with the leading educational institutes in the country and runs a variety of projects of national importance.

Indigeneity

Sarah Hunt
University of British Columbia, Canada

Indigeneity and indigenous geographies are relatively recent areas of geographic scholarship. Yet, beneath and before the conceptualization of nation-states and continents within Western European thought, indigeneity provided the originary modes of being in relation to diverse territories across the globe. Indigeneity – that is, the original peoples and their ways of being, knowing, and acting in relation to the territories on which they lived – existed prior to the formation of the discipline of geography and its subdisciplinary modes of inquiry. In settler-colonial countries such as Canada, the United States, New Zealand, and Australia, place-based modes of thinking and knowing began within the context of indigenous epistemologies before being represented within the colonial geographic imaginary. It is from this perspective of indigenous peoples’ diverse lived experiences, both precolonial and neocolonial, that this entry on indigeneity in the field of geography arises.

Indigeneity on its own terms

Conceptualizations of indigeneity are shifting and contested, and emerge within specific sociopolitical and historic contexts. The diversity of indigenous political movements, cultural practices, and critical scholarship cautions against representing distinct peoples as essentialized versions of indigeneity. In a literal sense, indigeneity is taken to mean anyone who is born in a place; thus anyone who has not migrated to that place may be regarded as indigenous. Yet, within the political context of ongoing neocolonial relations in places like North America, Australia, and New Zealand, indigeneity has a specific meaning intended to distinguish between colonized groups and colonizers or settlers. Thus, in this context, indigenous specifically means peoples with ancestral and spiritual ties to particular territories, whose ancestors lived in relation to that land prior to colonization and settlement by others. In colonial and neocolonial contexts, indigenous is also taken to mean nations that, in large part, remain under the power of the settler or colonizing governments.

To be precise in identifying indigenous peoples, the preference is generally to use indigenous peoples’ own names for themselves, in their own languages. Indeed, the process of identifying, categorizing, and naming indigenous peoples is one that has been inherent in colonialism the world over, and is thus also a key site of decolonial efforts. In the United States, indigenous people were named “American Indians” within national legal frameworks, which have shifted in recent years to the terminology of “Native Americans” and “Amerindians.” In the Canadian context, indigenous peoples have been legislatively categorized as “Indians” or as “Aboriginals,” with the limitations and definitions of this categorization determined by the state rather than by terms set by indigenous peoples themselves. This terminology has, over time, shifted to include “First Nations,” “Métis,” and “Inuit” categories, each with its own state-delineated definitions, rights, and status.
has been argued that the legal categorization of American Indians and Indian, Métis, and Inuit peoples has been designed within frameworks of extermination aimed at producing fewer and fewer natives over time. While legal definitions and formulations designed to count indigenous peoples have changed over the years, many state formulas continue to deny recognition of indigenous status to large numbers of people claiming indigenous heritage, particularly women. This gendered inequity of indigenous status is due to the patrilineal lines of descent written into current or past government policies. Indigenous people thus continue actively to resist and contest such state-defined formulations of indigeneity while asserting their own self-determined individual and collective identities.

Although definitions of indigeneity differ greatly across historic and current global sociopolitical geographies, indigenous peoples have identified some shared cultural markers. Indigeneity is generally rooted in living in a reciprocal relationship with the places that comprise indigenous peoples’ territories. Indigenous worldviews often recognize the active agency of the land and nonhuman actors, such as animals and spirits, and regard the relationships between humans and their environment as ones of reciprocity. Although the ability to honor these relationships has been deeply impacted by colonization, indigeneity is recognized as being alive in the bodies, teachings, and knowledge of indigenous peoples, despite the constraints placed on their ability to enact them as they did prior to colonialism. Displacement from their territories has also impacted indigenous peoples’ ongoing relationships with their lands. Numerous indigenous knowledge-keepers and scholars have described their orientation to these territories as mobile, whereby, although they may travel away from their lands by choice or by force, their orientation to these places remains active. While some indigenous peoples link indigeneity with an individual’s blood quantum of indigenous ancestry, others define indigeneity according to an individual’s orientation to indigenous principles, teachings, and ways of life. The ability of such markers of indigeneity to change over time is a point of difference between indigenous groups, yet there is increasing recognition that indigenous practices, beliefs, and traditions have always been adaptive and fluid rather than static. Indeed, Western scholarship has often portrayed indigeneity as static in order to justify imagining indigenous peoples as vanishing, as development, displacement, and conquest have impinged on their precontact ways of life. It is around the shared markers of indigeneity, as well as global struggles for indigenous rights and recognition, that the vitality of indigenous sociopolitical geographies has emerged in recent years.

While indigenous peoples may share certain commonalities, diversity and heterogeneity are a central aspect of indigeneity the world over. Indigenous peoples are necessarily different from one another, as indigenous political, cultural, and social practices and worldviews are lived in deep relationship to place. Despite the aforementioned state-determined processes for grouping indigenous peoples together under certain legal categories (e.g., “Indians,” “Métis,” “Inuit”) with attendant rights and status, indigenous people insist on the distinctness of each indigenous group, while acknowledging long-standing relationships across and between indigenous peoples in areas where territories are shared.

The long-standing place-based relationships of indigenous peoples to their territories are evident in place names and stories told about the land. Indigenous place names also mark reciprocal responsibilities to territories. Names, stories, and
meanings relating to place emerge within relationships with traditionally used lands, with many indigenous peoples seeing the land itself as integrally involved in meaning-making rather than humans as mapping meaning on top of the land. Processes of renaming previously held indigenous territories have been central to asserting settler presence while simultaneously erasing indigenous claims. Yet indigenous peoples continue to assert territorial naming rights. The stories and names that have been connected to specific places contain knowledge that is vital to their ecological wellbeing – something that has more recently been acknowledged within sustainability science and other environmental management fields.

Within many indigenous epistemologies, as mentioned above, animals, landscapes, oceans, and nonhuman elements are imbued with their own spirit and are also understood as having agency. Within long-standing relationships with such nonhuman elements, indigenous peoples often assert a responsibility to be in active communication with these elements of their cultural landscape. These understandings emerge within deeply relational and collectively formed place-based epistemologies, in which people, animals, and the natural world have a responsibility to one another extending back through millennia.

While the inclusion of indigeneity within the field of geography will be explored later in the entry, it should be noted that many indigenous scholars and scholars working with indigenous people internationally have used place-based analysis outside the discipline of geography and outside formal scholarly disciplines altogether. Indeed, indigenous peoples have long contended that indigeneity does not require formalization or recognition by scholars in order to gain legitimacy, but that indigenous ways of knowing and being are valid on their own terms. The reframing of indigeneity within various disciplinary frameworks has indeed been central to colonialism, and reclaiming indigenous control over representations of indigeneity is an important aspect of decolonization.

Some geographers working in the area of indigeneity have cautioned against creating a dichotomy between indigenous and Western, as there are many distinct cultural worldviews within each of these realms. Western epistemologies are broadly understood to mean modern systems of thought based in the Cartesian split between discourse and materiality, mind and body. This split is generally not found in indigenous worldviews, yet it has historically been used by many scholarly disciplines to represent indigenous epistemologies, reimagining them in this Western framework. For example, indigenous worldviews may understand meaning to be immanent within land, territory, and nature themselves; yet, when represented by Western academics, indigenous meanings are understood to be mapped onto the landscape rather than emerging from it. Indigenous peoples live in a great variety of urban and nonurban settings, negotiating hybrid identities, sometimes described as “thirstspace,” “fourth world,” or “dancing between worlds.” This hybridity of Western and indigenous epistemologies is arguably congruent with the fluidity of indigenous cultures, which were never static but changed and adapted over time, despite their representation within colonial discourses as static, backward, and temporally bound to premodern times. Thus, although indigenous and Western geographies are largely talked about as distinct schools of thought emerging within neocolonial power relations, this call for hybrid and nonessentialized indigenous geographic knowledge should be kept in mind.
Representations of indigeneity within geography

It has been argued that it is only since the mid- to late 1960s that the subdiscipline of indigenous geographies could be said to have existed. Indigenous geographies grew largely within critical and radical geographic scholarship, as geographers began to rethink commonly held views of indigenous peoples. Though geography’s engagement with indigeneity has been limited, the impact of Western geographic representations of indigenous peoples and their territories has been felt widely among indigenous communities the world over, as those representations were central to colonial processes and power relations.

In recent years, geographic representations of indigeneity and of traditionally held indigenous territories have themselves become subjects of critique as part of broad efforts to reflect critically on the discipline’s role in historic and ongoing colonialism. Historical approaches to indigeneity have been examined by critical geographers in order to denaturalize the racialized portrayal of indigenous people and knowledge as less evolved or as rooted in antiquated notions of “tradition” (see Cameron, de Leeuw, and Greenwood 2009 for a historical overview). Some of the more critical engagements with these representations have pointed out the inherently violent function and devastating outcomes of these representations, as well as their role in erasing indigenous peoples’ presence altogether, in some cases. Critical geographers in Canada and the United States have demonstrated that the role of geography and geographic discourses and practices in empire building must be acknowledged in order to move the discipline beyond its conventions.

Imagining empty lands

The Western geolegal concept of *terra nullius* – or the empty lands doctrine – is at the heart of colonial power relations. In order to imagine the lands of North America, and other parts of the world, as available for settlement, they needed to first be cleared of any legal “owners.” Racialized discourses about “Indians,” which categorized indigenous peoples as less than human, were embedded in Western legal discourse beginning with the doctrine of discovery, which served to neutralize the settlement of North America, as indigenous people could not be recognized as having legitimate territorial claims.

Further, the Western geographic imaginary imposed a Cartesian worldview on colonized lands, through which the lands could be imagined as blank spaces on which to map new areas of progress, extraction, and settlement. Combined with the authoritative legal power of the newly formed states, geographic tools such as grids, maps, and surveys effectively rendered invisible indigenous territorial relations and jurisdictions. Geographers have critically evaluated the role of these spatial tactics in naturalizing indigenous deterritorialization, arguing that they have worked to render the epistemic and material violence of settlement invisible.

One of the key outcomes of indigenous spatial erasure was the formation of Indian reservations or reserves. As geographers such as Cole Harris have shown, Indian reservations in Canada and the United States can be understood as a manifestation of colonial ideologies, produced in order to realize the ongoing dispossession of indigenous peoples of their territories, and to establish the sovereignty of the Canadian state. The creation of colonies entailed not only the mental work of imagining “Indians”
as without legal tenure, but also the practical work of individuals mapping out and setting aside lands to which indigenous people and their claims could be confined. Through this process, indigenous people became trespassers in their own territories whenever they traveled beyond these newly created borders. Although the reservation geography of settler-colonial countries is often taken as fixed or natural spaces of indigenous occupation, geographers, particularly those working in areas of colonial law and policy, have demonstrated the fraught nature of their construction and realization.

This geographic imaginary is not only historical, however, as indigenous peoples continue to contest the division of land within settler-colonial worldviews, thus undermining the naturalized character of terra nullius imaginaries. Reserve geographies are produced within the rationale of terra nullius, and in relation to the imagined frontier, which are all at work under the spatialization of contemporary sociolegal relations. The geographic examination of imagined and material colonial geographies is useful in understanding contemporary indigenous–state relations, as we can see how reserves continue to be produced as spaces of assumed neglect and violence, while “Indians,” inherently “of the reserve,” are produced as subjects of this naturalized marginalization. Representations of indigeneity today thus continue to be conditioned through neocolonial power relations, but they are also produced within the resistance and vitality of underlying indigenous territorialities.

While the mapping and dividing up of land, and the designation of certain spaces for natives, has clearly been a source of marginalization and oppression for indigenous peoples, it has also been a site of resistance. In the 1990s indigenous geographers and geographers working collaboratively with indigenous peoples began using counter-mapping to bring new form to indigenous knowledge using the technology of geographic information science (GIScience). Geographers have also studied the disruptive potential of blockades and other strategies of making indigenous jurisdiction visible, particularly in places such as British Columbia, Canada, where the legal status of lands is highly contentious. In these and other ways, geographers have contributed to making underlying indigenous geographies visible, responding to calls to decolonize the discipline of geography and, more broadly, to decolonize dominant settler–indigenous relations.

**Urban indigenous geographies**

In the processes of settlement described earlier, cities emerged in settler-colonial contexts as set apart from areas legally recognized as belonging to indigenous peoples. Sites of indigeneity were imagined as either temporally or physically at a distance from sites of civilization and progress. We see this imaginary at work when indigenous people are said to be “migrating” to cities from reservations. This representation naturalizes reserves as “Indian spaces” while reaffirming the whiteness of urban spaces and rendering underlying indigenous territories invisible. Urbanization has been facilitated by the material displacement of indigenous peoples from lands that were desired by settlers and, in the process, the prior relationships to those lands were frequently forgotten or erased. Indigenous people, in the meantime, have been imagined as belonging to “Indian spaces” such as rural areas, Indian reservations, and, in the context of urban centers, racial ghettos.

Since the mid-1990s, geographers have contributed to understanding how urban areas have been constructed through racial and gendered discourse and policies such that indigenous
peoples are “out of place” in these white settler spaces. Attention has been given to the ways in which certain racialized bodies, such as those of indigenous women, have had violence against them normalized both through social norms that render them as apart from the rest of society and through legal processes that are inherently colonial. In decolonizing these dominant relations, indigenous geographers have created accounts of indigenous women’s identities and resistance that unsettle dominant conceptions of race and gender in urban spaces. The memorialization of certain kinds of violence and certain kinds of bodies within urban centers has also emerged as an area of study among urban geographers, helping to contextualize the unwillingness to pay tribute to indigenous women who have faced widespread violence in urban spaces. In more recent processes of gentrification within poor and industrial areas of North American cities, geographers have demonstrated how frontier imaginaries are being mobilized to render those spaces as empty and thus available for development.

Another important theme within urban indigenous geographies is the reclamation of indigeneity, which is active and alive underneath urban geographies in settler-colonial countries. Indigenous people are reasserting indigenous place names within cities, using billboards, street signs, and other representational tools to make their long-standing presence known. The mobilization of urban indigenous people for various social justice causes, such as the disappearance of hundreds of indigenous girls and women, has also been a venue through which indigenous presence in cities has been asserted. These urban indigenous geographies remain an emergent area of study for geographers interested in decolonizing the discipline.

**Strengthening the presence of indigeneity in geography**

Since its emergence in the 1960s, indigenous geography has clearly been an area of innovation and critical research and of theoretical development within the discipline. Yet, more broadly within geography, indigenous issues and people continue to be identified as a gap in the field. The discipline’s historic lack of engagement with indigeneity is evident in the absence of indigenous knowledge, people, and ways of being in most geography textbooks and course offerings. This absence has been said to suggest that the dominant geographic imagination is not generally organized by a recognition of the indigenous title and territories underlying settler-colonial geographies. Perhaps most tellingly, it is only recently that the discipline has seen a growth in the presence of geographers of indigenous heritage.

Scholars in diverse areas of geography have pointed out that Aboriginal, Indigenous, First Nations, and Native American people and knowledge constitute significant gaps in the field of geographic research. This lack is made apparent in the evaluation that in the years 1997 to 2004 publications with the term “indigenous/indigeneity” represented less than 2% and “aboriginal/aboriginality/aborigines” represented 3.5% of international geography journal content (Shaw, Herman, and Dobbs 2006). Indigenous geographies have remained peripheral to broad geographic theory, as “indigenous geographies are somewhat removed from the rigors of disciplinary debate and remain out there, on the post-neocolonial edges of the disciplinary orbit” (Shaw, Herman, and Dobbs 2006, 269; emphasis original). Scholars have thus called for members of indigenous community movements to be more fully engaged as geographers, so that their expertise can be sought and learned
 Others have noted that creative effort is needed to improve First Nations and Native American studies in geography, as not only are indigenous people underrepresented within academic geography departments, but there is comparatively little work by geographers on the political struggles of indigenous groups in North America and internationally.

However, since the mid-1990s there has been a growth of spaces dedicated to indigeneity within the discipline, due in large part to the innovations of indigenous scholars working in geography, as well as their allies. These include the formation of the Indigenous Peoples Specialty Group of the Association of American Geographers (AAG) and the Indigenous Peoples Working Group of the Canadian Association of Geographers (CAG), as well as work to institutionalize indigenous issues within the International Geographical Union (IGU). International professional associations like the Institute of Australian Geographers have also seen the formation of such spaces dedicated to indigenous issues. These groups have developed funding support to assist in bringing indigenous students and community members to regional and national meetings, to encourage the growth of their voices within the discipline. The growth of these specialty groups has facilitated the development of sponsored conference sessions and keynote lectures by indigenous political leaders, experts, and knowledge keepers at annual meetings. Additionally, special issues of international geography journals, including Cultural Geographies and The Canadian Geographer, have been dedicated to themes of indigeneity, and Geografiska Annaler B: Progress in Human Geography has also recently included progress reports on indigenous geographies, indicating the increasing impact of this area broadly within the field.

In response to this growing interest in indigeneity, along with a recognition of the exploitative research practices that have typified scholarly engagements with indigenous peoples historically, power dynamics within knowledge production and legitimation have become a key area of critique. The foundations of knowledge production have been destabilized through the increasingly vocal mobilization of indigenous peoples’ self-determination struggles, which have included an insistence on developing their own methodologies. The reassertion of indigenous knowledge paradigms through indigenous-led research is integral to dismantling colonial power relations: “It has involved a ‘knowing of the colonizer’ and a recovery of ourselves, an analysis of colonialism, and a struggle for self-determination” (Smith 1999, 7). While differing widely, indigenous methodologies generally draw on culturally specific knowledge creation and mobilization principles, while taking colonial power relations into account. In a recent move away from its colonizing project, critical geography has seen renewed engagement with issues of indigeneity through careful, inclusive, and collaborative research initiatives. In these processes, indigenous people have sought control over representations of themselves and their knowledge, and have asserted that recognition of indigeneity is not required by formal disciplinary standards but is valid on its own terms.

Such assertions of self-determined representation have challenged geography, as well as other disciplines, to recognize methodologies that account for diverse expressions of indigenous knowledges, including those that are not written down but are presented orally. These methods continue to challenge the standards of many scholars across diverse fields of study. Geographers have been compelled to ask how research serves indigenous community concerns and how it might support, or detract from, self-determination at a personal and community level. Engaging in deeply relational,
place-based forms of indigenous inquiry, scholars are challenged to balance their accountability to institutions and communities which are culturally and epistemologically divergent (Kovach 2009). Ethical concerns about the long-term impact of research on indigenous peoples serve as a reminder that scholars cannot always know how knowledge will be used once it is made public. For example, the mapping of traditional uses of indigenous territories may benefit their legal land claims but risks being misused by people or industries that want to exploit that knowledge. Collaborative working relationships and obtaining prior informed consent for conducting research are thus key to allowing indigenous peoples to be actively involved in shaping research about them.

Alongside these developments in indigenous methodologies, some geographers have questioned the potentially harmful effects of achieving inclusivity of indigenous people and knowledge. For example, while community-based research (CBR) is often lauded as inherently decolonial, critical geographers have been careful to point out how the language of CBR can gloss over power dynamics and replicate some of the very colonial relations researchers are trying to avoid. Thus, geographers must remain attuned to the ways their work is shaped by institutional norms, including the push to publish solo authored papers, for example, and to adhere to institutional research ethics which may not match up with indigenous concerns. Additionally, institutions are still challenged to recognize CBR as legitimate scholarship, as so much of the relationship-building that goes into truly collaborative work with indigenous peoples cannot be captured by neoliberal methods of measuring research outputs. Decolonizing the discipline is thus a much larger project which must extend beyond geography associations and journals to the culture of the institutions in which geographers are situated.

One area of indigenous leadership over research has been in the development of decolonial principles to guide research. Indigenous peoples have developed the framework of ownership, control, access, and possession (OCAP) in shaping a self-determined agenda for scholarly research involving indigenous knowledge and communities. These principles are designed to allow indigenous people to shift the power over control of their knowledge into their own hands, with academic partners, researchers, and students conducting their work in response to these self-determined approaches. While institutional ethics protocols and legal ownership procedures are shifting slowly, challenges still exist as to how to ensure that OCAP principles do not conflict with institutional norms. Increasingly, indigenous peoples are initiating their own research agendas, writing their own stories, and capturing their own knowledge with geographers and other specialists as partners or collaborators, again ensuring that indigenous epistemologies are at the center of geographic knowledge production.

**Future directions**

As the presence of indigenous people as scholars and collaborators increases in the field of geography, the discipline’s engagement with indigeneity is bound to shift significantly. In particular, there has been a movement away from viewing indigenous peoples as victims of neocolonial relations, with increased attention on indigenous political resurgence, success, and survival. This is broadly true within academia, as indigenous scholarship has seen extensive growth since the 1990s, with the emergence of indigenous studies departments, indigenous-focused courses, indigenous research streams, and
departmental recruitment of scholars working specifically in areas related to indigeneity.

Calls have been made for geographers to acknowledge that some indigenous concepts can only be understood within indigenous spatiotemporal ontologies, which are distinct and locally situated. These calls, which have emerged within the recent “ontological turn” within the discipline (Cameron, de Leeuw, and Desbiens 2014), will undoubtedly continue to fuel discussion about how indigeneity is represented and mobilized within institutional contexts that remain fundamentally rooted in colonial power relations. Geography is challenged to allow for shifts in ontologies of space, place, temporality, and landscape, among other foundational geographic concepts, as indigenous epistemologies push at the limitations of the English language and challenge the terms in which geographic knowledge has developed from its Western roots. Critical geographers have examined the potential for encounters with indigenous and other non-European geographies in exposing the cultural specificity of modern geographic knowledge and providing challenges to geography’s reliance on Cartesian ontologies. At the same time, indigenous peoples have also called for geographers and other scholars to continue to be mindful of the capacity for academic appropriation and misrepresentation of indigeneity in the pursuit of unsettling disciplinary norms.

Indigenous health

Chantelle A.M. Richmond
Western University, Canada

Globally, there are approximately 370 million indigenous people (or 5% of the world’s population) living in 70 countries including the Circumpolar North; South, Central, and North America; Africa; Asia; the Pacific Islands; New Zealand; and Australia. The term “indigenous” is used to refer to the descendants of original populations who lived in an area before colonization. There are a number of characteristics that are generally included in the meaning of the term “indigenous,” including having a common ancestry, being accepted by one’s community, possessing a cultural distinctiveness from the majority population, and a common experience of dispossession from traditional lands and territories.

The term “indigenous” is generally used in a global sense, whereas indigenous groups and communities typically have geographically contextualized terms that relate to the places they inhabit, as well as the languages they speak. For example, in central Canada, the Ojibway people are often referred to as the Anishinabe, a term that reflects the language spoken by this group, Anishinabemowen. Around the globe, there are various other terms used to reflect one’s indigeneity, including “native,” “aboriginal,” “tribal peoples,” “original,” and “first.”

Indigenous people tend to speak languages and to practice traditions that are distinct from the dominant society, reflecting rich and diverse cultural knowledges, spiritual practices, values, traditions, customs, food preferences and practices, forms of livelihood, trade and economy, and the necessities of everyday living. There invariably is a significant and interdependent relationship between indigenous peoples and their local ecosystems, one that is central to the health of the people and vital for a way of life based fundamentally on the resources of their traditional environments. Prior to colonization, indigenous societies could be described as subsistence cultures, meaning that their daily nourishment was provided by the physical resources of the air, land, and water. This total reliance has fostered a deep respect on the part of indigenous people for the natural environment, but for many this relationship has also led to a deeper cognitive and spiritual relatedness wherein the environment is seen as conceptually interrelated with humankind. Here lies an important and often overlooked interrelatedness: the health of the environment is inseparable from the health of those whose existence has so emphatically relied on it. This relationship has been fostered, practiced, and celebrated in many ways by indigenous societies around the world. In contemporary times, many indigenous groups continue to live a way of life sustained by resources of the lands, air, and waters (e.g., harvesting and consuming “traditional foods” or “country foods,” as they are often referred to), but processes of environmental dispossession are changing the ways in which indigenous people can safely and reliably sustain themselves fully from a subsistence diet (Ford 2012).
Indigenous knowledge systems: meaning for health and ties to the land

In all indigenous cultures, daily life and continued wellbeing have historically depended on a deep knowledge and intimate relatedness to one’s local ecosystem, which can be referred to as an indigenous knowledge (IK) system. At the most basic level, it is this knowledge system that has enabled indigenous people not only to survive but to thrive, in some cases for millennia, in some of the harshest, most inhospitable environments on Earth, such as the Australian Outback, with its low annual rainfall, or the Canadian Arctic, where some of the Earth’s coldest temperatures have been recorded.

While there are no commonly accepted definitions of what an indigenous knowledge system is, it generally refers to the culturally and spiritually based ways indigenous people relate to their local ecosystems and to one another (LaDuke 1994). These relationships are centered on a number of key characteristics. First, an IK system is based on localized knowledge and understandings to utilize the resources of one’s ecosystem sustainably for medicines, food, shelter, and many other purposes related to everyday life. Second, it is a dynamic, applied knowledge. From season to season, for example, the patterns of flora and fauna (e.g., the migration and hibernation patterns of local birds and mammals), as well as weather patterns, vary. In order to learn how best to utilize these resources, indigenous people draw on their strength of observation of these constantly changing patterns. Third, an IK system is an integrated knowledge that consists of many parts and is thus best learned by doing or practicing. Because the interaction with the local ecosystem contains so many biological and physical processes, and also because most IK systems are maintained within an oral tradition, learning is best done by practicing, being out in the environment, and through firsthand observation.

Indigenous concepts of health

One of the consistencies in indigenous worldviews across the globe is the strikingly similar conceptions of health and healing, which may nevertheless be represented in diverse ways. Among Canada’s First Nations population, the medicine wheel embodies a common understanding of health: a circle divided into four sections representing the four elements of life – the physical, emotional, mental, and spiritual. If one element of the wheel is neglected or receives too much attention, health suffers in all four areas. Among New Zealand Māori, “health as a house” is one of many conceptual frameworks used to illustrate the multidimensionality of Māori health and wellbeing. Like the medicine wheel, this conception is represented by the four walls of a house: each wall is a different health dimension, and if one wall should fall the whole house (one’s health) will collapse. Among Aboriginal Australians, the three dimensions of healthy living are thought to be land, spirituality, and people; these three interrelated dimensions provide a blueprint for living.

Another key dimension of the IK system is its relational context – meaning that individual wellbeing reflects social and moral rules – and the inherent obligations one has not only to oneself, but also to the wider community and ecosystem. Inuit Qaujimajatuqangit (IQ) is the term used to describe Inuit epistemology or the indigenous knowledge among Inuit in Nunavut. This place-based worldview explicitly recognizes humans’ connection to the land, to the greater ecosystem, and to one another, and the term translates directly as “that which Inuit have always known to be true.” At the individual
level, a good or moral person is someone who is *inummarik*, or “a most genuine person.” From the earliest times, the sharing of food and resources was a central concept in Inuit life and social structure. The ways in which an individual’s wellbeing is bound by social values and his or her connection to wider community are also illustrated in the Native Hawai’ian context. Among Native Hawai’ians, a good or healthy person is thought to have the following values: *lokahi* (living in balance), *pono* (doing the right thing), and *kokua* (working without expecting reward). Here, the ultimate goal is not constrained to individual wellness, but rather seeks to strengthen and protect family and the wider community.

IK systems are not only based on an individual’s connection to physical and social dimensions, but are also fundamentally supported by a spiritual dimension. One of the most challenging parts of conceptualizing the IK system results from the fact that it is bound within a holistic philosophy that differs quite significantly from a biomedical, industrial, or capitalist philosophy that tends to frame Western notions of life, learning, or, for example, what it means to be healthy (Berkes 2012). A holistic philosophy is rooted in the understanding that life, learning, and wellbeing are part of a larger system that cannot be understood as separable, or as components, but rather as fluid, connected pieces. The complexity of this philosophy is embedded in many indigenous languages, including Anishinabemowen, which does not differentiate between male and female. Rather, in Anishinabemowen philosophy, all parts of our world are differentiated into animate and inanimate objects – meaning those things that have spirit or life and those that do not, respectively. The distinction between these categories is not straightforward in a way that sees objects in the natural world as having spirit or life (e.g., a tree) or not having spirit or life (e.g., a rock). Rather, the distinctions are deeply rooted in Anishinabe spiritual beliefs, including a relatedness that generally does not differentiate between the physical and spiritual worlds. These conceptual ideas stem from Anishinabe ideas of creation, many of which persist only in the oral tradition, and conceptualize human life as deeply connected to various parts of the physical world, including nonliving objects. Several Anishinabe artists – most prominently Norval Morrisseau – have used their craft to depict this complexity and the interrelated nature of the physical, biological, and spiritual worlds.

Probably the most important dimension of the IK system is that it is shared almost exclusively through an oral tradition. To learn and to be part of the IK system means practicing and living the knowledge. In practical terms, accumulating IK is based fundamentally on relating to the environment – through being out on the land and sea – and also through access to those who can teach the knowledge. In many indigenous cultures, there are varying levels of access to IK. Some are rooted strongly in daily life, in the basic struggle for survival, in the maintenance of cultural identity, and in interaction with the local ecosystem, but there is also applied or spiritual knowledge that may be accessible only through ceremony or role obligation, for example puberty rights or the practice of traditional medicines and healing.

### Environmental dispossession and indigenous knowledge systems

Given the special connection between indigenous peoples and their ecosystems, including the social, spiritual, and economic ties it supports, indigenous peoples are more vulnerable to the processes of environmental change and
environmental dispossession (Richmond and Ross 2009; Ford 2012), and with strikingly similar consequences for health and wellbeing. In the greater global context, IK systems are based fundamentally on local experiences and a connection with and ongoing observation of the local ecosystem. Because of the vast and often rapid changes brought on by global industrial development, including various types of contamination and climate change, indigenous peoples are particularly susceptible to these changes. In fact, environmental dispossession has become a common unifying experience among indigenous peoples, and could be framed as a second wave of colonization. Environmental dispossession refers to the processes by which indigenous peoples’ access to their traditional lands and territories is reduced or eliminated (Richmond and Ross 2009). These processes take various physical and political forms, were generated historically, mainly through processes of colonialism, and continue in contemporary times. The outcomes of these processes vary across place and culture.

Direct forms of environmental dispossession involve processes that physically disable use of the land, such as industrial activities or contamination events that may sever ties to traditional foods or resources required for sustaining daily activities. The effects of climate change are particularly prominent among indigenous peoples and populations (Ford 2012), many of whom inhabit the most fragile ecosystems globally. Indirect forms of dispossession occur as a result of policies or regulation that lead to the severance of indigenous peoples’ link to the land, and the indigenous knowledge it fosters. For example, indigenous peoples have been subject to massive relocation projects, as well as various assimilationist policies that have included the forced attendance of indigenous children at church- and state-run residential/boarding schools in Canada, the United States, and Australia. These processes have undermined the ability of indigenous peoples to practice their land-based cultures and IK systems. In contemporary times the processes of environmental dispossession have significantly disrupted indigenous peoples’ relationships to land, and thus to the cultural knowledge and sociocultural practices that are central to their maintenance of health and wellbeing (Big-Canoe and Richmond 2014).

Patterns of indigenous health

On a global level, the processes of environmental dispossession – whether operating in direct or indirect forms – have had significant impacts on the health and wellbeing of indigenous people because they work to destabilize IK systems. They do so by reducing indigenous people’s confidence in environmental conditions, for example, as climate change makes it more difficult to predict the weather (e.g., with extended dry or wet periods), or as migratory animals return later in the season than usual. While IK systems are dynamic, fluid, and constantly changing in relation to the natural rhythms of local ecosystems, the processes of environmental dispossession can accelerate these changes in a way that makes normal interaction with the land risky for human health (Ford 2012), for example, when local fish stocks or other country food has been contaminated by heavy metals. These changing conditions can lead to people spending less time on the land because the risk of doing so can become too great. Less time spent out on the land means that opportunities for sharing IK and for practicing skills may also become limited over time, leading to the weakening of cultural and social ties that fundamentally support indigenous cultural identity, social roles, moral obligations,
and self-esteem (Big-Canoe and Richmond 2014).

On a global scale, the consequences of environmental dispossession for indigenous health are remarkably similar. The reduced access of indigenous peoples to their traditional lands and territories has had many detrimental impacts for the preservation, practice, and intergenerational transmission of IK, leading to significant changes in their way of life and resulting in a contemporary health and cultural profile characterized by a greater burden of morbidity and early mortality than that of the nonindigenous population. While the last half century has witnessed significant gains in life expectancy for indigenous populations, and a considerable reduction in infant mortality, several other patterns of health are troubling, including a high prevalence of cardiovascular disease, type 2 diabetes, and cancers; mental illness, addictions, and violence; and food insecurity. While most indigenous populations have undergone the epidemiologic transition, where the main causes of indigenous morbidity and mortality have shifted from infectious to long-term chronic disease, infectious disease is common in the health profile of indigenous populations. The persistence of infectious disease among indigenous peoples includes many ailments that have been all but eradicated in the general population, such as active tuberculosis and rheumatic fever. International research indicates that these health disparities are linked to alienation from the land (Richmond and Ross 2009), to limited opportunities to practice activities that foster indigenous cultural and social connectedness, and traditional health and healing, and to a number of social determinants of health, including poverty.

Another significant outcome of environmental dispossession is an unprecedented shift to cities by indigenous populations. Over the course of the twentieth century, indigenous people in Canada, the United States, Australia, and New Zealand have moved, in considerable numbers, into urban areas and away from their ancestral lands. This pattern of urbanization has led to significant shifts in the cultural and social identities of indigenous people, but it is important to note that indigenous cultural identities and the urban environment are not mutually exclusive. Rather, the small base of literature on indigenous urbanization illustrates that urban indigenous people tend to migrate rather fluidly between the city and their traditional homelands. In the city, indigenous identity is sustained and exercised through participation in various social or political organizations, among other institutions such as university and college campuses where indigenous services and programming have been created to nurture indigenous students in the academic setting. Despite the growing trend of urbanization among indigenous populations worldwide, very little is known about the drivers and consequences of this migration; this is a decidedly underresearched topic in the geographical literature. An important recent text by Peters and Anderson (2013) details international indigenous experiences of urbanization and the ways in which indigenous cultural identities are constructed and reconstructed in cities.

Researching indigenous health and environmental repossession

In spite of the troubling patterns of health evident in indigenous populations, there are reasons to be hopeful. As noted, the wide gap in the health and social profile of indigenous people is slowly closing over time. There are many factors leading to the reduction in health disparities, including increased access to culturally safe and high-quality health care; the development of health and social policy that reflects
INDIGENOUS HEALTH

indigenous ideals and philosophies; the ongoing resolution of indigenous land claims; increased funding for indigenous social development and programming; and steady increases in socio-economic wellbeing (e.g., increases in high school completion and postsecondary attendance).

Perhaps one of the most important contributions to the closing gap between indigenous health status and that of the general population relates to a growing and hopeful movement of indigenous community participation in health and social research, that is, by indigenizing the way research is done. Building on Linda Smith’s seminal work on decolonizing methodologies, a wide body of indigenous research has been undertaken, led by a common goal of “centering our own concerns and world-views, and coming to know and understand theory and research from our own perspectives and for our own purposes” (1999, 39). Such methods require meaningful research partnerships between indigenous communities and researchers from universities and various governments and organizations, with the ultimate goal being to design and carry out research that will lead to improved local conditions. These partnerships are a method of decolonization, as the indigenous communities involved are placed at the center of the research, thereby empowering local people to influence research topics, debate, and research design, and prioritizing local influence in the development of community programs. Based on research with Anishinabe youth in Ontario, Big-Canoe and Richmond (2014) recently proposed the term “environmental repossession” to refer to the social, cultural, and political processes by which indigenous peoples and communities are reclaiming their traditional lands and ways of life. The concept of environmental repossession is rooted in the idea that indigenous people’s health, ways of living, and indigenous knowledge systems are highly dependent on access to their traditional lands and territories. As a response to the ongoing effects of colonization and dispossession, environmental repossession demonstrates a way of thinking and an applied practice that are in broad opposition to the hopelessness that is too often used to characterize patterns of indigenous ill-health and social problems, particularly in the North American context. Working within a decolonizing methodological framework, environmental repossession may provide a promising approach for researchers and communities to collaboratively document the unique and varied processes within which indigenous communities from around the globe are asserting their indigenous rights and improving their health and wellbeing.

Indigenous knowledge

David Barker
University of the West Indies, Jamaica

Indigenous knowledge (IK) is the body of traditional knowledge of people who have lived as a community in a local area over a long period of time. In the vernacular, indigenous knowledge is often referred to as traditional knowledge, local knowledge, or traditional wisdom. It can refer to a community’s rich knowledge of plants, trees, animals, and other facets of their local environment which are utilized in their livelihood activities. This includes knowledge of local soils, topography, water resources, and weather. It can refer to more specialized knowledge and use of specific natural resources, as in folk medicine, health, and nutrition. Indigenous knowledge is recognized as playing a role in community disaster management and conservation of biodiversity, and in contributing to our understanding of climate change. Respect for and legal recognition of the intellectual property rights of indigenous peoples and their indigenous knowledge systems was formalized in the United Nations Declaration on the Rights of Indigenous Peoples in 2007.

A precise definition of indigenous knowledge is elusive. Paul Richards, an early influential writer, tentatively suggested community environmental knowledge, folk ecology, and peoples’ science as useful descriptors. Warren’s (1991) definition is widely accepted: “Indigenous knowledge (IK) is the local knowledge – knowledge that is unique to a given culture or society. IK contrasts with the international knowledge system generated by universities, research institutions and private firms. It is the basis for local-level decision-making in agriculture, health care, food preparation, education, natural resource management, and a host of other activities in rural communities.” A cognate term is “ethnoscience,” defined as the study of the shared patterns of belief and knowledge within an ethnic group or community, and is widely used in anthropology.

“Indigenous peoples” are defined as ethnic groups with economic, social, cultural, and political characteristics distinct from the societies in which they live, and which have historical continuity with precolonial or presettler societies. However, the concept of indigenous can be less rigorously interpreted. In the insular Caribbean, Amerindians were annihilated as a result of colonialism, and a peasant class of small farmers emerged after the abolition of slavery, well after the onset of European colonization. Yet research among Caribbean small-scale farming communities also has produced valuable insights into traditional knowledge as a critical component of rural livelihoods and food security.

The main characteristics of indigenous knowledge are that it is community-based and unique, being indigenous to a specific culture group and particular to a geographical area. It is dynamic rather than static, and so enables a community to try to cope with and adapt to environmental change. The body of knowledge accumulates or is edited over many generations, as local circumstances dictate, and is communicated through interpersonal and intergenerational transmission. Thus, it is constructed, acquired, and articulated within an informal milieu, in contrast to knowledge acquired through formal educational institutional settings (based on Western science).
INDIGENOUS KNOWLEDGE

The corollary is that, in the past, IK was rarely written down. Following the United Nations General Assembly’s Declaration of the Rights of Indigenous Peoples (UNDRIP), indigenous peoples have been encouraged to document their knowledge and assert intellectual property rights.

An indigenous knowledge system is predicated on the identification and classification of locally relevant environmental and ecological phenomena, and interpretation of salient dynamic relationships between their cognitive categories. In this sense, the content of IK comprises detailed empirical local knowledge (using local names) of plants and trees, animals and insects, soils and topography, weather patterns, and so on. This empirical database forms an intellectual template within which practical livelihood skills, best practices, and traditional technologies are construed, learned, and employed in decision-making. The latter practical skills are sometimes termed “indigenous technical knowledge” (ITK), and may include cottage industry and food processing activities. The problem-solving functionality of indigenous knowledge is integral to successful livelihood strategies at the household level in resource-poor rural communities. While empirical knowledge and its content in theory can be distinguished from the practical applications of the knowledge, indigenous knowledge and indigenous technical knowledge are used interchangeably.

Epistemologically, for many ethnic indigenous peoples, IK is embedded within their local cultural and spiritual belief systems. Thus, indigenous knowledge systems reflect, concomitantly, a utilitarian classification of environmental phenomena and associated skills, and a broader cosmography of the community’s relations with the natural world. Anthropologists have documented the rich and sophisticated intricacies of indigenous peoples and their belief systems in elaborate detail. This permanent record is extremely important in the context of human history and world heritage because such ways of life and ideas are rapidly disappearing as globalization incorporates more and more of the world’s more isolated communities into the mainstream.

In geography, some of the first scholars to advocate the importance of traditional knowledge were Harold Brookfield (Pacific Islands), Paul Richards (Africa), and Theo Hills (Caribbean). Their research clearly demonstrated the utility of traditional knowledge and the inherent rationality of decision-making by tropical small-scale farmers in managing their land resources, especially with respect to risk minimization. Local knowledge underpins farmers’ choice of crops and crop combinations, techniques to manage soil fertility, methods of pest control, and many other aspects of land, crop, and animal management. Traditional knowledge is fine-tuned to specific, local sociocultural conditions and specialized agroecological regions. Early research juxtaposed the wisdom of indigenous knowledge against the negative stigmatizing and stereotyping of small-scale tropical farmers during colonial times, and lamented the discriminatory policy bias in favor of large-scale, export agriculture. Field research in geography drew inspiration from ethnography and cultural ecology. Appropriate research methodologies tapped into the emerging field of environmental perception, to explore novel ways of eliciting cognitive environmental data.

Holistic versus specialized studies of IK

A substantial amount of empirical academic research on indigenous knowledge has accumulated since the 1980s. Much of it has focused on identifying its sophisticated content and
demonstrating clever and innovative practical applications across many different cultures and agroecological conditions, and on all continents of human habitation. Since the livelihoods of indigenous peoples depend critically on the use of natural resources, studies of agriculture (crop cultivation and animal herding), artisanal fishing (coastal and riparian), and rainforest-based activities feature prominently in the literature. However, the bulk of this research relates to agriculture. Agricultural research can take a holistic view of a particular cultivation or pastoral system or focus on a specialized facet of indigenous knowledge within a local livelihood system or agroecological region.

A good example of a holistic approach is tropical home gardens. These cultivation systems occur throughout Africa, Asia, Central and South America, and regions of tropical islands such as the Caribbean and Pacific Ocean. They are known also as “compound gardens,” “kitchen gardens,” and “food forests,” and have numerous local names in local languages. Indigenous knowledge guides the spatial and temporal organization of these sophisticated agronomic cultivation systems. Tropical home gardens have dozens of different species packed together in a small geographical space, with symbiotic relationships between many plant species. Typically, there are three or four tiers of useful trees, bushes, and plants, ranging from tall trees to ground-level plants and tubers. Plant censuses of valuable species present in a single garden are as high as 150–250 in places like Java and Sri Lanka. They are highly productive and play a critical role in household food security. They provide a nutritionally well-balanced diet because small animals such as chickens, goats, and pigs are often incorporated into the assemblage. Many nonfood items, such as plants for folk medicines, dyes, cosmetics, herbal teas, craft and household items, and trees for construction, furniture, and roofing material are usually present in these gardens. Tropical home gardens help cement social capital within extended families and rural communities through the sharing and exchange of food, they play a role in children’s botanical education, and are mobilized as a form of community-based, disaster relief after a tropical storm or other natural disaster. Tropical home gardens are an example of traditional agroforestry, a more geographically extensive system of farming which provides households with additional economic opportunities through commercial tree crop production. It is particularly well documented for the Pacific Islands.

An example of research focusing on specialized facets of indigenous knowledge is the study of traditional methods of soil classification. Soil color and texture are universal practical methods used by farmers to assess local soil fertility. Ingenious, more ad hoc techniques include soil taste, the presence of earthworm casts, and depth of footprints. Africa is strongly represented in the ethnopedology literature. Research on indigenous pest control methods is another example of more specialized research. Its focus, not surprisingly, tends to be on visible insect and animal pests rather than on microscopic organisms. An important theme in traditional pest management is the biodiversity of cropping systems, which creates conditions in microhabitats for natural pest control through predation, and lower insect herbivore populations than in monocropping.

**IK and development planning**

In the 1980s, a new dimension to indigenous knowledge research emerged: its use as a potential tool in development planning. The new
direction resulted from the seminal work of Robert Chambers on rural development, which brought IK to center stage in the development discourse. He argued that local indigenous knowledge should play a more important role in development planning, in partnership with conventional scientific knowledge, to help empower rural communities in developing countries. Chambers (1983) explored connections between IK and participatory development, and reported on innovative community-based local methodologies such as participatory mapping and natural resource inventories. Later, Chambers was involved in developing the pivotal concept of rural sustainable livelihoods, which again highlighted indigenous knowledge and traditional sustainable farming practices as key components of successful livelihood strategies.

As indigenous knowledge was integrated into development thinking and development practice, it became part of the institutional conventional wisdom through endorsement by international agencies. For example, Agenda 21 and the Rio Summit in 1992 highlighted its potential role for sustainable development. Many traditional preindustrial communities whose ways of life were connected intimately to indigenous knowledge had once lived in harmony with the natural world. So, low environmental impact solutions to sustainable food production, for example, might be found in the best practices of livelihood systems based on indigenous technical knowledge. The 1992 UN Convention on Biological Diversity recognized the value of traditional knowledge in the protection of species, ecosystems, and landscapes while the World Bank’s endorsement of the value of indigenous knowledge in 1998 consolidated its place in international development policy debates.

An ongoing debate revolves around the perceived need to demonstrate the veracity of IK to a seemingly skeptical world of formal science-based knowledge. The classic example of the scientific validity of traditional farming practices is the use of intercropping or inter-tillage. Intercropping is ubiquitous in the tropics. But it was derided and held in low esteem by colonial agricultural officers trained in European farming techniques, until scientific research clearly showed it had many advantages over monoculture, and could be more productive and profitable. Often, Western science and indigenous knowledge are presented as two competing knowledge systems and there may be tension and conflict between their proponents regarding merits and demerits, often played out in relation to the adoption or nonadoption of agricultural innovations. Western science tends to be equated with modernism, objectivity, openness, transferability, and objective and detached rationality, whereas indigenous knowledge is seen as primitive, parochial, nonrigorous and therefore nonintellectual, emotive, and associated with “backward” ways of life. The situation is often characterized as “us versus them.” While there is some truth in these characterizations and conflicts, the widespread acceptance of integrated pest management, whereby traditional methods of pest control are combined with low-cost, low-environmental impact, science-based methods, illustrates that successful practical “partnerships” between science and IK are possible.

Briggs (2005) has argued that indigenous knowledge has not lived up to earlier expectations in promoting sustainable development in resource-poor rural communities. While acknowledging the literature successfully demonstrates its importance to local communities, such research has had little impact on development practice. He suggests this represents a “false dawn,” and that indigenous knowledge has become “the Cinderella of development.” Others, more trenchantly, label IK as a new rhetoric for development professionals. Briggs
argues a more comprehensive understanding of the epistemology of indigenous knowledge is required with a greater focus on process rather than content. This implies a shift toward a better understanding of how local people observe, discuss, question, and analyze their problems. It requires the interrogation of indigenous knowledge and externally referenced, science-based knowledge by local people and outsiders, and offers a better route for developing synergies between the two knowledge systems. By way of example, Jamaican farmers were insightful and reflective in their thinking about a government-sponsored innovation to introduce minissett yam. But ultimately they rejected the innovation, often with sound reasoning. In contrast, they were positive and constructive in their reactions to another proposed innovation, a plastic yam stick, and engaged researchers with their own suggestions as to how to improve the technology. Such reasoning underscores another important theme in the indigenous knowledge literature; small-scale farmers often conduct their own informal experiments which draw on their indigenous knowledge and experience, and that indigenous innovation is more common than generally acknowledged.

Two other important issues concern the relevance of IK to development planning. First, indigenous knowledge tends to be distributed unevenly within a group. Not all farmers or fishermen in a community are recognized as local experts by their peers. Further, the body of community knowledge may be differentiated and compartmentalized reflecting specialization and the division of labor within the group, or the distribution of age, wealth, and gender, or power and influence. All these variables present challenges in understanding resource management and production orientation, and are possible sources of conflict in mobilizing effective development initiatives. The second issue relates to the place-specific nature of IK, and the fundamental problem of transferability and scaling up. How can local knowledge that provides great insight into livelihood strategies within a particular location, with unique agroecological and socio-cultural conditions, be applied in another community or region, which is likely to have different conditions? Similarly, how can local knowledge be transferred to the national level or from one country to another country, again, where prevailing conditions are likely to be different? Strong reservations have been expressed by some experts about the usefulness of local knowledge to development planning outside the spatial locales in which it was contextualized.

**IK and climate change**

More recently, climate change has given a new impetus to research on indigenous knowledge. The detailed knowledge of farmers in identifying and monitoring changing weather patterns has long been recognized in the literature. Resource-poor farmers, whose decision-making and livelihoods critically depend on an acute understanding of weather patterns, are often the first to detect subtle changes in weather patterns. Many studies among arable farmers and pastoralists throughout Africa, Asia, and Latin America have documented the sensitivity of farmers to more extreme weather conditions, including increasing aridity and seasonal shifts or variations in the rainy season. Nigerian research, for example, illustrates how farmers factor traditional knowledge of rainfall, thunderstorms, wind storms and the harmattan wind into their decision-making. In the polar latitudes, where early signs of climate change are already evident, detailed ethnographic studies of indigenous people in Canada and the Russian boreal forest have
INDIGENOUS KNOWLEDGE

reported how they have been tracking climate change since the 1990s.

The Fourth Assessment Report (AR4) of the Intergovernmental Panel on Climate Change (IPCC) highlighted indigenous knowledge as an invaluable tool to help develop adaptation strategies for natural resource management in the face of environmental change. Not surprisingly, therefore, an active research field has emerged incorporating indigenous knowledge into a climate change framework. The IPCC, hitherto anxious to establish the scientific accuracy of its predictions of climate change, more recently acknowledged the potential role of the indigenous knowledge in corroborating scientific evidence through oral history. Indigenous knowledge, based on long-term observation of weather patterns by local people, can supplement scientific knowledge about climate change. An example is Jamaican research on small farmers’ knowledge of weather patterns, where their reports of changing weather patterns corroborated scientific findings based on satellite imagery, showing that the short rainy period May/June has become increasingly unpredictable in timing, duration, and the amount of precipitation over the last 30 years.

Recognition of the value of indigenous knowledge by the IPCC represents a new avenue that might reduce the bipolar tensions between Western science and indigenous knowledge, alluded to by Briggs. Oral history can complement scientific knowledge. But identifying cost-effective adaptive strategies among resource-poor communities is an urgent priority for the developing world. Indigenous knowledge and traditional best practices can be a foundation to help build capacity to mobilize participatory, community-based mitigation strategies in collaboration with external interventions. Current research on climate change and food security exemplifies such an approach; this burgeoning research field is replete with projects focused on how to use traditional practices to strengthen community resilience to climate change for a more sustainable future.

American Indian reservations experienced a remarkable turnaround in economic development following the passage of the 1988 Indian Gaming Regulatory Act, which sanctioned the legal recognition of tribal rights to operate gaming enterprises. By 2008 tribal gaming revenues topped $26.7 billion, creating more than 636,000 jobs for the 233 Indian tribes and two Alaska Native Villages that operated 411 casinos, bingo halls, and pull-tab operations in 28 states. Tribally owned and operated casinos reached annual revenues and employment that exceeded all of the non-Indian gaming in Las Vegas (Schaap 2010, 369). The success of tribal casino gaming has also expanded into other aspects of economic, community, and regional development. This dramatic success of tribal casino development does not affect all reservations equally, however, and many continue to reflect persistent poverty and lack of economic opportunity. Research has shown that it is not only economic factors that impact tribal success, but that success is linked to the effective evolution of tribal governments as tribes have taken control of their own programs, lands, and resources and seek to reinvest to create sustainable, sovereign tribal nations.

Indigenous economies: from success to dependency

American Indian tribes established successful Indigenous economies prior to European
contact that evolved over time, linked to the unique resources available within their Indigenous lands and surrounding areas. These successful economies were greatly disrupted as a result of European contact, and during the following centuries the expansion of European colonies sought to ignore or eliminate those cultures through isolation, removal, and acts of genocide that denied political and economic, rights, despite the official “recognition” documented in treaties and the establishment of reservations. American Indian nations were categorized as “wards” of the federal government and became dependent upon federal rations, resources, and allocations through a special “trust” relationship established in those treaties.

A central factor of tribal economic transformation has been the ability of tribes to overcome the dependent status and isolation of many reservations through the concept of sovereignty: each American Indian reservation retained powers, generally expressed in treaties, executive orders, or congressional action, that identified American Indian reservations as empowered through federal relations with each individual sovereign tribal nation. Each tribe also retains inherent sovereignty from the powers understood in the meaning of words within each tribal language and culture when treaties were formed regarding their lands, resources, and culture.

A number of books have documented the resiliency of American Indian culture (see McNickle 1968) and the perseverance of American Indian peoples and cultures, despite forced assimilation and acts of genocide. Despite isolation on the periphery of non-Indian economies for many reservations, and woeful records of the lack of support for the education of American Indian peoples and their rights to support and develop their own tribal governments, specifically through the 1934 Indian Reorganization Act and the 1975 American Indian Self-Determination and Education Act, tribal governments have emerged since the 1990s as effective decision-makers and agents of good government for each American Indian reservation. The expansion and success of tribal governments has been a catalyst to overall reservation economic development, with tribal governments emerging in the twenty-first century as a major employer on the reservation, and a major employer within their region.

Understanding tribal economic development

A major force in understanding tribal economic development has been the long-term engagement of the Harvard Project on American Indian Economic Development, started in 1987 “to understand and foster the conditions under which sustained, self-determined social and economic development is achieved among American Indian nations through applied research and service” (http://www.hks.harvard.edu/hpaied/). Working directly with individual tribes in ongoing research and recognition of best practices and successful economic development, four major findings emerged through this research as central to tribal economic development success: sovereignty matters, institutions matter, culture matters, and leadership matters (Harvard Project on American Indian Economic Development 2011).

The persistence of poverty on reservations remains, however, and Leichenko (2003, 367) found that increasing regional disparities in income seem to be getting worse for rural areas – and potentially for American Indian reservations – as a result of globalization, and that “tribal areas may be among those that are most likely to be left behind because of lower levels of human capital, poor access to
markets, poor infrastructure, and other constraints.” Leichenko’s research also recognized the complexity of tribal economies and the continued role of noncash exchange and obligations, which remain important aspects of reservation economic analysis.

**Barriers to American Indian reservation regional development**

As a legacy of economic dependency on the federal government and the structures that created and restricted full tribal control of decisions, many barriers and restrictions to tribal economic development remain. A major issue is land ownership on reservations which were initially established on tribal lands held “in trust” for the whole tribe, with no fee-simple ownership. Tribal trust lands were subsequently subject to allotment through the Dawes Act in 1887, which allocated tribal lands to individual tribal members and their families, and allowed any surplus lands to be transferred to non-Indians. As a result, over 90 million acres were removed from Indian ownership (Indian Land Tenure Foundation 2014). Not all reservations were impacted by allotment, so a complex system of land ownership exists in terms of tribal trust lands, tribal lands assigned to individuals, tribal member ownership of reservation lands, and non-Indian ownership of reservation lands.

In addition, under the General Allotment Act the Bureau of Indian Affairs (BIA) established a complex structure for allotted lands so that when the allottee died, title ownership was divided among all of the heirs, but the land itself was not physically divided (Indian Land Tenure Foundation 2014), resulting in fractionated ownership where reservation lands owned by American Indians could be owned in part by hundreds of descendants (heirs), each with a vote for a percentage of “shares” so that no leases or transfer of lands could occur without a majority vote of all heirs. Only recently have tribal codes and changes in federal law sought to resolve this issue as a result of tribal initiatives. These two factors create uncertainty in land ownership and questions about transfer or sale of land on reservations, a major barrier to standard US development and investment patterns, where land can be used as collateral for loans.

A third factor related to land ownership is the overall development patterns on reservations. As a result of the complex land-ownership patterns, many reservations located tribal offices, housing projects, schools, health care, and other facilities on isolated tribally owned lands, often separated by great distances. As non-Indian communities embrace “smart growth” as a means to overcome auto dependence and the failure of suburban land-use patterns to create livable communities, American Indian reservations are left with some of the worst, least sustainable land-use patterns in the nation, which result in dysfunctional, auto-dependent settlements that fail to provide access for many within each reservation, and restrict the opportunities for health and livability.

Transportation is often associated with economic development in terms of access to markets, and reservations were intentionally located away from urban non-Indian communities. Many reservations developed with limited or no funding for transportation, so that non-Indian regional interests and priorities demanded federal and state roads through reservation lands. One solution that tribes have actively implemented since 2008 is the creation of tribal transit programs to create access and resolve tribal transportation needs, along with the active assumption of responsibility for tribal transportation programs.
Tribal development beyond the casino

Tribal governments are making changes toward the future that incorporate strategic planning, comprehensive plans, and seven-generation (150-year) plans as mechanisms for tribal leadership to address the future and to engage tribal communities in effective decision-making. A major response to new revenues from casinos has been the purchase of critical Indigenous tribal lands that should remain part of the reservation “trust” lands, or that have potential for development. Many tribes have made major investments in tribal language, history, and culture programs, and in tribal wellness and educational-cultural facilities. Sustainability, including local foods/cultural foods and initiatives to create more compact settlements and sidewalks, paths and trails separated from highways to promote walking, access and exercise, are also part of long-range planning. Investment and governance development strategies that impact over seven generations and that frame sustainable sovereign tribal nations and tribal economies are a priority for many reservations.

Indigenous technical knowledge

Mara J. Goldman
Eric Lovell
University of Colorado Boulder, USA

“Indigenous technical knowledge” (ITK) is a term broadly used to refer to knowledge about the local environment that is produced, held, and used by indigenous communities. The term is often used interchangeably with the following terms: “traditional ecological knowledge” (TEK), “indigenous knowledge” (IK), “local ecological knowledge” (LEK), “local knowledge” (LK), and “indigenous technology,” which are all commonly defined in contrast to scientific knowledge – epistemologically and ontologically. ITK is assumed to be handed down from one generation to the next, and to be culturally and geographically situated. Scholars and activists often refer to ITK as a “way of life,” suggesting a knowledge–belief–practice system, embedded in everyday performances. While the value of ITK has been heralded by groups as diverse as the World Bank, the United Nations, and indigenous advocacy organizations, the problematic nature of the terminology and its application have been actively debated within the academy.

Discussions about ITK emerged alongside the “farmer first” movement within development, which called for more participatory forms of development and a focus on farmers’ pre-existing knowledge about their local environment. The argument was made that rural development should be based on indigenous and local knowledge about local environmental conditions, since such knowledge is more reflective of and adapted to local conditions, does not rely on heavy technical inputs, and is more culturally appropriate than Western interventions. Practically, the farmer-first movement sought to proactively involve farmers in development, through participatory processes and by challenging power dynamics and hierarchies of knowledge between Western scientists, extension officers, development workers, and local communities. Theoretically, this challenged the superiority and universality of Western scientific knowledge, raising the possibility of multiple ways of knowing. Such calls were taken up in allied fields (academic and applied), with claims of the importance of ITK for biodiversity conservation and ecosystem management. Geographers entered the debate both as proponents and as critics, discussing the use of ITK as it related to rural development, conservation, and mapping.

The acknowledgment of the existence of ITK was an important step in providing indigenous people with a voice concerning the management of land and resources, while challenging conventional wisdom regarding environmental processes and knowledge production more broadly. Recognizing and naming ITK enabled more robust discussions of ecological management as well as of the politics of mapping in indigenous territories. It also raised complex questions and critiques related to what ITK means, how it should be studied, and how it can be used, including problems with the “indigenous,” “technical,” and “knowledge” components of the name itself. This is evident from the use of multiple acronyms to refer to ITK.
INDIGENOUS TECHNICAL KNOWLEDGE

To start with, ITK must, by virtue of its name, refer to knowledge held by "indigenous" people or communities. This raises important practical and political questions regarding who is indigenous and how this gets decided. For many, the indigenous aspect of ITK is strategically important, drawing attention to specific knowledge and ways of life of indigenous peoples, while highlighting the politics of knowledge suppression and hierarchy that corresponded with the spread of imperialism and the growth of modern science. This is particularly important as indigenous peoples struggle to maintain rights to their own land and resources around the world. However, defining who is indigenous is not always a straightforward process, reflecting political motives and questions of origin. The process of designating certain people as "indigenous" often excludes others, such as more recent migrants to particular areas who are also vested in management outcomes. Additionally, a focus on "indigenous" knowledge as somehow isolated and different risks essentializing and romanticizing the knowledge and the communities as homogeneous and isolated from larger political economic contexts.

The T part of the ITK acronym suggests a focus on technical knowledge which can be incorporated into modernist projects and scientific studies with relative ease. While initial proponents argued that this focus put ITK on a similar footing with science in providing particular techniques for development and conservation projects, others have suggested the focus is misguided. Scholars and activists alike have argued that a focus on "technical" knowledge not only disempowers the very users of ITK but also dilutes the value of the knowledge at hand. If the embedded and active nature of ITK is acknowledged, then it must be seen as linked to entire belief systems from which particular "techniques" cannot and should not be extracted. Doing so ignores the cultural processes of knowledge production and risks turning complex multifaceted knowledge production processes into discrete pieces of data. Extracting particular techniques, separate from the culture and beliefs to which they are tied, risks losing the meaning and value altogether. Some have argued that this process disempowers indigenous communities by recognizing only certain aspects of their knowledge as valuable, and only when it can be adequately incorporated into Western science.

This gets to the final part of the ITK acronym, "knowledge." ITK is often discussed as an altogether different type of knowledge than science. ITK is often viewed as practical (utilitarian) knowledge based in craft (i.e., techne) and intuition. Science, on the other hand, is viewed as grounded in theory, empirical analysis, and justified belief (i.e., episteme). While some scholars argue that ITK is also based in experimental knowledge, it is often still understood in relation to (and often opposed to) Western science. ITK is holistic, situated (i.e., local), embedded in a worldview, fluid, experiential, relational, and closed (to new ideas/innovations). Science, on the other hand, is understood as reductionist, rational, abstract, universalizing (i.e., global), rigid, predominately quantitative, and open (to paradigm shifts). Consequently, in order for ITK to be useful for science and management, it must be “integrated” into science. Some have critiqued this process as furthering the dominance of science while simultaneously diluting ITK and disempowering ITK holders (Nadasdy 1999; Louis 2007). Others have opted to talk about bridging knowledge types so as to avoid upholding knowledge hierarchies while still bringing indigenous knowledge into conversation with Western science (Rocheleau 2003). Yet others have argued against the focus on difference altogether, arguing that such a focus upholds
knowledge hierarchies and ignores the historical situatedness of Western science itself (Agrawal 1995). However, some scholars and activists insist that there is a need to recognize differences – in methods, epistemology, and ontology – as based in the colonial and imperial relations and highly contested politics associated with the production of Western science (Goldman 2008).

Recent work within geography and allied fields have taken discussions of ITK further, drawing from the traditions of political ecology, science studies, posthumanist theory, and participatory mapping. Political ecology has highlighted the historical links between indigenous communities and larger political economic processes that have impacted processes of knowledge production, transfer, and use over time. This has often included a focus on the creation of “hybrid” knowledge across indigenous and nonindigenous groups, including scientific communities. Political ecologists have also stressed differences that exist within communities that impact knowledge production and use (i.e., gender, class, caste, ethnicity). This work has promoted the importance of recognizing ITK, while simultaneously problematizing how it is perceived, studied, and discussed. Much recent political ecology work has also drawn on science studies for a more robust treatment of knowledge production that recognizes the situated, embodied, and performative nature of all knowledge – science and that which is called ITK.

These insights are also reflected in the cartographic wing of geography, particularly in relation to participatory geographic information systems (GIS) and indigenous mapping. Here, scholars and activists have been actively engaged in the political and theoretical questions raised earlier. There has, for instance, been a large focus within the Association of American Geographers (AAG) Indigenous Peoples Specialty Group on the importance of indigenous voices in geographical research (Louis 2007). Scholars have emphasized ethical concerns that arise when working with indigenous peoples and on ITK, and the methodological, ontological, and political issues related to the interpretation and representation of ITK with Western scientific tools (GIS and cartography). Specifically avoiding the pitfalls raised earlier about extracting data, such work calls into question how maps can be created with the tools we have and challenges us to be more open to other ways of knowing. This reflects ontological as well as epistemological questions and pushes our understanding and use of ITK in new and critical directions. All of these new directions focus on the importance of seeing knowledge as process, which expands how ITK (and scientific knowledge) can be viewed and understood.

Industrial agglomeration

Ke Chen
East Tennessee State University, USA

Industrial activities have never spread evenly over a featureless plane. While some industry development is driven by natural resources, such explanation cannot fully illuminate industrial agglomeration in most cases. Instead, the very nature of being close to each other may be a fundamental mechanism that accounts for the spatial formation of urban areas and industrial development. From early scholars such as Alfred Marshall and Alfred Weber to modern ones like Paul Krugman and Michael Porter, the phenomenon of industrial agglomeration has attracted keen attention from economists, planners, sociologists, and historians, as well as geographers. Numerous studies have been conducted to unravel the myth of the power of geographic proximity in economic activities, various terms have been created to highlight some distinct natures of industrial agglomeration, and a wide variety of methodologies have been proposed to scrutinize the formation of business concentration. Despite the centrifugal force of globalization to re-organize industrial activities on a global scale, the centripetal power that draws businesses in spatial proximity endures.

Advantages of industrial agglomeration are first mentioned in Alfred Marshall’s prominent book Principles of Economics in 1890, where he explicitly describes how localized small businesses of similar characteristics can benefit from external returns to scale. According to Marshall, industrial agglomeration can originate from natural conditions, including favorable soil and climate characteristics, proximity of mines and quarries in the neighborhood, and easy accessibility by land or water. It can also develop from social and historical reasons, such as family groups expanding into villages, the patronage of a court, and the systematic summoning of artisans by rulers to build a town. Sometimes, the emergence of a localized industry may appear by chance. No matter for what reason industries start to emerge and concentrate, all of the businesses in the locality can take advantage of being close to each other. Although Marshall does not develop a fully-fledged theory of industrial agglomeration, he lays the foundation for the investigation of the subject.

Twenty years after Marshall published his original book, another economist, Alfred Weber, developed a theory of industry location based on minimum cost in production (Weber 1909). Weber defines agglomeration as the concentration of economic activities or entities in particular localities. Agglomeration allows individual firms to enjoy both internal and external economies, where benefits come from reduced cost in transportation and infrastructure, improvement in labor organization, and enhanced efficiency. Weber’s theory on industrial agglomeration is regarded as classical and his insights on the role of transportation costs have been inspirational for geographers in both theory formulation and empirical studies.

While stressing the importance of spatial concentration, Weber’s theory does not make a distinct difference when explaining internal scale economy and external scale economy. It is Hoover (1948) who fills this gap and clarifies
three types of agglomeration: (i) internal scale economy, (ii) localization economy, and (iii) urbanization economy. Internal scale economy refers to the return to increased scale of operation for individual firms. Localization economy benefits from the clustering of firms in the same industry, similar to that described by Marshall (this text uses Marshallian-type agglomeration to refer to the localization economy). Urbanization economy denotes the concentration of industries in urban areas to take advantage of lower infrastructure cost, large market, extensive knowledge spillovers, and large labor pool.

Although it may be a difficult task to quantify the importance of internal and external agglomeration effect in the formation of business activities, some analyses of employment growth across American metropolitan systems support the claim that external economies of scale are replacing internal scale economy in industrial locations (Ó hUallacháin 1990). In this entry, terms that are closely related to localization economy, for example, industrial complex, industrial district, and industrial cluster, are first introduced. The cause and impact of urbanization economy are discussed next, and then recent studies on the key factor of knowledge creation in industrial agglomeration in the era of knowledge economy are discussed.

Localization economy: industrial complex, industrial district, and industrial cluster

In the 1950s, Isard developed a concept of industrial complex to describe a set of activities at a specific location that are linked by certain technical and production interrelations. In Isard’s (1959) study of regional economies of Puerto Rico, he found that traditional economic theories on individual industries failed to develop appropriate spatial concepts to explain the economic growth of the region in a historical perspective, since any basic industry is always interrelated with other sectors. To fill the gap, Isard developed a model of industrial complexes, where businesses benefit from agglomeration by reduced transportation and transaction costs within the input–output network, a large labor pool of professionals, and technology spillover (Gordon and McCann 2000), all of which resonated with earlier literature in industrial agglomeration.

Isard’s ideas and methods in industrial complex theory are followed and improved by some later scholars (Czamanski and Ablas 1979; Roepke, Adams, and Wiseman 1974; Ó hUallacháin 1984). Nevertheless, reliance of input–output tables for identifying industrial complexes becomes more and more subject to criticism. For instance, Latham (1976) pointed out that input–output tables are purely aspatial and concludes that they are unsuitable to help identifying industrial complexes. Ó hUallacháin (1984) acknowledged the weakness of principal components analysis for detection of vertical value chain linkages. Moreover, too much focus on technical issues has limited the application of the industrial complex as a policy tool to boost regional economies in the 1970s, when the world was going through substantial changes in a more globalized world: international capitals were moving more easily into developing countries and manufacturing companies were shifting their location of production to cheap-labor abundant parts of the world. Studies of industrial complexes fail to address new patterns of production and international division of labor, and therefore start to lose popularity in both academics and public policy.
When the western world was hit severely by the oil crisis in the late 1970s and early 1980s and fell into economic recession, some peripheral areas in northern Italy surprised the industrialized nations with remarkable resilience and growth, driven by small-scale businesses in labor-intensive industries. Under such a background, the Italian type “industrial district” became a popular phrase, and the model motivated economic development organizations across the world as an approach to stimulate economic growth and job creation.

Becattini (1990a) defined an industrial district as a socioterritorial entity that is characterized by the active presence of both a community of people and a population of firms in one naturally and historically bounded area. In a district, unlike in other environments such as manufacturing towns, community and firms tend to merge, sharing knowledge on a specific industry originated in history and tradition. Some industrial districts in northern Italy, such as textile businesses in Carpi and Prato, and the furniture industry in Brianza and Cascina, have a coherent location and a narrow specialization profile. Locating in such a district enables many Italian small businesses to become competitive against large enterprises in the international market.

An important characteristic of industrial districts is that such local milieus are occupied with small or medium-sized firms, a production system totally different from the vertically integrated Fordist model. In addition to the classical driving forces in Marshallian-type localization economy, another key for the success of industrial districts in previously peripheral places is an environment of cooperation and competition in the social structures and practices. Such a setting supports dense information exchange, knowledge creation, and technology innovation in both traded and untraded forms (Piore and Sabel 1984; Becattini 1990b; Scott 1994). Success of industrial districts can also be attributed to a strong sense of belonging, where a local community of people shares similar values and views, as traditional Italian culture is based on the idea that social relationships of kinship and friendship coexist with market relations. Some other essential factors for success include an ethic of labor and activity, credit system for small firms and so on (Becattini 1990a). Overall, innovation associated with social ties and network is pervasive in industrial districts.

Unlike investigations on industrial complexes that emphasize the use of quantitative methods to identify interindustrial trade relations, studies of industrial districts are more focused on places, historical context, social structures of production, and the creative environment in the local milieu. Industrial district models show that, with limited resources to invest in research and development, firms are capable of remaining competitive in a new international production and distribution system. Therefore, “industrial districts” became a much more popular term than “industrial complexes” as a policy tool for regional development and industrial strategy in the 1980s.

However, while scholars have applauded the use of industrial districts as a potential model for economic growth or recovery, they faced an even more challenging economic picture in the late twentieth century. With a more deepened level of globalization, advanced economies continue to lose comparative advantages in manufacturing jobs and capital flows. Although there are a few successful industrial districts, the social, economic, and historical peculiarity of such districts makes it hard to easily replicate and provide a general formula for similar success in the industrialized world.
INDUSTRIAL AGGLOMERATION

Against such a background, Harvard Business School scholar Michael Porter (1998), in his renowned book *The Competitive Advantage of Nations*, discusses the innovative nature of competition of industrial clusters. Porter defines clusters as geographic concentrations of interconnected companies and institutions in a particular field. Clusters encompass an array of interlinked industries and other entities important to competition, including suppliers of materials, services, and specialized infrastructure. Clusters also often extend downstream to include customers, manufacturers of complementary products, and companies related by skills, technologies, or common inputs. Furthermore, many clusters include governments and other institutions, such as universities, standards-setting agencies, think tanks, vocational training providers, and trade associations.

Porter’s cluster theory particularly addresses the difference from the classical theory of comparative advantage, which is based on factor endowment. In comparison, Porter argues that prosperity is created, not inherited. It does not grow out of natural endowments, labor pool, or current economic situations such as interest rates or exchange rates. Instead, a locality, region, or nation can create new advanced factor endowments such as skilled labor, a strong technology and knowledge base, government support, and culture.

In particular, Porter stresses the active role of governments to grow industrial competitiveness, where the government may act as a catalyst and challenger to encourage or even push companies to raise their performance. Governments may stimulate early demand for advanced products, focus on specialized factor creation, and encourage local rivalry by limiting direct cooperation and enforcing antitrust regulations. Meanwhile, these government actions are different from traditional industrial policies, where government targets desirable industries and intervenes in competition to tilt market outcomes in a nation’s favor. In cluster theory, all clusters can improve productivity and deserve attention. The focus is not on distorting competition but removing obstacles and constraints to grow productivity.

Compared to the concepts of the industrial complex and industrial district where success rests on trade linkages, culture, tradition, history, and community sense, the model of industrial clusters is more encompassing by offering a more universal and practical framework for local businesses and governments to improve competitiveness in a global economy. As a result, cluster theories have been warmly received among regional planners and industrial strategists since the 1990s. It is considered a canonical model for economic development in recent years. The idea itself is also related to the knowledge economy or applied to knowledge-based clusters (Maskell 2001).

Urbanization economy

A second type of external industrial agglomeration effect comes from urbanization economy, which denotes the concentration of industries in urban areas to take advantage of reduced transportation and transaction costs, lower infrastructure cost, a large urban market, the availability of specialized inputs, large labor pool, and extensive knowledge spillovers (Mills 1967). Overall, there is a positive connection between city size and productivity, where increases in scale are likely to generate greater specialization, higher levels of human capital, and other positive externalities.

One set of theories about external effect emphasizes the gains that come from reduced transportation costs of goods and people (Krugman 1991). For firms of all kinds, locating in urban areas means proximity to both suppliers
and customers. In the study of manufacturing belts in the United States, Krugman addresses the importance of proximity to market based on increasing returns to scale. It is cheaper to produce one single product in large quantity than a variety of products in smaller quantities. With fixed production costs, transportation costs become an important factor in the firm’s location decision, which can be reduced by locating in proximity to large markets. In Krugman’s model, urbanization economy, together with the effect of internal scale economy, helps to increase profits at the firm level.

In addition to reduced transportation and transaction costs that come with city size, Chinitz (1961) provides some more insights on the effect of urbanization economy. Based on his observations of New York and Pittsburgh, the former being a large urban area and the latter a localized economy, Chinitz argues that a large urban economy tends to have a more diversified industry structure. This implies more entrepreneurial supply and capital supply, which is particularly essential for small businesses. Overall, a diversified urbanization economy has a higher prospect of success than localization economy. Jacobs (1969) also stresses that diversity is the source of urban economic growth. Her thesis is that cities grow because of innovation they stimulate and urban areas that contain many independent firms performing a multitude of tasks will grow rapidly.

A more recent argument on the positive externality of urbanization economy can be related to Richard Florida’s (2002) thesis of the creative class. Florida views creativity as the precursor of competitiveness. He keeps on arguing that, in the era of globalization, US cities with diversified economic activities and human capital have developed a creative class while others have witnessed the erosion of creativity. Comprised mainly of scientists, engineers, artists, and other professionals, the creative class generates or advances technology to produce commodities and services, and constitutes a significant part of the population of cities that are characterized by diversity and tolerance in terms of ethnic, cultural, religious, and sexual orientation. Therefore, urban areas that can provide creative classes with amenities that nurture their creativity will enjoy prosperity and lead economic growth.

To summarize, there is a growing shift in the study of urbanization economy from transportation costs and market size to urban diversity and innovation. Urban economists like Glaeser and Gottlieb (2009) and Fujita and Thisse (2002) agree that earlier manufacturing firms cluster to reduce the costs of moving goods, but this force no longer appears to be important in driving urban success in the contemporary world. Instead, modern cities are far more dependent on the role that urban size and diversity can play in speeding the flow of ideas and generating new technology.

Agglomeration economy and knowledge creation

In the more recent literature on industrial agglomeration, there seems to be a tendency to investigate the social nature rather than the pecuniary nature of the benefits from agglomeration, whether it is localization or urbanization economy. A careful examination of industrial cluster and creative class accounts shows that both agree on the importance that geographic proximity plays in innovation. But why is it so? Some scholars propose that the key to understanding industrial agglomeration lies in its superior capability of creativity and innovations due to face-to-face contact, networks, and social interaction (Fujita and Thisse 2002). Storper and Venables (2004) develop some foundations for
face-to-face contact amongst economic agents and show how these improve coordination and collaboration, and subsequently increase productivity in close geographic proximity. They view the understanding of industrial agglomeration as incomplete unless grounded in the most fundamental aspect of face-to-face contact, which is an efficient communication technology, which helps solve incentive problems, is capable of facilitating socialization and learning, and provides psychological motivation.

While the diffusion of knowledge within the local milieu is rapid, it can be quite slow outside the industrial cluster. Although an increasing proportion of skilled human capital such as top management and experts has become internationally mobile, an important part of human capital resides in a multitude of local formal and informal networks that have been built over a long time, and therefore cannot be taken out of context without losing much of their value. Furthermore, the large groups of middle and lower level managers and workers, who make up an important part of the formal and informal relationships between firms, are typically much less mobile than top management and experts. As a result, a large literature has demonstrated the existence of localized, industry-specific knowledge spillovers within the science and technology communities.

Geographic proximity, characterized by face-to-face contact may also facilitate cross-sectorial specialized networks and social interaction. Networks of firms and industries clustered within regions interact more heavily with university-based scientists in proximity than with those further way. For example, Washington DC has become a major high-technology region in biotechnology due to close interactions with government agencies such as the National Institutes of Health. The accomplishments of Silicon Valley and the biotechnology cluster in San Diego can also be attributed to the close communication among scientists, entrepreneurs, and venture capitalists. Co-location is especially important to these processes because it provides a low-cost means for new ideas and talent to make their way into existing activities, by facilitating access for newcomers and by lowering the costs of evaluation on the part of those already in the relevant loops. New relationships are hence made easier, cheaper, and much more effective than they would be without close geographic proximity and the opportunities it provides in terms of face-to-face contact and social networks through formal and informal ways.

These explanations offer some essential accounts on the localized nature of technology spillover and knowledge creation in industrial agglomerations. In today’s global economy, the advancement of transportation and communication and the integrated global market have led to a predictable surge of outsourcing, with companies relocating many facilities to areas of low wage, taxes, or other input costs. However, competitiveness in the long run will rest on a locality’s knowledge pool, human capital, social interaction, and the associated innovative capabilities, all of which are enhanced by geographic proximity.

Conclusion

To summarize, over a century has passed since the original work on industrial agglomeration was published, and the concept has evolved from emphasis on economic cost reduction and benefits from trade relations to social structures and environment that support dense information exchange and constant innovation. Even though the forces of globalization have modified the world production system and spread industrial
INDUSTRIAL AGGLOMERATION

activities from advanced economies to developing countries, the centripetal agglomeration force that attracts businesses together still remains, and proves to be even more important for knowledge generation.

Industrial complex

Ke Chen
East Tennessee State University, USA

Walter Isard (1960) defined an industrial complex as a combination of industrial activities occurring at a given location that are subject to important production, marketing, or other trade relations. By locating in an industrial complex, individual firms may reduce transportation and transaction costs within the particular input–output production network (Isard and Vietorisz 1955). Firms in an industrial complex may also enjoy a large labor pool, and take advantage of potential technology spillover, as a result of social structures and practices that support information exchange and innovative activities (Gordon and McCann 2000). Therefore, a region with an industrial complex has comparative advantages over other places and may be more likely to achieve economic prosperity.

Isard, Schooler, and Vietorisz (1959) developed this idea of the industrial complex in their study of the regional economy of Puerto Rico in the 1950s. The purpose of the study was to identify specific combinations of industrial activities in which Puerto Rico had an advantage, and to estimate the magnitude of the locational advantage of such combinations. Isard and his colleagues first examined some conventional approaches in regional economics, including broad economic development methods, comparative-cost analysis for individual industries, the location quotient, the coefficient of localization, the labor coefficient, and input–output approaches. They found that these techniques of regional analysis were valid, with each being pertinent for certain regional situations but not others. However, none of these traditional economic methods was entirely satisfactory for explaining the economic growth of the region in a historical perspective. Any basic industry is always interrelated with other economic sectors; the connection grows even more intense over time; and the development in an area comes to influence the location pattern within and outside the region through direct and indirect linkages.

To address these issues, Isard, Schooler, and Vietorisz (1959) devised conventional analytical techniques to deal with various aspects of regional development. The major method of analysis was an extension of input–output or interindustry analysis called activity analysis, in which a process may produce more than one output and there may be more than one process that generates a given output. In the study of Puerto Rico, 73 production processes were described in terms of their physical outputs and inputs. The input and output levels of the 76 commodities other than labor and capital were assumed to increase in proportion to process levels, while labor and capital inputs were presumed to obey the fractional power law and thereby increase less than proportionately to process levels. Altogether, 19 preliminary industrial complexes covering operations from refinery through synthetic fiber production were selected for further analysis. Then, for each complex, total inputs by type and outputs by type were calculated. Cost and revenue differentials between Puerto Rico and alternative mainland locations were estimated for each input and output. In the next step, Puerto Rico’s preliminary locational advantages or disadvantages were
obtained for each complex through multiplying input and output levels by the appropriate price differentials and summing all inputs and outputs of the refinery processes. A region is assumed to have an advantage if the sum is positive and a disadvantage if the sum is negative. Regions should focus on those of its industrial complexes that possess locational advantages.

From a viewpoint of economic development, there are several advantages of developing an industrial complex. First, by locating in an industrial complex, individual firms may reduce transportation and transaction costs within the input–output network (Isard and Vietorisz 1955). This is in line with traditional Weberian industrial location theory which emphasizes cost minimization. Second, industrial complexes generate a large pool of trained labor and professionals. This effect is well recognized in the literature on industrial agglomeration, particularly the Marshallian-type localization economy. Another important benefit of being in an industrial complex is the potential technology spillover, resulting from dense information exchange and constant innovation among adjacent companies. These advantages are essential for understanding major industrial developments not only in the fiber industries in Puerto Rico, but also in the Ruhr manufacturing region, with its heavy orientation to steel-fabricating complexes; the Gulf Coast agglomeration, with its primary focus on hydrocarbon complexes; the American Midwest region, with its automobile complexes; and the more recent spatial formation of Silicon Valley, with its competitiveness in electronics complexes.

In the 1960s the concept of the industrial complex refreshed the fields of economic geography, regional economics, space economy, and economic planning. Its use of quantitative approaches has also advanced the study of industries and localities by filling an important gap in the relevant fields, demonstrating how the investigation of individual industries and regional economies may be supplemented and complemented with analysis of the interrelations of these industries in a region. In an era when quantitative revolution prevails in academia, these mathematical techniques that combine an input–output table with an analysis of the factors leading to regional differences in costs and revenues are particularly appealing to scholars who are seeking to make regional studies more scientific.

Following Isard’s initial publications, scholars attempted to study the spatial groupings of industries and to identify complexes that enjoy locational advantages. In general, they relied heavily on input–output tables to reveal vertical trade relationships. For instance, Czamanski (1971) used multivariate analysis on purchases and sales data in an input–output table to classify industrial complexes. Using a slightly different technique, Roepke, Adams, and Wiseman (1974) employed factor analysis to group industries for industrial complex identification. In a later study, O hUallachain (1984) evaluated the use of principal component analysis in the industrial complex studies and suggested that this technique may provide more information on the industrial structure. Hewings and Jensen’s (1986) review of regional and interregional models also placed much reliance on the input–output table to discuss the interconnectedness and interrelatedness between industries and regions.

While methodological concerns have dominated the research in the literature of industrial complexes, studies in regional economics in the 1970s and 1980s failed to apply the concept and the technique as an effective policy tool to address economic recession and to boost regional economies in a global market. In addition, the compound quantitative nature of the approach in industrial complex analysis may have deterred many regional planners who did not possess the
necessary mathematical skills to use the concept. As a result, passion among scholars started to fade, and use of the term began to decline from the 1980s. Instead, a similar but new term, “industrial district,” gradually began to gain popularity both among scholars and in public policies, when a few manufacturing regions in northern Italy exhibited remarkable resilience and growth during a time of economic stagnation and recession in many advanced economies (Pyke and Sengenberger 1992). In contrast to the concept of the industrial complex, studies on industrial districts argued that the high economic growth rates and significant improvement of social conditions in these industrial districts were causally related to the properties of Marshallian agglomeration economies, where small and medium-sized businesses specialize in particular tasks (Piore and Sabel 1984; Pyke and Sengenberger 1992). Another major difference is that, in contrast to the highly quantitative analysis in the industrial complex approach, studies of industrial districts do not place much emphasis on the input–output table but more on the historical and social context of the region. Gradually, the idea of industrial districts gained prominence among regional planners and industrial strategists, who advanced the concept as a policy tool for industrial restructuring, regional development, and economic renewal.

However, the concept of the industrial complex has not totally disappeared in more recent literature. Instead, techniques used in the industrial complex approach have seen some rejuvenation since the 1990s with the emergence of the industrial cluster model. Industrial clusters refer to the geographic concentrations of interconnected companies, specialized suppliers, service providers, and associated institutions in a particular field (Porter 1990; 1998; 2000). A major difference from earlier theories on industrial agglomeration is that the cluster model focuses on competitive advantages instead of comparative advantages, arguing that the innovative nature of competition in geographic clusters can be nurtured. This new model has gained acceptance among scholars and practitioners, and has been considered a canonical model for economic development and revitalization in recent years. An important task in the industrial cluster is to identify industries that hold competitive advantages, and some scholars resort to the techniques used in industrial complex analysis – the analysis of input–output tables – to reveal interindustry linkages and regional advantages.

In retrospect, industrial complex analysis remains an important approach in regional economic development that has general significance beyond its pathbreaking application to Puerto Rico. It outlines the importance of spatial proximity between firms, emphasizes the industrial growth of a region in a historical perspective, and advances the uses of regional and interregional input–output tables in economic growth analysis. It is an important concept in the literature of agglomeration economy, location theory, regional studies, and space economy. Its concept and methods can be used by regional economists, city and regional planners, business executives concerned with location decisions, and community and state industrial development groups.

Industrial conversion

Ray Hudson
Durham University, UK

Places develop distinctive industrial structures, a response to specific combinations of circumstances at particular times. For example, the conjunction of particular raw materials and technological developments that enable them to be used in commodity production can provide the basis for mono-industrial towns. The subsequent development of economies of scope and scale in production can then lead to the creation of major industrial complexes in particular cities and regions. In response to this, people migrate in large numbers to such places in search of work, often from rural and agricultural areas that have lacked an industrial past, sometimes from places in which industry had developed but has subsequently declined and jobs disappeared. In time such new industrial spaces may form their own distinctive place-based communities, grounded materially and institutionally in the industries that form the rationale for the place.

However, a characteristic of capitalist development is that it tends to erode the conditions that originally made an industry successful, so that capital is devalorized, written off in some places and reinvested in others. As such, devalorization is always of necessity place specific (Harvey 1982), so that the decline of an industry inevitably has place-specific effects and consequences. The question to be explored here – essentially that posed by Doreen Massey (1979) as “in what sense a regional problem?” – or put slightly differently, “who is a regional problem a problem for?” – is what happens when, for whatever reason, that favorable conjunction of circumstances changes and the economic viability of those industries and places is compromised and eroded and people’s livelihoods are imperiled as employment disappears? This is fundamentally a political question: to borrow a phrase from the striking steel workers of Longwy as they and their families and friends marched through Paris in 1979 (Carney, Hudson, and Lewis 1980), do people have the right to live, learn, and work in a place even though the capitalist interests that originally invested to give rise to that place no longer have an interest in it?

Declining profitability does not necessarily mean that capital abandons a location, however. Companies may respond to growing pressures on profitability by seeking to restructure in situ, changing production processes and/or products, adopting strategies of innovation, and learning to change business models and move onto new Schumpeterian trajectories of growth. They have considerable place-specific sunk costs that outweigh any benefits in terms of cost reduction as a result of relocation – for example, because of pools of skilled labor that cannot be re-created elsewhere, ties into supplier chains that are critical to success, or brands that are strongly identified with production in a particular location. For instance, in the United Kingdom high quality ceramics production has remained and revived in “the Potteries” as companies have adopted new business models and production strategies as mass produced products became no longer economically viable there. There is a downside for workers in such strategic responses,
however, for they may – and typically do – result in considerable job losses. While they may be efficacious for capital, they impose considerable costs upon labor. Even so, trades unions and other labor organizations may acquiesce in such strategies as part of place-based cross-class alliances, defending industry in place on the basis that to retain some jobs is better than to retain none.

The alternative to in situ restructuring for capital is to disinvest from some places, possibly devalorizing capital there, and/or moving capital to invest in new locations that offer greater prospect of profit. This does not mean that capital has been destroyed and industry come to an end but rather that as capital disinvests from some places and moves production elsewhere in search of greater profits, initially intranationally, increasingly internationally, as evidenced most strikingly in the rise of China as a center of industrial production, it helps establish the material and social bases for creating new production structures in “new” places. This could involve producing existing commodities in these new locations with new or existing processes or moving into new products and sectors there.

Capitalist development is always inherently uneven, with growth in some places inextricably linked to decline in others. Important though the dynamics of that process of uneven development are, though, they are not the main concern here. The focus here is on the consequences in those places that suffer decline, upon what happens in those places that one set of capitalist interests has abandoned as their inhabitants, social groups, and political forces seek to construct a new economic rationale for them, typically by enticing new capitalist interests to invest and create employment there. What happens to those places that once were centers of industrial production – workshops of the world – but no longer are as capital is devalorized and/or moved to other parts of the world?

State policies and industrial conversion

While corporate self-interest alone may be sufficient to stimulate in situ restructuring, it often needs positive intervention by the state (at national, subnational, or in some instances, such as the European Union, supranational levels) to bring it about. State involvement can be particularly visible when the state has been involved in the destruction of the pre-existing industrial base. Industries that were once nationalized as part of social-democratic industrial strategies, such as coal and steel, became subject to, first, rationalization, capacity closure, and job loss, and then terminal decline and complete closure as part of a neoliberal turn in economic policy that began in the United Kingdom with the Thatcherite governments of the 1980s (Beynon, Hudson, and Sadler 1991; Hudson 1989) and quickly spread elsewhere (Hudson and Sadler 1983). This helped create pressures for state action to mitigate the effects of the resultant job losses, via various incentives to new industry to invest in such places – for example, in the form of branch plants or new small and medium-sized enterprises (SMEs), discussed further below.

In other circumstances, rather than seek to eliminate particular industries, state policies seek to effect a transition from “old” to “new” industries, preserving and adopting skills and production capacity from the former to the latter. Examples include the shift from coal and steel to environmental engineering in the Ruhr in the 1980s (Refeld 1995) and the transition from shipbuilding to the production of offshore electricity turbines in northern Germany in the 2000s (Fornahl et al. 2012). Such restructuring and reconversion programs often lead to job losses but are justified on the basis that they adapt existing skills and competences and create “better,” more skilled and remunerated jobs as a result. However, such restructuring in search
of profitability can also lead to deskill ing and “worse” jobs, justified on the grounds that some jobs of whatever quality are better than none.

In all these cases, however, one key effect of state involvement either to remove some industries from particular places or to preserve others is that it can lead to substantial net reductions in employment and become the proximate cause of pressures for the state to intervene in the place market to seek to attract new forms of employment and work to those places. The threat of capacity closures and job losses in existing industries has led to political pressures to entice new industries to replace them via incentives of various sorts – infrastructure investment, grants to cut the cost of fixed capital, wage subsidies or grants to retrain and upskill workers. Through such incentives public authorities seek to move to a new industrial structure, manufacturing, and/or services, involving some or all of the following: branch plants, SMEs, call and contact centers, new retail parks, or different forms of tourism (including industrial heritage). More recently there have been attempts to encourage and promote the emergence of so-called learning regions, knowledge-based economies, and smart specialization, linked to learning and knowledge transfer from universities as well as between firms and other place-based civil society organizations. These options are explored below.

Branch plant economies: from global outposts to embedded branch plants?

A common policy response to the decline of one industry or related complex of industries is to seek to attract inward investment in companies and industries that are new to that place. While this may involve the relocation of entire companies, more often it involves the attraction of branch plants that are part of wider company structures. As the scale of production has increased, the intracompany organization of production has become more complex, enabled by advances in transport and communication technologies. Companies have increasingly created intracompany spatial divisions of labor, (re)locating particular production functions in those locations most appropriate for them. This has offered opportunities for areas that previously were industrialized, but which have become deindustrialized, to seek to attract new activities, typically branch plants producing or assembling components (Massey 1984). Such plants are typically attracted by combination financial incentives and other subsidies to production costs as well as by the availability of large amounts of labor – both workers with experience of industrial work who have lost their former industrial jobs and others, often female, drawn into the wage labor force for the first time.

While such branch plant economies often contain a wider variety of industries than the original industrial economies of such places, and in that sense can be seen as more diversified, in another sense they are more homogeneous as they tend to comprise routine assembly or production functions employing predominantly unskilled or semiskilled labor. Moreover, such branch plant economies, “global outposts” located at the extremities of global chains of corporate command and control, are vulnerable, susceptible to decisions about investment and disinvestment taken in distant boardrooms. They can be vulnerable to closure, especially in circumstances in which companies have adopted multiple sourcing strategies that enable them to play off one branch plant against another. Consequently, such economies can be subject to further deindustrialization, as branch plants reach the end of their product life cycle, or are closed prior to that point because of falling
demand or because branch plants in other places are more profitable. As spatial divisions of labor have increasingly been recast from the intra-national to the international scale, amid claims of a globalizing economy and “global shifts” (Dicken 2011) to the BRICs (Brazil, Russia, India, and above all China) and the MINTs (Mexico, Indonesia, Nigeria, Turkey), branch plant economies in deindustrialized regions in the historic capitalist cores of Europe and North America have become increasingly vulnerable to devalorization and disinvestment of capital.

At the same time, however, partly enabled and necessitated by a shift to new methods of flexible high volume production, incorporating principles of “just-in-time” and “lean” production, there has been a shift from “global outposts” to “embedded” branch plants, with a mandate for limited process-related research and development (R&D) and with some parts of supply chains co-located adjacent to – or in extreme cases, actually within – assembly plants. This reliance upon localized supply chains and the pools of appropriately skilled and socialized labor and support services that develop around the assembly plants (allegedly) ties the latter more effectively to place. An iconic example of such an embedded branch plant is Nissan’s assembly plant at Sunderland in the United Kingdom, established in 1986 and now employing some 7000 workers with perhaps another 4000 employed in component suppliers in the local supply chain as an automobile rolls off the line every 60 seconds. With the recent decision to locate production of the new Juke model at Sunderland, employment could increase further. As well as this Nissan plant, there are other well-known examples from the automobile industry (Hudson and Schamp 1995). Such localized supply chains typically involve components that are bulky and difficult to transport and/or of low unit value. However, it is often unclear as to the extent to which this is more of a discursive shift rather than one reflecting a generalized shift in corporate practices, and in so far as it is a matter of practice, the extent to which it is one that is limited to a narrow range of products – for example, in consumer electronics as well as automobiles – while many branch plants remain as classic global outposts.

Enterprise cultures and new SMEs?

As a result of the changes outlined above, and recognition of both established industries and branch plants relocating and those that remained restructuring and shedding labor in an effort to remain competitive, attention came to focus upon the size of firms and plants. Over much of the capitalist world, “big” became seen as the problem, “small” as the solution to fill the space and solve problems of industrial decline and unemployment. Drawing on perceptions of the experiences of places in which development seemed to be based upon small firms (for example, parts of southern Europe: Garofoli 1992), this led to the widespread emergence of policy responses that focused on endogenous development and encouraging the formation and subsequent growth of new enterprises, often linked to ideas about the (re)birth of an entrepreneurial culture, as the route to regional economic regeneration. The reality, however, is that in old deindustrialized places such developments were more often a response to and an alternative to the reality or perceived threat of unemployment as people established one-person firms, often in various services (such as taxi driving or window cleaning) rather than in manufacturing, using redundancy payments from their previous job and/or grants from the state initially to establish their firm. The rationale of such firms is not, however, enterprise and
innovative growth but the provision of work and an income stream to the owner, self-employment as a tacit recognition of the absence of secure and well-paid waged work in the local labor market.

To some extent, the growing emphasis on small firms reflected a recognition that parts of the world that historically were not seen as industrial powerhouses nevertheless had become successful centers of industrial growth, based on collaborative networks of small firms, such as those of the “Third Italy” (Bagnasco 1975; see also Local development). Equally influential were perceptions of previously unindustrialized places that grew rapidly around clusters of small firms in new high-technology areas – with Orange County perhaps the emblematic new industrial space (Scott 1988). What policy initiatives that sought to reproduce such development in deindustrialized places largely ignored, however, were the very specific political-economic and cultural conditions in these regions that enabled them to develop successful industrial economies, conditions that could not be replicated in old industrial regions that had declined.

Typically, industrial districts such as those of southern Europe were specialized in the production of mature consumer goods, with relatively low-technology production methods but dense collaborative networks of economic and social relations between participants in the district. In time, however, these places too became vulnerable to competition from lower wage cost places, as geopolitical changes opened the economies of eastern and central Europe and China to capitalist investment and routine production functions were decentralized from established industrial districts to new and cheaper locations (Hudson 2003). Ironically, just as such models of industrial districts were being lauded as the way forward in deindustrialized areas in northern Europe, they were entering crisis and collapsing in the “model regions” of southern Europe in which they had formerly flourished (Hadjimichalis and Hudson 2014).

In other deindustrialized areas, the emphasis was placed much more upon “high technology” SMEs, often seeking to capitalize on innovation based in scientific research in local universities, and these are discussed below in the context of new knowledge-based economies. To some extent this reflected the influence of research in the United States, especially California with Orange County perhaps the emblematic “new industrial space,” which investigated the new industrial districts based on information and communications technology (ICT) and new technologies and their links to leading research universities (Scott 1988). This encouraged public authorities in very different parts of the world to seek to encourage “knowledge transfer” links from cutting-edge research in universities there in electronics, ICT, biotechnology, and advanced materials into new small firms that would both grow and form links with other firms to create vibrant new industrial districts. Typically, however, such policies were attempted in places that lacked both an entrepreneurial culture and the infrastructure (hard and soft, but especially the latter) needed for such policies to succeed. Typically, too, they lacked the level of state support that came from links to defense industries and the military-industrial complex in the United States. As a result, the effects in terms of net job creation have typically been disappointing, although in other respects there has been some limited diversification of economic structures.

From manufacturing to services?

While industrial conversion can involve seeking to replace one type of manufacturing activity with another, it often involves a shift from manufacturing to service sector activities,
reflecting broad sectoral shifts in the structure of capitalist economies and the growing recognition that manufacturing was more likely to be a sector of employment loss than employment growth. The service sector is, however, loosely conceptualized and embraces a plethora of different types of activities. As might be expected, given the diversity of activities within the categorization of “services,” the following discussion will of necessity be selective. First, consider the attempts to attract back office functions such as call and contact centers to replace jobs lost in manufacturing and/or mining. This approach has been followed in many deindustrialized places, such as northeast England, parts of the former German Democratic Republic, and in Cape Breton in Canada. Such activities do have the capacity to bring relatively large numbers of new jobs to places which are desperate to attract employment, albeit often part-time and poorly paid and requiring different types of skills and competences to those found in previously industrialized places. They often seek to recruit female workers, rather than men who have lost their jobs in manufacturing, as one element in a changing gender division of labor there – men who in any case may be resistant to such forms of work. In many ways these are the service sector equivalents of the old manufacturing branch plants, the latest variant on the theme of “global outpost,” vulnerable to closure as firms both outsource and offshore such activities, to locations such as India, with a resultant loss of employment. A second strategy in many deindustrialized places is to seek to commodify their past industrial glories and heritage and turn to industrial heritage as a basis for tourism. In the process, such places undergo a transformation from places of production to places of nostalgia – no longer places of material production but of an often rose-tinted nostalgia for an industrial past. Examples include Big Pit in south Wales and Beamish in northeast England, but there are many more. This is but one facet of a broader turn towards tourism of various sorts in the search for new bases of economic development in deindustrialized places (Hudson and Townsend 1992).

Third, there has been an emphasis on retailing and consumption as bases for economic regeneration, but of course, like tourism, employment in such activities is dependent upon people in other places having jobs and enough money to spend. However, the growth of out-of-town shopping centers and retail parks in many former industrial areas attests to the fact that this has been a common element in many attempts to regenerate these areas. Moreover – as with heritage tourism – this has increasingly involved a turn to the “experience economy,” in which the rationale is not simply purchasing and then consuming commodities but the experience of purchasing itself, whether of material goods, or a holiday, or entry to a museum and, as a result, increasingly creating or tailoring built environments to that end (Lorentzen and Jeannerat 2013).

While involving very different sorts of activities, these service sector jobs have certain characteristics in common. They tend to be linked to significant shifts in gender divisions of paid labor, to be poorly paid, to be regarded as unskilled, and often to be part-time or casual, often seasonal. Thus they offer very different forms of paid work to those formerly found in now deindustrialized places and provide a rather fragile and precarious base around which to seek to reconstruct a local or regional economy.

Knowledge and learning regions: old wine in new bottles

To some extent the growing interest in place-specific conditions as critical to suc-
cess cuts across the manufacturing/services dichotomy, recognizing that many functions once based in manufacturing companies have now been outsourced to separate service sector companies, that product and not just process innovation has become increasingly important in relation to competitiveness, and that increasingly the knowledge and symbolic content of many commodities is of growing significance. From the late 1980s there was a growing recognition that industrial success and the sources of competitiveness lie not simply within the boundaries of the firm but also in the relationships between firms, public authorities, community groups, and diverse organizations in civil society in a specific territorial domain, recalling the nineteenth-century economist Alfred Marshall’s concept of industrial districts and the importance of “something in the air” to the economies of successful places. In short, this was a recognition that proximity and links to others and “being there” (Gertler 1995) matter to the success of individual firms and so to regional economies. This led to new ways of thinking about how to regenerate regional economies that had experienced severe economic decline and introduce new areas of growth to them.

As a result, there was growing interest in and emphasis on regional innovations systems (Braczyk, Cooke, and Heidenreich 1998), on knowledge spillovers and the significance of embedded and often embodied tacit as opposed to codified knowledge, on pools of appropriately skilled labor and input–output relations between firms, on the social relations of civil society beyond the workplace, and on the complementarities of activities between firms in an intraregional territorial division of labor that combined both “traded and untraded interdependencies” (Storper 1995). In response to this body of research, public policies in many parts of the world sought to create the conditions in which such knowledge-based economies and learning regions could emerge and flourish, although others were more skeptical as to what was new in these approaches and how successful they had been and can be in regenerating deindustrialized places (Hudson 1999, 2011).

A later variant on a related theme is the emergent interest in “smart specialization” as a strategy to build on key competences that remain in a region but to adapt these to the production of new commodities for which there are perceived to be growth opportunities and in this way to convert and reconstruct regional economies. Smart specialization has been defined as a strategic approach to economic development through targeted support to research and innovation, involving a process of developing a vision, identifying competitive advantage, setting strategic priorities, and making use of smart policies to maximize the knowledge-based development potential of any region, strong or weak, high-tech or low-tech (European Commission n.d.). Related to the emphasis on knowledge and learning, there has been growing interest in creativity and culture as a route to reconstructing the economies of cities and regions (Cooke and Lazzeretti 2008). Whether such approaches will be any more successful than earlier ones remains to be seen as they require quite precise social and material conditions to have a chance of success. Finally, we cannot eth that there is also recognition that the authenticity of products in some cases crucially depends upon where they are produced and that this identification of product with place offers an opportunity to reconstruct regional economies by moving up the value chain. One example of this is the resurgence of the mechanical Swiss watchmaking industry and the capacity of such watches to command premium prices precisely because they are known to be produced in Switzerland, indeed in particular parts of
Industrial Conversion

Switzerland, with the result that both firms and regional economies have prospered (Jeannerat 2013). Authenticity is not, however, something that can be transplanted to other places and so appeals to authenticity as a strategy for regional economic revival are strictly limited.

Beyond the formal mainstream: social enterprises, informality, and illegality

With the increasing difficulties of providing replacement jobs via any form of mainstream private sector development, in many areas that suffered severe industrial decline there has been growing interest in a range of social economy alternatives, such as social enterprises, community businesses, and cooperatives. This is a very different approach to industrial conversion, concerned at least as much with the social relations of the economy as with products and processes. While diverse, these approaches share a common characteristic in not being driven by concerns to maximize profit and shareholder value (Gibson-Graham, Cameron, and Healy 2011; Hudson 2009). Social enterprises and cooperatives do seek to generate a surplus but are committed to using this for collective social and economic development purposes rather than private gain. Other forms of social economy organizations do not seek to generate a monetary surplus but rather focus on providing services that help lead to environmental and health improvements or training to enable those who have been unemployed, especially the long-term unemployed, to acquire new skills as a first step onto the ladder back into the formal labor market. Often such initiatives have involved learning from experiences in peripheral parts of the global economy in the Global South (Amin 2009).

In some places that have suffered the effects of deindustrialization and economic decline, and in which policies of reconversion and regeneration fail and state support for those without work is meagre, there may be industrial conversion of a very different sort as the void in the economy may be filled by illegal activities of various sorts as people seek to construct individual and household strategies to “get by” and survive. This can involve activities that are legal but pursued by people who are not authorized to perform them (often referred to as activities in the “informal” sector). It can also involve activities that are simply illegal. This could encompass both the production of things that are illegal or more typically revolve around activities that involve trade and trafficking in a variety of goods, both those that are illegal and those that are legal but illegally acquired, often the proceeds of criminal activities, but also often linked into the formal legal economy (Hudson 2014).

Conclusions

This entry has summarized some of the main ways in which, via state policies and the actions of various civil society organizations, attempts have been made to address the problems that result as one set of industries decline in a place. This can involve restructuring those industries in situ, attracting inward investment, or developing a variety of endogenous local alternatives. The form and content of these responses has changed over time, though there is no simple linear sequence of policy responses that is universally applicable. Moreover, what has been successful in one place and time is by no means guaranteed to be so in other times and places. Given the character of capitalist economies, with the restless movement of capital in search of profits, industrial change and conversion is an ongoing process for many places. Some achieve this relatively unproblematically – for example, the
considerable loss of manufacturing employment in London was offset by a compensating growth in banking, financial services, and associated service sector activities, albeit at the cost of much more deeply segmented labor markets and income inequality (Buck et al. 2002).

For most other places, however, the process of policy-steered industrial conversion is much more challenging and difficult, not least because of structural and spatial change in the economy itself. Often these places have been the site of a succession of policies seeking to attract manufacturing branch plants and service sector back offices, encourage the formation and growth of indigenous small enterprises across the whole spectrum of the economy, and foster the development of a tourism economy based around industrial heritage. Typically, too, such policies have all failed to have their intended effects in terms of the emergence of a new economy and new sources of formal sector employment. As a result, such places remain blighted by unemployment, worklessness, and poverty and so may become places in which the process of conversion is a more radical one, from legal to illegal economy.

Industrial districts

Liang-Chih Chen
Shiuh-Shen Chien
National Taiwan University

An industrial district (ID) is a spatially defined production system characterized by the concentration of firms specializing in certain industrial sectors. The emergence and development of such a system is emphasized to be deeply linked to the local contexts and social relations of the area which it embeds. The concept of IDs originates from Alfred Marshall's work (1961/1890) identifying the external economies associated with agglomerated small- and medium-sized enterprises (SMEs) in regions like Lancashire and Sheffield in England during the nineteenth century. In the 1970s and 1980s, the term “industrial district” was coined by a group of scholars to describe SME-based regional economies, notably the Third Italy (i.e., the central and northeastern regions), that demonstrated higher competitive and economic resilience. Being able to secure productivity and competitiveness advantages through the creation of external economies of scale and by promoting flexible specialization for the agglomerated SMEs, IDs were further considered as an alternative model to the industrial organization of large firms. Examples of well-known IDs include ones such as Emilia-Romagna in Italy, Silicon Valley in the United States, Baden-Württemberg in Germany, Ishikawa in Japan, and Hsinchu in Taiwan.

Two general features of IDs are often stressed (Rinaldi 2005). The first emphasis focuses on the industrial structure in which the production system is composed mainly of small, independent firms which are geographically agglomerated and are specialized in one or a few phases of a complete production process. As these ID firms often have a low degree of vertical integration and only a small portion of them produce finished products, the production process has to be carried out through the collaboration of local firms tied together by subcontracting arrangements.

The second key feature of IDs focuses on its governance mechanism. As opposed to the traditional agglomeration theory that conceptualizes local economies as collections of atomistic competitors regulated mainly by price/cost signals, the ID concept emphasizes the greater reliance of firms on locally embedded social relationships in governing their interfirm transaction (Harrison 1992). The institutional environments of ID have produced an atmosphere of trustful behavior, allowing for the emergence of cooperative competition and interactive learning among ID firms.

Factors accounting for ID dynamism

Aside from the typical notion of agglomeration economies, the ID concept specifically addresses key industrial and social settings that facilitate the economic vibrancy of such a territorial industrial system. First, from the perspective of industrial organization, owing to spatial concentration, ID firms are able to build up networked production systems, giving rise to an extensive division of labor between local firms, allowing these individual firms and the
industry as a whole to increase their competitiveness through flexible specialization in production. In addition, the ID environment promotes the development of SMEs as smaller firms can rely on external sources to grow rather than engaging in expensive vertical integration. Expanded entrepreneurial opportunities then induce a constant influx of entrepreneurs who not only sustain the dynamism of the production systems, but also inject innovative ideas and vitality.

Second, one should understand that the most important advantage of ID is the development of local economic-social communities based on non-economic factors such as local cultures, norms, and institutions. In such a kind of community, people share common culture, values, or beliefs, and so on, which help to lubricate social relations, build consensus, support group loyalty between entrepreneurs and employees, and provide a common language to speed innovation and information exchange (Rinaldi 2005). The prevailing social and economic interactions further nurture the development or reinforcement of mutual trust (or social capital) between ID firms, allowing them to develop reciprocal relationships and engage in joint action, thereby enabling the smooth and sustained operation of the ID’s production networks.

Third, the geographical and institutional settings of IDs are particularly instrumental to promoting innovation. The industrial atmosphere of IDs can enhance the potential of firms for acquiring knowledge and skills to support the development, adoption, and diffusion of innovation. On the one hand, the existence of close social relations or high degrees of trust among ID firms not only facilitates the broad and fast circulation of information and knowledge, but also fosters the formation of innovative cooperation. On the other hand, geographical proximity also helps to provide good opportunities for frequent interpersonal face-to-face contact to ensure efficient exchanges of tacit knowledge and interactive learning among local actors. In addition to the abovementioned institutions, which are often informal in nature, one should note that the interaction and cooperation between ID firms in terms of production and innovation might also be encouraged by the existence of formal support institutions, such as industrial associations or research institutes, whose establishments have often been the results of public and private joint efforts.

**The changing characteristics of IDs**

The current global economy is characterized by the inevitable and intensified interconnectedness of different localities, including IDs. In this regard, the conventional ID model that explains a district’s global competitiveness by looking solely at the structure and dynamics of its local industrial system has been unable to provide a satisfactory explanation in regards to the development and evolution of IDs. On the one hand, economic actors within the IDs might require closer and more formalized collaboration allowing them to enhance or sustain competitive edge vis-à-vis those foreign larger firms in the world market. On the other hand, it is also observed that ID firms actively acquire new knowledge or capabilities from multiple geographical sources in addition to those situated within their IDs. As a result of these trends some prototypical characteristics of IDs have undergone notable changes. Two phenomena – the greater external openness of the ID industrial systems and the rise of large firms, particularly business groups within local production networks, have been addressed in literature concerning the recent evolution of IDs.
The increasing openness of IDs

To understand the current dynamics of IDs, the self-contained character of industrial organizations of IDs should not be overemphasized. Recent studies have noted a trend of increasing openness of IDs in the sense that districts’ production systems have not only been penetrated by external actors, but have also extended their spatial boundaries to other localities within or outside their home countries. On the one hand, seeking opportunities to exploit the advantages provided by IDs, some outside firms, including multinational corporations, have been attracted to invest in districts and consequently have emerged as important members of these districts’ production communities. On the other hand, some larger ID firms have expanded to a transnational and global scale with the capacity and motivation to establish extensive production and business networks beyond their local territory. Moreover, facing increased competition in the global market, other ID firms have sought to subcontract to extra-district suppliers so as to obtain specialized or cheaper supplies. Studies of Italian IDs, for instance, have pointed out that the majority of subcontracting work now relies on extra-district suppliers. The destination of outsourcing has not only been these Italian IDs’ neighboring regions in Central and Eastern Europe, but also some distant Asian countries, such as China.

The opening up of IDs is generally viewed as a critical development for sustaining the vitality of IDs by allowing previously closed systems to access external capability and knowledge and thus avoiding lock-in effects. Acknowledging the fact that ID firms have significantly increased the volume of their operations outside their home region and the IDs’ territorialized production systems seem to be undergoing a de-location process, one might wonder if such developments would impair interfirm production and social relationships within the districts and whether the characteristic local embeddedness of the ID model may become obsolete. However, some current ID studies have shown that, while the opening of IDs has substantially influenced the nature of interaction among district firms, it has not necessarily led to the complete abandonment of local relationships. For instance, ID firms are observed to rely mainly on extra-district suppliers only for standardized production activities and still work closely with their local partners on more important tasks such as product design and development. Scholars also maintained that the development of IDs’ local and nonlocal relationships might actually be complementary. Although the spatial boundaries of production networks in the IDs are indeed not confined to the locality, ID firms depend greatly on the districts’ pre-existing locally rooted relationships to manage their non-local networks better. To be sure, many of these critical nonlocal networks might actually fail to emerge or develop without the production advantages derived from the IDs’ industrial networks. Furthermore, it is also due to the existence of knowledge sharing and learning mechanisms within the IDs, one firm’s improved competence, as a result of their internationalization, would be diffused to others, leading to a synchronized improvement of all ID firms.

The emergence of business groups within IDs

In the recent evolution of organizational structures of IDs, there has been a strong tendency toward an increase in firms’ concentration. More specifically, the escalation of leader firms with the rise of business groups established by the former has become an emerging trend in the growth process of IDs. Owing to their business success, a handful of local SMEs have expanded in size and, consequently, gained predominance
in affecting the changes of the districts. In addition, some of these leading firms have sought to reorganize themselves into business groups, that is, a set of firms which are legally independent but are established under the same control and ownership.

As suggested by some scholars, the establishment of business groups is especially suited to facilitate the growth process of SMEs. The emergence of such groups in IDs have further received wide discussions since it represents one specific organizational form adopted by ID firms to cope with new conditions of market and technology (Cainelli and Iacobucci 2007). Studies on Italian IDs, for example, have discovered that, rather than increasing the internal sizes of their original firms, district firms tend to acquire other local firms to form business groups in response to the need to expand in size, as related research have found that business groups tend to be more common in IDs than in non-district areas.

Generally, the increasing relevance of business groups in IDs is seen as resulting from a process of concentrating ID outputs and the ability of district firms to achieve better governance over the often loosely coupled subcontracting relations within their networks. It is both the defensive and aggressive strategies employed by leading firms that stimulate the formation of business groups. To protect core knowledge from leaking out to their neighboring counterparts through the district's embedded social and production networks, leading firms would buy out subcontractors or competitors so as to enclose and control externalities within the same corporate structure. Besides, with their superior access to markets, information, knowledge, and finance, some leading firms would seek to increase their dominance over their districts through promoting industrial consolidation.

In addition, the specific characteristics of ID firm executives, and the unique production and institutional environments in the districts are also stressed as critical factors for stimulating the emergence of business groups as the preferred modes of organization and governance.

First, ID firms are renowned for obtaining competitive advantage through specialization, and they might wish to extend such practices to their new ventures. By establishing business groups, the leading firms control overall strategy and achieve economies of scale in some activities (e.g., marketing, finance, R&D, etc.), while simultaneously maintaining an organizational structure in which each group firm specializes in specific products or markets. Such arrangements also offer contractual autonomy to firms in the group, since each firm has the autonomy needed to adapt its contractual relationships with customers and suppliers to its specific and changing needs.

Second, the stronger entrepreneurial culture found in IDs also influences the development of business groups, particularly the internal dynamics within the formation process. Business groups enable each legal unit to retain higher degrees of autonomy thus preserving the entrepreneurial style of management that characterizes many ID firms. Moreover, the formation of business groups could be the result of the entrepreneurial reproduction process within the IDs. In some cases, the setting up of a new firm within the group might aim to provide entrepreneurial opportunities for their more talented and ambitious people from the leading firms while keeping that talent within the existing group.

Third, the geographical and social proximities of ID firms also help to nurture the creation of business groups by facilitating the matching processes of consolidating firms. Collocation enables the rapid circulation and sharing of information among local firms, allowing those who are to form business groups to efficiently learn and
screen suitable candidates for acquisition. By exploiting their social networks within the IDs, these entrepreneurial firms further gain additional knowledge about potential buyout targets, providing them with additional confidence in their expansion strategies.

Future of IDs

IDs have continued to be considered as critical engines of regional, national, or even world economies. The competitiveness of IDs has still been argued to be largely derived from the efficiency and innovativeness of their local production networks. Nevertheless, such perspectives have been challenged by scholars who warned that an ID’s local networks that are too closed and exclusive might actually harm its sustained development due to over-embeddedness. Furthermore, it is also noted that the development of information and communication technologies and advanced transport has greatly relaxed the spatial constraints of distant relationship building and knowledge exchanges. As a result, spatial co-location might therefore become less relevant or even disadvantageous for ID firms’ attempts to maintain or advance their competitiveness, consequently leading to these firms’ dis-embeddedness from their districts. However, in our discussions regarding the changing characteristics of IDs, it is noted that local embeddedness still plays an essential role in stimulating the restructuring and reconfiguration of industrial organizations of IDs. While other factors, such as firm capabilities or external shocks, may indeed affect the evolutionary processes and outcomes of a particular region, it is still believed that the geographical concentration of actors within IDs remains a preferable arrangement to support individual firms and the industry as a whole in coping with volatile business environments.

Industrial geography

Canfei He
Peking University, China

Shengjun Zhu
Swansea University, UK

Industrial geography has traditionally been defined as the study of the spaces, places, and geographical circulation of industry. It is a sub-branch of economic geography and deals with the spatial arrangement of manufacturing or secondary activities. Due to the transformations in the production system and the emergence of new kinds of output, organization forms, distributive functions, and new modes of competition, it is increasingly more difficult and less meaningful to distinguish clearly between manufacturing and other forms of economic activities. It has been widely acknowledged that, in order to thoroughly understand spatial arrangement of industrial activities, attention should be paid to the assemblage of a wide range of factors, in particular the broader societal, economic, political, institutional, and technological context in which industrial activities situate. In this sense, industrial geography encompasses not only the location of manufacturing or secondary activities but also the broader processes of structural change in the production of goods and services and various ways in which space, place, and geographical circulation are part of these processes.

The discipline was established in the early twentieth century in both Western Europe and the United States, driven partly by theoretical arguments developed in economics, and remains an important subfield within Anglo-American geography. It has been energized and replenished in a decentralized manner by researchers asking different questions within the same subdisciplinary space. Change has been incessant, and the history of industrial geography has been punctuated by numerous moments of disciplinary reinvention and reconfiguration. Industrial geographers thus never settle on one single methodology, theoretical framework, set of techniques, or perspective. For instance, a persistent theme in industrial geography has been examinations of the spatial distributions of industrial sectors, based on a perspective of industries. Industries are composed of companies, which make location decisions to open and close facilities of different production capabilities. These create the “geography of enterprise” and a firm perspective. Complementing the systematic approaches by sector and by company is the regional perspective. Another reason why industrial geography has been subject to so much change is that the discipline has been highly empirically grounded and closely tied to its empirical object of study, which over time has constantly undergone fundamental alteration. This is especially true, for example, at the end of the twentieth century and the beginning of the twenty-first century, resulting from technological advances in terms of transportation and communication, on the one hand, and a process of globalization and marketization in countries and regions that had not been fully exposed to market economy before, on the other hand (e.g., China, India, and former communist countries in central and eastern Europe).

This entry is organized along a rough timeline. The next section seeks to review briefly the main phases of the discipline's historical development.
from the early twentieth century when industrial geography was institutionalized in both Western Europe and the United States to its most recent situation. The third section outlines the contemporary research in industrial geography by listing some of the primary groups of theoretical and empirical studies. The last section concludes this entry and discusses the future direction of industrial geography.

Historical development of industrial geography

Before the formal institutionalization of the discipline, commercial geography – the precursor of economic geography – which was formally established in 1882 by German geographer Götz, had conducted some rudimentary industrial geography studies and researched the causes and reasons of economic geographical specialization, production of commodities, and movements of goods. However, commercial geography had been less an academic discipline than a tool serving the European imperial project and providing practical knowledge and information about where places were located and the specific commodities they produced, to colonist states (Barnes 2009). Works on industrial geography conducted in this period, such as George Chisholm’s Handbook of Commercial Geography, were mainly written in a commercial geography style, filled with maps, tables, and industrial geographical facts. Chisholm (1889) argued in his Handbook that the environment made each place uniquely suitable to undertake a specific type of industrial activity.

Location theory and spatial science

While pre-war geographers focused on global commodity production and trade, with environmental determinist and colonialist overtones, other competing academic disciplines had proceeded with conceptual and statistical advances. Specifically, a number of social sciences and even some humanities, especially in the United States, shifted towards an approach that stressed rigorous statistical techniques of description and analysis, and turned on the widespread use of scientific methods and philosophy. This gave rise to a new generation of geographers with a shared view of developing a thorough, mathematically justifiable geographical science that could be taken seriously by other competing academic disciplines. The subsequent shift to spatial science, also known as the “quantitative revolution” fundamentally altered the discipline, emphasizing the systematic application of scientific forms of generalization, inferential statistical methods, and abstract modeling – often inspired by other disciplines such as physics, mathematics, sociology, and particularly economics.

As the quantitative revolution proceeded, industrial geography started to massively import theories and methods from economics, especially those on industrial location patterns. The birth of modern industrial location theory dated back to 1909, when the German economist and location theorist Alfred Weber published his seminal book, Theory of the Location of Industries. This formed the basis for variable cost analysis, which was further extended significantly by Tord Palander and Edgar M. Hoover. At the same time, development of theory on locational interdependence provided the foundations for the variable revenue analysis. In much of the 1960s, the variable cost analysis dominated in industrial location research, whereas the variable revenue approach, mainly in market area analysis, found its most obvious expression in the context of central place theory. The fusion of these two approaches had proved to be very difficult theoretically, and the most influential attempts in this respect were those made by
August Lösch, Melvin L. Greenhut, and Walter Isard.

However, theoretical contributions by geographers at this stage were limited. In 1910, Chisholm introduced Weber’s work into geography, to interpret “the seats of industry.” Throughout the late 1950s and most of the 1960s, industrial geographers embraced the work of Weber and other members of the German Location School (e.g., Johann Heinrich von Thünen, August Lösch, Walter Christaller, etc.), and predicated the interpretation of industrial location patterns on a type of neoclassical economic theory of rational choice and maximizing behavior. This theoretical and conceptual shift resulted from a combination of the quantitative revolution unfolded not only in geography but also throughout other academic disciplines, which paid specific attention to statistical techniques and scientific abstraction, and the influence of regional science that applied neoclassical economic theories to the measurement of industrial location patterns and to the identification of optimal location of industry. Common themes at this stage included the locational decision-making behavior and distribution of industrial activities, geographical diffusion over time, and the geography of land rent in cities and its impact over the distribution of industrial activities.

The behavioral approach

As neoclassical formalism and traditional location theory were increasingly criticized during the ascendancy of the behavioral approach, geographical contributions became more prominent by the end of the 1960s. The transformation from abstract modeling and scientific generalization based on assumptions of rational choice and maximizing behavior, to observation and analysis of actual location practice accorded with the traditionally more empirical predilections of the geographers. Because the data demands of variable cost and variable revenue models could not be easily met, it was often difficult to apply location theory to spatial economic analysis. Formal location theory was also inadequate to totally interpret real-world locations of industries for some other reasons. For instance, it was unable to deal appropriately with spatial disequilibria and to incorporate the wide range of factors, other than economic ones, which played significant roles in shaping locations of industrial activities. Rather, the empirical identification of locational decision-making was much easier to undertake. The behavioral approach thus relies on in-depth interviews with corporate locators, ranging from asking about the opening or closing of a specific plant to considerations of the working of the local network and of the influence of corporate culture on the structure of the firm.

The 1970s had witnessed two distinct but interconnected themes emerging in the behavioral industrial geography. One focused on the location decision-making process and stressed suboptimal outcomes rather than maximization, and the other, also known as “geography of enterprise” or “corporate geography,” emphasized the role of industrial organization in the location decision-making process and in the spatial organization of industrial activities in general. Unlike neoclassical regional science that often treated firms as undifferentiated and rational decision-makers and privileged external spatial patterns over internal corporate structures, behavioral industrial geography thus considered the firm as a complex entity, like an organism, that evolved, adapted and struggled in a larger competitive setting, was often not rational, and whose inner workings defied formalization. Studies predicated on the behavioral approach gradually broadened, from preoccupation with the location of single-plant firms, through the
INDUSTRIAL GEOGRAPHY

complexities of giant multiplant, multisite, and multiproduct firms, to concern with entire spatial industrial systems.

Marxism, the radical approach, and regulation theory

From the late 1970s to the end of the 1980s, developments in industrial geography reflected the applications of Marxian economics to location issues, in lieu of the neoclassical economics. Dissatisfaction with the abstract, socially irrelevant and apolitical conceptualization of industrial geography that neoclassical location theory provided surfaced in the 1970s when David Harvey started to reject spatial science that he had earlier championed in his Explanation in Geography. The intellectual shift towards the radical approach, colored especially by Marxism, accorded with shifts in the real world. The restructuring of industrial activities, as well as deindustrialization, especially in the seemingly entrenched Western industrial regions attracted increasing attention, within the broader context of change in the capitalist economy. The traditional industries of Western countries, such as textiles, iron, and steel, were subject to severe economic trauma as firms shut down, moved offshore or turned lean and mean, resulting in massive manufacturing job losses. The radical approach and political economy, with its emphasis on economic crisis and uneven development, thus offered an ideal theoretical framework. In the United Kingdom, Doreen Massey’s watershed book, Spatial Divisions of Labour, offered original theoretical interpretation and trenchant empirical analysis. Her work was influenced by political economy as well as a new methodological approach, critical realism, codified and circulated primarily by the economic geographer Andrew Sayer, which linked industrial geography methodologically with intensive, on-the-ground case studies of specific industries and their geographical sites.

A group of radical geographers in California also conducted significant theoretical and empirical research, not on cases of decline in capitalism, but on the flip side of capitalism: its innovativeness, creativity, and power of revival. During the 1980s, drawing on both political economy and institutional economics, the California School, including Anna Lee Saxenian, Allen Scott, Michael Storper, and Richard Walker, carried out a series of theoretical and empirical studies based primarily in California, especially on the vibrant high-tech, garment, and film industries. They emphasized capitalism’s vitality and capability to reorganize its industrial geography and recuperate, though the United States was also suffering severe economic decline, manufacturing job loss, and deindustrialization, especially in its Midwest, Rust Belt region.

The underlying clash between the UK and US versions was reconciled in the late 1980s through regulation theory, which set the intellectual agenda for industrial geographical work for the next decade. Developed by the French economists Alain Lipietz and Robert Boyer to explain why capitalism survived in spite of Marx’s best prediction of its demise, regulation theory argued that capitalism endured because historically an appropriate conjunction formed between the regime of accumulation and the mode of production. In this sense, UK and US versions were just two sides of the same coin, because while UK industrial geographers were documenting the disintegration of an older Fordist regime of accumulation (based on mass production and mass consumption) and mode of regulation (Keynesian welfare state), their US counterparts were examining the formation of a new regime of accumulation (post-Fordism or flexible production) and a new mode of regulation (neoliberal, deregulated state).
Industrial district, embeddedness, and cultural turn

In analyzing the geographical character of post-Fordism and flexible production during the 1990s, industrial geographers rediscovered the idea of industrial district that underscored the predilection of firms in the same sector to cluster and co-locate geographically, and to become closely tied and interconnected. This idea was initially formulated by the English economist Alfred Marshall, and significantly extended by Michael Piore and Charles Sabel in their influential book *The Second Industrial Divide*, which contended that industrial district was central in the shift from mass production to flexible production. As post-Fordism and flexible production had come to characterize the economy, small firms reemerged as a focus of interest during the 1990s. Increasing attention was also directed towards networks of information exchange, which might have been partly replacing traditional concerns such as input costs as factors influencing the location of industrial activities. Economic and industrial activities remained central, but softened by recognition of the social institutions, and even the culture, in which they were embedded. The idea of industrial district and flexible production was quickly related to “embeddedness,” a concept associated with the economic anthropologist Karl Polanyi and sociologist Mark Granovetter, implying an inseparable relationship between the economic and the sociocultural. Proponents argued that it was this inseparability that characterized and contributed to the rise of post-Fordist industrial districts such as the Third Italy, Silicon Valley, and Baden-Württemberg, which flourished because firms in these industrial districts were tightly embedded in the cultural institutions, social relations, and forms of life cultivated over time in those places.

Increasing emphasis on industrial district and embeddedness in industrial geography also reflected the intellectual shift in the larger discipline of economic geography or even human geography, where “cultural turn” gradually became keywords. Rather than treating the economy as a single inviolable object, geographers needed to reject the idea of a monolithic, purified economy and to conceive it as a culturally and socially constructed product, fragile, performed, and capable of realization in various forms. Similarly, “relational turn” drew attention to the ways in which sociospatial relations of economic actors are intertwined with processes of economic change at various geographical scales; “institutional turn” stressed the role of institutions in influencing firm’s behavior, particularly in relation to inter-firm networking and industrial relations. These “turns” represented an attempt to rethink the very nature of the discipline, its empiricist epistemology, its entrenched masculinism, and its economistic logic, and to use case studies of particular substantive topics to work through a cultural, institutional, and relational methodology. These turns are far from dominant, however, and criticism quickly mounted. For instance, some argued that these turns might result in a loss of important knowledge within industrial geography, such as literature on branch plant location decisions, because this type of research was perceived as outdated. The most striking attribute of the history of industrial geography is the absence of overall disciplinary progress, and there is no standard paradigm within the field. Instead of new paradigms emerging and completely erasing the old ones, industrial geography is more a multilayered field where past versions coexist with the new ones, and old approaches continue contributing to the discipline side by side with the emerging ones. For instance, despite these
and other contemporary developments, neo-classical location theory in the space economics tradition still has its adherents, and the traditional models still have some utility as both predictive and prescriptive devices in a competitive capitalist economy. While there is no single leading approach, the discipline may look messy but vibrant and lively as a variety of approaches complement and/or conflict with each other.

Contemporary research in industrial geography

Globalization

An interest in globalization has recently defined the field, with research on both new geographical patterns of production and new forms of industrial organization that make the former possible. After a long period of being overlooked by industrial geographers as the discipline became the study of only Western industrial economies, globalization regained its position in the 1970s. The emergence of a new international division of labor, the rise of multinational corporations (MNCs), the development of new forms of transportation and communication technology, and the growth of international financial capital and foreign direct investment (FDI) reminded industrial geographers that they needed to have a more holistic geographical view and to take into account the whole world. Furthermore, it forced industrial geographers to realize that exclusively focusing on the West and separating it from the rest of the world was not just problematic but obstructive, as places around the globe were increasingly connected by globalization. Peter Dicken’s *Global Shift* was one of the first to focus on this point through a study of FDI, which was mainly carried out by large MNCs around the world. Partially driven by the increasing size, number, and dominance of MNCs and FDI was the drastic industrialization in the Global South, including not only the so-called newly industrialized economies in East and Southeast Asia, but also the emerging economies such as China, India, Russia, and Brazil – the reverse side of deindustrialization in the Global North. A novel conceptual vocabulary and theoretical framework are being forged, as well as new methods, such as global networks, global commodity chain analysis, and the analytics of MNCs. All have contributed to studies on spatial patterns of FDI, multinational corporations and their temporal changes, interregional shift in production, and subsequent rise and fall of industrial regions around the world.

On the other hand, Dicken critiqued the idea championed by economists in some instances that globalization represented “the end of geography,” and he emphasized the process of globalization was not seamless, eliminating all geographical differences. Geography was still of central importance but in a different form, and geographical differentiations were preconditions for globalization. Similar conclusions have been reached in subsequent work in industrial geography over the last decade. Geography matters fundamentally in the process of globalization and it determines the spatial patterns of FDI, MNCs and their temporal evolution, the ways in which firms are managed and the spatial organizations they forge, interregional shift in production, how global commodity chains connect distant places to one another, and industrialization and deindustrialization around the globe. Recent works on reindustrialization in the Global North, as well as the emergence of new considerations in global sourcing, such as the importance of short-cycle replenishment, lean retailing, or just-in-time production, have added further stickiness to the flow of global financial capital and investment, reinforcing the importance of geography and spatial proximity. In this sense,
Globalization is thus not smooth and homogeneous, flattening geographical distinctions; rather it is uneven, occurring in very particular places and strongly determined by spatial variation, differentiation, and diversification (Barnes 2009).

**Firms, networks, institutions, and poststructuralism**

The focus on firms in industrial geography reflects a deep-seated belief that “the firm” is a fundamental category to define the arbitrary boundary of industrial geography. The firm became central in industrial geography when location theory was introduced into industrial geography to interpret “the seats of industry.” Each new generation of industrial geographers has thereafter provided its own interpretation of the firm. In the 1930s, Michael Wise focused on small firms and the idea of “industrial district,” formulated by Alfred Marshall, which stressed the propensity of firms to co-locate and cluster geographically. The 1960s and 1970s witnessed the emergence of “geography of enterprise” or “corporate geography” in the behavioral industrial geography that was preoccupied with complexities of giant multiplant, multisite, and multiproduction firms. In the 1980s and 1990s, small firms and innovative firms regained their position and became the key focus of empirical research for many industrial geographers. These firms were deemed dynamic and able to make crucial contributions to regional development. However, the most recent studies have pointed out that the key is not the size of the firm per se, but rather the ways in which firms of different sizes cluster together in the form of a network, and the social, technical, and economic relations that make the clustering possible. There can be many types of networks, such as business networks to supplier commodity chains, production networks, and innovative networks, and they function as both a governance structure and a process of socialization through which disparate actors and organizations are interconnected in a coherent manner for mutual benefits and synergies (Yeung 2000).

In addition to the analysis of firms and networks in recent industrial geography, attention has also been drawn towards the relationship between institutions and firms, exemplified by key concepts such as “institutional thickness” (Amin and Thrift 1994). On the one hand, strong institutional presence may help to embed relatively footloose industrial firms in specific localities and regions, and to reduce their propensity for relocation. Strong institutional presence may also reinforce firms’ growth potential and innovative capacities, induce new firm formation, and enhance the competitiveness of existing firms. On the other hand, strong institutional thickness and dense network may be a positive hindrance to development and growth if they are anti-growth (Yeung 2000).

Paralleling the work on firms, and drawing partly on cultural turn and poststructuralism, was allied research on firms and the sociocultural, which sought to rethink the “firm” as one of the most contested analytical categories in industrial geography and to point out that it is not a self-contained and homogeneous black box driven purely by profit-maximization motives, as argued by the neoclassical industrial geography. Instead, it is internally heterogeneous and contested by different interest groups and corporate actors that possess different levels of power and varying knowledge and resources, and these actors are also subject to multiple discourses (Schoenberger 1997). The “monolithic” understanding of the firm as well as the economy has been thereafter deconstructed to show the ways in which firms and their geography specificity are socially and discursively constructed (Gibson-Graham 1996).
Industrial district, embeddedness, cluster, and agglomeration

Ideas of both industrial district and “embeddedness” have been at the forefront of an outpouring of work on industrial cluster, agglomeration, innovation system, and innovative milieu, much of which is also more or less interconnected with studies listed in the previous section, on the firm and networks. During the 1980s and 1990s, Allen Scott was one of the first to rediscover Alfred Marshall’s idea of industrial district and constructed a new theory of the dynamic firm based on transaction costs, external economies, and spatial linkages. The industrial district, defined as a tight-knit agglomeration of small and dynamic firms with a high degree of specialization and production interconnection, became a focal point for a large amount of work primarily carried out by Allen Scott and other members of the California School. Furthermore, Michael Piore and Charles Sabel’s influential book *The Second Industrial Divide* took this strand of literature to new heights, by claiming that industrial districts were central in the shift from mass production to flexible production. Later work within this field became increasingly diverse: some of these studies tested the idea of “innovative milieu” by examining the formation and transformation of industrial districts; some were concerned with defining different types and forms of industrial districts; some emphasized the importance of an appropriate institutional framework (see above “institutional thickness”), in particular the presence of thick social relations among firms and the larger communities in which they embedded (Karl Polanyi and Mark Granovetter’s idea of “embeddedness”); some focused on the coherence, spatial boundaries, and openness of clusters, and analyzed clusters along multiple dimensions, such as horizontal, vertical, institutional, external, and power dimensions (Bathelt 2005). Concepts of social embeddedness and industrial district have also been applied to analyze innovation and high-tech development. For instance, Michael Storper, member of the California School, coined the term “untraded interdependencies” in his work on high-tech industrial districts to better understand the role of cultural and social relations.

The most recent studies are becoming highly critical of the industrial district literature as a success story and as a universal model for policy initiatives. In many of these studies, the flexible specialization on which industrial district is based has been challenged by an alternative interpretation that there is no inevitable transition from one mode of production systems (mass production) to another (flexible production). Often observed is the simultaneous existence of both mass production for scale economies and flexible specialization for scope economies even in the same sector located in similar regions (Hullacháin 1992). Contrary to predictions derived from the industrial district model, horizontally and vertically integrated firms may be no less competitive than their specialized counterparts. Other studies have also stressed that traditional industrial district model and previous studies on cluster tend to focus on the local network of social relations (“local buzz”) at the expense of extra-local linkage (“translocal pipeline”) (Bathelt 2005). The central question is thus at what spatial scales industrial districts and clusters are constructed and analyzed.

Global production networks, global commodity chains, and global value chains

The above-mentioned contemporary research in industrial geography has all influenced what could be called the Manchester school of global production networks (GPNs) around Peter Dicken, Neil Coe, Martin Hess, Henry Yeung, and others. The GPN approach, defined as...
the globally organized nexus of interconnected functions and operations by firms and nonfirm institutions through which goods and services are produced and distributed, provides a broad relational framework for the study of economic globalization. It offers an open and geographically sensitive perspective that goes beyond the more restricted and linear framework proposed by the related concepts of global commodity chains (GCCs) and global value chains (GVCs), which are defined as a network of labor and production processes whose end result is a finished commodity. Specifically, on the one hand, these three approaches share something in common. They all focus on the globally coordinated inter-organizational relationships that underpin the production of goods and services, and the power and value dynamics therein. On the other hand, the GPN approach has five distinctive features that are absent in GCC/GVC analysis: first, by explicitly taking into account the extra-firm networks, GPN necessarily incorporates the broad range of nonfirm organizations that may shape industrial activities; second, GPN analysis is designed to be multiscalar and to stress the interactions and mutual constitution of all spatial scales from the local all through to the global; third, the adoption of the metaphor of networks over chains helps to avoid deterministic linear interpretations of how production systems operate and generate value; fourth, governance structures of GPNs are conceived as more complex, contingent, and variable over time than is suggested in GCC/GVC analysis; finally, GPN analysis is not to consider the networks in an abstracted manner for their own sake, but to reveal the dynamic developmental impacts that result for both the firms and territories that they interconnect (Coe 2011). More recently, GPN and GVC/GCC analysis have been gradually converging as the differences between the two approaches are narrowing.

The GPN approach is based on three conceptual categories (MacKinnon 2012). The first one is value, which aims to incorporate both Marxian notions of surplus value and orthodox definitions of economic rents. One subsequent question is about which actors and locations in the networks are able to capture and retain value. The second conceptual category is power, defined primarily as a practice in terms of the capacity to exercise power, including corporate, institutional, and collective power. The last one is embeddedness, which exists in three forms in GPN analysis – societal, network, and territorial embeddedness. In this sense, regional development is considered as a product of the dynamic process through which actors in cities and/or regions coordinate, mediate, and arbitrage strategic interests between local actors and their counterparts in the global economy, that is, “strategic coupling.” While recent GPN analysis has started to examine the so-called dark side of strategic coupling, it still tends to overlook the tensions that arise from the differential powers of key agents, such as the often unequal nature of the relations between transnational corporations and local residents and communities (MacKinnon 2012; Coe 2011).

Labor and labor market

Given the emphasis on production by industrial geographers, it is odd that labor and the labor market until recently received so little attention. For instance, by focusing on trust-based ties and dense social networks, industrial district literature in some instances tended to underplay the role of other important factors, such as power and inequalities within industrial districts, the limitations of networks, the informal economy, gender and ethnicity, the generation gap, wages and working conditions, and so on, and portrayal of networks as webs of trustful
ties led to a tendency to overemphasize their more “benevolent” attributes and to overlook the dark side of industrial districts and networks. Recently the attitude to labor and the labor market has changed and it has become a fertile topic of research. In part, the new interest stems from globalization, which has stimulated research at both the high and low end of the labor market. On the one hand, there is work examining the international movement of various high-earning, highly skilled international business elites, such as bankers, managers, and entrepreneurs, and highlighting their high level of mobility around the world. On the other hand, increasing attention has been directed towards the unequal and highly segmented nature of the contemporary labor market, contingent and precarious work, “docile” and “submissive” workers in developing countries, and the immigrant workforce.

Furthermore, there is a significant movement away from geographies of labor to labor geographies. While the former treats labor as the passive victim and conceives geographies of labor as a passive territorial outcome of industrial restructuring, labor geographies reconceptualize labor as an active constituent of the global economy, and ascribe causal power to workers as active geographical agents and to labor relations as a key set of forces transforming contemporary industrial landscapes. The viability of labor geography does not hinge on arguing that labor is powerful, but hinges on underscoring that labor can be a distinct and autonomous force in specific temporal and spatial circumstances. Four major strands in the literature on labor geographies can be identified: restructuring of labor markets as a result of increasing numbers of new entrants (such as women and immigrants); social regulation of labor markets and their distinctive geographies of governance; labor organization and unionism; labor market segmentation (Yeung 2002).

The evolutionary approach

The use of the evolutionary approach in industrial geography is far from new. Evolution was central to behavioral understandings of the “geography of enterprise” or “corporate geography” in the 1960s. Radical approach and Marxist theorization of industrial geography in the 1970s and 1980s were centrally concerned with the long-term development and transformation of the capitalist space economy. The use of evolutionary terminology such as “path dependence” and “lock-in” in research on regional economic change by industrial geographers has really taken off since the 1990s, as part of a wider institutional turn driven by fertile engagements with economic sociology and the embeddedness-network paradigm (Coe 2010). For instance, a range of work on changing geographies of production in old industrial regions has tended to focus on regional development trajectories, and analyses have been predominantly preoccupied with regional path dependence and lock-in. The last few years have even seen a conscious effort to develop a more systematic and rigorous theoretical framework for the evolutionary approach. However, the various deployments of evolutionary terminology in industrial geography still fall short of offering a coherent analytical framework. Some concepts are deployed in an isolated manner, and the entire evolutionary project remains pluralistic, incorporating a range of theoretical approaches, such as evolutionary theory of the firm, Darwinian notions of variety, selection, and heredity, and complexity science. Coe (2010) has identified three main branches of evolutionary research: work on path dependence and lock-in in different geographical contexts; research pertaining to clusters, localized learning, and related variety; and analyses of the spatial evolution of industries across the economic landscape.
Conclusion

When most people talk about industrial geography, they refer to an intellectually lively, open, eclectic, versatile, dynamic, and pluralistic discipline, particularly from the latter half of the twentieth century onwards, which encompasses a diversity of ways of describing and examining the spaces, places, and geographical circulation of industry. Due to this, industrial geography is necessarily an interdisciplinary pursuit, one that evades precise definition and intellectual closure. Contemporary industrial geographies are hybrid formations in which multiple paradigmatic viewpoints, drawn from multiple historical and spatial contexts, coexist and jostle within the same institutional and subdisciplinary spaces. The last decade has witnessed increasing intrusions by other social science disciplines into industrial geography’s traditional intellectual territory. While it is tempting to turn one’s back on such intrusions, an alternative strategy is to embrace them, learn from them, and explore industrial geography’s connections with studies of regional development, labor markets, and industrial change in development studies, economic sociology, international political economy, business and management studies, gender studies, and so on. There are also ongoing reflexive debates about the relationships between industrial geography and economics. This strategy not only gets the discipline of industrial geography better recognized in the postdisciplinary era, but also inherently benefits its research and public reach.

The final question for this academic discipline concerns what industrial geographers can do to change the real world. Since the introduction of location theory into industrial geography there has always been an interest in problems of planning industrial development and the policy relevance of the discipline. This policy relevance ranges from the strong impetus provided by industrial geographers working with local economic development authorities, to the involvement of industrial geographers in shaping business strategies and practices at the firm level. There is clearly a need for industrial geographers to be much more proactive in influencing public policy and setting policy agenda. In other words, industrial geographers have to reach out to the actors who are not just at the receiving end of economic changes but, equally important, also at the beginning of the decision chain that produces economic changes, and to widen the audience that industrial geographers are speaking to (Yeung 2002). In short, industrial geography remains a work in progress, as are its object of inquiry, theoretical framework, methodology, set of techniques, perspective, and policy relevance.

Industrial linkage can be broadly defined as the contacts and flows of information and/or materials between two or more industrial sectors or firms. The concept is widely used in industrial and economic geography to portray interfirm interdependence. A firm’s linkages can be divided into: (i) **backward linkage**, which provides goods and services for its production activities; (ii) **forward linkage**, which refers to links with customers purchasing its products; and (iii) **sideways linkage**, which refers to interactions with other firms involved in the same processes. Here information linkages are as important as material linkages. There is no universal consensus among geographers as to what industrial linkages are. Geographers sometimes deliberately define “industrial linkage” differently to make their studies manageable and/or to plug some perceived gaps in the literature. For instance, some take a tight manufacturer-to-manufacturer view of linkages while others incorporate all economic activities. Micro-level research focuses on interfir or interplant linkages, whereas macro-level research may examine intersectoral linkages owing to the lack of relevant data.

Geographers who have rediscovered Alfred Marshall’s (1920/1890) idea of the “industrial district,” which underscores the predilection of firms to cluster and co-locate geographically tend to place emphasis on the spatial binding forces exercised by industrial linkages. They argue that industrial linkages are still a powerful sustainer of industrial agglomerations, and thus have fundamental impacts on firms’ location/relocation decision-making. The interactions between linkage partners represent one of the routes through which the economic multiplier operates, to further enhance some initial change in the economy through its interdependencies with others. This argument was extended by François Perroux’s (1955) idea of “growth centers” or “growth poles” to establish, in a confined geographical area, a nexus of linked economic processes to the mutual convenience and economic benefit of all concerned. Albert Hirschman (1958) further elaborated the ways in which diffusion of economic growth would be propelled through forward and backward linkages. The last type of practical importance of industrial linkages is that material and information linkages also serve to widen a firm’s knowledge of space, and this in turn encourages and facilitates further spatial expansion when needed. Industrial linkage does not necessarily occur in a “short distance,” as depicted in the industrial district and agglomeration research. Instead, its geographical patterning is dependent on transportation costs, development of telecommunication technology, standardization of production, as well as political, institutional, and societal factors. Studies on industrial linkages are often based on: (i) macro-level studies employing an input–output framework, industrial employment analysis, an agglomeration approach, or spatial linkage analysis; (ii) static micro-level studies of national linkages using cross-section data; (iii)
INDUSTRIAL LINKAGE

dynamic and quasi-dynamic micro-level studies of material linkages; and (iv) information flow studies.

However, it has been argued that a traditional and neoclassical understanding of industrial linkages tends to rob industrial geography of the ability to perceive and treat plants and business organizations as unequal participants in webs of interactions, that is, in power networks. Power in the studies of industrial linkages can be defined as the capability of one organization to control the resources necessary for the functioning of another, such as capital, finance, materials, land, and labor. In this sense, industrial linkage is reconceptualized as the operational manifestations of power relationships, and as the spatial dimension inherent in all power networks.

Industrial location theory

Dean M. Hanink
University of Connecticut, USA

Industrial location theory concerns the determination of the optimum location of commercial establishments (typically factories, but farm production and service production are also included), although many of its essential constructs are also often applicable to non-commercial facilities. It falls within the general class of normative theory, so it primarily concerns ideal locations rather than actual ones. It does, however, generate empirically testable propositions. Fundamentally, industrial location theory for market economies can be reduced to a simple tenet: firms or individuals locate production facilities so that profits are maximized. While the tenet is simple, it hides a very complicated reality consisting of variations in costs, prices, geographical markets, uneven spatial distributions of resources, and so on that require attention in the interest of gaining insight into specific principles of location.

Foundations

Transportation costs are perhaps the most common complicating factor considered in industrial location theory and models. The impact of transportation costs on the location of production is considered essential in two fundamental early formulations of location theory: von Thünen's theory of the location of agricultural production and Weber's theory of the location of manufacturing. Both Thünen's and Weber's theories assume producers are price-takers in competitive markets, and in their simplest forms concern the location of a single producer.

Johann Heinrich von Thünen's work, initially published in German in 1826, extended David Ricardo's theory of land rent by placing it in a spatial context (Dunn 1955). Ricardo's theory essentially states that land use sequence resulted from variations in fertility. The most fertile agricultural land is used first; the least fertile land is used last. That result is essentially a response to the relation between market prices and production costs. Highly fertile land requires little additional cost in production while less fertile land requires fertilizer, for example, which is costly. Less fertile land will only be put into production when market prices are high. The difference between market price and production cost (including normal profit) is called economic rent, and land is only used when that rent is non-negative. Thünen's work is concerned with location rent, the expected profitability of agricultural production at a particular location.

Thünen made simplifying assumptions in focusing on the impact of location on agricultural production. One is that all commercial agricultural output is consumed locally at a town – a point location. Another is that the town and its surrounding land are located on a homogeneous plain. There is no variation in soil fertility, which is everywhere sufficient for crop production, and the plain is isotropic, so that movement is possible everywhere with uniform cost per unit of distance regardless of direction. There are variations in market prices for individual crops, and variations in production costs based on their characteristics rather than
soil fertility, but the really significant variation in Thünen’s theory is in the transportation costs of individual crop varieties: wheat, for example, has one transportation cost, corn another, and so on. From the general propositions of Thünen’s theory a location rent (LR) identity can be defined:

$$LR_{ij} = Q_i(p_i - c_i) - Q_f k_j$$  \(1\)

where \(Q_i\) is the quantity produced of the \(i\)th crop, \(f_i\) is its cost of transportation per unit of distance (e.g., kilometers), and \(k_j\) is the distance from some production point, \(k\), to the marketplace point. (This rent identity was actually provided by Dunn (1955); see next section.) Production of a crop can occur anywhere that \(LR \geq 0\) (Figure 1). In Thunen’s system the expansion, or contraction, of agricultural land use does not vary with environmental quality as in Ricardo’s, but rather varies with transportation costs. Cheaply transported products can be grown at relatively great distances from the marketplace, while those that are expensive to transport must be grown relatively close to where they will be consumed. Further, a decrease in transportation costs in general, due to technological improvement, for example, extends the total area over which agriculture is profitable, while an increase in general transportation costs decreases the area of feasible production.

The crop that can earn the highest location rent at any particular point is expected to be grown at that location in a market economy. Thünen’s theory leads to a rationalized landscape of concentric zones of homogenous production when extended to multiple crops. Crops of a single type, for example wheat, are grown within certain radii of the market where they enjoy, as a group, higher location rents than other crop types, while crops of other types have their own zones, with again each defined by a commonality of relatively high location rents within types.

Thünen’s theory was developed for its time in the early nineteenth century so it concerned agriculture. Working early in the twentieth century, Alfred Weber’s (1909) industrial location theory concerned manufacturing. Like Thünen, Weber assumed punctiform demand, with the simplest system based on a single location of consumption of the manufactured good. Raw materials required for the production of the manufactured good are not evenly distributed across a homogenous plain as in Thünen, however, but normally, like the market, located at points. Weber’s theory in its basic form defines the optimum location for manufacturing a product to be at the point where the total transportation cost of shipping the raw materials from their sources to the factory plus the cost of shipping

![Figure 1](image-url)
the finished product to market is minimized. Finding the point where such transportation cost is minimized is often called the Weber problem, and underlies a class of mathematical problems in location analysis and operations research that have objective functions of distance-related cost minimization.

Weber used the product of weight × distance as an equivalent to the cost of transportation, so raw materials with lower weights have less impact on the selection of a factory’s optimum location than do raw materials that are heavier. In addition, the weight of finished products relative to the weights of their raw material inputs plays an important role. A comparison of the raw material and finished product transportation cost is embodied in a material index (MI): $MI = \frac{\text{weight of localized raw material}}{\text{weight of finished product}}$. When $MI > 1$ then manufacture of the product in question has a raw material orientation; that is, its likely best point of production is nearer the raw material source(s) than it is to the marketplace. When $MI < 1$, then manufacture of the product has a market orientation; its optimum production location is likely nearer the marketplace than it is to the raw material source(s). The value of $MI$ can only be greater than one when a nonlocalized (non-point-specific location) raw material, or ubiquity, is used in production. If only ubiquitous raw materials are used, the optimum plant location is at the marketplace (Figure 2).

Weber extended his plant location calculus to include the impacts of labor availability and also the achievement of external economies of scale (decreased average production costs induced by proximity to other producers or large populations) through the agglomeration, or spatial concentration, of manufacturing plants. As with raw materials, low-cost labor sites are assumed to exist at particular points that are not coincident with either the locations of raw materials or the marketplace. If labor costs at one of those points are low enough to offset the increase of transportation cost incurred by moving from the point that minimizes them to the labor source, then those low labor costs would have an effect on a plant’s location. The availability of external economies of scale is treated in the same way. If a decrease in costs associated with agglomeration is greater than the increase in transportation costs associated with the relevant change in the plant’s location, then the site of the agglomeration is the optimum location.

Both Thünen’s and Weber’s approach to location theory postulated markets at fixed points, and concentrated on minimizing the transportation costs incurred in supplying those locations where demand occurs. An alternative to that geography of demand is to assume it occurs over a continuous surface, and that is the supposition followed in location theories.

Figure 2 The basic Weber model. The best location for the plant ($P$) is determined by the pull-effects of raw material sources ($M_1$ and $M_2$) and the market ($C$). Source: Hanink DM 1997. Fig. 7.9, p. 254. Reproduced by permission of John Wiley & Sons, Inc.
that focus on revenue maximization, rather than cost minimization, as their means of maximizing profits. The basic format for revenue maximization location models was developed initially by the German geographer Walter Christaller (1933) in his central place theory – a theory of the spatial hierarchy of settlement. Christaller’s theory is essentially top-down. Given a uniform distribution of population across a uniform plain, a central place that is a distribution point for all goods and services can be expected to form in the actual spatial center of the population. Given that place’s location, a series of lower-order central places can be located that minimize goods- or service-price to transportation:cost ratios for consumers and, at the same time, provide sufficient numbers of consumers to make the distribution of goods and services from particular locations profitable (Figure 3).

The German economist August Lösch (1954), working at about the same time as Christaller, formalized the relationship between cost minimization for consumers and revenue maximization for producers as the foundation of the spatial economy. Lösch also developed a central place system but, unlike Christaller, took a bottom-up approach that provided a comprehensive location theory of the firm. Again, the initial assumption is that consumers are evenly distributed over a large plain, which is boundless for all purposes. The plain is also isotropic, a simplifying assumption with respect to making transportation costs uniform. Given that simple landscape, where should a producer locate? The answer to that question depends upon what is being produced. Production costs are not an explicit issue in the location model, but price in relation to transportation costs is the characteristic of interest.

As in Christaller’s system, location on the Löschian landscape depends upon the joint evaluation of consumer and producer needs. The distance over which a good or service can be sold is called its range. The range of a good or service is dependent upon the ratio of its purchase price to its transportation price (as in Christaller’s system), which is assumed to be paid by consumers. At extremes, expensive goods and services that have low transportation costs can have very long ranges, while inexpensive goods that have relatively high transportation charges have short ranges, as consumers are unlikely to pay more for a good’s or service’s transportation than for the good or service itself. There are a variety of intermediate relationships between purchase price and transportation costs, each defining the critical characteristic of a good or service.

Figure 3 The basic geometry of central places. High order places (H) include low order places (L) in a nested spatial hierarchy. The markets have hexagonal forms to ensure full coverage without any overlap. Source: Hanink DM 1997. Fig. 8.3, p. 286. Reproduced by permission of John Wiley & Sons, Inc.
with respect to its location of production. Every good and service has an *outer range*, which is the greatest distance it can be sold from its place of production. Expensive goods and services are assumed to be bought infrequently by consumers, while inexpensive ones are purchased with relatively high frequency. The volume of sales a producer needs to exist, or minimum operating scale of production, is called the *market threshold*. Market thresholds can be defined by spatial extents, because consumers are uniformly distributed across the plain. Market thresholds define market areas that are necessary to support the minimum operating scale of the producer of any particular goods or services. In the absence of competition, each area that just contains the market threshold is a circle with a radius called the *threshold range*.

In the simplest case, the Löschian landscape would have a uniform distribution of a series of producers with circular market areas, but that shape is unsustainable. If the circular market areas do not overlap then some consumers would not be in range of a particular good or service, and if the circles overlap then producers may not have market threshold demand. Rather than circular market areas, a developed Löschian landscape contains a series of producers serving hexagonal markets, with shape being the regular tessellation that minimizes the aggregate transportation cost to consumers while ensuring that market areas do not overlap, thus ensuring that threshold demand is met for each producer in an effective spatial monopoly. In its basic form, the necessity of spatial monopoly to ensure producer survival means that concentrations of producers of the same good or service cannot exist. Spatial concentrations of producers do emerge, however, but only of those producing different goods and services. For example, a concentration of producers of goods A, B, and C could emerge, but two producers of service A or of good B would not be found at the same location.

The monopolistic competition in Löschian location theory runs counter to a spatial extension of Harold Hotelling’s (1929) principle of minimum differentiation. That theory actually concerned the tendency of competitors to minimize the differences of their products so as not to risk losing market share to each other. One company’s cornflakes are very similar to another’s, and so on. Hotelling used a locational analogy of competing firms locating along a main street in a town to illustrate the principle. As in Lösch, consumers are uniformly distributed, so barring differences in the firms’ products they are likely to simply shop at the firm nearest to them. If there is one firm, it could locate anywhere on the street, but if there are two firms, their best strategy is to co-locate so that neither has a locational advantage. Just as locations are the same for the competing firms, in an aspatial context their products would be very similar as well. In Hotelling’s model, if there is more than one producer then a spatial monopoly would likely lead to diminished profits rather than the assurance of survival as in Lösch’s location model.

**Extensions**

Thünen’s original land use theory is part of the body of classical economics that also includes work by notable early economists such Adam Smith and David Ricardo. A more contemporary, neoclassical, version of Thünen’s theory was provided by the economist Edgar Dunn (1955). Dunn relies on the basic assumptions of Thünen’s model, a homogeneous plain, a central market, and so on, but expands the analysis by developing the marginal rent function, described previously, that explicitly ties land/location rent to distance. By formalizing the concept...
of distance decay, Dunn was able to specify the locational limits for crop production singly, but more importantly was able to specify the equilibrium spatial pattern of a series of crops that are essentially treated as competitors for locations in a regional economy. Dunn also introduced a dynamic analysis in which changes in transportation prices induced changes in the locational patterns of agricultural production.

William Alonso (1964) extended the Thünen/Dunn analysis to urban land. In doing so, Alonso developed the concept of the bid–rent curve, which allowed for a more direct analysis of the market – supply and demand – for locations within a metropolitan area. Alonso’s city is assumed to have essentially the same simplifying background conditions as the agricultural region of Thünen and Dunn. Instead of a central marketplace where agricultural goods are sold, Alonso’s city has a central business district (CBD) that typified many American cities at the time. The CBD was just that because it is a transportation sink, the point in the urban region where aggregate transportation costs are minimized. As in the Thünen/Dunn analysis, the region has an isotropic surface that allows transportation costs to be uniform across the region without the complicating factor of transportation arterials channeling flows.

The effect of transportation costs in the Alonso model is not, however, the same as in the agricultural land use model. Businesses in the urban region do not transport their goods or services to a central place of consumption, thus lowering their transportation costs if centrally located themselves. Instead, their costs of doing business are increased with distance from the central point for two reasons. One is that their selling cost is raised as their distance from the transportation sink is increased, because the transportation cost for local consumers increases, on average, with distance from the center. That increased transportation cost requires the business to provide some sort of offset, such as a price discount, to attract sales. The second reason that business costs increase away from the center is that the business’ employees have, on average, increased commuting costs when working away from the transportation sink. Businesses must provide higher wages with distance from the center. The transportation-related factors attract business toward the center in the region, but the higher land costs at the center due to competition for low business-cost locations raise the price of land. Bid–rent curves trace the tradeoff between higher (lower) land prices and lower (higher) selling/labor costs for each business in the urban area. A business’ location is determined by the tangency of its bid–rent curve with the land price gradient that peaks at the center and declines with distance from that point. Businesses with the need for frequent interaction with customers and that are labor intensive are likely to be found near the urban center, while those that interact with customers infrequently and use less labor are likely to locate in less central locations.

The relationship between selling and labor costs and distance from the urban area’s transportation sink provides a theoretical foundation for the spatial concentration of businesses in urban places. An alternative theoretical foundation for such concentrations was developed as an extension of the Hotelling principle of minimum differentiation in its spatial context by Yorgo Papageorgiou and Jacques-François Thisse (1985) and by Masahisa Fujita (1988). These models concern the interaction between households, which prefer to be near a large number of businesses so that they have access to a wide variety of goods and products, and business, which, in turn, are attracted to locations with a large number of consumers. Complete spatial concentration of business and households
is limited by two factors. One factor is that consumers must pay high rents when located in proximity to business. The other factor is that businesses are faced with significant competition in such concentrations. Under such conditions, significant spatial concentrations only occur when consumers place very high values on access to a wide variety of goods and services.

The interaction of consumers and producers is also the focus of numerical models that are focused upon retail business’ location and market areas. At the aggregate scale, Reilly’s Law of Retail Gravitation (Reilly 1931) concerns the spatial extent of a city’s retail area and can be used to define a breakpoint between cities in terms of their spatial retail market share domination. The model ultimately has its foundation in Löschian analysis, but is probabilistic rather than deterministic in defining spatial markets. The geographer David Huff (1963) provided a microscale retail location model that also relies on probabilities of consumer attraction to particular places to delineate spatial markets, and also allows for potential competition among retailers to play a role in their selection of a location.

The economist Walter Isard (1956) extended many strands of location theory. Some of his work fuses aspects of the work of Thünen, Lösch, and Weber into a general theory of the space economy. He also tried to integrate location theory into broader economic analysis by treating transportation cost as an input in the same way that capital (including land) and labor are considered. In a standard production function, the volume of output is a response to capital and labor inputs. Those capital and labor inputs may be substituted for each other within certain limits, so labor will be substituted for capital if it is efficient to do so, and vice versa. In Isard’s analysis, transportation inputs may be substituted for each other, so that raw materials from less costly sites are used in preference to those from more costly sites. Isard also extended location theory by considering the effects on site selection and market areas of transportation costs that are not simply linear functions of distance. Another of his extensions considered the impacts of internal economies of scale, which are decreases in average costs associated with increasing volumes of production, on the size and location of competing businesses in a spatial economy.

While the foundations of location theory and its early extensions were established before game theory was developed, that analytical approach was later used in location theory that implicitly or explicitly requires interaction among producers or producers and a government entity. For example, the spatial version of the Hotelling model yields a Nash equilibrium, a basic construct of game theory, if two businesses locate in the same place, albeit under some restrictive assumptions including constant prices and a uniform market of consumers. Isard (1966) used game theory in analyzing the location of producers and the development of agglomerations, as considered earlier by Weber. Weber’s agglomerations are established where conditions beneficial to producers with respect to increasing output and lowering transportation costs occur. Isard showed that benefits to economic growth in a region could induce its government to provide a side payment to producers to establish geographical concentrations within its jurisdiction. The payments are made in a game that has producers and government as players. Robert Cromley and Dean M. Hanink (Hanink and Cromley 2008) extended the analysis and related the interaction between producers and government to the cluster policies used by a large number of governments in the interest of regional development.

In addition to the increasing sophistication of its principles and relaxation of its more restrictive assumptions, location theory was also extended
by its operationalization in various forms of mathematical optimization. The economists Martin Beckman and Thomas Marschak (1955) described the locational decision of a business as a type of activity analysis in which each of its actions has an implication for its location, or locations, of production. The objective function of the analysis is typically profit maximization, and its input requirements, distribution costs, and so on can be treated as constraints that limit not only profitability but locational choices as well, due largely to transportation costs. The regional scientist Benjamin Stevens (1961) formulated the Thünen model as the transportation problem of linear programming. In this case, the minimization of transportation costs is the objective function and constraints concern volumes of production and demand.

Criticisms and redevelopment

Location theory has received criticism on several counts. One of the most telling is that its predictions are not consistently empirically observed; locations of production often do not appear in expected places or patterns. The geographer Glen Norcliffe (1975) cited several factors that apparently undermined the applicability of location theory’s basic forms. One was that the declining relative importance of transportation costs in the entire production process undermined the usefulness of theory in which such costs play a major role. The expansion of light industry (especially compared to the situation when Weber developed his least-cost model), an increasing efficiency of material use and substitution, improved transportation technologies, and economies of scale in freight movement have all contributed to a declining impact of transportation costs on industrial location. Instead of transportation costs playing a pivotal role in the location of a producer, Norcliffe and other theorists argued that place characteristics, such as market size and land costs, should be considered the foundation for a new location theory that would provide better insight into location decisions and resulting location patterns than can theory based on transfer costs.

Criticisms such as Norcliffe’s are based on changes in production and transportation technology that seem to make the critical assumptions of location theory, and even its objectives, moot. The geographer Doreen Massey (1973) criticized industrial location theory on more profound grounds. Massey criticized the entire notion of location theory as an entity unto itself for three reasons. One is that the location of production cannot often be disintegrated from the other economic decisions of a business. Another is that the location of production is rightfully considered as the result of factors specific not to an individual business, but rather to the interaction of the business with its sociopolitical environment. The third is that the aspatial characteristics of an economic system have a spatial manifestation that can override the locational preferences of any individual business. Massey also argued that the partial equilibrium approach in location theory, which treats business locations as independent of other location decisions, would be better formulated in a general equilibrium context that considers the effects of those location decisions on other agents in the economy. Massey had specific criticisms in addition to her more general ones. With respect to individual approaches, she noted that Weber assumed perfect competition among businesses within an industry, but perfect competition is unlikely in a spatial economy. Another criticism, leveled at much of economic theory, is that the location decision is made by a completely rational actor with complete information, leaving no behavioral variation. Massey also criticized
the Lösch model, noting, as have others, that its location decisions are based on spatial monopoly but yield a system of places with varying levels of spatial agglomeration as the unlikely result of profit maximizing behavior by businesses that leads to fulfilling welfare criteria such as minimizing consumer travel.

The economist Paul Krugman (1995) has been more recently critical of industrial location theory. He noted the criticisms of its unlikely assumptions, but was sympathetic in their usefulness as simplifying constructs that allow a focus on the most important factors in the location decision. More tellingly, Krugman criticized received location theory as being more geometric than economic in its analysis. The locational patterns expected in location theory are derived largely with respect to principles of space, but the economic content is thin. Krugman questioned, for example, the structure of Weber’s theory, almost in a way that mirrors Massey. He points out that Weber’s theory does not consider the prices charged by the producer, or whether there are competitors, or whether multiple sites of production are better than a single one. There is no context for the location decision, and without prices the theory does not even meet the requirements for providing a true partial equilibrium model. Krugman also has criticisms of central place theory. The Lösch model, for example, has an outcome based on spatial optimization rather than (aspatial) market processes and while Christaller’s model has outcomes based on market processes, it is unclear about market structure.

The simplifying, but restrictive, assumptions of industrial location often lead to challenging tests of empirical verification. The geographer E.M. Rawstron (1958) provided three principles of industrial location that make location theory more flexible with respect to its predictions and also provide guidance with respect to the addition of controls in empirical testing of its models. The principles are physical, economic, and technical restrictions to locational choice that effectively elaborate upon the context of a theoretical model and define the possibility of a range of potential locations within the restrictions rather than focus on one particular site. The geographer David Smith (1971) elaborated upon Rawstron’s work and described spatial limits to production profitability that combined elements of revenue maximization and cost minimization in defining a geographical range of suitable locations that extended beyond a single optimum site. The approach is in line with the principle of satisficing as a decision-making criterion introduced by Herbert Simon (1947) in which choices are made based upon the achievement of an acceptability threshold rather than a maximizing criterion.

Behavioral location theory was developed by the geographer Alan Pred (1967). In his approach, location decisions were no longer implicitly made by completely rational agents with perfect knowledge and perfect information, but rather made by agents with varying levels of ability and information. While particular locational patterns are still expected in the behavioral models, they are much more accommodating of exceptions and conform well to Smith’s spatial limits model.

Industrial location models have also been modified to incorporate uncertainty and risk. Work on locational behavior of businesses recognized that modern corporations have multiple objectives that are beyond the scope of classical location theory. In an uncertain business environment, firms must plan an overall investment policy accounting for risk. The geographers Robert Cromley and Dean Hanink (1985) used portfolio theory from financial economics to model location strategy. In their approach, as
INDUSTRIAL LOCATION THEORY

in the behavioral models, location is not deterministic but rather is related to the firm’s utility function. As management varies in its goals from total risk aversion to full profit maximization, the optimal pattern of location is altered. Additionally, their model incorporates existing patterns of locations into the business’ investment planning by finding a new pattern of investment that is complementary to the existing distribution.

Paul Krugman (1995) developed the currently dominant variant of industrial location theory in the 1990s in what is now called the new economic geography. The model is largely consistent with many earlier ones in that the location of a business’s production faces two often contradictory forces. One is a centripetal force caused by the benefits of economies of scale that make the business want to have all its production in one place. The other is a centrifugal force caused by transportation costs incurred by consumers, which makes the business want to have a dispersed number of locations. If transportation costs are very low and economies of scale are significant, then businesses are large in size and located in one or a very few locations. If transportation costs are very high, and economies of scale are minor, then businesses are small in size and spatially dispersed. Krugman’s contributions were to provide a general equilibrium location model and to use on a Dixit–Stiglitz utility function for consumers that ultimately allows imperfect competition among businesses. The resulting model is very similar to that of Lösch in its potential development of a landscape of hierarchical agglomerations. It also accounts, however, for the prices of goods and services, and the wages of the labor force that comprises the set of consumers, thereby providing a complete picture of a spatial economy not developed in other theoretical approaches.

While aspects of location theory have been subject to criticism, it is widely held that the principles of location theory, even in the most basic forms, are useful in providing insights into current and future spatial patterns of economic activity (Kilkenny and Thisse 1999; McCann and Sheppard 2003). For example, the flow of foreign direct investment from wealthier countries to poorer ones in the interest of securing low cost labor is easily explicable in the context of Weberian location theory. In addition, the Alonso model provides a rationale for the spatial concentration of business in city centers, but can easily be extended to more contemporary circumstances in which metropolitan areas have several places with high levels of accessibility, and to the problem of urban sprawl. Even the early Thünen model is useful in analyzing contemporary patterns of urban-centered agricultural production for local markets, while the recent theory of the new economic geography has been useful in predicting the impacts of enlargement of the European Union.

INDUSTRIAL LOCATION THEORY

Industrial restructuring

Chun Yang
Hong Kong Baptist University, China

Industrial restructuring refers to structural changes of territorial economies from the manufacturing to services sector at a range of spatial scales involving national, regional or city levels. It contains a quantitative dimension, typified by the loss of manufacturing jobs and the growth of services; a spatial dimension, usually associated with the geographic redistribution of manufacturing jobs at national and international scale; and a qualitative one, suggested by the greater incidence of both low-wage, low-skill jobs and high-level professional jobs in service industries, a decline in wages and unionization rates in manufacturing jobs, and a feminization of the job supply. Since the Industrial Revolution, industrial restructuring in the advanced economy has experienced two major stages. Firstly, in the early part of the nineteenth century, the advanced economy completed the shift from an agrarian economy to an industrial and service economy, with the change of population shifting from a predominantly rural one to an urban one. Secondly, by the end of the twentieth century, the advanced economy shifted from an industrial economy to a services economy, with employment in manufacturing declining and employment in the service industries dramatically increasing. Such changes may represent a response to changed conditions induced, for instance, by time–space compression, technical change, or conflicts between labor and capital in the workplace, or transmitted through the competitive conditions endemic to capitalism. Restructuring may involve one or more of a number of transformations, including structural adjustment, which is defined as adaptation to sudden or large, often unexpected changes in the context of economic geography.

The decline of manufacturing and shift to services raise questions about changes in the economic base of cities and the impact of these changes on employment and income distribution. The shift to services and the spatial redistribution of manufacturing received considerable attention throughout the 1970s and this continues today. The locational patterns of the new leading industries, particularly producer services, and their impact on urban economies and the urban hierarchy are significant outcomes of industrial restructuring. Moreover, industrial restructuring has resulted in uneven geographical impacts, such as the rise of world cities, spatial mismatch, and metropolitan growth.

Sectoral and spatial dimensions of industrial restructuring

Sectoral transformation of industrial restructuring

Industrial restructuring is marked by a process of structural transformation as reflected in employment and value added in primary, secondary, and tertiary industries. According to Simon Kuznets, structural transformation occurs when the share of nonagricultural sectors in an economy increases. A reconstruction of national accounts from a variety of sources for western countries shows that such a transformation...
INDUSTRIAL RESTRUCTURING

raised overall productivity and increased the returns to workers and capital. For instance, from 1800–1849 to 1951–1960, agriculture as a share of gross domestic product (GDP) declined from 30% to only 5% in the United Kingdom and from 20% to 4% in the United States. The share of industry inclusive of manufacturing meanwhile increased from 23 to 56% in the United Kingdom and from 33 to 43% in the United States (Kuznets 1966). The sectoral shift is mirrored in the structure of employment. In consequence, the population is redistributed from rural to urban areas and the capital:labor ratio in the nonagricultural sectors of the economy rises. History indicates the critical role of industrialization as an engine of sustained growth in the long term. Since productivity growth is associated with technological change and industrial upgrading, continuous structural change in technologies and industries is the main feature of industrial restructuring in modern economy. Manufacturing has contributed to the modernization of the agricultural and mining sectors, which provide raw materials through backward linkages, and spawning services through forward linkages. Since there is a tight nexus with the services sector, technological progress and growth in manufacturing lead to a larger demand for services, propelling overall economic growth.

Long-term economic trends from the pre-industrial stage of development in a large number of developed countries confirm that at the end of each episode of catch-up, the fast grower’s economy had a structure closer to that of a developed country as opposed to a low-income one. Industrial Revolution started in the United Kingdom in the 1700s but for about 50 years it did not spread to other countries because the British government forbade the export of machinery, manufacturing techniques, and skilled workers. Eventually, in the nineteenth century, it gradually spread to other countries in Western Europe. The earliest center of industrial production in continental Europe was Belgium, where production of coal, iron, textile, glass, and armaments flourished. By 1830, French firms had employed many skilled British workers to help establish the textile industry, and railroad lines began to appear across Western Europe. Germany was a latecomer in developing industry, mainly because no centralized government existed there. Relative to the United Kingdom, industrialization was delayed in the United States because the country at that time lacked the basic factor endowments – labor and capital – to invest in business. When it finally picked up in the 1820s, its growth was explosive. Laborers and capital came from Europe, where political revolutions sent immigrants to the United States. Rapid industrialization and structural transformation then followed. In 1800, farmers comprised 85% of the US population, but the proportion declined to 50% in 1860. Starting with an income level that was only one-third of that in the West during the 1850s, Japan achieved rapid development in fifty years to become the first industrial country in Asia in 1904. After opening up trade in 1854, its government encouraged learning from Western technology and institutions by sending high-level missions including about half of the ministers to the United States and Europe for nearly two years.

The economies of Western Europe and Japan have enjoyed unprecedented growth and technological upgrading in the decades since WWII in the so-called “golden age of capitalism” (1950–1974). During this period, nearly all developing countries pursued dirigiste capitalism, except for Japan, South Korea, and other Asian NIEs. The crux of Japan’s and East Asia’s success was that their development followed closely their comparative advantage and their governments played the role of facilitators.
Japan’s historical labor statistics record that a rising share of labor in Japan’s manufacturing sector coincided with a declining share of labor in the manufacturing sectors of the United States. In the 1960s–1970s, Japan supported its heavy manufacturing sectors, including machinery and automobiles. In the 1980s–1990s, just as the United States was upgrading its industrial base, Japan expanded its shares in the home appliance, electronics, and computer markets (Figure 1). Restructuring of Japanese economy during the last three decades had involved two distinctive transformations: in the secondary sector, the emphasis has shifted from heavy to light industry, particularly consumer industry and high-technology industry; contraction of the primary sector has been offset by expansion in the tertiary sector. The first change was made because of Japan’s declining competitiveness on the world markets for heavy industrial goods (e.g. steel, ships, chemicals) and the rising costs of labor. The second change was triggered by a massive shakeout of agricultural labor and by the advent of the affluent society in Japan with its greatly increased expenditure on consumer goods and services.

Figure 2 shows the employment shares in the United States between 1958 and 2005 for five subsectors selected from 99 manufacturing industries, ranked from most labor intensive to most capital intensive. As the capital:labor ratio increases over time, industrial and employment structures change dramatically; specifically, the share of labor employed in the most labor-intensive sectors, such as fabrics, declined monotonically. In sectors such as computer manufacturing, the share of labor employed first increased and then declined, showing a hump or inverse shape. In industries such as aircraft and automobile manufacturing, which are capital intensive but subject to labor-saving scale economies, the share of labor showed a slow and declining trend. In the most technology-intensive sectors, such as plastics, including fiber optics and lens, the share of employment shows a monotonic increase, indicating that the United States still maintains a comparative advantage in these industries.

Spatial shifts of industrial restructuring

Studies on industrial restructuring were initially grounded in a detailed empirical analysis of intranational spatial restructuring in the UK economy in the 1960s and 1970s (Massey 1984), in which the emergence of a new spatial division of labor in manufacturing was based upon a separation of skilled and managerial tasks (performed in many cases in London and the Southeast) from unskilled manufacturing work done in so-called branch plants (located in areas such as northeast England and southeast Wales). The industrial restructuring has expanded from the 1960s onwards, with the emergence of a new international division of labor (NIDL), in which developing countries took on new roles within the global economy through the offshoring strategies of transnational corporations (TNCs).
Since the 1970s, industrial restructuring has been extended to involve the establishment by European, North American, and Japanese TNCs of a global manufacturing systems based on developing labor-intensive export platforms in so-called “newly industrialized economies” (NIEs) in East Asia, namely, Hong Kong, Singapore, South Korea, and Taiwan. In response, TNCs used their global reach to relocate production from the industrial core to low-cost production sites in the NIEs. The manufactured goods were then, in turn, exported back to core markets in the West from the offshore branch plants.

With the global shifts of industrial activities from North America and Western Europe to Japan and later on to the first and second generation of NIEs, such as China, India, Malaysia, the Philippines, and Thailand in Asia, the process of industrial restructuring has extended over time.
and across space to Asian NIEs and recently to emerging economies such as China. From 1965 to 1990, Japan emerged as the world’s biggest exporter of manufactured goods, increasing its share of the world market from 8 to 12%. Japan’s success was followed by a second generation of newly industrializing economies in the 1970s (Hong Kong, South Korea, Singapore, and Taiwan), a third generation in the 1980s (Indonesia, Malaysia, Philippines, and Thailand or ASEAN 4), and a fourth generation in the 1990s (China and later Vietnam). Taking South Korea as an example, the share of manufacturers in GDP rose from merely 9% in 1953 to 30.1% in 1988, while that of the agriculture and mining sector shrunk to single digit figures in the 1990s. During the phase of industrial restructuring guided by export-oriented industrialization, the benefits of economic backwardness were exploited with sequential structural transformation from labor-intensive industries (e.g., clothing) to capital-intensive industries (e.g., machinery and transport equipment). Since 1983, capital-intensive machinery and transport equipment products have accounted for the majority of total exports. After the mid-1990s, their share exceeded half of total exports.

Since the 1970s, Asian NIEs have been facing labor shortage as a result of their demographic transition. Because of rising incomes, attitudes towards manual jobs and work ethics are changing. In association with labor shortages, wage rates have been increasing rapidly. The unionization of labor also contributes to wage increases and to strained labor-management relations. International forces, including growing competition from other Asian economies, particularly Southeast Asian countries and China (in labor-intensive low-skill products), increasingly competitive markets for low-technology and medium-technology manufactured goods, pressure from the United States and the European Community for currency revaluation and open trade, and a growing protectionist tendency in the North American and European markets, put considerable pressure on the Asian NIEs to restructure their industrial economies. Research has demonstrated how the rapid appreciation of the Japanese currency, the yen, during the 1980s – the “endaka” phenomenon – undermined the export competitiveness of Japanese manufacturers and, by cheapening imports, triggered decentralization of their production networks more broadly within East Asia. In later waves, deindustrialization has hit both South Korea in places such as Busan and Ulsan in the south, and Taiwan within and beyond Taipei. Industrial restructuring has created unprecedented challenges for these developmental states and their export-led industrialization strategies that they are only now struggling to come to terms with. In addition, Hong Kong had experienced deindustrialization from the 1980s through the 1990s, where manufacturing collapsed from 17% to less than 2% of GDP and decline of manufacturing in employment composition (Figure 3) in the context of an export-dependent economic structure and a noninterventionist state (various authors 1993).

More recently, the collapse of Asia’s exports to the West during the 2008–2009 global financial crisis caused concern about the sustainability of external demand as an engine for growth. It is argued that Asia needs to rebalance away from dependence on exports to the United States and the European markets. Growth instead should be driven by domestic and regional demand. Asian economies need to reform their industrial structure to mitigate the negative impacts of the global financial crisis and to support long-term growth and development (Thorbecke and Hsieh 2013). Notably, the Chinese central government designated the transformation from export-led to domestic consumption-driven...

development in the national 12th Five-year Plan (2011–2015) in the wake of the 2008 global financial crisis. Over the past three decades since China initiated its opening and reform policy in late 1970s, the export-led industrialization has been designated as a model for industrialization and economic growth, and contributed to the rise of China as the “world factory” (Table 1). Since 2000, the institutional environment for the export-oriented industrialization in the 1980s and 1990s has changed dramatically. The industrial restructuring of the export-led regional development, particularly the market rebalancing of TNCs from external to China’s domestic market, has turned out to be a viable strategy but daunting task in the context of the changing global–local dynamics (Yang 2012).

Consequences of industrial restructuring

Demographic and employment change

Traditionally, industrial geography has been primarily concerned with the location of industrial firms. Since 2000, a growing attention has been paid to the interrelationship between industrial restructuring and labor markets (Yeung 2002). For instance, it is demonstrated that the general employment decline and the rise of “flexible” employment in British retail banks in the early 1990s resulted from financial liberalization and competitive restructuring in the British banking industry. Empirical studies are devoted to analyze the impact of industrial restructuring on labor processes at the national, metropolitan, and community levels.

The peculiar outcome of industrial restructuring is deindustrialization, which refers to the

decline (relative or absolute) in the importance of manufacturing experienced by most developed countries since the mid 1960s, as measured by its contribution to GDP and its percentage of the total labor force. It is explained by declining productivity and strong foreign competition, particularly from countries where labor is less costly and unionized. The United States and United Kingdom have been among those countries most affected to date, and their areas of heavy (iron and steel, ship-building) and traditional (textile) industry have been hardest hit. A significant amount of the manufacturing lost by developed countries has been relocated in less developed countries, with their attractions of cheaper land and labor and less stringent controls on pollution. The deindustrialization of manufacturing employment has exacerbated joblessness in the poor black community, correlating with a rise in single-mother households, high premature mortality rates, and increasing incarceration rates among black males (Wilson 1980). This creates a growing economic class division within the black community accentuated by global economic restructuring without government response to the disadvantaged. Furthermore, Wilson asserts that as the black middle class leaves the predominantly black inner city neighborhoods, informal employment information networks are eroded. This isolates poor, inner city residents from the labor market, compounding the concentration of poverty, welfare dependency, rise of unemployment, and physical isolation in these areas.

The declining manufacturing sector leaves behind strained blue-collar workers who endure chronic unemployment, economic insecurity, and stagnation (Logan and Swantrom 1990). Meanwhile, widening of the social hierarchy occurs when high-level, high-income, salaried professional jobs expand in the service industries alongside a greater incidence of low-wage, low-skilled jobs, usually filled by immigrants and minorities (Sassen 1990). The effects of social polarization include the increasing concentration of the poor, blacks, and Hispanics in large US cities and distinct social forms, such as the underclass, informal economy, and entrepreneurial immigrant communities. In addition, a notable qualitative dimension involves the feminization of the job supply, as more and more women enter the labor force, usually in the service sector.

### Producer services as leading industries in post-industrial cities

Since the 1970s, industrial restructuring has been used to remedy the situation through the geographical redistribution of production and consumption. City economies across the globe moved from goods-producing to service-producing outlets. Breakthroughs in transportation and communications made industrial capital much more mobile. In consequence, producer services emerged as a fourth basic economic sector, where routine low-wage service employment moved to low-cost sites and advanced corporate services centralized in cities (Sassen 1990). These technological upheavals brought about changes in institutional arrangements with the prominence of large corporations, allied business and financial services, nonprofit, and public sector enterprises. Global cities, such as New York and London, become centers for international finance and headquarters for multinational corporations offering cross-currency exchange services as well as the buildup of foreign banking and trading. Other cities become regional headquarters of low-wage manufacturing. In all these urban areas, the corporate complex grows, offering banking,
INDUSTRIAL RESTRUCTURING

insurance, advertising, legal council, and other service functions. Global industrial restructuring allows markets to expand in size and capacity from regional to national to international scopes.

The institutional arrangements buttressed by improved technology reflect the interconnectedness and internationalization of firms and economic processes. Consequently, capital, goods, and people rapidly flow across borders. Global economic changes and technological improvements in communications and information systems encourage competitive organizations to specialize in production easily and assemble temporary workers quickly for specific projects. Thus, the norm of standard, steady employment unravels; this began in the mid-1970s. As industrial restructuring encourages high-technology service and knowledge-based economies, massive public de-investment results. Across many parts of the United States and the industrialized Western nations, steep declines in public outlays occur in housing, schools, social welfare, education, job training, job creation, child care, recreation, and open space. To remedy these cutbacks, privatization is installed as a suitable measure. Though it leads to some improvements in service production, privatization leads to less public accountability and greater unevenness in the distribution of resources. With this reform in privatizing public services, neoliberalism has become the ideological platform of industrial restructuring. Free market economic theory has dismantled Keynesian and collectivists’ strategies and promoted the Reagan and Thatcher politics of the 1980s. Moreover, industrial restructuring requires decentralization as states hand down power to local governments. Where the federal government focuses on mainly warfare–welfare concerns, local governments focus on productivity.

Spatial effects on economic landscapes

Industrial restructuring has brought about a significant change of urban landscapes, especially in the United States. Cities such as Baltimore, Detroit, St. Louis, and others face population losses that result in thousands of abandoned homes, unused buildings, and vacant lots, contributing to urban decay. Such transformations frustrate urban planning and revitalization, fostering deviance in the forms of drug-related activity and vagrancy. Older, compact, industrial US cities have been rendered obsolete. Urban spaces become playgrounds for the urban gentry, wastelands for low-paid service workers, and locations for the underground economy. In some areas, gentrification projects have caused displacement of poverty-stricken residents. Sunbelt cities, such as Miami and Atlanta, rise to become key business centers while snowbelt cities, such as Buffalo and Youngstown, decline. Even housing markets respond to economic restructuring, with decaying housing stocks, escalating housing prices, depleting tax base, changes in financing, and reduction in federal support for housing. Soon, spatial divisions among wealthy and poor households are exacerbated. Moreover, with the movement of blue-collar employment from central cities, geographically entrenched housing discrimination, and suburban land use policy, African American youths in inner cities become victims of spatial mismatch, where their residences provide only weak and negative employment growth and they usually lack access to intrametropolitan mobility.

High-order services, an expanding sector in the industrialized world, become spatially concentrated in a relatively small number of large metropolitan areas, particularly in suburban office agglomerations.
New tendencies of industrial restructuring in the globalizing world

In the wake of the 2008 global financial crisis and economic downturn, a new round of industrial restructuring, characterized by re-industrialization in advanced Western countries, has been witnessed. Some developed countries have been encouraging reinvesting or “reshoring” back to their own markets, as a boost to their own struggling sectors. For instance, the United States launched its official “reshoring initiative” in 2010. According to a recent survey, as many as 39% of companies operating abroad were reported to be considering moving some manufacturing activities back to the United States (BCG 2011). Executives indicated that their companies are “likely” or “very likely” to bring back the various categories of work, including IT services (42% of executives), components/products (37%), services (e.g., customer services, call centers) (35%), and material (34%). In all, 37% of businesses are likely or very likely to bring goods and services work back to the United States – and/or a similar percentage are moving work closer to home (e.g., Mexico, Latin America). This means that as much as 5% of overall US procurement may come home. The huge numbers could dramatically impact US trade balances – and should provide an enormous boost to domestic manufacturers, retailers, wholesalers/distributors, and service providers. There is no doubt that growing efforts by the United States and the European Union to boost their own domestic manufacturing will certainly impact China as a “world factory.” It will, however, be limited, owing to the differences in industrial structures between China and the United States, and countries in the European Union.

Furthermore, the severe economic downturn has led to declines in manufacturing wages in some regions of advanced economies. As noted, in the United States, for instance, real wages in manufacturing have declined by 2.2% since 2005 (BCG 2011). This argues that China’s overwhelming manufacturing cost advantage over the United States is shrinking fast. In 2005, the average cost of Chinese labor was 22% of that of US labor. By 2010, average labor costs had risen to 31% of the US level. It is forecast that rising Chinese wages, higher US productivity, a weaker dollar, and other factors will virtually close the cost gap between the United States and China for many goods consumed in North America. Companies will undertake a rigorous product-by-product analysis of total costs, rather than just factory wages. For many products sold in North America, the United States will become a more attractive manufacturing option. For products that have a high labor content and are destined for Asian markets, manufacturing in China will remain the best choice because of technological leadership or economies of scale. China is certainly no longer the default option. However, these likely trends do not suggest that Chinese manufacturing will decline or that transnational corporations will shut down their mainland plants. More Chinese production capacity will be devoted to supplying the country’s enormous domestic market, which is gaining millions of new middle-class households each year, as well as other growing economies in Asia.

According to research by McKinsey Global Institute (2012), when offshoring entered the popular lexicon in the 1990s it became shorthand for efforts to arbitrage labor costs by using lower-wage workers in developing nations. As a “new normal” is settled in to – catalyzed by the global financial crisis, the ensuing recession, and an uneven global recovery – traditional arbitrage models seem increasingly outmoded. For some products, low labor costs still furnish a decisive
INDUSTRIAL RESTRUCTURING

competitive edge, of course. But as wages and purchasing power rise in emerging markets, their relative importance as centers of demand, not just supply, is growing. It is postulated that a next-shoring perspective emphasizes proximity to demand and innovation. Both are crucial in a world where evolving demand from new markets places a premium on the ability to adapt products to different regions and where emerging technologies that could disrupt costs and processes are making new supply ecosystems a differentiator.

The witnessed recent increase in manufacturing output and employment has taken place not only in North America but also in emerging markets, for example, China, since demand bottomed out during the recession following the financial crisis of 2008. Meanwhile, surging local demand helps explain why rapid wage growth in China has not choked off manufacturing expansion. The narrowing labor-cost gap between China and advanced economies reinforces the importance of local demand factors in driving manufacturing employment. Relocating manufacturing close to demand makes it easier to identify and meet local needs. Certainly, next-shoring will look at different locales. Near-shoring and re-industrialization have emerged and no doubt will evolve in unexpected ways that deserve close observation and investigation.

The concept of industrial upgrading

One of the feasible responses of firms to maintain or increase their competitiveness in the increasingly globalized economy is to upgrade their production. The concept of industrial upgrading – making better products, making them more efficiently, or moving into more skilled activities – has often been used in the literature on competitiveness (Porter 1990; Kaplinsky 2000). Similarly, in the global commodity chain and global value chain approach, the concept of industrial upgrading refers to the process by which economic actors – nations, firms, and workers – move from low-value-added to relatively high-value-added activities in global production networks (Gereffi 2005).

Gereffi (1999) has argued that upgrading could take place at different geographical scales: first, at the factory level, upgrading could be shifting from production of simple and cheap to complex and expensive items, as well as from small to large orders; second, within interfirm networks, upgrading involves shifting from mass production of standardized items to flexible production of differential items; third, upgrading, within local or national economies, also refers to moving from simple assembly and processing with supplied materials to higher-value-added and more complicated original equipment manufacturing (OEM) and original brand manufacturing (OBM) that involve a higher degree of integration of forward and backward linkages at the local or national level; finally, at the regional level, upgrading involves moving from interregional trade flows to a more fully developed intraregional cooperation incorporating all parts of the commodity chain from supply of raw materials, through production and distribution, to consumption. Different mixes of government policies, institutions, corporate strategies, technologies, and worker skills are associated with upgrading success. The implicit normative expectation in this work has been that firms and countries that upgrade produce higher-value-added products and/or take on more sophisticated functions over time and this captures a higher proportion of value in the chain, while firms and countries that are unable to add functions, change products, or change their relationship to others in the chain may see orders decline, their costs squeezed, and their employment prospects diminish.

Different types of industrial upgrading

Industrial upgrading is vital for creating possibilities to enhance value and thus for creating possibilities for economic development. Industrial upgrading debates have framed this issue in terms of, first, the structure of production, where upgrading is considered as an increase in the complexity of production activities and a movement from assembly to OEM, original design manufacturing (ODM), and OBM; second, intrasectoral upgrading, mainly involving a greater use of forward and back linkages along the commodity chain; third, moving from labor-intensive production activities to
more capital-, technology-, and skill-intensive economic activities, based on organizational learning in order to improve the position of firms and nations in global production networks; fourth, value capture, particularly as firms, regional networks, and local and national economies are moving from low-value-added to high-value-added activities along the value chain (Gereffi 1999).

Humphrey and Schmitz (2002a) have attempted to systematize these forms of upgrading in four ways: process, product, functional, and chain upgrading.

1. **Process upgrading**: incorporation of more sophisticated technologies into production and/or re-engineering production lines, such as in lean manufacturing.
2. **Product upgrading**: producing higher-value products.
3. **Functional upgrading**: moving to higher-value functions.
4. **Chain upgrading**: leveraging expertise gained in one industrial sector to enter a new sector.

Although helpful as a starting point, there are some difficulties in working with the four-type classification of upgrading highlighted above (Ponte and Ewert 2009). First, it is sometimes difficult to distinguish between product and process upgrading, especially as, in some industrial sectors, the introduction of new processes also leads to new products. Second, in some value chains, the capability to provide a wider range of related products with different specifications is a more important aspect of upgrading than the capability to produce higher-value-added products. Third, to operate profitably in some value chains, some other factors are also of central importance, such as scale economies, which require firms not only to achieve process upgrading, but also to move from small to large orders. However, moving from small to large orders often entails product downgrading since low-value-added products sold in larger amounts may easily enable some firms to aggregate orders to increase the volume of sales and thereafter to become more profitable. Finally, the status of “intersectoral” upgrading is unclear, as it relates to a trajectory of upgrading, while the other three categories describe what aspect of a given business is being upgraded.

Industrial upgrading in clusters and global value chains

This section examines the impact of governance over industrial upgrading by drawing on two sets of literature. On the one hand, the industrial district literature emphasizes the advantages that come from local-level cooperation; on the other hand, global value chain theory emphasizes the importance of cooperation between firms in developed and developing countries (Humphrey and Schmitz 2002b). These two lines of work both highlight the importance of upgrading so as to increase competitiveness in the globally distributed production networks. Likewise, they both pay special attention to the ways in which industrial upgrading is shaped by governance, which is defined as coordination of economic activities through nonmarket relationships. Governance plays a critical role in the processes of knowledge transmission, diffusion, and spillover, as well as in the processes of innovation and firm learning. However, these two lines of work see governance operating at different scales, and therefore with different implications for upgrading opportunities, mechanisms, and prospects for firms in developing economies.

Governance and upgrading in clusters

The importance of governance and inter-firm cooperation at the local level has been
emphasized by cluster studies, since actors are likely to enhance ties with partners that they have the most interactions with and are geographically close to, especially if those ties involve complicated interactions and trust. Specialized labor markets and exchanges of tacit knowledge are especially dense, efficient, and vibrant when it is possible for agents to have face-to-face interaction. Competitiveness of firms partly hinges on their embeddedness in local clusters. Cluster studies therefore focus on the local sources of industrial upgrading driven by local economic agents and interfirm synergies which generate collective efficiency and knowledge spillovers, embeddedness, and traded and untraded interdependencies. The cluster literature in general and the industrial district literature in particular claim that knowledge generation, transfer, and diffusion among firms within the same cluster are based not only on interfirm synergies – the so-called industrial atmosphere – but also on policy networks and public/private governance (Humphrey and Schmitz 2002b). The cluster literature sees governance mainly as operating at the local level, and local public and private governance designed to support industrial upgrading are understood as an essential complement to the incidental interfirm synergies arising from agglomeration.

This set of literature recognizes the importance of firms’ and clusters’ external linkages, particularly as some firms and clusters are export-oriented. However, the nature of these external linkages is characterized explicitly or implicitly as arm’s length, and these linkages are therefore often treated as exogenous factors in the analysis of upgrading. For instance, conventional cluster studies tend to portray industrial districts as incorporating all phases of the commodity chain or at least the full range of activities to produce finished products. Even when some production activities are outsourced to lower-cost locations outside the district, core functions remain in the district. In addition, these districts are capable of acquiring and absorbing codified knowledge from external sources if needed and therefore able to innovate and improve their performance. In short, to achieve industrial upgrading, local enterprises need to rely to a large extent on local sources of innovations, which are not only the result of knowledge spillovers and interfirm synergies within a local cluster but are also fostered by policy networks of public and private actors. The sources for upgrading come from within the cluster at the local level, while firms’ and clusters’ external linkages are considered as less important and remain the least developed dimension in such analyses.

**Governance and upgrading in global value chains**

The literature on global value chains, which believes that the design, production, and marketing of products involves a chain of activities divided between different enterprises often located in different places, takes a very different view of knowledge transmission and interfirm linkages. It also focuses on upgrading and its relationship with governance, but the upgrading process has been attributed to the knowledge and information flow within global value chains from lead firms to their suppliers (Gereffi 1999). In other words, upgrading refers to acquiring new capabilities and increasing competencies through participating in particular chains. Gereffi (1999) has defined governance structures in global value chains as authority and power relationships that determine how financial, material, and human resources are allocated and flow within a chain, in order to stress the important role played by global lead firms that undertake the functional integration and coordination of internationally dispersed activities. In this sense, the global value chain literature often argues that the actions and
motivations of global buyers are the key causal forces in the organization of global contracting systems, and further determine the upgrading opportunities and prospects of local producers. Interfirm relationships within the value chain are of central importance no matter where the firms are located, while interfirm relationships within the locality are given much less attention.

First of all, by highlighting the asymmetric power relationship between local producers and global lead firms, the global value chain literature calls attention to the fact that the organization of global contracting and sourcing systems is heavily affected by the actions and motivations of global lead firms, as the latter firmly control the access to the end market in the North. Second, local producers could learn from global lead firms about how to transform inputs into outputs more efficiently and quickly (process upgrading). Third, product upgrading is also facilitated, particularly in the process of “organizational succession” through which local producers begin supplying low-end global lead firms and then move up to lead firms catering for the high end of the market (Gereffi 1999). In other words, this succession enables local producers to achieve product upgrading as they meet global lead firms’ demands for higher-end, more complicated and sophisticated products. Finally, global value chain analysis also emphasizes a network of labor and production activities that are often globally distributed and interconnected. Firms and localities may specialize in a narrow range of functions. The process of moving from low-value-added to high-value-added functions and acquiring new functions that generate higher value is a critical part of functional upgrading strategy. In all types of upgrading, learning from global buyers is especially crucial for local producers in the developing countries that are new to the global economy and have no prior experience in supplying end market in the North. Although the knowledge and information flow with global value chains has high value for local firms, the role played by the global buyers in fostering and supporting local firms’ upgrading process is less clear. Gereffi (1999), mainly focusing on East Asia, makes a rather optimistic conclusion, stressing the role of global lead firms that almost simultaneously promote process upgrading, product upgrading, and functional upgrading among local producers. However, since the seminal work of Humphrey and Schmitz (2002b), it has been increasingly accepted that, sometimes, global buyers both contribute to the process and product upgrading of local suppliers and place limits on functional upgrading and market diversifications. Functional upgrading has been viewed as encroaching on the core competence of the lead firms, while process/product upgrading remains in the interests of global buyers. In other words, global value chain governance can create barriers to local upgrading, and power relations may inhibit upgrading and limit knowledge transfer within the chain. While the conclusions differ, they have a common emphasis on the global/external powers that influence upgrading in the cluster.

Industrial upgrading in cluster and global value chain studies

The cluster literature highlights the need to improve interfirm cooperation and governance at the local level, and sources for innovation and upgrading are seen largely to derive from within the locality. Links with the wider world are frequently acknowledged, but they are often underestimated. Overall, the external world is characterized as a market presenting competitive challenges that must be met through improved organization and effort within the cluster.
Risk-coping mechanisms within the cluster make these challenges easier to meet.

In contrast, the global value chain approach highlights links with the external world, leaving the locality largely unexplored. While it does not exclude possibilities for local institutions to affect outcomes, the role of business associations and local interfirm cooperation in competitiveness and industrial upgrading has been underestimated. Upgrading takes place as a result of learning by exporting and by participating in global value chains. Interfirm knowledge transfer from global lead firms to local producers also helps to attenuate the risks for the latter of entering global markets. Interfirm cooperation within the chain rather than within the locality is considered as the source of competitive advantage and industrial upgrading.

How value chain governance influences upgrading in the clusters

Studies on clusters and industrial districts focus on the significance of linkages within the locality while the global value chain analysis stresses the impact of interfirm cooperation and governance at the global level over industrial upgrading. There is a need to reconcile these two perspectives, particularly as local clusters are increasingly integrated into globally organized production systems. In order to answer this question, Humphrey and Schmitz (2002a, 2002b) have distinguished between four types of upgrading (see above) and four types of chain.

1 *Arm’s length market relations*: because the product is standard (or easily customized) and buyers’ requirements could be easily met by a wide range of suppliers, buyers and suppliers do not need to collaborate closely.

2 *Networks*: the relationships between buyers and suppliers are more or less equal and often characterized by reciprocal interdependence. Buyers and suppliers collaborate in product definition and innovation, and combine complementary competencies. Buyers may specify certain standards (e.g., quality and speed), but the risk to buyers is low because suppliers are capable of meeting them.

3 *Quasi-hierarchy*: buyers play a dominant role in product definition and exercise a high degree of control over suppliers. They have to face losses due to the suppliers’ performance failures. In other words, the high level of control of buyers over suppliers results not only from the buyers’ dominance in product definition, but also from buyers’ doubts about the competence of suppliers. Where high competence of the supply chain is not generalized, buyers tend to invest in specific suppliers and exercise control over the first-tier suppliers and, in some instances, indirect suppliers along the chain.

4 *Hierarchy*: suppliers are directly owned by buyers in the chain.

Different forms of chain governance have different upgrading implications: (i) In a quasi-hierarchical chain, global buyers both contribute to process and product upgrading of local suppliers and place limits on functional upgrading and market diversifications. Buyers are responsible for product definition and logistics, therefore investment and risks involved in entering export markets are considerably reduced. However, functional upgrading is often hindered, because functional upgrading of developing country producers encroaches on the core competence of their main buyers. (ii) In a market-based chain, process and product upgrading tend to be slower, because, when entering export markets, developing country producers do not receive information about market requirements nor
assistance to meet these requirements in the way that firms in quasi-hierarchical chains do. Functional upgrading is not necessarily easy but there is no barrier purposefully created by buyers. Compared with quasi-hierarchical chains, market-based chains provide more space for functional upgrading. In some instances, local governance (public, private, and public–private) acts as a substitute for some of the governance processes seen in quasi-hierarchical chains. While this probably slows down process and product upgrading, in the longer run it might create local capabilities that would enable functional upgrading and market diversification strategies.

(iii) Although insertion into a network-based chain offers the most favorable conditions for upgrading, suppliers in developing countries are often unlikely to participate in this type of chain because of their low level of competencies. It is therefore particularly important to take into account the interrelationship between interfirm learning within global value chains and within clusters. Insertion into global value chains does offer favorable conditions for suppliers’ upgrading and competency improvement. However, entry into network-based global value chains also requires investment in upgrading and related services within the cluster at the local level. Rather than substituting local-level investment, the entry into chains characterized by network governance is reliant on intensive investment in upgrading and competency improvement within the clusters at the local level. Finally, there are other determinants of local upgrading, such as the strategic intent of local firms, that is, their conscious effort to learn and their willingness to make the required intra- and interfirm investment, and the supportive policy environment created by various levels of government.

Further development of the concept of industrial upgrading

While conventional upgrading studies focus on manufacturing and use the concept of “industrial upgrading,” recent work on upgrading has moved beyond manufacturing and increasingly sought to include sectors related to agriculture and services where the term “industrial upgrading” is less appropriate. Industrial upgrading is therefore replaced by a more generic concept – “economic upgrading” – which applies across sectors (Barrientos, Gereffi, and Rossi 2011). Whereas most studies on upgrading, in particular from the global value chain perspective, emphasize promoting economic development and growth, few have focused on what such upgrading means for social wellbeing and living standards, including not only wages and working conditions but also rights and entitlements of workers. A growing body of evidence calls for more attention to a more extensive definition or conceptualization of upgrading where criteria beyond economic development are encompassed. This gives rise to work on social upgrading, which is the process of improvement in the rights and entitlements of workers as social actors, and of enhancement of the quality of their employment (Barrientos, Gereffi, and Rossi 2011). It can be subdivided into two components: measurable standards (e.g., type of employment, wage level, social protection, and working hours) and enabling rights (e.g., freedom of association, the right to collective bargaining, nondiscrimination, voice, and empowerment). Recent upgrading studies have increasingly stressed that economic upgrading in value chains does not automatically translate into social upgrading through better wages and working conditions, and the links
between economic and social upgrading are often complex.

Industrialization is the process by which the industrial sectors come to play a dominant role in a national economy and an agrarian society transforms into an industrial society. The most pervasive feature of industrialization is the transformation of the structure of production, whereby the industrial sectors typically grow more rapidly than agriculture (Chenery, Robinson, and Syrquin 1986). This transformation is accompanied by similar changes in the structure of demand, international trade, and types of occupation in the industrial sectors. The process of industrialization is closely related to historical, technological, and social-economic factors.

The process of industrialization

The Industrial Revolution that occurred in Great Britain in the eighteenth century is considered to have been the beginning of the process of industrialization (Mantoux 2013). In developed countries, industrialization has a history of more than 200 years. Generally, there are three main stages in the process of industrialization.

In the early stages, light industries and labor-intensive industries (e.g., the textile industry) grew at high speed and became the leading industries in the national economy. Technical improvements were the driving force behind the process, rather than the result of it (Mantoux 2013). The invention of the steam engine was the symbol of the first Industrial Revolution, and it was widely used in various industries, such as cotton spinning and weaving, and paper-making. Therefore, autarkic production in small volumes was gradually replaced by mass production in factories that could produce goods for larger and more distantly located markets. The productivity of the society was hugely improved, specialized industrial regions grew up, and internal and international trades emerged (Smith 1863).

In the middle stage of the process of industrialization, heavy industries such as raw materials, energy, electronic, chemical, and mechanical industries became important in the economy. The dominant industries at this stage were capital- and technology-intensive. Electric power was widely used and the production process was highly mechanized. Rapid progress in industrial organization and management meant that enterprises could take advantage of the large volume of production and enjoy economies of scale. Therefore, multi-factory, multilocalational, and multioperation enterprises emerged, and these large-scale enterprises become influential and had a great impact on society. Moreover, industrialization became significantly concentrated in urban areas (Kim 2006).

With the advancement of technology after World War II, industrialization entered a new phase in which production conditions and productivity greatly improved. The knowledge-intensive industries, such as information and communication technology,
biotechnology, nuclear technology, space technology, new materials, micro-electronics, and so on, became leading industries. The high-tech industries grew rapidly, replacing traditional industries and becoming dominant in the national economy. With the continuing growth of productivity, fewer workers were needed in some industries. In addition, with the increase in income, the proportion of it spent on food in relation to total consumption (the Engel coefficient) declined sharply. Therefore, consumption patterns changed and service sectors boomed. Industrialization entered its final stage.

Bell (1973) called the new stage postindustrialization, where the main industries shifted from the industrial sector to the service and advanced knowledge and technological sectors. From the 1970s, some developed countries began to enter the era of postindustrialization (Keinath 1985). Lever (1991) described the shift from the manufacturing to the service sector as deindustrialization. In this stage, manufacturing sectors have a lower share of the total output or employment, while the service industry becomes increasingly more important in the national economy.

Some studies have attempted to measure and evaluate the stages of industrialization according to the evolution of industrialization in developed countries. Hoffman (1969) measured a country's stage of industrialization using an index known as the Hoffman index, which is the difference between the net output of consumer goods and that of the capital goods industries. Kuznets and Murphy (1966) and Chenery, Robinson, and Syrquin (1986) defined the stage of industrialization according to the industrial structure: that is, the proportions of primary industry, secondary industry, and tertiary industry in the national economic output.

Pathways to industrialization

There are different pathways to industrialization for each country as a result of different political, economic, and social factors. Given the importance of industrialization to the national economy, many countries, especially developing countries, have adopted strong policies to encourage or enforce industrialization. There is no single successful model of industrialization with unique characteristics. However, the pathways of industrialization in different countries can be divided into categories according to some general factors.

Market-oriented industrialization: Europe and North America

Great Britain was the cradle of industrialism (Smelser 2013). In the eighteenth century the process of industrialization via innovation in manufacturing began with the Industrial Revolution in the northwest and Midlands of England. The commercial expansion, redistribution of land, and growth of new industries helped facilitate the market economy in Britain in the preindustrialization period (Mantoux 2013). In the eighteenth and nineteenth centuries Britain experienced a massive increase in agricultural productivity, and unprecedented population growth. Thus, the preconditions for industrialization, including the accumulation of capital, a commercial economy, and a large workforce, were in place. The invention of the steam engine accelerated the process of industrialization. From then on, Britain entered the era of industrialization and, by the 1830s, it was the first country in the world to achieve a high level of industrialization. Later, the industrialization process spread to other parts of Europe, for example France, Germany, and Russia.
Industrialization in the United States can be seen as a further development of the model of Britain. The availability of capital, free market, plenty of land, an educated labor force, and so on all contributed to the United States’ rapid industrialization. Industrialization in the United States also started in the textile industry with innovations in machinery. By using technologies imported from Britain, and later relying on domestic technology and management innovation, the United States realized its potential for large-volume production in a relatively short period and became a powerful industrial county.

Import substitution: industrialization in Latin America

The less developed economies of countries in Latin America sought to develop their industrial capacity by producing as many sorts of products as possible, so that they could reduce the import of goods from other countries. This strategy is called import substitution. Since the mid-to late twentieth century, import substitution (inner-directed) industrialization has become the main development model in most Latin American countries, such as Brazil, Argentina, and Mexico (Baer 1972). In order to clear the obstacles to industrialization in Latin America (James 1950), states took measures to improve and protect domestic industrial capacity by subsidizing the vital industries, imposing high taxes on imports, and using other trade protection policies. These countries developed their economies by relying on their own labor, raw materials, and technology as much as possible to produce what was needed for the domestic market, and tried their best to avoid importing manufactured goods. This pattern of industrialization proved to be a failure in fostering social and economic development in Latin America in the long term.

Export-oriented industrialization: East Asia

Japan started its path to industrialization after the Meiji Restoration and achieved a high level of industrialization, similar to that in Western countries. After World War II, Japan and other Asian economies adopted an export-oriented strategy to catch up with the developed countries and to achieve industrialization. In this model, firms are encouraged to export goods in which their country has a comparative advantage.

The late twentieth century saw the phenomenon of the rise of the Four Asian Tigers (Hong Kong, Singapore, South Korea, and Taiwan), all of which had adopted an export-oriented strategy and successfully achieved industrialization. The success of these economies also relied on other factors, including a stable political environment; a well-structured society; a strategic location; a large amount of foreign investment; a skilled, motivated, and cheap workforce; a competitive exchange rate; and low custom duties, among others. These economies took advantage of developed countries shifting their labor-intensive industries to developing countries. They adjusted their economic development strategy, given that they were able to offer sufficient cheap and high-quality labor (Brohman 1996). They encouraged export and also welcomed direct foreign investments: the two reinforced each other. Their success in attracting foreign investment further facilitated the export economy. All in all, the Four Asian Tigers succeeded in rapid industrialization and economic growth by adopting an export-oriented strategy.

The unevenness of industrialization across the world

Despite the rapid industrialization of some less developed countries in the past several decades, the global unevenness of industrialization has
INDUSTRIALIZATION

persisted. Most developed countries have been in the stage of postindustrialization for a long while. However, some countries in the Global South are still in the early stages of industrialization. The existing global governance of economy and politics has impeded the industrialization of some less developed countries. The industrial sectors in these countries have faced competition and exploitation as a result of the dominance of multinational corporations, which are mostly based in the rich countries of the Global North and increasingly in some emerging economies.

Entering the twenty-first century, emerging countries, including Brazil, Russia, India, China, and South Africa (BRICS), are becoming increasingly influential in the world economy because of their rapid and successful industrialization (Mudambi 2008; Winters and Yusuf 2007). Both India and China have achieved a high economic growth rate and their high-tech sectors have also made rapid progress (Arora and Gambardella 2006); these sectors have also started to make significant investments in developing countries as well as developed countries. China has become the world’s factory. Industrial clusters have grown up in China, and a large number of cities have seen significant growth of industry (Fan and Scott 2003; He and Pan 2010; He, Wei, and Xie 2008). India has been famous for its competitive high-tech sectors such as bioengineering, pharmaceuticals, and information and communication industries.

In addition, the geography of industrialization within some countries is also significant, especially in some large developing countries such as China and India. The achievement of a more evenly distributed geography of industrialization within these countries depends very much on the convergence policies and their implementation. However, unlike global unevenness, the variation of industrialization within countries is easier to overcome.

Consequences of industrialization

Industrialization has completely changed the world. On the one hand, it has brought great changes for society. One of the most significant consequences is urbanization. Urbanization is the fundamental transformation of society caused by industrialization (Kim 2006). In the process of industrialization, the major resources are allocated to the industrial rather than agricultural sector (Kuznets and Murphy 1966). The system of mass production in industrial activities is also associated with a large volume of the workforce migrating from rural areas to cities to work in the industrial sectors. The concentration of labor in cities has given rise to large towns, resulting in large-scale urbanization (Scott and Storper 1992). The spatial pattern of the metropolis is created by the intricate ramifications of the social division of labor, the transactional structure of production, and the dynamics of local labor market formation (Scott 1986). During the process of urbanization, family structure (Wong 1975) and the rural landscape (Claval 1988) also undergo significant changes.

Another consequence of industrialization is economic growth and regional development. Industrialization has greatly improved productivity and can lead to significant economic growth and regional development. Manufacturing industries can provide a large number of jobs and generate a huge amount of tax and wealth for an economy. Creating industrial agglomerations is one way to boost industrialization and improve economic growth and regional development (Scott and Storper 1992). The process of industrialization is also closely related to technological innovation. For those who benefit from it, rapid industrialization has improved the standard of living enormously, and it underpins further advancements in science and engineering.
Industrialization has greatly transformed human civilization. In the transformation from an agricultural-based economy to an industrial-based economy, traditional, small, family-run workshops have been replaced by large-scale production in factories, and an agricultural civilization has changed to an industrial civilization. With the significant rise of their capacity to change the world, people’s attitudes to nature have also changed with the process of industrialization.

On the other hand, large-scale industrialization has also caused many problems. The first is population explosion. With great improvements in productivity, the population also grows very quickly. A larger population needs a greater volume of industrial products for consumption, as well as other natural resources, which may threaten the sustainability of the planet. In addition, the concentration of the population in urban areas places great pressures on a society. A shortage of housing, expensive health care and education, insufficient clean water and food, and high crime rates are all serious problems that face large cities.

Industrialization also leads to environmental problems. Environmental pollution such as air pollution, water pollution, noise pollution, and so on is widespread. Most pollution is released from industrial facilities or is related to industrial production. Environmental pollution may harm human health as well as jeopardize the survival of other species and their habitats. Other environmental problems caused by industrialization include deforestation, land degradation, extinction of species, and global warming.

Moreover, rapid industrialization exacerbates the shortage of natural resources. Fossil fuels and other mineral resources are basic inputs for industrial production, but stocks of these natural resources are limited. The price of these raw materials will eventually increase to very high levels, which may lead to severe problems for industries. For example, an oil crisis that originates locally could lead to serious consequences for the global economy (Akins 1973).

It has become a key challenge for humans to achieve sustainable development in the future. The benefits of industrialization are obvious, but many countries are still suffering from poverty and a lack of industrialization. The pursuit of rapid industrialization in these countries is reasonable and should be encouraged, but the side effects of industrialization are also alarming. All countries need to work together to solve or at least alleviate the problems caused by the process of industrialization.

**INDUSTRIALIZATION**

Inequality

Michael Webber  
University of Melbourne, Australia

Inequality, according to the Oxford English Dictionary, is the difference in size, degree, or circumstances (www.oxforddictionaries.com) or more simply, the condition of being unequal (http://dictionary.reference.com). The latter adds the useful information that equality is correspondence in quantity, degree, rank, or ability. In geography, references to equality and inequality are usually concerned with qualities such as wellbeing, health, income, wealth, or social status. These qualities are commonly measured at the level of individuals or groups within an area (thus, interpersonal inequality or household inequality in China or in Rome) or as regional averages (e.g., interregional inequality or international inequality). Of itself, the concept of inequality carries no judgment about the fairness of the differences that are observed nor about the origins of those differences. Equity, by contrast, does involve such judgments, referring as it does to the quality of being fair or impartial (www.oxforddictionaries.com). Inequality is about difference; equity is about fairness.

Inequality bears some relation to another important concept, poverty. Dearth (sometimes called absolute poverty) is being unable to satisfy one’s basic human needs, including for food, safe water, sanitation, health, shelter, education, and information. It is commonly measured by a set standard that is constant over time and between countries: the World Bank currently sets this standard at $1.25 per person per day (in US prices). Absolute poverty means the inability to participate effectively in society. In rich countries, such as Australia, effective participation in society means having sufficient clothes to present for school or work, having access to news and information through computers and television, having money to pay for transport, housing, and so forth, all of which cost a single person about $400 per week in 2010. In principle, both dearth and absolute poverty are unrelated to inequality: high-income countries, with few poor people, may have high inequality; low-income countries, with low inequality, may have many poor people. Relative poverty, however, is closely related to inequality. Understood as the daily perceived contrast between the lives of the poor and the lives of their peers around them, relative poverty is often measured as the proportion of the population with incomes less than some proportion (such as 60%) of the median income. Such a measure is independent of the average income of a society: both high- and low-income countries can exhibit high rates of relative poverty.

Both words, equality and inequality, first appeared in late Middle English: that is, the late fourteenth century, but before that the word, and so the concept, were available to the middle and upper classes through Latin. However, it was not really until the eighteenth century, and the Enlightenment in Europe, that the tools with which to think about inequality were first developed. These tools included the notion of social reform or progress and Locke’s epistemology of
INEQUALITY

empirical observation, which in turn gave rise to the emergence – as a program, if not yet as a set of results – of the human sciences. Especially important among these new human scientific works for the study of inequality was Rousseau’s Discourse on Inequality (Rousseau 1755). In this Discourse, Rousseau argued that in “primitive” human societies there were small differences in wealth and status between families; however, once the division of labor emerged as a way of raising agricultural and metallurgical output, so private property, social class, and, therefore, inequality were introduced too. Apart from the original sources, a good introduction to Rousseau’s thought is provided by the Internet Encyclopedia of Philosophy (Delaney, n.d.).

Measurement of inequality

To say anything useful about trends in inequality or about differences in inequality between different places, we must be able to measure it. This means in the first place that the quality of interest – health status, for example – must be measured as a scalar variable; ranking measures will not do, for we are interested in the magnitude of the differences between individuals, not simply in the fact of the differences. It means in the second place that we must agree on the variables that will be used to measure the quality of interest. For complex qualities, such as wellbeing, health, or social status, these measures are highly disputed. Even for apparently simple qualities, such as income, consumption, or wealth, alternative ways of measuring them have a tremendous impact on apparent inequality. One specific form of this requirement is the need to agree on whether input or output measures of the quality are more desirable. In political debates, for example, those on the right tend to favor measures that reflect “equality of opportunity” whereas those on the left tend to favor measures that reflect “equality of income or wealth.” Box 1, which lists some of the variables that are used to measure income, reveals just how disparate measures of even a single quality can be. And third, it means that we must agree on how to transform these measures at an individual level into an aggregate measure of inequality.

There are a huge number of ways of measuring inequality in a variable (Coulter 1989 identifies about 50), but four are common: the Gini index, a ratio such as the 20:20 ratio, the Theil index, and the Hoover index (Fleurbaey 2012 provides a thorough introduction to the measurement of inequality). That is, so long as we can provide a number to measure an individual’s, group’s, or region’s wellbeing, health, income, wealth, or social status, then we can calculate the inequality of that variable. Consider the example of income measured at the level of individuals. The Gini index ranges between 0 (complete equality) to 1 (all income is concentrated in the hands of one person). It is perhaps the most commonly used measure of inequality, but it does have problematic properties (for example, the Gini coefficients of different regions within a country cannot be added to derive the Gini coefficient for the country as a whole) and quite different income distributions can generate the same coefficient value. A whole body of literature is devoted to identifying means of discriminating between income distributions that are more equal (or less) at low incomes and less (or more) equal at high incomes. The income ratios are easy to comprehend: How much do the richest 20% have compared to the bottom 20%? The ratio starts at 1 (complete equality) and has no upper bound. But information about the majority of the population (the 60% in the middle) is lost. The Hoover index is simple to calculate and understand: What
Box 1 Variables used to measure inequality of income

1 Equality of opportunity versus equality of outcome: Does everyone have the same chance of earning a high income versus does everyone in fact have the same income?

2 Household income versus individual income: Do we simply calculate inequality from total household incomes (which implicitly assumes that everyone in the household has the same income) versus do we calculate the actual incomes of each person in a household separately? Do we include children and others still in education? Do we include retired people? Do we include non-employed homemakers? (Note: measuring the income of everyone in a household poses great conceptual and practical difficulties. Is a standard of living shared equally? And whose account of income sharing within a household should be believed?)

3 Total income versus income after taxes and transfers: Do we include the imputed value of owner-occupied housing? Do we include the imputed value of subsistence production and directly exchanged goods? (Note: inequality of earnings is usually computed from data on individual employment-related income, before tax, excluding transfers and imputed incomes.) These differences are important because taxes and transfers form different shares of total income at different income levels; they are also different between countries. In different countries, housing, subsistence production, and direct exchange form different shares of total income.

4 When making international comparisons (and some within-country ones too), do we measure incomes at official exchange rates or at PPP rates? (Note: PPP = purchasing power parity. If a Chinese woman (say) goes to the United States and purchases an average standard of living, it costs her RMB 6.06 to buy each US dollar (USD) worth of commodities. This is the official exchange rate. If she bought an equivalent standard of living inside China, each USD of purchases would cost less than this, because prices in China are on average lower than in the USA, relative to exchange rates. According to the World Bank’s development indicators (http://data.worldbank.org/?display=default), in 2012, the PPP exchange rate between USD and the RMB was 4.06. Roughly, incomes in China are one-third higher than official exchange rates suggest. The number, 4.06, is the PPP exchange rate between RMB and USD.)

Proportion of the total income would have to be moved from the richest people to the poorer people in order to equalize incomes? It ranges from 0 (no income has to be shifted: that is, all incomes are equal) to 1 (all income has to be shifted: that is, one person earns all the income).
INEQUALITY

The *Theil index*, though less easy to calculate than the others, has a desirable property, notably decomposability, which is extremely useful in geographic analyses of inequality. This property means that the Thiel index of inequality within a country equals the index of inequality between provinces plus the average of inequalities within each province (weighted by provincial shares of national income). Here is how to calculate and interpret these four measures of inequality.

Suppose that there are $N$ groups of people, ranked according to their income. Group 1 consists of people with the least income; group 2 has those with the next lowest incomes; ...; and group $N$ consists of the people with the highest incomes. The groups are not necessarily of the same size, so let $P_i$ denote the number of people in group $i$, for $i = 1, 2, \ldots, N$. The total population is

$$P = \sum_{i=1}^{N} P_i$$

The proportion of the population in group $i$ is then

$$p_i = \frac{P_i}{P}$$

Let $V_i$ denote the total income earned by all the people in group $i$. Again, the total income earned by all the people is

$$V = \sum_{i=1}^{N} V_i$$

The proportion of the total income earned by group $i$ is then

$$v_i = \frac{V_i}{V}$$

Finally, let $s_i$ denote the cumulative shares of total income earned by the groups up to and including group $i$: $s_0 = 0$; $s_1 = v_1$; $s_2 = v_1 + v_2$; and so on. With these definitions, the four measures are:

$$G = 1 - \sum_{i=1}^{N} p_i [s^i - 1 + s_i]$$

$$H = \frac{1}{2} \sum_{i=1}^{N} |v_i - p_i|.$$

$$T = \frac{1}{N \cdot \ln(N)} \sum_{i=1}^{N} \left[ \frac{v_i}{p_i} \cdot \ln \left( \frac{v_i}{p_i} \right) \right].$$

$$z : \text{z ratio} = \frac{V_N}{V_1}$$

provided that group 1 and group $N$ contain the same proportions of the population (e.g., $z\%$).

Measures of inequalities in health or wellbeing can, in principle, use the same indexes. However, the literature about health inequalities is dominated by a concern with the sources of the observed differences in health status; thus many measures of and studies about health inequality rely on indexes of health status that are calculated for separate groups, classified for example by gender, age, ethnicity, or income. A good introduction to this literature is provided by Asada (2010).

All of these differences of opinion about good measures of a quality and about good indexes of inequality in those measures mean that trends in inequality or differences in inequality between places are hardly robust. Different variables and different indexes can provide quite different results. It is desirable, therefore, that studies of trends in inequality or spatial differences in inequality use different measures and different indexes to identify the extent to which the results depend on the variables and the indexes used. In understanding inequality as a quantitative variable, robustness demands a variety of measures and indexes, and caution must be used.
in interpreting arguments that rely on a single variable or index.

Furthermore, all these measures are independent of the mean. That is, inequality depends on the dispersion of an index, not on its average value. Inequality can be high in high-income and in low-income societies, and low in both, too. Thus, some argue that in high-income countries, inequality (and relative poverty) is less important than in low-income countries: in rich countries, everyone has enough, it is said, so being relatively poor is not so important. This argument, though, faces two problems. First, even if everyone has enough, it is not clear why some should have so much more (this is the equity question).

Second, there is evidence that happiness within society depends on one’s relative position as well as on one’s absolute position, at least for those who have adequate incomes – the striving for more material goods is driven by relative scarcity as well as simply absolute poverty.

Global inequality

Figure 1 suggests that levels of income inequality are highest in countries in southern Africa (South Africa, Lesotho, Botswana, and Namibia) and some other countries in sub-Saharan Africa (Sierra Leone and Central African Republic).
INEQUALITY

High levels of inequality (Gini over 0.44) are also recorded by the United States, Mexico, most countries in South America (but not Venezuela), southeast Africa, China, Iran, Malaysia, Singapore, and the Philippines. At the other extreme, the lowest levels of inequality are recorded by Sweden, Slovenia, Montenegro, Hungary, Denmark, and Norway. Most European countries apart from the United Kingdom have Gini indexes of less than 0.36, as do Australia, Canada, several North African countries, Pakistan and Bangladesh. However, remember the caveats about data, measures, and indexes. The website http://commons.wikimedia.org/wiki/File:Wealth_gini_2013.svg also contains a map of Gini coefficients for wealth rather than income. Inequalities of wealth are far higher than inequalities of income. There are also discrepancies in the relative ranking of countries by inequalities of wealth and of income: Russia and the United States both record wealth coefficients over 0.85; the Scandinavian countries and Germany also exhibit high wealth coefficients (in contrast to their low coefficients of income). But southern America and southern Africa both exhibit high inequalities of wealth, as of income.

There is also inequality between countries. According to Davies et al. (2008), North America, with 6% of the world’s adult population, controls 34% of the world’s wealth; the rich countries of the Asia-Pacific (principally Japan, South Korea, Taiwan, Australia, and New Zealand) have 5% the world’s population, but 24% of the world’s wealth; while Europe contains 15% of the world’s population, but 30% of the world’s wealth. In contrast are Latin America (8% of the adult population, 4% of the wealth), Africa (10% and 1%), China, India, and other Asia-Pacific countries (50% and 6.5%). These data are at official exchange rates, which do slightly overstate concentrations of wealth in the richest countries. Trends in inequality of incomes between countries are confusing (Milanovic 2012).

1 If we consider countries as the units of observation and calculate the Gini coefficient of their average household incomes, then we see that this rose sharply after World War II (from about 0.47 to 0.52), was stable in the 1960s and 1970s, and then began to rise again with the onset of neoliberal globalization after 1980 (reaching 0.58), before declining since 2000 to 0.55.

2 If we consider countries as the units of observation and calculate the Gini coefficient of their average household incomes, weighted by their share of the world’s population, then the Gini coefficient has fallen slowly from about 0.66 in the early 1950s to about 0.63 in 1990 and then more sharply to 0.53 in 2010.

3 The sharp difference in these trends is driven by the fact that average household incomes in two of the poorest countries in 1950 (China and India) have grown relatively quickly, especially since the mid-1990s.

However, these relatively small changes in between–country inequality since the 1950s come after very rapid and much larger increases during the nineteenth century and the first half of the twentieth century.

Another popular method of measuring the global distribution of wellbeing is the Human Development Index (HDI), produced by the United Nations Development Programme and published in its annual Human Development Report (UNDP 2013). This is a measure that combines measures of life expectancy at birth, average years of schooling, and gross national income per capita. Until 2009, these measures were normalized (so that each had a range between 0 and 1) and then the average taken,
Figure 2 Human Development Index by major world regions, 1975–2004.

Note: To develop a sense of scale, HDI indexes in 2013 have the following components, on average:

<table>
<thead>
<tr>
<th>HDI</th>

</tbody>
</table>

so that each index had the same weight in the final index. Since 2010, a slightly different method of normalizing and averaging has been used. Figure 2 illustrates trends in this index, by region. In all regions except sub-Saharan Africa the HDI has been rising since the mid-1970s, at roughly the same rate, though Eastern Europe and the Commonwealth of Independent States (CIS) saw a sharp decline in HDI at the time when the communist regimes were overthrown, and East Asia has been growing slightly more quickly than everywhere else. The real tragedy is in sub-Saharan Africa, where average levels of HDI have hardly changed over 30 years. The data for some individual countries are presented in Table 1 (the full data are available in the annual World Development Reports).

Also important is inequality at a global, individual level. This is difficult to measure in the long run because data on income or

wealth inequalities within many countries are only available for the past 25 years or so. Furthermore, the definitions and meanings of wealth and income differ between countries. So the following history is only tentative. The Gini coefficient of household income (measured in PPP dollars) across all the people in the world, considered as individuals, is about 0.7; it rose slightly in the 1990s and fell equally slightly in the 2000s (Milanovic 2012). This is roughly 0.1 higher than the Gini coefficient for Brazil, itself one of the most unequal countries in the world. Milanovic (2012) also presents a fascinating graph of changes in income according to income – that is, which people saw their income grow during the 1990s and 2000s? His graph is reproduced as Figure 3. Milanovic’s calculations indicate that two groups of people have done well in the 20-year period and two groups have fallen behind.

The people who were the poorest in the world in 1988 have hardly seen their incomes change. These are people of average and below average incomes in poor countries, and people of very low incomes in richer countries.

2 The people who were between the poorest 10% and the wealthiest 30% received large increases in income in this period – 40% or more. This group contains most of the population of China, many Indians, and large numbers of wealthy people in moderately well-off and poor countries. Milanovic calls these people the global middle class.

3 People whose incomes put them in the top 75th–95th percentile witnessed either a drop in income or only a small increase. These include many of the moderately well-off people in Eastern Europe, the former USSR, and Latin America, as well as poorer persons in the rich countries.

4 The people who were in the top 5% of global income earners in 1988 saw their incomes increase by 20–60% (and the more they started with, the greater their increase). This group contains the middle classes of rich countries and the richest groups of people in moderately well-off and poorer countries.

According to Milanovic, about two-thirds of between-person inequality these days is due to differences between countries, rather than differences within countries.

Credit Suisse (2013) has estimated the global distribution of wealth in the early 2000s. Their data suggest that the bottom 58.7% of the world’s adults who have a net wealth of less than US$10,000 own only 3% of the world’s wealth. By contrast, the 0.7% of the world’s adults who have a net worth of more than US$1 million control 41% of the world’s wealth. Half the world’s wealth is owned by just 2% of the world’s adults. The global wealth Gini of adults is estimated at 0.892 (Davies et al. 2008), the same level as would be recorded by a population of 100 individuals in which one person owns $900 and the other 99 persons own $1.

Figure 3 Change in real income (PPP dollars) for people at different percentiles of the global income distribution, 1988–2008. Source: Milanovic (2012).
Why inequality?

Summarizing these data, we might say that at a global level, income inequality between individuals is high, but has been stable in the past 20 years or so; within most countries, though, income inequality has been rising in the last 20–30 years. There are generally larger inequalities of wealth than of income within countries and globally.

The principal source of this inequality is unequal ownership of assets. In agrarian economies, such as rural areas of India, Indonesia, and Latin America, the principal asset is land, and inequalities in ownership of land drive inequalities in income and wealth. Some people own large farms, others have smallholdings, and yet others own no land and so are forced to work as landless laborers. Data on inequality of land holdings are to be found at developmentdata.org (http://www.developmentdata.org/inequality.htm) and a review of the relations between inequality of land ownership and income inequality is provided by Carter (2000). The interplay between these inequalities and the emergence of such new agricultural technologies as the green revolution provides a fertile ground for understanding the dynamics of inequality (Patel 2013).

The changeover from communist rule in Eastern Europe, the former USSR, and China provides direct evidence of the impacts of asset ownership on inequality. In those countries, between the 1950s and the 1980s, most forms of industrial and agricultural production were organized through communally owned assets – state-owned enterprises and communal farms. There certainly existed inequality in those societies – most notably between urban and rural areas, between managers and workers, and between the politically connected and everyone else; the evidence suggests that this level of inequality was rather low, compared to levels that currently exist in those countries. There were important differences between those societies and the manners in which they removed the communist organizational forms after 1989, but the privatization of these formerly state- or communally owned assets led to new inequalities in asset ownership and an increase in income inequality. The privatization of productive assets did not occur through the equal division of those assets to all households, but rather through a process in which some individuals or groups acquired majority interests in those assets. In China, for instance, this meant that many state-owned enterprises were effectively converted to private enterprises when their managers or bureaucratic superiors simply assumed ownership of them; land has remained in communal ownership, and equally distributed to farm households, but is increasingly being commandeered by local arms of the state for conversion to urban and industrial purposes. In effect, bureaucratic position, state power, and personal connection have been converted into unequal ownership, which in turn has spurred differences in income and wealth between the new class of owner-managers and the workers in those farms. This process is called primitive accumulation.

Political economic geographers begin their analysis of inequality in societies where capitalist production is already generalized as the outcome of a class society in which ownership of assets is unequally distributed, production is controlled by a small group of owners and managers, and the actual work of producing goods and services is performed by ordinary people, often working for relatively low rates of pay. The level of inequality in such a society is then understood to broadly reflect the share of society’s net product that goes to the owners and managers as compared to that which goes to workers, mediated by the degree to which governments tax and redistribute. This division of the social product is a matter of
struggle between classes, and one of the direct indexes of that struggle is the share of net product that is profits, compared to the share that is income. In Europe, North America, Australia, Japan, and India, the share of wages in national net income has fallen consistently since the early 1970s, and in China since the mid-1990s.

As a first approximation, then, we can understand inequality of income as reflecting inequality in the distribution of assets, which generates differences in the tasks performed by those who own and those who do not own those assets, and which is the site of struggle over the division of the net social product between classes. It is also clear that in many rich and moderately rich countries, the redistributive system (taxes on the side of governments’ income; social expenditures on the side of governments’ expenditures) has increasingly failed to remedy these inequalities. Reductions in the rates of tax paid by the highest income earners, relocation of assets offshore, income splitting schemes, and other allowable deductions from income have produced the same effect; goods and services taxes (or value added taxes, or consumption taxes) mean that the poor are on average taxed more heavily than the rich, since poorer people spend a higher proportion of their income on consumption than do richer people.

One of the richest men in the United States, Warren Buffett, made the point:

Actually, there’s been class warfare going on for the last 20 years, and my class has won. We’re the ones that have gotten our tax rates reduced dramatically.

If you look at the 400 highest taxpayers in the United States in 1992, the first year for figures, they averaged about $40 million of [income] per person. In the most recent year, they were $227 million per person – five for one. During that period, their taxes went down from 29 percent to 21 percent of income. So, if there’s class warfare, the rich class has won. (Buffett 2011)

Most billionaires are less honest than Buffett: an Australian government proposal to impose a special tax on the super-profits enjoyed by mining companies during booms led to outrage in the mining industry, prompting the CEO of one of the biggest mining companies, Fortescue Metals’ Andrew Forrest, to declare that the proposal represented class warfare. The term “class warfare” has been used to delegitimate proposals to rein in the incomes and entitlements of the rich, while moves against the poorest are “fiscal responsibility.” Inequality, apparently, is seen as the product of a class war, at least in the richer countries of the world.

Of course, there are then questions about the reasons why some workers earn more than others. Two general approaches to this question have developed. One, orthodox within economics, is that such differences in income reflect differences in the “human capital” brought to the labor market by workers: those with high skills can demand higher wages than those with lower skills. (It also turns out that gender, age, ethnicity, and such other variables also influence wage rates.) In such theories, the incomes of owners and managers are then interpreted as just returns for their efforts in initiating and managing production. As a first approximation, in this approach, incomes reflect relative productivity. A somewhat looser sociological statement of the same principle is that social inequality is thus an unconsciously evolved device by which societies insure that the most important positions are conscientiously filled by the most qualified persons (Davis and Moore 1945, 243).

The second approach argues that such differences in income reflect the segmentation of the labor market into separate sections with different requirements for membership and separate reward structures. Entry into these sections of the labor market is mediated by a variety of institutions, including corporate managers, job
INEQUALITY

allocation agencies, school counseling, unions, and the like, all of which bring their prejudices about the skills and attitudes of different kinds of people (i.e., of men and women, of younger and older people, of this ethnic group and that). For descriptions of segmented labor markets in Europe see Pratschke and Morlicchio (2012).

Why should we care about inequality?

There are two groups of answers to this question. The first centers on fairness. This can be cast in two different forms. The first argument about fairness is that there is a lot of evidence that incomes do not reflect simply human capital, that people’s earnings do not simply reflect their productivity. Differences in earnings by gender and ethnicity, for example, are mostly about prejudice rather than productivity – that is to say, these differences persist even among people of comparable “human capital” (Karlsen 2012). Furthermore, there is no evidence at all that a manager who earns 1000 times the wage of one of his (usually) ordinary workers is responsible for 1000 times the product (though there is evidence that good managers are worth a lot in terms of stock values). Such differences in income, unrelated to productivity, are unfair on anyone’s terms. The second argument about fairness goes deeper: From whence come those differences in human capital that are supposed to be responsible for differences in incomes? A typical girl who grows up in a white, middle-class, liberal household in a rich country might expect high educational standards, encouragement to learn and acquire skills, self-confidence, and a range of social contacts and skills that are not directly productive but useful in speaking the language of managers. A typical boy who grows up in a poor district of a country like Ghana might expect none of these advantages and has no opportunity to develop similar skills (unless he happens to be good at football). The girl has high “human capital,” the boy little; their earnings are correspondingly different, but it is clearly unfair that they have these differences in “human capital,” and so it is unfair that their earnings are different.

The second argument about inequality concerns its effects. Again, there are two general forms to this argument. Those in favor of inequality argue that differences in income and wealth provide an incentive to those who are not rich – an incentive to poorer people to improve themselves by becoming an entrepreneur, learning a new skill, or moving to a place or industry where incomes are high. Inequality, it is said, is a cause of high rates of growth of national output. To evaluate this argument, we would want to know the following:

1. Is inequality actually associated with high rates of growth of output? The evidence does not support the argument that inequality is good for growth (for a review, see Gallo 2002). For example, data about many of the G20 countries indicate that an increase in the share of income going as profits reduces private consumption and has a positive but smaller effect on investment; higher profit shares tend to reduce domestic demand and tend to reduce rates of gross domestic product (GDP) growth.

2. To what degree do we want to value high rates of growth of output in comparison with other social goals? Those who make the incentive argument usually assume that asserting it is sufficient (see Barro 2000 on higher-income countries). However, the economy (output) is not a thing separate from society; it is merely one particular evaluation of society. Thus, even if the incentive argument is correct, it is still necessary to demonstrate that the incentive effect outweighs other social considerations.
Sridaran (2012) makes this argument well: “[the incentive argument] cannot prevail because the reasons for moderating income inequality are dictated by societal wellbeing and political democracy, reasons which are not subordinate to economic policy.”

And this leads to the second argument about the effects of inequality: is social life better in societies with higher rates of inequality than in societies with lesser rates? One fundamental reason for preferring low rates of inequality was provided by Blum and Kalven (1953), who argued that genuine democracy requires that all citizens have similar political power, and that in turn requires that all citizens have similar levels of resources at their command. A remarkable book by Wilkinson and Pickett (2009) demonstrates more concrete relations between inequality and social dysfunction. Compared to countries in which levels of inequality are low, countries with high levels of inequality:

- have higher infant death rates (comparisons between Europe, North America, Australia, New Zealand, Israel, and Japan);
- have higher rates of mental illness (comparisons between Europe, North America, Australia, New Zealand, and Japan);
- have a higher incidence of drug use (comparisons between Europe, North America, Australia, New Zealand, Israel, and Japan);
- have higher high school dropout rates (comparisons between states of the USA);
- have higher rates of prison incarceration (comparisons between Europe, North America, Australia, New Zealand, Israel, Japan, and Singapore);
- have higher rates of obesity (comparisons between Europe, North America, Australia, New Zealand, and Japan);
- have lower rates of social mobility (comparisons between Scandinavia, the United Kingdom, North America);
- exhibit lower levels of interpersonal trust (comparisons between Europe, North America, Australia, New Zealand, Israel, Japan, and Singapore);
- have higher rates of homicide (comparisons between Europe, North America, Australia, New Zealand, Israel, Japan, and Singapore);
- give less foreign aid, as a proportion of national income (comparisons between Europe, North America, Australia, New Zealand, and Japan).

Infiltration

Carol P. Harden
University of Tennessee, USA

In the hydrologic cycle, the process of infiltration – the downward entry of water into the soil – divides surface from subsurface water. Soils with high infiltration rates absorb most or all of the water that reaches them, but soils with low infiltration rates absorb water very slowly, causing water to remain at the surface in puddles or to become surface runoff. By controlling this separation of water pathways, infiltration is a key component of the hydrologic cycle.

The proportion of snowmelt and rain water that infiltrates the soil controls the amount of moisture available for plant growth and groundwater recharge, the delivery of water to streams and rivers, the heights and depths of floodwaters and low flows in rivers, the likelihood of flooding, and the composition of particulate and dissolved materials carried by surface waters. Anthropogenic changes to infiltration rates are widespread, important ways in which human activities alter the hydrologic cycle. People alter natural rates of infiltration by paving, plowing, and trampling the land.

During the process of infiltration, water molecules on the soil surface enter pore spaces in the soil and are pulled into the soil matrix by the force of gravity or by forces of adhesion and capillarity. The infiltration rate depends on characteristics of the soil. Some characteristics, such as soil texture, vary over space, while some, such as soil-moisture content, also vary over time. Infiltration occurs at the soil surface, but the infiltration rate is partly controlled by the capacity of the subsurface soil to store and transmit moisture. Thus, the rate of infiltration depends on characteristics of the soil surface and also on the availability of space within the soil, which, in turn, depends on the size, distribution, and status of soil pore spaces.

Infiltration rates are affected by a suite of physical, chemical, and biological factors. These include soil texture; antecedent soil moisture; site conditions, including irregularities of terrain, the depth to the water table, and soil hydrophobicity caused by forest fire; landscape position; and precipitation characteristics. Soil texture is a major control. In sandy soils and soils with stable aggregates, spaces between soil particles are relatively large and well interconnected, thereby facilitating water storage and movement. Where soil pores connect directly to the atmosphere, and especially in larger pores (macropores), such as those created by burrowing organisms, cracks in the soil, or the decay of plant roots, gravity is the dominant force that moves water downward into the soil. Fine-textured soils, even those with a high proportion of their volume as void spaces may contain tiny pores in which the forces of adhesion and capillarity (called “matric potential”) can exceed the force of gravity. Fine-textured soils, are slow to absorb moisture and very slow to release it. Infiltration rates in clay soils are on the order of 1–5 mm hr⁻¹, compared to rates of >20 mm hr⁻¹ for sandy soils.

The amount of moisture already present in soil determines the amount of space available for additional water molecules. No new water can enter the soil when all of the pore spaces are full. When rain falls on a dry soil, infiltration proceeds rapidly at first and then decreases with time as soil
pores become water-filled (Hillel 1971). Within minutes to hours, under conditions of steady, uniform rainfall, the infiltration rate stabilizes at a quasi-steady state. The United Nations calls this the “basic” infiltration rate (Brouwer et al. 1998). In a homogeneous, structurally stable soil, the basic infiltration rate essentially equals the saturated hydraulic conductivity of the soil (the rate at which water moves through saturated soil). In other words, once the pore spaces become largely occupied by water, a column of soil can only take on new water as fast as its older water can move away.

The slope of the land affects soil infiltration rates by controlling the amount of time water spends at a given place on the land surface. Gentle slopes, irregular surfaces, and depressions hold water, giving it time to infiltrate even where the infiltration capacity is low. In contrast, steep, smooth slopes do not allow water to linger and present fewer, briefer opportunities for infiltration. Vegetative litter or mulch can increase infiltration by slowing the movement of overland flow and by collecting and holding moisture on the surface of a slope.

When a soil nears saturation, conditions that slow the movement of soil water hinder infiltration. Infiltration is slowed by clay particles that swell when they become wet and by ice that blocks subsurface pathways of water movement. The presence of impermeable layers or bedrock at shallow depths in the soil restricts the capacity of soils to store and move water. For example, shallow soils can quickly become saturated during a storm if they are not well drained. Some soils form thin surface crusts after the physical impacts of raindrops break weak soil aggregates apart, redistributing fine particles, such as clays, which clog soil pores. Soil crusts can also form where clay particles, carried into a puddle during a rainstorm, remain as a thin layer after the puddle has disappeared.

The maximum rate at which soil can absorb moisture is frequently called the infiltration capacity (Dunne and Leopold 1978). The word “capacity” may be misleading, as infiltration capacity is a flux (rate of change) rather than a volume, but the term has persisted among hydrologists and soil scientists despite efforts to rename it (e.g., “soil infiltrability” proposed by Hillel 1971). By comparing the maximum infiltration rate to measured and predicted rainfall intensities, researchers can identify threshold rainfall conditions at which overland flow will begin and flooding may become a concern.

Because infiltration is strongly affected by the conditions of the soil surface, human uses of the land surface change infiltration rates and patterns. Infiltration capacities become reduced when soils are trampled by people or animals, or compacted by vehicles and heavy equipment; and infiltration is reduced to zero when the land is paved with an impervious material. Such alterations are typically the unintended consequences of actions designed to achieve other objectives, such as creating a parking lot and constructing buildings. Human activities that inadvertently promote soil erosion or deliberately remove the uppermost layers of soil, as during construction, decrease infiltration rates by removing the most absorbent (O and A) soil horizons and exposing denser soil horizons with lower infiltration capacities.

Like rain and other components of the hydrologic cycle, infiltration is reported in units of depth per time (e.g., mm hr\(^{-1}\)). Infiltration rates are most effectively measured on the flat surfaces of deep, homogeneous soils; thus, measurements made on agricultural soils dominate the scientific literature of infiltration rates. To measure infiltration rates, water is applied to the soil surface and the amount that disappears into the ground is recorded over intervals of time. Water can be applied with a sprinkling system, but most infiltration measurements are made with...
INFILTRATION

Water ponded within a metal cylinder that has been driven about 15 cm into the soil. Lateral movement of water through the soil is avoided by using a double-ring system. Water in the outer ring moistens the surrounding soil and reduces the matric potential so that water in the inner cylinder can move downward into the soil. The constant depth of ponded water in the rings exerts a positive pressure on the soil surface. Assuming that evaporation has been minimized, the amount of water added to maintain a constant water depth equals the amount that has infiltrated. Quantities of water applied typically reach or exceed amounts that would occur in a high intensity rainfall in the area, but such large quantities are intentionally applied to exceed, and thus help identify, the infiltration capacity or maximum infiltration rate of the soil.

Because of the spatial and temporal variability of soil characteristics, measurements of rainfall infiltration have more value as relative rather than absolute rates. Nonetheless, general trends, which are well known from comparable measurements, have supported the development of mathematical models that are used to predict infiltration rates under different conditions. Hydrologic models that predict rainfall runoff for applications ranging from flood hazard zone mapping to irrigation management must include sections that calculate infiltration rates.

Infiltration is difficult to measure in irregular terrain, on steep slopes, or where roots interfere with the process of inserting an infiltration ring and the disturbance created by cutting roots and forcing the rings into the ground alters the infiltration process. Despite the challenges of making measurements in forests, data indicate that infiltration rates in forests exceed those of grasslands by an order of magnitude, largely due to the greater presence of macropores in the forest (Taylor, Mulholland, and Thornburrow 2009). The need to keep infiltrometer rings level to maintain a constant head essentially prohibits the use of double-ring infiltrometers on sloping lands. Sprinkling infiltrometers can apply water to slopes, but water that does not infiltrate flows downhill and pools in the downslope portion of the plot.

When the multiple controls of infiltration are understood, land managers can intervene to increase infiltration rates. In rural landscapes, infiltration rates can be raised by increasing the organic matter content of soils to promote aggregate stability, improving soil drainage, and altering land cover to facilitate the development of root channels and other macropores. In steep-lands, terraces slow the movement of overland flow and give water more time to infiltrate.

As the footprint of urban areas increases, more attention is being paid to increasing infiltration rates in places where they had been reduced by impervious surfaces. Cities and states in the United States are now making efforts to capture the first few centimeters of storm water runoff by creating new opportunities for infiltration and storm water retention. Where surfaces have been paved, impervious pavement can be replaced with semi-pervious surface materials, and areas of impervious surface can be punctuated with structures, such as retention basins and rain gardens, that collect and hold rain water. Although the rate of input of storm water to those structures may greatly exceed their infiltration rates, the water they capture has the chance to infiltrate slowly over time rather than pass by as overland flow. The benefits of infiltration-promoting structures in urban areas include the removal of pollutants as infiltrated water passes through soil systems, the reduction of flood-producing storm runoff, and the local recharge of groundwater resources.

The term “informal sector,” coined by Keith Hart, was popularized by the International Labor Office (ILO) World Employment Program (see in particular ILO 1972). Economic activities recognized and fostered by the state were designated as the formal sector, and those ignored by the state constituted the informal sector. Although the activities in different sectors may often be similar, the risks are magnified in the informal sector due to lack of state support. The ILO frames the “problem” of the informal sector as one of inequality, to which it recommends greater incorporation of the informal sector within the formal one.

Incorporated into international development discourse since the 1970s, the original definition of the informal sector was critiqued for creating an untenable binary, which led to single policy prescriptions covering a wide range of activities because of a failure to appreciate how the fractured nature of labor markets creates a continuum of degrees of formality which are not independent but continually interacting. Furthermore, applications of the concept have been deemed urban-centric and criticized for defining a present with no future (since advocates promote formalization) and eliding neighborhoods, households, people, and activities with enterprises (by failing to recognize, for example, that people may work in both formal and informal sectors at different times of day, year, or life course). Critics also charge that the urban poor are often conflated with the informal sector, ignoring waged workers who have low paying jobs and little job security. By 2002, the ILO itself endorsed a move to using the term “informal economy” as a means of encompassing the expanding and increasingly diverse group of workers and enterprises in both rural and urban areas that are not recognized by legal and regulatory frameworks, and therefore face heightened vulnerability. The ILO currently promotes “decent work” along an informal/formal continuum, while continuing to promote a transition to formality.

By most estimates, the number and proportion of people working in informal economies has grown considerably over the past 30 years, due to rural-urban migration, structural adjustment policies, political crises, and globalization, particularly the flexibilization of production and employment relationships. The related concept of informality has also been developed to describe modes of governance through which differential spatial value is produced and managed. Thus urban informality is a “heuristic device that uncovers the ever-shifting urban relationship between the legal and illegal, legitimate and illegitimate, authorized and unauthorized” (Roy 2011, 233). Recent studies have also examined how different modes of informality describe and prescribe housing, citizenship, and the lives of rich and poor in both the Global North and Global South.

Information and communications technology

Barney Warf
University of Kansas, USA

Information and communications technologies (ICTs), which include various forms of telecommunications such as the telegraph, telephone, satellites, fiber optics, and the Internet, play a central role in the contemporary global economy and our daily lives, shuttling massive quantities of information between firms, individuals, and places, and contributing to the significant waves of time–space compression that characterize the contemporary world. Telecommunications performs a pivotal role in the organization and transformation of economic activity. As production systems have become stretched over ever larger distances, and have simultaneously become more information-intensive, the need and ability to transmit vast quantities of data have grown accordingly. For more than 150 years, telecommunications has been crucial to accelerating the long-distance flow of information and bringing places closer to one another in relative space.

The origins of telecommunications can be traced to the invention of the telegraph in the early nineteenth century. This innovation initiated the process by which communications became detached from transportation, a process that was advanced in 1876 when the telephone allowed aural information to be included. Telecommunications was essentially synonymous with the simple telephone service, which became critical to the growth of industrial city systems, allowing multiepablishment firms to centralize their headquarter functions in the cores of large cities while they spun off branch plants to smaller towns. Even today, the telephone remains by far the most commonly used form of telecommunications for businesses and households.

In the late twentieth century, as the cost of computing capacity dropped and the microelectronics revolution rapidly increased the capacity of electronic equipment, fiber optics and satellites drastically increased the capacity of telecommunications. With the digitization of information, telecommunications companies formed worldwide integrated information networks.

This entry considers ICTs from several angles. It looks at fiber-optic lines, which now comprise the backbone of the global telecommunications industry, and at satellites, then turns to the Internet, now used by 46% of the people on the planet, which has essentially dissolved the boundaries between the virtual and the physical worlds, so that dichotomies such as online/offline fail to do justice to how closely interwoven cyberspace and real space are. Social and spatial discrepancies in Internet access, loosely termed “the digital divide,” are examined. The entry also explores how ICTs have reshaped the world of global finance, and their effects on global back-office relocations; how digital networks have contributed to an ongoing reconstruction of urban space; how mobile (or cellular) phones have put more people in touch with one another than at any other time in world history; and how social media are having enormous impacts on how individuals view themselves and communicate with one another.
The two primary technologies deployed by the global telecommunications industry are satellites and fiber-optic lines. Firms that provide these services serve overlapping but slightly different markets: satellites overwhelmingly dominate mass media transmission, although fiber carriers have recently begun to invade this market (e.g., cable television). Fiber carriers are heavily favored by large corporations for data transmission and by financial institutions such as banks for electronic funds transfer systems (EFTs), partly because of the higher degrees of security and redundancy they offer.

Since the late 1950s, more than 5500 satellites have been launched worldwide, the vast majority having been sent into orbit by the United States and the Soviet Union/Russia. In addition to military applications, satellites are used extensively by telecommunications companies, multinational corporations, and the global media to link far-flung operations, including international data transmissions, telephone networks, teleconferencing, and television and radio programs. Satellites in orbit appear in a variety of sizes and degrees of technological sophistication. Large satellites capable of handling international transmissions sit 35,700 km (22,300 miles) high in geostationary orbits. From its vantage point, a broad-beam geostationary satellite can transmit to (i.e., leave a “footprint” over) roughly 40% of the Earth’s surface, creating instantaneous time–space convergence. Because the cost of satellite transmission is not related to distance, it is commercially competitive in rural or low-density areas (e.g., remote islands), where high marginal costs often dissuade other types of providers, particularly in fiber optics (Warf 2006; 2007).

Increasingly satellites have been marginalized by the growth of fiber optics. Fiber optics are long, thin, flexible, highly transparent rods of glass (or, less commonly, plastic) about the thickness of a human hair, which can transmit light signals. Because light oscillates much more rapidly than other wavelengths (200 trillion times per second in fiber cables vs 2 billion times per second in a mobile phone), such lines can carry much more information than other types of telecommunications. Modern fiber cables contain up to 1000 fibers each and are ideal for high-capacity, point-to-point transmissions. The transmission capacities of fiber optics grew rapidly in the late twentieth century in parallel with the microelectronics revolution. Financial and producer services firms led the way in the construction of a vast, seamless integrated network of fiber cables which allowed the deployment of EFTs. These constitute the nervous system of the international financial economy, largely because of the higher degrees of security and redundancy that this medium offers. Banks can move capital around at a moment’s notice, manage arbitrage interest rate differentials, take advantage of favorable exchange rates, and avoid political unrest. Although their transmission costs have declined, satellites have failed to match the latest leaps in fiber optics’ capacity and compete with transoceanic submarine cables only with great difficulty; today 94% of all international telecommunications traffic is transmitted via cables (Warf 2006).

The worldwide network of fiber lines links cities, markets, suppliers, and clients, and constitutes the backbone of Internet traffic (Figure 1). The geography of global fiber networks centers primarily on two distinct markets crossing the Atlantic and Pacific oceans, connecting the major engines of the world economy, Europe, North America, and East Asia. In 1988 AT&T initiated the world’s first transoceanic fiber-optic cable, which carried 40,000 telephone calls simultaneously. Because large corporate users are the primary clients of such networks, it is
no accident that the original and densest web of fiber lines connects London and New York, a pattern that resembles that of the telegraph and telephone. In the 1990s a growing web of transpacific lines mirrored the rise of East Asian trade with North America, including the surging economies of the newly industrialized countries.

The complex interplay of deregulation, globalization, and technological change increased the international transmission capacities and traffic volume for fiber-optics carriers exponentially. Between 1988 and 2003, for example, transatlantic fiber-optic cable capacity increased from 43,750 voice paths to 45.1 billion (an increase of 103,000%), while across the Pacific Ocean cable carriers’ capacity rose from 1800 to 1.87 billion voice paths (an astonishing 1.6 billion percent).

In addition to these two major markets, fiber lines have extended into several newer ones. In 1997 several firms opened the Fibeeroptic Link Around the Globe (FLAG), the world’s longest submarine network, which connected Europe, the Middle East, and Southeast Asia via routes across the Indian Ocean.

The Internet

The largest, by far, and perhaps most important ICT network is the Internet. In November 2015 it connected an estimated 3.36 billion people in more than 200 countries, roughly 46% of the planet’s population (Figure 2). From its military origins in the United States in the 1960s, the Internet emerged on a global scale through the integration of existing telephone, fiber-optic, and satellite systems, a process made possible by the technological innovation of packet switching, in which individual messages may be decomposed, the constituent parts transmitted by various channels, and these parts then reassembled instantaneously at the destination. Spurred by declining prices of telecommunications, services, and equipment, the Internet diffused rapidly, allowing any individual with a microcomputer and modem access to cyberspace. In poorer countries, cybercafes often provide a major point of access.

The Internet has had significant economic and social impacts. For well-educated elites, it offers a means of connection to the global economy even
as they become increasingly disconnected from the local environments of their own cities and countries. Online retail shopping, or “e-tailing,” has grown exponentially, particularly for large firms, and given birth to entirely virtual stores such as Amazon.com. The Internet is central to reservation and ticketing systems for airlines and hotels. The higher levels of competition facilitated by the Internet have reduced costs for consumers. Many schools and universities use it for online courses, allowing students who may otherwise not have access to their services to participate in education. Most newspapers offer online versions, greatly facilitating access to the news. The downloading and streaming of music files and films has become a big business, raising concerns over intellectual property rights. Internet-based telephony (e.g., Skype) has grown rapidly. E-business allows firms to advertise, recruit, submit contracts and bills, monitor inventories, and perform other functions quickly and cheaply, reducing transaction costs and raising productivity. Weblogs, or blogs, have allowed vast numbers of people to share their opinions publicly. Graphical user interfaces have enabled the Internet to become a major source of recreation, including online games, while others browse for pornography, raising widespread concerns about its impact on traditional mores, and especially its effects on children. For many users, cyberspace allows for the creation of “communities without propinquity”: that is, groups of users who share common interests but not physical proximity. Political groups of various types and other groups, such as gay people, have used the technology to great advantage. The extent to which digital relations can substitute for real-world face-to-face interactions, however, is open to debate.

The Internet is also used for illegal, unethical, or illegitimate purposes. Spam, or unsolicited email advertising, makes up a large share of the traffic on the Internet. Online gambling has grown rapidly. Electronic systems are used to monitor everyday life, including credit cards, visas and passports, tax records, medical data, police reports, telephone calls, utility records, automobile registration, crime statistics, and sales receipts. These, together with the growth of Internet fraud and identity theft, raise serious concerns about privacy. Thus, telecommunications can be used against people as well as for them.

**Digital divides**

There remain significant discrepancies in access to the Internet worldwide. In all countries, access to the Internet is highly correlated with income, educational level, and employment in professional occupations. Rural areas often have slow or substandard connections. Difficulties in procuring the skills, equipment, and software necessary to access the Internet threaten to exclude economically and socially marginalized groups from the benefits of cyberspace. Thus, the microelectronics revolution has accentuated the digital divide between groups that are proficient in computer technology and those that neither understand nor trust it.
At the international level, inequalities in access to the Internet reflect the long-standing bifurcation between developed and developing countries (Figure 3). The best-connected nations are the Scandinavian countries, Canada, Australia, and Singapore, where more than 90% of the population is connected. In the United States, the Internet penetration rate was 87% in 2015 (with substantial internal variations). Outside of the economically advanced countries, the vast bulk of the world’s people – that is, the developing world – have comparatively little access, particularly in Africa, although mobile phone use has made great advances. Low incomes, inadequate infrastructures, and unhelpful or oppressive governments play major roles in this context.

The digital divide, or social and spatial differentials in Internet access, has been the subject of a growing body of literature (Howard, Busch, and Sheets 2010; Korupp and Szydlik 2005). Fundamentally, this question is about who has access to and can use the Internet and who does not. Admittedly, “access” and “use” are vague terms and embrace a range of meanings, including the ability to log on at home, in school, at a cybercafe, or at work. Rather than a simple access/nonaccess dichotomy, it is more useful to think of a gradation of levels of access, although data at this level of subtlety rarely exist. Thus, it is increasingly common to speak of digital differentiation rather than a divide (Selwyn 2004).

The digital divide is a complex, changing, and multidimensional phenomenon that reflects the diverse channels through which social inequalities are reinscribed in cyberspace. Everywhere, age plays a key role: the elderly are inevitably the least likely to adopt the Internet. In some places, gender is important too: in North America the gendered divide has disappeared, but in Europe it persists, and in the developing world it is pronounced. The digital divide is also a geographical phenomenon. Everywhere, large urban centers tend to exhibit higher rates of connectivity than rural areas (Mills and Whitacre 2003).

As the uses and applications of the Internet have multiplied, the costs sustained by those who are denied access rise accordingly. At the historical moment that professional success came to rely on digital technologies, large pools of the economically disenfranchised have been shut out from cyberspace. As the upgrading of required
skill levels steadily renders information technology skills necessary even for low-wage service jobs, the lack of access to cyberspace becomes increasingly detrimental to social mobility.

In addition to international discrepancies in access, Internet usage is also uneven within countries: invariably, the poor and elderly, ethnic minorities, and those in rural areas enjoy markedly less access (Chakraborty and Bosman 2005). Unfortunately, relatively little is known about this issue, largely because of lack of data. However, the enormous growth of the Internet means that the digital divide is also changing rapidly and, as access improves for many hitherto marginalized groups, it may slowly decline over time.

The latest frontier in the digital divide is the arena of broadband delivery services, which varies widely in availability between the world’s countries. Broadband applications include digital television, business-to-business linkages, Internet gaming, telemedicine, videoconferencing, and Internet telephony. With large, graphics-intensive files at the heart of most Internet use today (e.g., downloading forms, reading online newspapers), broadband has become imperative for web browsing. However, the geography of broadband access replicates the globe’s geographies of wealth and power – it is largely confined to the economically developed world. Thus, rather than eliminating the digital divide, broadband reproduces, and in some cases accentuates, it.

ICTs and global cities

As the Internet unfolded across the world stage, globalization generated a resurgence of “global cities.” Such places are by definition connected via vast tentacles of investment, trade, migration, and telecommunications to clients and markets, suppliers, competitors, consumers, and producers around the world. Not surprisingly, global cities, and indeed most large metropolitan areas, are well-connected hubs with extensive fiber-optic linkages, within which constellations of Internet-related businesses are generated.

Face-to-face contact is essential to the performance of actors engaged in nonroutine functions in global cities, which is critical to the creation and communication of expertise. Despite the enormous ability of ICTs to transmit information instantaneously over vast distances, face-to-face contact remains the most efficient and effective means of obtaining and conveying irregular forms of information, particularly when it is highly sensitive (or even illegal, as the current wave of corporate malfeasance and insider trading demonstrates). In the context of face-to-face meetings, actors can monitor one another’s intentions and behavior through observation of body language, which is essential to establishing relations of trust and mutual understanding. Digital interactions are not a viable substitute for face-to-face communication because they do not convey the subtleties that the latter can.

The continued importance of global cities in the face of a networked global economy is worth emphasizing. Repeated claims that advances in telecommunications would allow everyone to engage in telecommuting, dispersing all functions and spelling the obsolescence of cities, the death of distance, a “flat world,” and a “borderless world” have fallen flat in the face of the persistent growth of dense urbanized places. Indeed, financial and business services firms not only pay high rents to be near city centers, and endure the congestion of such locations, but spend lavishly to fly their executives around the world to meet with their counterparts in person. Even electronic conferencing, such as that offered by Skype, has been unable to replace direct personal
contact. For this reason, a century of technological change, from the telephone to fiber optics, has left most high-wage, white-collar, administrative command and control functions clustered in downtown areas. In contrast, telecommunications are ideally suited for the transmission of routinized, standardized forms of data, facilitating the dispersal of functions involved with their processing (i.e., back-offices) to low-wage regions.

In short, despite the near-ubiquity of the Internet in economically advanced countries, global cities retain their importance and continue to exert hegemony, precisely because they facilitate the sorts of interactions that cannot be conducted easily over the web.

**ICTs and global financial markets**

Few industries have been more profoundly reshaped by ICTs than finance, notably the shift into digital money that began in the late twentieth century. Electronic funds transfer systems constitute the architecture of foreign exchange markets and transaction payment systems. Using the worldwide network of fiber optics, international banks and speculators can shift vast sums around the world at a moment’s notice, creating havoc with national monetary controls. As a result, the velocity of global capital has accelerated to unprecedented speeds: freed from many technological and political barriers to movement, capital has become not merely mobile, but hypermobile.

Capital markets worldwide were profoundly affected by the digital revolution. Electronic funds transfer systems reduced transaction costs, increased the velocity of money, improved capital market efficiency, and generated economies of scale in finance. They eliminated transaction and transmission costs for the movement of capital much in the same way that deregulation and the abolition of capital controls decreased regulatory barriers (Batiz and Woods 2002).

One of the primary forms of EFTs is real-time gross settlement (RTGS) systems (O’Mahony, Peirce, and Tewari 2001), which handle money flows between financial institutions and governments. The largest of these is the US Federal Reserve Bank’s Fedwire system, which allows depository institutions with a Federal Reserve account to transfer funds to the account of any other depository institution. In 2007 Fedwire traffic amounted to $2.1 trillion per day (Federal Reserve 2009). The other major US payments mechanism is the privately owned Clearing House Interbank Payments System (CHIPS) in New York, which clears about $1 trillion in daily transactions. In Europe, the Belgian-based Society for Worldwide Interbank Financial Telecommunications (SWIFT) plays a comparable role. Formed in 1973, SWIFT extends into 208 countries and handles €2.6 trillion in daily transactions. In the United Kingdom settlements are made through the Clearing House Association Payments System (CHAPS), run by the Bank of England since 1984, while in the European Union the Trans-European Automated Real-Time Gross Settlement Express Transfer (TARGET) is used to settle transactions involving the euro. In Japan the Bank of Japan Financial Network System (BOJNET) fulfills a similar function.

Private firms have similar systems. Citicorp has a global information network that allows it to trade $200 billion daily in foreign exchange markets around the world. MasterCard has its Banknet, which links all its users to a centralized database and payment clearing system. Reuters accounts for 40% of the world’s financial trades each day. Other systems include the London Stock Exchange Automated Quotation system (SEAQ), the Swiss Options and Financial Futures Exchange (SOFFEX), and the
The rise of EFTs fundamentally undermined the traditional role of national monetary policy. National borders and monetary policies mean little in the context of massive movements of money around the globe, rendering central bank interventions increasingly ineffective. EFTs present the global system of states with unprecedented difficulties when they attempt to reap the benefits of international finance while simultaneously attempting to avoid its risks. The power of electronic money is evident when currency speculators mount an attack on a given national currency, such as that launched against the Thai baht in 1997, which initiated the disastrous Asian financial crisis.

Offshore banking

ICTs have also accelerated the rise of offshore banking (Warf 2002). Roberts (1994) identified five major world clusters of offshore finance, including the Caribbean (e.g., the Cayman Islands, Bahamas, Panama); Europe (the Isle of Man, Jersey, and microstates on the continent); the Middle East (Cyprus, Lebanon, and particularly Bahrain); Southeast Asia (Hong Kong, Singapore); and the South Pacific (Vanuatu, Nauru). New ones have emerged in Africa and the Indian Ocean. Such places provide commercial investment services, foreign currency trades, asset protection (insurance), investment consulting, international tax planning, and trade finance (e.g., letters of credit). Offshore banking is relatively capital-intensive compared to the labor-intensive headquarters in global cities, and generates relatively few jobs.

Offshore centers are the black holes in the global topography of financial regulation, a status that emanates directly from the enhanced ability of large financial institutions to shift funds electronically to take advantage of lax regulations and
freedom from taxes and currency control restrictions. As the technological barriers to moving money have fallen, legal and regulatory barriers have increased in importance. Even relatively minor differences in regulations concerning corporate taxes or repatriated profits may attract large quantities of capital to particular places, or repel it.

Offshore banking centers have long suffered from suspicions that they constitute little more than havens for tax evasion and money laundering of illicitly obtained funds. As electronic money has come to dominate global finance, the use of offshore banking centers for illegitimate purposes has grown apace, including tax evaders, drug cartels, arms traffickers, terrorists, and corrupt government officials. Given that they often straddle the boundary between legitimate and illegitimate financial activity, a key issue in the success or failure of offshore banking centers is the degree of confidentiality that investors feel they offer. Indeed, the quality of offshore banking centers is often judged by the quality of the laws protecting the privacy of investors.

Back-offices, call centers, and the offshoring of services

Another domain heavily affected by ICTs is low-level, routinized back-office functions. Back-offices perform clerical functions such as data entry of office records, library catalogs, payroll or billing information, bank checks, insurance claims, and magazine subscriptions. These tasks involve unskilled or semiskilled labor, primarily women, and operate on a 24-hour basis.

Historically, back-offices were located adjacent to headquarters in downtown areas to insure close management supervision. However, with ICTs, many service firms uncoupled their headquarters and back-office functions, and moved the latter to cheaper locations on the urban periphery. Recently, back-offices have relocated on a much broader, continental scale. Many clerical tasks have become footloose and susceptible to spatial variations in production costs. Digital call distribution systems have made possible the relocation of phone services that were once confined to large cities.

Internationally, this trend has taken the form of the offshore office. The primary motivation for offshore relocation is low labor costs, although other considerations include worker productivity, skills, turnover, and benefits. Notably, many firms with offshore back-offices are in industries, including insurance, publishing, and airlines, which face strong competitive pressure to enhance productivity. Offshore back-office operations remained insignificant until transoceanic fiber-optic lines made relocations on an international scale possible. Inputs, usually documents or magnetic tapes, are sent by air to offshore processing facilities. After processing, the results are returned via satellite or fiber-optic line.

For example, several New York-based life insurance companies established back-office facilities in Ireland. Often situated near Shannon Airport, they move documents by FedEx and the final product back via satellite or one of the numerous fiber-optic lines that connects New York and London. Likewise, the Caribbean, particularly Jamaica and Barbados, has become a particularly important locus for American back-offices. In Asia, India has an enormous number of foreign back-offices and Manila has emerged as a back-office center for British firms, with wages 20% of those in the United Kingdom.

Offshore data entry functions have been supplemented by other types of job. The animation
of television programs such as *The Simpsons*, for example, has been outsourced to India. American high school students can email Indian tutors for help with their homework (Lohr 2007). Some US video game players, seeking to skip the easy and boring early stages of online role-playing video games, outsource this stage to hired, often impoverished, Chinese players known as “gold farmers,” allowing them to advance rapidly to the later, more challenging, stages (Barboza 2005). Offshoring also includes higher-skilled jobs such as radiological readings of x-rays and PET scans and tax preparation. Increasingly, chip design and software debugging are moving to India too, as have editing and proofreading functions.

A related form of low-wage, low value-added service involves call centers, which include sales, marketing, customer service, telemarketing, and technical support or other specialized business activities (Richardson and Belt 2002). Like back-offices, call centers are primarily screen-based and do not require proximity to clients. The major cost consideration is labor, although the workforce consists primarily of low-skilled women, and high turnover rates are common. They are thus the epitome of a foot-loose industry. There are an estimated 80,000 to 100,000 call centers in the United States, which employ between 3% and 5% of the national labor force (Uchitelle 2002), the majority of which are located in urban or suburban locations.

Like back-offices, call centers have become increasingly globalized. India has attracted a significant number of customer service centers near its software capital of Bangalore, where workers are trained to speak American English (Waldman 2003). Wages there, which average $2000 per year, are higher than average Indian salaries but are only 10% of what equivalent jobs pay in the United States.

### ICTs and urban space

ICTs have had profound effects on the organization of urban space. Although large cities typically have much better developed telecommunications infrastructures than small ones, the technology has rapidly diffused through most national urban hierarchies.

One example is “teleworking” or “telecommuting,” in which workers substitute some or all of their working day at a remote location (almost always home) for time usually spent at the office. Teleworking is most appropriate for jobs involving mobile activities or routine information-handling such as data entry or directory assistance. Proponents of teleworking claim that it enhances productivity and morale, reduces employee turnover and office space, and leads to reductions in traffic congestion, air pollution, energy use, and accidents.

However, the growth of teleworking may, ironically, increase rather than decrease the demand for urban transportation services, as was widely expected. While telecommuters travel to their workplace less frequently than most workers do, many have longer weekly commutes overall, leading to a rise in aggregate distances traveled. In addition, the time released from commuting may be used in traveling for nonwork-related purposes. Moreover, even if telecommuting did reduce some trips, the associated reductions in congestion could simply induce other travelers onto the roads.

Another potential impact of information systems on urban form relates to transportation informatics, including smart metering, electronic road pricing, automated toll payments and turnpikes, automated navigation and travel advisory systems, remote traffic monitoring and displays, and improved traffic management and control systems. Such systems are intended to minimize
congestion and optimize traffic flow, especially during the rush hour peak travel times.

Mobile telephones and Internet telephony

Since the mid-1990s, the mobile (or cellular) telephone has become the most widely used form of telecommunications in the world (Campbell and Park 2008; Comer and Wikle 2008; Ling and Donner 2009). Rapid decreases in the cost of mobile phones have made them affordable for vast numbers of people, including in the developing world. In 2014 90% of the world's inhabitants — 6.5 billion people — used mobile phones, more than twice as many as used the Internet. Because mobile phones are convenient and require much less infrastructure than landlines, it is not surprising that mobile phone usage has leapfrogged over landlines in the developing world, particularly in sub-Saharan Africa and South Asia, which generally lacked investment in the copper cable telephone systems that formed the basis of landline telephony during the twentieth century.

The extent of mobile telephony worldwide is evident in Figure 4. Average penetration rates exceed that of landlines in every country, and in many there are more mobile phones than people. China has the world's largest population of mobile phone users (Ding, Haynes, and Li 2010). Even in sub-Saharan Africa, half of the population uses this technology. Moreover, mobile phone growth is explosive: between 2005 and 2015, the world's number of mobile phone users jumped by 280%. This growth was unevenly distributed and was related to inequalities in income and literacy, gender barriers, and other dimensions of social life. While the rates of increase were modest throughout the economically advanced world, in much of Africa and Central Asia they exceeded 100% in 7 years.

At the same time, the number of the world's landlines fell roughly 2% annually, including reductions in the number of public pay phones and home landlines. Even in the United States, less than half of the population used a landline in 2010. Thus, mobile telephones are largely substitutes for, not complements of, landlines.

Mobile telephony has had important repercussions for the contours and rhythms of daily life, including a growing porosity between private and public realms as once private conversations are held in public spaces (Ling 2004; Ling and Campbell 2009). It has, for example, allowed for sharply improved coordination of mobility, better use of time, and security in case of emergencies, and its enhanced connectivity erodes the disadvantages of physical isolation.

One of the prime applications of mobile phones is text messaging. In 2014 81% of the world's mobile phone users engaged in texting, sending a total of 6.3 trillion messages, or 200,000 per second. Everywhere, teenagers took the lead in adopting texting at far higher rates than their elders (Bolin and Westlund 2009). In poorer countries, texting is a popular substitute for voice traffic because it is considerably lower in cost. Instant messaging services such as Twitter have also grown explosively. Starting in 2006, Twitter grew to include 316 million users worldwide in 2015, who send more than 510 million tweets per day.

Mobile Internet access, still largely in its infancy, may well help to mitigate the digital divide. In many developing countries, wireless telephony allows increasingly large numbers of users to bypass the high access costs of fixed-line technologies. Indeed, it is not unrealistic to claim that the growth of mobile broadband services is
erasing the boundaries between telephony and the Internet altogether.

Another impact of the Internet is Voice over Internet Protocol (VoIP), or telephone traffic conducted entirely through cyberspace, which allows users to bypass public switched networks. VoIP is not a new product per se, but a means of utilizing the existing Internet infrastructure more efficiently. It has grown rapidly at the expense of public switched telephone network (PSTN) traffic; from a minuscule 4% of the world’s telephony traffic in 2000, VoIP has expanded to roughly 28% in 2011.

The world’s most popular VoIP application by far is Skype. In 2009 more than 580 million Skype users (see Figure 8 below) accounted for 12% of the world’s international telephony minutes, or half the global total of VoIP call minutes. Skype is particularly important in international telephony, as it is now the world’s largest international provider of telephony services. Half of Skype calls are between countries, and account for one-fourth of all calls that cross national borders. Video calls have also surged in popularity among Skype users and now comprise 40% of its call volume.

Social media

Social media include ICTs used for personal communications. Facebook is by far the most popular networking site in the world (Kirkpatrick 2010), with more than 1.5 billion users in 2015 (Figure 5), or 21% of the planet’s population. Its users are unevenly distributed across the planet (Figure 6). The United States, with 157 million users (or half of its population), forms the largest single national group of Facebook users. Within the United States, the
highest Facebook penetration rates are found in relatively wealthy, educated states such as Massachusetts, New Jersey, and Washington, and those with a large metropolitan area, such as Illinois and Georgia (Figure 7).

While it is the largest, Facebook is only one of several social networking sites worldwide (Figure 8). In Russia and neighboring states, the Kontakte network is popular. China has promoted its home-grown Qzone system, while in Brazil Zing reigns supreme. Dozens of other smaller sites also exist, such as Maktoob in the Arab world, hi5.com in Mongolia, and Habbo in Finland.

Social media have given rise to new forms of individual identity and behavior in which interpersonal actions are increasingly telemediated (Valentine and Holloway 2002). However, the extent to which digital interactions can replicate or substitute for close interpersonal connections has been widely debated (Nie 2001). Some hold that social media can successfully replicate the emotional depth of face-to-face contacts (Hampton and Wellman 2001), that Internet users have more offline social interactions than nonusers, and that digital interactions are displacing place-based communities as the primary vehicles of sociability. For example, the enormous popularity of massively multiplayer online role-playing games (MMORPGs) such as World of Warcraft, with 8 million players worldwide, reflects like-minded people defined by shared interests rather than spatial proximity (Li, Papagiannidis, and Bourlakis 2010).

However, others maintain that, precisely because digital interactions allow anonymity and disallow nonverbal cues, they discourage the formation of intimate ties. From this perspective, the Internet and mobile phones complement, but do not substitute for, face-to-face interactions. Haythornthwaite (2005) maintains that meaningful interactions via social media are invariably preceded or accompanied by face-to-face ties. As a result, digitally mediated communities are typically ephemeral and lack significant levels of trust or emotional depth. For example, Hampton et al. (2011) argue that the average Facebook user has 229 “friends,” although an overabundance of such friends may actually undermine the capacity to sustain close, strong ties. Telemediated ties have difficulty negotiating social difference: thus few Facebook users cultivate friends with
Figure 7  Facebook penetration rates in the United States, December 2012. Based on Internet World Stats (2015).

Figure 8  Dominant social networking services, December 2012. Based on Vincos (2014).
people who are dissimilar to themselves (Vasalou, Joinson, and Courvoisier 2010).

Digital social media may actually make people less, not more, sociable. Turkle (2011) asserts that Internet and mobile phone use isolate users from one another and deprive them of intimate ties. In her view, telemediated ties lead people to feel alone even when they are together, and she blames texting in particular for an ostensible decline in conversational capacity. Because they confuse being connected with intimacy, heavy users of social media become unable to be alone, and thus often feel lonely. Not surprisingly, therefore, the growth of ersatz intimacy on Facebook has been accompanied by rising levels of loneliness (Marche 2012). What is equally disturbing is that the Internet may generate subtle but pervasive changes in brain structure, including shortened attention spans (Jackson 2008; Carr 2010).

Forging close personal ties necessitates the exchange of tacit knowledge and the cultivation of trust. Thus, the creation of close interpersonal relations is never completely free from the need for face-to-face contacts. Social media are a poor substitute for face-to-face connections, which are fundamental to the creation and transmission of tacit knowledge. The reasons that face-to-face contact is so essential is that it allows for the use of body language and emotional cues, eliminates the possibility of the anonymity that haunts digital encounters, and creates a common feeling of belonging to a community, which are prerequisites for the creation of trust and mutual understanding in a dense network of individuals in close contact with one another.

At the scale of the individual, digital media have changed “what a person can be” (Lanier 2010). The enormous enhancement of human extensibility offered by telemediated ties (Adams 2005) has arguably led to a far-reaching redefinition of the self as social networks increasingly shift from a series of one-to-one ties to webs of one-to-many connections. Digital social media blur the boundaries of the autonomous individual.

Information synthesis

Daniel Sui
Ohio State University, USA

Information is an elusive concept as James Gleick (2012) described so eloquently in his best seller “The information – a history, a theory, and a flood.” In the age of big data and knowledge discovery, we seem to have lost sight of the complex meanings of information. In general, information is understood along the data–information–knowledge–wisdom hierarchy, although in recent years the boundaries among the four terms have been increasingly blurred. Nonetheless, data generally refers to the raw facts or descriptions about the world; information is regarded as the processed/structured data that gives the user a special purpose and meaning, and both data and information are needed to produce knowledge – a logical, organized, or structured description about the world. Wisdom generally refers to the application of knowledge at the right place and right time for the right reasons.

Synthesis literally refers to a combination of two or more entities together to form something new. Synthesis (“syn” – putting together) is often understood in the context of analysis (“ana” – breaking up), and the precise meaning of synthesis can be wildly different across the disciplines in science, engineering, social sciences, humanities, and the arts. As a methodology, information synthesis is generally about “organizing the different pieces to create a mosaic, a meaning, and a beauty greater than the sum of each shining piece” (Keene and Zimmermann 2007, 5). Although the precise meaning may be different technically, multiple other terminologies have been used in the geographic literature to refer to synthesis, such as fusion, integration, combination, amalgamation, assimilation, and so on. In essence, synthesis is essentially an abductive sense-making process (Couclelis 2009). Different from induction (something may be true) and deduction (something must be true), abduction only alleges something may be true – typical after vast amount of information is synthesized.

Information synthesis: why (necessity and importance)

In the age of big data, we have continued to witness the exponential explosion of information, increasing rapidly every minute (if not second). To make sense of the latest data and information deluge, we need to develop better ways to carry out both analysis and synthesis, and yet, despite the widely claimed importance of synthesis for both research and education, scholarly coverage on synthesis is far less than that of analysis. Meaningful synthesis is urgently needed more than ever for both intrinsic/cognitive reasons and extrinsic/contextual reasons. Intrinsically, humans are inherently meaning-seeking species, which by default requires us to constantly connect the dots and integrate vast amount of information. It is primarily this advanced cognitive capability that differentiates humans from other species. Meaning-seeking underlies almost all human activities, ranging from basic economic activities for simple survival to all kinds of other social, cultural, political, scientific activities for meeting a hierarchy of human
INFORMATION SYNTHESIS

needs. Extrinsic, humans have had to deal with various threats from either the environment or other hostile forces in the environment since the dawn of civilization. To alleviate these threats, humans have realized the necessity of synthesizing information, thinking outside the box, and making connections for things that seem to be independent and separate at the surface.

Both analysis and synthesis play important roles in geography as an intellectual enterprise, but different research paradigms in geography may have emphasized analysis and synthesis in different ways. For example, among geography’s four traditions as defined by Pattison (1964), synthesis plays the leading role in the area studies (also known as regional geography) tradition whereas the spatial analysis tradition favors more analytical approaches. The man–land relationship (or human–environment interaction) tradition uses a more hybrid approach of both analysis and synthesis, depending on the research questions involved. Analytical approaches used to dominate the Earth science tradition (otherwise known as physical geography) but, increasingly, synthesis has also become more important in recent years with the incorporation of the concepts of place and storytelling into physical geography and Earth sciences (Phillips 2012). In recent years, the discipline of geography as a whole has made enormous methodological efforts to cross the quantitative–qualitative chasm with the goal of developing a new level of synergy of both analysis and synthesis in geographic inquiry (Sui and DeLyser 2012).

Geography as a discipline has oscillated between analytical and synthetic paradigms. During the first decade of the twenty-first century, along with geographers’ current and recent turns to specific domains and approaches (e.g., the critical turn, the cultural turn, the relational turn, the computational turn, the communicational turn, the mobilities turn, the performative turn, etc.), one turn deserves particular attention here: the turn to synthesis and to holistic approaches. At least three trends over the past ten years provide broader context for this synthetic and holistic turn.

First, calls for a unified geography as the new disciplinary identity and synthesis will be the driving methodology for studying our planet not bit by bit but all at once. As a conceptual framework, hybrid geographies are proposed as the first step towards a unified geography. Rose (2000, 364) observes that hybrids “transgress and displace boundaries between binary divisions and in so doing produce something ontologically new.” Through a higher level of synthesis, hybrid geographies aim to end two major divisions within geography: the partition between physical and human geography, of nature from society; and the separation of spatial-analytical geographies, which attempt to create a mode of disembodied geographical analysis, from social, cultural, and political geographies. Also sometimes known as the boundary projects, hybrid geographies seek to integrate elements thought to be incompatible or conflicting in grounded practices. Hybrid geographies challenge existing boundaries and forge creative connections within geographies – physical and human, critical and analytical, qualitative and quantitative – aiming to integrate perspectives on space, place, flow, and connection.

Second, the first decade of twenty-first century has witnessed a spatial turn across the physical sciences, social sciences, and humanities, with scholars from different disciplines using their domain expertise to address challenging issues from a spatial perspective. Space has become an integrating theme across the social sciences – evidenced by emerging spatially integrated social sciences (http://csiss.org) – and scholars across the humanities have made GIS
and spatial analysis integral parts of their research methodologies (Warf and Arias 2008; Scholten, van de Velde, and van Manen 2009).

The science of complex systems has advanced dramatically in recent years, as research has shifted from an older model of the single investigator to today’s multidisciplinary collaborations. Future scientific advances are likely to involve mining of multidimensional datasets and to require the kinds of data synthesis that can only be achieved if systems are to a large degree interoperable. Early calls for a new emphasis on synthesis in geography (Gober 2000) are also reflected in recent efforts in adjacent disciplines to accelerate synthesis in and between ecology and the environmental sciences (Carpenter et al. 2009).

Neither has this spatial turn been confined to the Ivory Tower. Policymakers have realized the crucial importance of space and place in understanding the complexity of the world’s problems, and have sought solutions to these problems that will work well under diverse local circumstances. The World Bank framed its 2008 world development report entirely from a geographical perspective, concluding that alleviating, and eventually eliminating, poverty problems must start with reshaping the world’s economic geography; and the White House under President Obama urged all US federal agencies to develop place-based policies to address the pressing problems facing American society. The revenge of geography in global economic and political lives (Kaplan 2012) will further elevate the stature of synthesis as a dominant mode thinking about the global issues facing the world today.

Information synthesis: what to synthesize and the general process

The dearth of information on synthesis is paralleled by a paucity of literature on how to conduct synthesis. Although the technical descriptions on synthesis may be abundant in various specialized fields, general descriptions on synthesis as a way of thinking or as a method of research are lacking. To be successful in synthesis, certain philosophical predispositions are almost a prerequisite in order to encourage synthesis. Gardner (2009) argues that the adoption of multiperspectivalism can enhance one’s proclivity to synthesize. The so-called multiperspectivalism recognizes that each different analytical perspective can only contribute partially to the phenomenon being studied. To gain a more complete, or holistic, elucidation of an issue at hand, one by necessity must synthesize those partial results from analysis in order to avoid synecdoche – as it is revealed in the six blind men and the elephant allegory. Multiperspectivalism enables us to appreciate the complementary strength of different perspectives, each contributing to the understanding of the organic whole.

Information synthesis is an integral component of geographic scholarship of all kinds. Synthesis can take place at different levels of granularity or scale covering varying breadth and depth of a topic, depending on the goals, objectives and audience. For example, synthesis can be done for a particular topic in a subfield, between two subfields, or even between/among several different disciplines – more popularly known as interdisciplinarity or transdisciplinary synthesis. All synthesis work needs to balance breadth and depth, and there is typically a tradeoff between the two. Synthesis with both breadth and depth is possible, but extremely difficult to achieve.

Generally speaking, synthesis can be done at the data, methodological, and conceptual levels. Data can exist in different formats and media, including text, image, audio, video, and maps. This entry focuses on information/data synthesis, but issues related to methodological
and theoretical synthesis are also be discussed for hybridizing physical with human geography.

In general, any efforts to synthesize entail the following four loosely ordered steps.

1 Setting the goal: a simple statement or concept of what the synthesizer is trying to achieve; define the topic and relevant information about the topic, the purpose of the synthesis, and the target audience.

2 Gathering information: with a starting point – an idea, image, or any previous work on which to build, systematically gather the relevant information, and assess the validity of the information.

3 Selecting a strategy and method: during this stage, the synthesizer’s disciplinary training comes into play. The synthesizer must choose a qualitative, quantitative, or a combination of qualitative and quantitative approaches to achieve the goals of synthesis; some of the tools may be discipline specific, with predictable fit for the goal.

4 Presenting results and obtaining feedback: take an initial crack at a synthesis by presenting validated information in a way useful to the target audience; the first cut, provisional synthesis. The first drafts are often crude and primitive but often contain the crucial elements of final product, abduction.

One area that best depicts the broader synthesis efforts is geographers’ recent attempt to synthesize across different domains by hybridizing physical and human geography. Although geographers following the cultural/political ecology tradition have been working on topics that link physical and human geography for decades, the growth of hybrid geographies has drawn an increasing number of human and physical geographers (who normally would practice either human or physical geography exclusively) to cross the physical–human divide. Neil Smith (1998) speculates on the emergence of what he called the El Niño capitalism – both literally and metaphorically – noticing the striking similarities in the rhythms of El Niño Southern Oscillation (ENSO) and capitalism’s periodic crises, and striving to link them in a causal chain. Although intriguing, El Niño capitalism remains controversial, and others have disputed the extent ENSO has affected US macroeconomic performance. Using data for ENSO fluctuations and the rates of US inflation and economic growth over the 1894–1999 timespan, Berry and Okulicz-Kozaryn (2008) explored whether there has been any co-cyclicality between the two phenomena and whether aperiodic ENSO shocks have had any impact on these macroeconomic parameters. They discerned no co-cyclicality or aperiodic shocks, concluding that while ENSO may briefly influence the performance of particular sectors of the economy in particular regions, such locally important effects “vanish into the noise surrounding macroeconomic trends in an economy as large and complex as that of the US” (Berry and Okulicz-Kozaryn 2008, 625).

It is not only human geographers addressing topics typically thought of as physical in new ways; physical geographers have also embraced topics more traditionally human – hybridizing physical and human geography is a two-way street. Inspired by Allan Pred’s work (1984) on the formation of place, Phillips (2001) highlights the primacy of place in human impacts on the environment, and contingency of place has been a dominant theme in his subsequent publications (Phillips 2009). In parallel to human geographers’ efforts to examine economic impacts of global climate change, physical geographers have studied the environmental consequences of the rising divorce rate. Yu and Liu (2007) tracked carbon footprints of couples in twelve countries who married and then divorced, stayed married,
or divorced and remarried. Because divorced couples typically require two residences, Yu and Liu found that energy consumption, water usage, and the amount of space occupied per person all increased dramatically with divorce. While perhaps unsurprising in its results, their study points to the real significance of social and cultural issues affecting individuals on large-scale processes (typically thought of as purely physical) such as global climate change.

More broadly, Clifford (2009) suggested that the study of globalization need not be the exclusive domain of human geographers or social scientists. Instead, he argued that physical geography has always been global at heart, and that globalization must be seen historically in the global export of western science – including physical geography – that underpinned colonial resource exploitation. And Mistry, Berardi, and Simpson (2009), drawing from their field experiences for a water-quality project in Guyana, traced their journey as three physical geographers from identifying themselves as top-down experts to becoming participatory facilitators – addressing issues of reflexivity and positionality often (mistakenly) thought only of concern to human geography.

Continental philosophy, long of interest to human geographers, has become a source of methodological reflection for physical geographers. Using Nietzsche, Comrie (2010) aimed to engage physical geographers and fellow physical scientists to reconsider their roles as scientists. Debunking the mystique of science and the misconception of seeing science as independent of people and society, Comrie showed that science gains its power by the way meaning is attached to it and its findings, so we should act on our ability to bestow that power. Through Nietzsche, Comrie challenged physical geographers to overcome their trained tendency toward detached environmental science and, instead, fashion a new physical geography that includes meaning and action. Recent calls for physical geographers to have more intellectual interactions with critical human geography (Lave et al. 2014) further reflect this synthesis trend in the discipline to hybridize human and physical geography.

**Information synthesis: methods and tools for synthesis**

Multiperspectivalism is necessary but not sufficient for meaningful synthesis to take place. A variety of methods and tools are needed in order to achieve the goal of synthesis. According to Gardner’s (2006) theory of multiple intelligences, humans possess seven high-level intelligence capabilities other species lack in one way or the other: musical–rhythmic, visual–spatial, verbal–linguistic, logical–mathematical, bodily–kinesthetic, interpersonal–intrapersonal, and naturalistic. As far as the specific synthesis methods or tools are concerned, people with different aptitudes tend to rely on different strategies for synthesis. For example, those who are strong in verbal–linguistic capabilities may rely on stories and narratives for synthesis whereas those logical–mathematical types always crave new concepts and theories to achieve the goal of synthesis. Of course, synthesis could occur across multiple intelligence domains. An Oscar-winning movie is usually a successful synthesis of verbal, visual, logical, and musical components.

Generally speaking, approaches for synthesis can be grouped into the three broad categories identified here, although a higher level of synthesis could happen between or among these three types of syntheses:
INFORMATION SYNTHESIS

Synthesis through qualitative/narrative approaches

This is perhaps the most frequently used approach for information synthesis. Vast amounts of information can be synthesized through some simple taxonomy and classification, such as Linnaeus taxonomy for plants or Köppen’s classification for climates. These taxonomies and classifications are usually based upon scientific concepts or models or rules that are commonly accepted by the scientific community. Developing models or theories is also sometimes the most effective way to achieve the goal of synthesizing vast amount of information.

Although reductionism has dominated scientific practice since the scientific revolution in the sixteenth century, scientists in various fields have never abandoned their search for a more holistic understanding of how the universe works. From the unified theory of fields in physics to the Gaia hypothesis in ecology, from evolutionary economics to Gestalt psychology and holistic health in medicine, scholars have never ceased their quest for a more comprehensive understanding of the world and ourselves. Although much of the success of our scientific enterprises to date has come from a reductionist analysis of a system’s parts, understanding and seeing the whole can be fundamentally more gratifying. Higher level synthesis often leads to major breakthroughs in science. Ample examples can be found of successful synthesis stories throughout the history of science. A good example is James Maxwell’s synthesis work that unified electricity and magnetism in the nineteenth century. A more recent effort is David Deutsch’s (1998) attempt to synthesize quantum theory, critical epistemology, computation theory, and evolution theory to better understand the fabric of reality.

Perhaps there is no better word to capture the spirit of synthesis than consilience, a term originally coined by British philosopher William Whewell in the mid-nineteenth century, but popularized by E.O. Wilson (1998) in his best-seller Consilience: The Unity of Human Knowledge. Consilience literally means “jumping together of human knowledge” and is used widely to refer to the unity of human knowledge in the conceptual realm.

One such consilience effort was made by Anne Buttimer (2002), who argued, with compelling evidence, that most models or theories in geography are conceptually motivated by four metaphors or analogies: the world as forms, the world as machines, the world as organisms, and the world as spontaneous events. Inspired by Buttimer’s work, Sui (2011) further argued that most urban models developed so far are drawing from these four metaphors as well – cities as forms, cities as machines, cities as organisms, and cities as spontaneous events.

Narratives and metaphors are certainly not confined to synthesis in human geography only. In fact, physical geography (and Earth sciences more broadly) is full of stories as well. Phillips (2012) found that recent Earth science literature followed eight predominant story lines (cause/effect, genesis, emergence, metamorphoses, destruction, convergence, divergence, and oscillation) in explaining the Earth surface evolutionary processes. Physical geographers may strictly follow a scientific approach but the scientific questions they pose are more or less dictated, consciously or subconsciously, by those metanarratives (or archetype story lines).

Synthesis through quantitative and mapping approaches: from overlay to mash-up

Besides the qualitative/narrative approaches, quantitative/modeling approaches are also important means for synthesizing information, ranging from regression models to multicriteria evaluation to Bayesian modeling. The growing
literature on space–time integration represents geographers’ systematic effort to synthesize information across both space and time using a variety of quantitative methods and techniques (Dijst 2013).

Also, with growing importance, synthesizing vast amounts of information is taking place through mapping vast amounts of digital geocoded information. The first decade of the twenty-first century saw the explosive development of Web 2.0 technologies along with major advances in geoweb and geospatial technologies, including traditional geographic information systems (GIS), remote sensing (RS), global positioning systems (GPS), and location-based services (LBS) to reach an unprecedented moment in human history: we can now know where nearly everything, from genetic to global levels, is at all times. These technological advances can be brought to bear on the corresponding data avalanche – the vast amounts of user-generated content and volunteered geographic information (VGI) that pours out as individuals become sensors, gathering and disseminating data about their environments and themselves with increasing spatiotemporal granularities. These vast amounts of big spatial data are also increasingly linked, otherwise known as the vinculation, which has greatly facilitated a more sophisticated level of synthesis work.

Many forms of synthesis in the context of online digital information can be described as mash-ups. Borrowed from the music industry, the term originally refers to a song or composition created by blending two or more songs. Yet in the context of web-based applications, a mash-up may have multiple meanings. At the functional level, a mash-up may be a web page or application that combines data or functionality from two or more external sources to create a new service. In terms of actual content, a mash-up can be a digital media file containing a combination of text, map, audio, video, and animation, which recombines and modifies existing digital works to create a derivative work. The term implies easy, fast integration, frequently using open application program interfaces (APIs) and data sources to produce something new. A growing number of industry leaders, such as Google, Microsoft, Yahoo, Mapbox, and Cartodb, have developed APIs that users are adapting to develop their own creative applications. But mash-up is much more than a technical advance, and we believe that the true significance of mash-up lies in its potential promotion of a new habit of mind towards synthesis.

When mash-up is used to integrate multiple sources of data based on shared references to the same geographic locations, the operation is conceptually related to the traditional GIS function of overlay, a type of spatial join, although the technical processes are quite different. Pioneers such as Manning, Dusseldorf, Lewis, and McHarg used manual overlay methods to integrate multiple layers of information, in order to develop a comprehensive understanding of spatial patterns and relationships (Elwood, Goodchild, and Sui 2012). Better integration and synthesis of diverse sources of georeferenced information were a top priority during the early days of GIS development in the 1960s and 1970s. However, spatial analysis has been at the forefront in GIS during the past 20 years, with a primary focus on improving spatial-analytic functions. The spatial analysis tradition often took a reductionist approach, focusing on individual layers to identify spatial patterns, rather than on the synthesis of multiple layers. We contend that the growth of mash-up practices in the age of Web 2.0 is revitalizing an interest in synthesis in GIS. Mash-up, as both a concept and a practice, resonates well with the traditional spirit of geography in its quest...
INFORMATION SYNTHESIS

to understand the multidimensional nature of
the Earth’s surface. Although often couched in
different terms (e.g., data conflation, data fusion,
or data integration), geographers, in general,
and GIScientists, in particular, have developed
a considerable number of useful techniques for
synthesizing data from multiple sources. Soft-
ware tools, such as Microsoft’s Photosynth, IBM’s
ManyEyes, HistoryFlow, and TouchGraph, can
further facilitate the synthesis of data in diverse
media.

Admittedly, synthesis is much more chal-
lenging than analysis from a methodological
perspective, due to its involvement with data
in multiple formats and media (number, text,
oral story, photo, video, simulation, etc.). Geog-
raphers’ current efforts to develop a more
eclectic approach by linking diverse quantitative
and qualitative methods may be tapped for
VGI applications. Unlike the spatial analysis
of a previous era that was often conducted by
a lone analyst, synthesis of VGI tends to be
much more participatory, through a mixing
and remixing of multiple data and methods,
as demonstrated in VGI applications in several
recent disaster-relief efforts. Instead of seeking
truth, the new mash-up efforts focus more on
developing narratives about various locales.

Synthesis by crossing
the qualitative–quantitative chasm

The interdisciplinary nature of geography itself
can foster a methodological synthesis in the
mixing of qualitative and quantitative meth-
ods, and recent work features sophisticated
mixed-methods approaches that cross the divide
between spatial-analytical and social-critical
approaches in human-geography research (Sui
and DeLyser 2012), revealing the binary between
approaches as pseudo rather than real. Critical
geography need not be qualitative and can use
numbers – after all, Karl Marx used quantitative
methods extensively in his work. As Elwood
(2010) points out, thoughtful mixed-methods
research must bridge not only methodologi-
cal but also epistemological and philosophical
divides. “Cherished theoretical principles”
may “become renegotiated” – and Bergmann,
Sheppard, and Plummer (2009, 265) seek noth-
ing short of a “methodological reinterpretation
of what employing mathematical arguments
could mean within larger, postpositivist theoret-
ic projects in critical human geography.”

Mixed-methods research offers human geog-
raphers the opportunity to identify the appropriate
role for different methods and, in transport
geography, to explore how context affects
human travel behavior. Zolnik (2009) devel-
oped a multilevel, mixed-methods approach to
address some of the criticisms of quantitative
methods in transport geography, revealing that
quantitative modeling (at a single level) can
complement qualitative analysis (across multiple
levels). Goetz, Vowles, and Tierney (2009)
examined recent transport-oriented research in
highly cited geography journals, revealing that
geographical research on transport topics is much
more prevalent and (though often influenced by
civil engineering approaches) reflects a wider
range of epistemological and methodological
approaches than frequently assumed, propos-
ing a critical-transport-geography research
agenda that calls for a more seamless integration
of qualitative analysis into the predominant
quantitative-modeling approach.

Perhaps most dramatic in mixed-methods
research in human geography is the development
of qualitative GIS (Aitken and Kwan 2010),
which, along with participatory GIS, feminist
GIS, and critical GIS, works to reconceptualize
GIS as more than only quantitative in terms
of data, analysis, and representation. Emerging
in response to critiques that characterized GIS
as rooted in positivist epistemologies and most suited for quantitative techniques associated with the discredited spatial science, qualitative GIS reveals that GIS, from its inception, “has been more than quantitative” (Cope and Elwood 2009, 171). Using mixed, or hybrid, methods in representation, mode of analysis, and conceptual engagement, qualitative GIS embraces noncartographic forms of data, qualitative analysis, and multiple modes of representation (Cope and Elwood 2009).

Knigge and Cope (2009) show how the inductive, iterative analysis practices of grounded visualization can engage scale in GIS as both a cartographic representation and a sociopolitical construction. Elwood (2009), drawing from her work related to grassroots GIS practices, demonstrates how cartographic representations generated in a GIS might be engaged to produce multiple and different understandings of neighborhood, negotiating the meanings and characteristics associated with neighborhood as flexible and fixed, and engaging them as both material and imagined space. Aitken and Craine (2009) show how a nonrepresentational reading of GIS-based representations can illuminate greater insights into affective and emotive politics than more traditionally technical readings. Indeed, the boundaries between qualitative and quantitative are not so clear-cut and are often crossed and synthesized these days. Most recent work in the broadly defined spatially integrated social sciences and humanities embodies the spirit of synthesis at data and methodological level. Kraak’s (2014) book is a remarkable success for location-based storytelling, in which he artfully synthesized historical and geographic analysis with cartographic visualizations and fascinating historical narratives about Napoleon’s Russian campaign of 1812.

Information synthesis: assessment and educational challenges

Cognitive psychologists have suggested that synthesis, rather than analysis, is the defining characteristic of human creativity (Wallace and Gruber 1989; Gardner 2009), and there has been a turn towards synthesis in multiple disciplines in the age of big data. Geography is uniquely positioned to lead this new wave of synthesis with respect to geographic information due to its traditional emphasis on synthesis.

The goal of information synthesis is to bring together disparate information in order to develop a more complete and comprehensive understanding of the situation or problem at hand. Synthesis can be transdisciplinary, but also is domain specific. Contingent upon the topic and mission, what is considered as a good synthesis in one area may be inappropriate in another area. Synthesis normally involves creative leaps, and creativity typically entails synthesis – one type or another (sometimes colloquially known as “connecting the dots”). For analytical results, multiple qualitative and quantitative measures have been developed to assess their effectiveness and validity. Unlike analysis, assessment on the quality of synthesis can be tricky. Although synthesis is normally desired, there is no a standard set of criteria and protocol to assess the quality of synthesis. It is still an ambivalent business to decide when a productive synthesis has been accomplished, as opposed to when the proposed synthesis is premature, misguided, or even fundamentally “wrong-headed” (Gardner 2009).

Generally speaking, quantitative synthesis can be evaluated and replicated better than qualitative synthesis (assuming all the data used in the synthesis work are made available). The assessment of qualitative synthesis is a bit more challenging.
INFORMATION SYNTHESIS

Sometimes, superficial synthesis by simple juxtaposition and lumping can be easily spotted, but problems for qualitative synthesis can run much deeper because, during the synthesis, concepts can be misleading, metaphors can be deceptive, and theories can be misguided. On top of all of these, a variety of technologies and tools are used these days in synthesis related to big data. The enframing nature of technologies has further exacerbated the hidden biases embedded in the process. For example, quite a bit of synthesis work using social media data (such as Twitter) has been reported in recent years to infer social, political, health, and consumption trends, and yet social media data such as Twitter are normally very biased to begin with (e.g., only a very unique subset of the population tweet on a regular basis), and currently we do not have a good set of tools to handle such hidden biases, which will ultimately affect the quality of the synthesis work.

The difficulty in assessing the quality of synthesis work poses serious educational challenges in terms of how and what our students should be taught to do a better job in synthesis, with the ultimate goal of achieving creativity in whatever they do. The coverage on synthesis in the literature is rare because synthesis as a method is often incorporated subconsciously into the process of an intellectual endeavor. What was tortuously achieved by hard work can only be shared by intuition, so obvious and omnipresent that its provenance is hard to track. Indeed, scholars rarely write about synthesis because most of them write with it.

As Isaiah Berlin (1993) described so eloquently in his classic The Hedgehog and The Fox, all writers and thinkers throughout human history can be divided into two categories: hedgehogs, who view the world through the lens of a single defining idea (examples given include Aristotle, Shakespeare, Montaigne, Goethe, Pushkin, Balzac, and Joyce). Cognitively, Berlin’s hedgehogs and foxes can be related to Gardner’s (2009) laser intelligence versus searchlight intelligence. Laser intelligence probes deeply into a topic but ignores opportunities to cross-pollinate, which is often best suited for work requiring discipline. On the other hand, searchlight intelligence may not probe as deeply but is always scanning the environment and may, therefore, more readily discern connections (and identify differences) across spheres. Both hedgehogs with laser intelligence and foxes with searchlight intelligence may have the proclivity to synthesize, but the contents that they synthesize and the criteria for success may differ widely. It remains a challenge for educators to develop effective strategies and methods of teaching synthesis for both hedgehogs and foxes. Most pedagogic materials developed in geography and GIS are still focusing on analytical skills despite the importance of synthesis skills.

Summary and conclusions

Like spatial analysis, information synthesis is an integral part of geographical scholarship that transcends subdiscipline specializations. Indeed, analysis and synthesis are two inseparable aspects of a holistic geographic methodology. Analysis and synthesis always go hand in hand; in most cases, they complement one another – there are important situations in which one method can be regarded as more suitable than the other. Meaningful synthesis is built upon the results of preceding analysis, and meticulous analysis...
makes more sense only when a subsequent synthesis is achieved. Successful geographic research typically rests upon an artful combination of analysis and synthesis.

In this entry, a broad survey on why, what, and how to conduct synthesis in geographic research has been presented. Hybridizing, remixing, and mashing up conceptual frameworks, data sources, and modes of analysis in the spirit of synthesis, as some of the most recent works have revealed, may provide the best hope to cross the methodological and epistemological chasms that have divided geographic and GIScience research. Although the adoption of multiperspectivalism can enhance one’s proclivity to synthesize, the difficulties of synthesis should not be underestimated. Meaningful synthesis is harder to achieve than analysis and the quality of synthesis is also often difficult to assess. As Wyly put it, “how can we ever find the time to master the dizzying array of traditions and techniques required to create truly hybrid geographies, without giving up the depth that comes with specialization in social theory or spatial econometrics or feminist ethnography or participant observation or policy analysis or the list goes on?” (Wyly 2009, 319). Even institutional culture often discourages transdisciplinary research. And yet, as Turner (1989) argued, neither has a single-minded analysis nor synthesis approach served the discipline well. Instead, a balanced analysis–synthesis approach adapted in each new situation may prove to be the most effective methodological framework in the age of big data.

Information technology and mobility

Tim Schwanen
University of Oxford, UK

Transportation and information technologies (ITs) are two sides of the same coin: both have been developed and are deployed to overcome the friction of distance. When drawing and writing were invented, transportation and communication began to be disjointed but they only become separate domains with the diffusion of telegraph, telephone, radio, and television. The advent of the information age has accelerated this process of separation. At the same time, digitalization and computerization have also multiplied the intensity and complexity of linkages between ITs and transportation.

Geographers have examined the spatiality and geographical implications of those linkages since at least the 1960s. Analytically inclined transport and urban geographers have undertaken the bulk of research, but geographers working on “mobilities” have also made important contributions. Spatial-analytical research has, from the start, been preoccupied with the promise of “substitution” of physical movements of people and goods by interaction-at-a-distance via landline telephones, wired computers, and wireless devices. This is unsurprising, given that substitution has long been considered the most desired outcome by transportation planners seeking to reduce congestion, productivity and monetary losses, adverse environmental effects, and transport poverty. Since the mid-1980s, however, geographers have argued that a wider range of relations among transportation and ITs should be considered. Salomon (1986) argued that direct impacts “resulting from a change in the relative use of the two technologies” (page 223) should be distinguished from long-term indirect impacts of IT use on transportation via changes in the spatial organization of activities and land use. Among direct impacts substitution is certainly not the only possibility. Generation may also occur: more IT use for communication purposes can induce more transport activity and vice versa. Moreover, ITs can be used to improve the operational efficiency of transportation systems, and ITs and computer code are now indispensable to the functioning and optimization of any system for motorized transportation. This is perhaps most evident for freight transport and logistics, where information sharing is widely used in supply chain management and IT-enabled decentralized intelligence – the localization of decision making on routing – is believed to create further efficiency enhancements in the near future. Whether efficiency increases reduce transport volumes is a moot point. Evidence is scant to date, but rebound effects in the form of more travel across longer distances may be quite common.

Salomon’s taxonomy of interactions has proven influential; numerous studies in passenger transport have sought to establish which type of impact prevails, when, where, and in what circumstances. The effects of teleworking on commuting and non-work travel have been examined most widely, although the past decade has witnessed greater attention to the transport implications of e-commerce, online leisure, and videoconferencing. Results vary across studies and are difficult to generalize; whether IT
use substitutes, modifies, or generates transport activity varies spatially and depends on the specifics of place. It nonetheless appears that (modest) substitution of passenger transport is the most common net effect. The traditional focus on substitution has diminished somewhat over the past decade; however, the need to reduce greenhouse gas emissions from transportation at a time of unabated growth of global transport volumes – particularly long-distance travel – keeps fueling the hope for significant substitution of physical transport by IT use. Resilient optimism regarding IT’s substitution potential can also be observed among freight transport researchers and stakeholders.

Analytically inclined geographers have also moved beyond questions of substitution of passenger transportation. Drawing on time-geography, they have examined how individuals’ IT use displaces time for offline activities (and vice versa) and relaxes space-time constraints on activity/travel practices. Discarding the “death of distance” hypothesis and the idea that ITs allow everything to be done everywhere, they have shown that space, time and activity are only partially decoupled and that the constraint-relaxing effects of ITs are dependent on place-specific social and cultural contexts. Mei-Po Kwan and colleagues, for instance, have shown that differences between men and women in activity/travel practices and space-time constraints are hardly reduced with the advent of the internet and mobile phone because the effects of IT use are mediated by place-specific gender regimes (Schwanen and Kwan 2008).

The geographies of everyday activity/travel practices are nonetheless changing in many ways. First, activities are being “fragmented” (Couclelis 2004): ITs afford people the opportunity to disaggregate activities that previously were conducted in specific places and times (e.g., shopping) such that they are disassembled into smaller bundles that can be carried out in other places (at home, on public transport, etc.), at other moments (outside store hours), and in alternative sequences (e.g., online information search, experience the product in a store, buy it online, receive at home or at a collection point). Consequently, the “contact set” of locations that are contacted physically or via electronic mediation will expand; more agents and stakeholders may participate in the activity; and the timing, destination, and length of physical trips may change. Second, ITs have greatly facilitated multitasking, allowing people to do multiple things simultaneously (e.g., work aboard a train) or switch continuously between activities (e.g., gaming on a mobile device and watching TV). According to many commentators, IT-enabled multitasking may increase people’s willingness to travel in general and as a passenger in particular. This can increase the attractiveness of sustainable transportation modes (e.g., public transportation) but may also increase travel distances, congestion, and greenhouse gas emissions. To date, however, there is only limited empirical evidence and further empirical research is clearly required. Third, IT technologies have boosted the rise of “personalized networking” (Wellman 2001): social relationships are now increasingly person based rather than territorially based, with social media allowing individuals to create their own unique networks for informational and emotional support, sociability, identity formation, and to satisfy belongingness. This may generate more social travel – particularly over long distances – but robust empirical evidence is again scant.

The effects of IT technologies on social networks have also been studied by mobilities scholars. Part of their argument is that IT devices and competencies contribute to individuals’ “network capital” (Urry 2007) to support “mobile lives” – everyday activities
and identities organized around modern and fast transportation and communication systems and characterized by individuality, flexibility, adaptability, and reflexivity (Elliott and Urry 2010). “Network capital” refers to individuals’ capacities to enter into and maintain beneficial social relations at-a-distance through digital and physical mobilities. For Urry this capital produces new social hierarchies alongside, for instance, gender, class, and race/ethnicity. Like other mobility scholars, he draws attention to the ways in which the physical and digital mobilities of certain individuals “immobilize” others. This is because the mobility of the former is made possible by place-based workers who ensure the smooth functioning of mobility systems (from airport baggage handlers to mobile phone company helpdesk workers in countries and regions with ample cheap labor), cleaning and hospitality staff, and other service sector employees.

The work by Urry and other mobility scholars also shows how physical mobility and IT use coalesce into complex hybrids so that mobility practices are intensely and often iteratively coordinated with others using mobile devices; rescheduled on-the-fly; and adapted in response to real-time information from “formal” sources, such as transportation system managers and service providers, and informal expertise provided by fellow users via Twitter and specialized smartphone applications. The experience of being on the move is changing accordingly. There is some evidence to suggest that the coalescence of physical and digital mobilities into hybrids increases a sense of security and comfort but further research on this topic is required.

In short, the interrelations of IT use and physical mobility are changing rapidly. Further research that critically examines the conjectures of academics, the media, and others about those interrelations is therefore desired, and working with young people as frontrunners in the adoption of new ITs and with stakeholders in the freight sector is advisable. However, given that IT use and physical mobility are refracted through place-specific social and cultural contexts and (re)shape sociospatial inequalities, it is equally important to examine empirically who – which individuals, social groups, and economic activities – and which places gain and lose because of changing relations between transportation and IT. The political potentials of the changing inter-relations of transportation and IT also deserve critical attention: developments in smartphone technology are expanding the opportunities for public participation in the governance of transportation systems through crowd sourcing, citizen science, and other initiatives. Perhaps this offers greater potential to make transportation systems more efficient and sustainable than the decades-long quest for substitution of physical transportation by digital mobility.

Infrastructure and everyday life

Heather Chappells
University of British Columbia, Canada

Background

Infrastructure can be understood as the physical and organizational structures and facilities (e.g., buildings, roads, power supplies, water systems, telecommunication networks) needed for the operation of a society. More than systems of technical hardware, infrastructures embody the rules, standards, norms, and protocols of their structuring institutions and societies. Access to infrastructures enables personal and societal mobility through the circulation of goods, services, knowledge, people, and power. At a macroscale, infrastructures are of key importance for the security of national and global economies and for societal functioning and wellbeing. Critical infrastructures include those that provide services vital to national security, such as energy, water, transportation, and telecommunication systems. Such large technical systems dynamically evolve in accordance with shifting societal and political priorities. Calls for global, national, and regional integration have seen the scale, reach, and interdependency of infrastructures increase. Integration has improved network coordination and service efficiencies but also increased the potential for economic and social disruption from cascading failures. As more infrastructures come under the control of private companies rather than being managed as national assets, the meaning of strategic and sustainable management has shifted, bringing new social and environmental challenges. New flexible and mobile configurations of infrastructure, as seen in the digital convergence of telephony and other media, can both empower and marginalize consumers.

Infrastructure networks support everyday life in the realms of home, work, and leisure through facilitating an array of differentiated service needs. The power we use in our homes, the water we drink, the transportation that moves us, and the communications that connect us form the backbone to everyday life. Central as they are, the criticality of these background networks may rarely be reflected on by those living in industrialized nations. The extent of everyday human reliance on critical infrastructures is highlighted primarily at times of disruption and breakdown, including power cuts, gridlock, and drought. At such moments the sociotechnical resilience embodied within different infrastructural arrangements is exemplified through differentiated opportunities for individual and institutional adaptation, such as utilizing backup systems or modifying demand to meet changing conditions. In the context of climate change and resource scarcity, understanding the scale of potential future disruption and the potential for adaptation in everyday life takes on a renewed sense of urgency.

Scholarly interest in infrastructure and everyday life transcends many disciplines, including geography, sociology, science and technology studies, anthropology, political economy, history, and urban planning. Within these diverse fields, infrastructures have been variously represented as simple technical networks for the delivery of...
INFRASTRUCTURE AND EVERYDAY LIFE

resources, politically defined conduits for the structuring of power relations, and sociomaterial assemblages through which citizen and provider roles in resource management are reproduced. Specific topics and themes reflect macro- to microscales of interest, from understanding the role of large systems in constituting the underlying fabric and flow of urban life, to exploring the local–global interfaces between infrastructure networks or their role in the microstructuring of household routines. How infrastructure shapes institutional dependencies, social inequalities in resource access, and differentiated capacity to respond to crises have been other recurrent themes.

Multiple configurations of infrastructure

Different social, political, and cultural factors have shaped the development of infrastructure networks. Bearing in mind that historical timescales and geographical reference points are fluid, three predominant modes of urban infrastructure development can be discerned. Each mode is associated with distinctive technological, spatial, and social arrangements that reflect shifting political ideologies and changing relations between consumers and providers.

The establishment of early infrastructure networks has been described in terms of a deliberate manufacturing of demand, with the construction of infrastructures to meet emergent new service needs. For example, lighting was one of the first services developed in the electricity sector but this was only needed after dark, so utility providers sought to design other services to spread demand out over the entire day and justify the cost of infrastructural investments. In the context of Britain, early twentieth-century utility networks have been described as localized and piecemeal, with many small networks emerging to meet different user needs for services such as lighting, heating, drinking, bathing, sewage, and solid waste disposal (Graham and Marvin 1995). This patchwork of local systems also produced differentiated user experiences in terms of standards of supply and prices, with service disruption a common occurrence.

A second major configuration of infrastructural development refers to a large-scale expansion, consolidation, and standardization of networks and services, usually at a national scale. Early examples are the expansion of British and American railroads in the nineteenth century to facilitate trade and promote national unity across regions and territories. This required both technological standardization of equipment (e.g., engines, track gauges, signaling) and sociopolitical innovation (e.g., federal regulation, standard time systems, and operating protocols) (Edwards 2003). Later developments during the mid-twentieth century saw energy and water planners in Britain and other industrialized nations use demand models and projections to determine future infrastructural requirements for national economic growth. This “predict and provide” approach to infrastructure planning justified the construction of large-scale reservoirs, networks of power stations, and integrated grids of cables, pipes, and wires sufficient to meet universal demand. In the context of Britain, Graham and Marvin (1995) describe an era of Fordist consolidation with the development of integrated networks operated by large centralized organizations, including nationalized public utility companies. Within this integrated model consumers were positioned as the mass recipients of undifferentiated resources, standardized services, and unlimited supply. Large-scale integration and uniformity of service generally have less saliency in the Global South, where many consumers remain off-grid even today (Edwards 2003).
A third mode of infrastructural development reflects new priorities of political, economic, and environmental restructuring, within what has been termed a market-environmentalist regime (Bakker 2005). Infrastructural unbundling is a key feature of this developmental mode, with previously integrated elements and functions being separated and reorganized to facilitate privatization and competition. In contrast to the centralized, homogeneous, and unified character of large nationalized networks, infrastructures today are heterogeneous and diversified. This heterogeneity may be manifested in new physical grid arrangements, but more often involves restructuring and coordination at an institutional or virtual level. Advances in communication technologies, including smart grids and meters, enable new service configurations that are laid over existing infrastructural arrangements. The supplementation of traditional landline telephony services with satellite and cellular services offered by multiple providers to meet the needs of diverse customer segments is one example of this reordering.

Within this third infrastructural orientation the focus is on managing differentiated consumer service needs rather than meeting universal requirements. The rolling back of universal service provision under market-based regimes has been associated with the intensification of social and spatial inequalities in access to utility services. As national monopolies and public service providers have been replaced by multinational and privatized utility companies, consumer rights to resources and services have been renegotiated. Concurrent processes of social dumping of marginal customers and cherry-picking of lucrative customers have been highlighted in England and Wales in the context of the energy and water privatizations of the 1980s and 1990s, with prepayment meters implicated as a utility-based tool for policing of access to basic services (Guy et al. 2011). Elsewhere in the world, violent disputes over the takeover of local public utility services by transnational corporations have been well documented, as in the struggles of Bolivian water users against water concessions in the city of Cochabamba, or resistance to the use of prepayment meters for electricity and water services in the townships of South Africa.

Infrastructures in interaction with everyday life

Infrastructures are macroscale constructions but also exist at the microscale of the household or workplace where they are implicit in the regulation of everyday life (Shove, Trentmann, and Wilk 2009). Networks enable spatial and temporal ordering and the synchronization of daily interactions that may serve to regulate the lives of citizens through supporting or prohibiting particular activities (Shove, Trentmann, and Wilk 2009). The scheduling of national railways in nineteenth-century Britain and United States required the coordination of regions and activities to standard rather than local time. Later, electrification programs enabled the reordering of activities, which were no longer confined to daylight hours as a result of advances in lighting. Global accounts of drinking-water access further reveal the mediating power of institutions through specific configurations of infrastructure, as in the West Bank where Israeli control of aquifers and piped-water networks has historically served to regulate the flow of water to Palestine. Such situations exemplify how infrastructures are sociopolitical entities supporting power relations through physical entrenchment in material arrangements.

Consumers are not passive recipients of infrastructures but actively shape them. Consumer resistance to emergent infrastructural...
INFRASTRUCTURE AND EVERYDAY LIFE

arrangements has been well documented, as in the aforementioned cases of Bolivia and South Africa. The coordinating role of infrastructures in relation to the modifying role of consumers engages with a fundamental debate in the social sciences concerning the relative role of agency (individual choices) and structure (social and institutional rules and resources) in defining everyday life. Under a universalizing mode of infrastructural development, users have been depicted as passive recipients of undifferentiated goods and services. The dominant market-environmentalist discourse, which underpins contemporary infrastructure arrangements, points to a more active role for consumers in differentiating between service options and providers. Sociologists and geographers have debated this point, demonstrating that collective sociomaterial influences can be just as important as individual choices in shaping consumer practices. This argument is particularly relevant with respect to forms of consumption that are delivered directly via physical infrastructures, such as energy and water grids, which render the home both a private and a public space (Gronow and Warde 2001). This structuring role of institutions is evident in situations where utility providers have exerted control over resource use at times of energy crisis or drought. Recent contributions from sociology, anthropology, and cultural geography offer deeper insights into the engagement of infrastructures within the cultural and material geographies of the home. It has been observed, using the example of energy, that resources are not directly consumed but are used to provide a range of domestic services, such as lighting or comfort, the meaning of which is culturally and materially defined (Shove 2003). Decisions about how to heat or cool a home, or provide a particular ambience, are thus influenced by cultural and collective ideas about domesticity and coziness, as much as by functionality or efficiency. They are also assisted or thwarted by existing material infrastructure arrangements. This can help to explain why seemingly irrational household behaviors persist, as where people continue to use open fires for coziness or retain incandescent lights for a softer glow, when more energy-efficient options are available.

Implications for sustainable infrastructures and the reordering of everyday life

Understanding the way in which infrastructures and everyday life interact takes on a new urgency in the context of contemporary concerns about promoting environmental sustainability and adapting to climate change. Predominant policy approaches to the greening of household consumption have tended to prioritize the agency of individuals as the key to managing resource-intensive lifestyles, as exemplified in the multitude of programs to encourage people to make environmentally conscious lifestyle choices. This approach has had some impact on the intensity of resource use, but it has not tackled trends supporting less sustainable living arrangements, such as increases in house size or more single-person households. The development and diffusion of new kinds of consumer goods, and the global convergence of Westernized comforts and conveniences such as air-conditioning, have further contributed to increasing resource demand. Given the ongoing reproduction and escalation of resource-intensive ways of life, it has been observed that making consumers aware of environmental concerns is not always enough to redefine expectations or break unsustainable habits (Shove 2003). What may be required is a totally new way of thinking about the services that infrastructures provide, people’s cultural attachments to them, and the
alternative sociomaterial arrangements through which they might be met.

The concept of *coprovision* has been utilized to evaluate the relative agency of individuals in relation to the environmental modernization of infrastructures (Vliet, Chappells, and Shove 2005). Within this framework, citizen-consumers are viewed as active partners in reconfiguring utility services, while they are, at the same time, structurally constrained by the different collective sociomaterial arrangements they encounter. An example of new coprovision arrangements is the trend toward the decentralization of infrastructure networks observed in the context of microgrid development. These new infrastructural arrangements can radically reconfigure established relations between consumers and service providers, as in cases where households construct their own minigrids to harvest rainwater or generate renewable energy on-site. Such local infrastructure arrangements further transform space and the ordering of everyday life through establishing proximity to resources and imposing local limits on resource availability that are not necessarily apparent when services are delivered through large-scale centralized grids. These new sociomaterial arrangements have reopened questions first raised in the 1960s about the appropriate scale for infrastructure as a means to promote environmental sustainability and facilitate sociotechnical resilience. However, rather than being framed in terms of finding the optimal system scale, new infrastructural arrangements are seen to offer coexisting sociotechnical trajectories that can produce multiple, flexible, and sustainable reorderings of everyday life.

In countries where centralized access has never been universally available or accessible, localized infrastructural arrangements at a household or community level are often the norm. In the context of intensifying resource shortages and health concerns in developing regions, there has been renewed interest in providing infrastructural solutions that are both sustainable and adapted to local needs. A key message of studies of technological diffusion is the need for culturally adapted innovations that fit within the distinct material geographies of home and utilize local distribution networks (Akrich 1992). For example, in India attempts to diffuse new types of cookstoves based on more efficient and healthier fuel sources than biomass, such as kerosene, have only been partially successful. It has been observed that, if a modern distribution system is not in place, households cannot obtain access to alternative fuels, even if they can afford them. Furthermore, the availability of energy-using equipment is just as important as the affordability of fuels in the switch away from biomass. Moreover, cultural traditions are found to determine household fuel choices regardless of fuel availability and income, as where some affluent Indian households keep a biomass stove to prepare bread in a traditional way. Difficulties in adapting new technologies to incumbent sociotechnical arrangements may thwart the adoption and uptake of infrastructural innovation, but there is also evidence that more flexible arrangements can act to empower citizens. The rapid rise of mobile telephony in Africa since the early years of the twenty-first century serves as an example of how new configurations of infrastructure can act to empower citizens and enable social change. In a region with limited landline network coverage, mobile phones, cellular service, and prepaid financing options have proved to be a flexible and popular communication option. While service inequalities still exist, mobile telephony has improved communication between those living in rural and urban areas, reduced the need for travel, and provided access to services such as banking from which many citizens were previously excluded.
Critical infrastructures, disruption, and resilience

Disruption can provide further insights into the tenuous and dynamic relationship between infrastructures and the organization of everyday life and reveal options for restructuring in the context of calls for sustainability and resilience. It has been asserted that greater material and technological dependence has increased the risk of breakdowns in everyday life and that the increased sophistication and complexity of networks reveal the possibility of systematic and cascading failure in critical infrastructure (Trentmann 2009). In this respect, it is important to consider where the points of criticality lie within current infrastructural arrangements and how institutions and governments might reconfigure systems to be adaptive to these challenges. As recent blackouts have shown, relying on air-conditioning for comfort is not a robust solution during heat waves when electrical networks are already overburdened. In such situations more creative and innovative social and cultural adjustments, such as the Cool Biz campaign in Japan, focused on adaptations in clothing, or “forced” vacations and homeworking may offer solutions that are both socially and technically resilient to changing conditions.

Drawing on the lessons of coprovision, more fluid and flexible arrangements, including more decentralized grids and local backup systems, may offer further adaptive opportunities where large-scale interconnected networks fail. In this sense, lessons might be learned from the history of infrastructure development and the relative flexibility that different sociotechnical arrangements have embodied for providers and consumers at past points of criticality. Solutions that are adapted to the local context and to the needs and expectations of different consumers are also highlighted from a sociopolitical perspective. For example, appeals to citizens to curb energy use, as successfully utilized in the 2001 California energy crisis, have been resisted in situations where citizens have viewed continual access to resources as a right. In this context, renegotiating the entitlement to universal service such that consumers are willing to practice demand-side management at times of acute need might be required, while ensuring that those most in need of essential services maintain access. From a geographical perspective, certain places and people are also more likely to be affected by infrastructural breakdown, as illustrated in the Chicago heat wave of 1995, when social infrastructure and neighborhood environment dramatically shaped adaptive capacity, with the most isolated members of society struggling the most to adapt. Such cases have highlighted the need to address inequalities in access to service provision and the importance of building community-scale resilience that is inclusive of all sectors of society.

Finally, it has been observed that no one mode of infrastructural configuration is likely to guarantee smooth flow and universal access at all times, and that the rupture of routines is a perfectly normal feature of human society (Trentmann 2009). From this perspective it is instructive to reflect on the purpose of infrastructure within the realm of everyday life, and on what resilience and sustainability actually mean from a sociocultural as well as an engineering vantage point. This approach might reveal alternative system configurations that respond to variable user requirements for continuity or discontinuity of service, as where industry is asked to shut down systems during times of energy crisis, rather than follow a more traditional approach of building more robust but ultimately unsustainable systems to meet every need and eventuality. This line of argument supports a view of infrastructures not as providing resistance to floods, droughts, or power outages through
material reinforcement, but as embodying fluid resilience that encompasses socially and culturally appropriate modes of adaptation.

Infrastructure and regional development

Kingsley E. Haynes
Zhenhua Chen
George Mason University, USA

Definitions

First, infrastructure is defined as the basic physical and organizational structures that provide support for the economy and society to function, and is divided into two categories: (i) physical or economic infrastructure and (ii) soft infrastructure, also referred to as social overhead capital (Haynes and Nijkamp 2006). The first includes all kinds of capital facilities such as buildings, water and sewer systems, road networks, railway and air transport, and telecommunications. The second includes parks and recreation areas, open spaces, social welfare support, education facilities, and health and hospital systems. Infrastructure contributes to regional development by facilitating mobility and communication and providing the physical and social underpinnings that improve the quality of life.

Regional development is, however, a different concept, which encompasses a range of objectives and concerns, centered around goals of enhancing the base of jobs, income, and business activity in a region. Its scope includes the process and policies by which a region improves the economic, political, and social wellbeing of its people (O’Sullivan and Sheffrin 2003). The term includes institutional shifts that vary between short-term concerns and long-term strategies to improve regional function and social and economic wellbeing.

Infrastructure is central to the support of high-density environments and, hence, underpins regional agglomeration and urbanization. Everything from water and wastewater services to transportation are central to infrastructure investments. Infrastructural investments are strongly concentrated geographically in urban areas with interregional infrastructure connecting cities and regions and connecting urban centers to labor, energy, water, materials, and so on. These considerations link the discussion of agglomeration economies and productivity with the drivers of urbanization.

Infrastructure plays a vital role in promoting regional economic development. All levels of government and international organizations invest heavily to improve infrastructure to facilitate economic activities. Every year the World Bank provides a large amount of financial support to developing countries in order to help them build infrastructure and promote regional development. In the past decade, China has experienced a rapid expansion of massive transportation infrastructure with strong central government support. A national high-speed rail network with a total distance of over 17,000 km has been built to boost regional economies. In the United States, infrastructure investment is one of the major policy instruments being examined to stimulate economic growth and development. During the great recession in 2009, US$30 billion was dedicated to infrastructure investment in the American Recovery and Reinvestment Act of 2009 with the purpose of stimulating economic recovery and job creation.
INFRASTRUCTURE AND REGIONAL DEVELOPMENT

Mechanisms

How does infrastructure facilitate regional development, and what are the linkage mechanisms between infrastructure and regional development? To answer these questions, one should note that the influence of infrastructure on regional development varies during different periods in its life cycle. During the construction period, its impact on regional development is achieved through capital expenditure and resource accumulation. The need for labor and capital input drives the expansion of consumption which promotes the growth of gross regional product. Since economic output depends heavily on factor inputs, the impact of infrastructure investment on regional development is relatively immediate and short-term through reducing the costs of factor input accumulation and agglomeration support to increase productivity.

After completion of an infrastructure project, its contribution to regional development is more likely to be achieved through network and spatial spillover effects. For most infrastructures, such as road, railway, airport, and broadband, regional connectivity and accessibility are normally achieved after network completion. Regional development is thus expected to occur at multiple locations along the network through spatial spillover effects. The decline of mobility and communication costs further facilitates economic activities through the increase of both demand and supply and the support of specialization. Gross regional product and the employment rate are thus expected to increase.

Impact assessment

To empirically assess infrastructure’s impact on regional development is not an easy task. The assessment has to be based on economic and geographic analysis and is subject to data availability. While the impact assessment of infrastructure can be conducted in various ways, the following economic theories have been most widely applied: neoclassical economic theory, spatial economic theory, and general equilibrium theory. For the ease of presentation, only transportation infrastructure is referred to in the following discussion, but it is just one of a set of infrastructure investments that can be assessed in this way.

Neoclassical economic theory

Impact assessments of infrastructure on regional development were not well developed until the emergence of a series of papers starting in 1989 by Aschauer. The fundamental argument Aschauer made is that the enhancement of infrastructure provision through public expenditure facilitates a region achieving its economic potential. Since then, a large number of studies evaluating the regional impact of public infrastructure investment have been conducted by following neoclassical economic theory through some form of aggregated production function approach (Gramlich 1994; Fernald 1999; Boarnet 1998). Because of different evaluation methods, time periods, measures of economic outcomes, and control variables used, the findings of these studies are not consistent. For instance, some find that the US highway infrastructure has a positive and significant effect on productivity (Fernald 1999), although such an effect diminished after the completion of the systems (Fernald 1999). Others cast doubt on even the positive effects of public infrastructure by adopting different data and evaluation methods (Boarnet 1998).

Specifically, Aschauer (1989) and Munnell and Cook (1990) analyzed the relationship between public infrastructure capital and economic performance for the period 1970–1986 at the US national and state level, respectively.
The elasticity of output (economic returns) with respect to infrastructure was found to range between 0.38 and 0.56 in Aschauer’s study and was 0.15 in Munnell’s study, with highway alone contributing over a third of that benefit. The elasticities of output (economic returns) with respect to infrastructure indicate that the amount of output would rise and returns would increase for each percentage increase in the nation’s infrastructure stock.

Scholars also argue that the scale of analysis matters in this kind of assessment. The rate of return may decline in significance as the scale of analysis is altered. By using a partial equilibrium model as well as state-level public capital data, Holtz-Eakin and Lovely (1996) found that public capital did not affect output significantly. Many of these studies have been subject to a range of criticisms. Gramlich (1994) provides the following summary on the defects of these studies.

- Unclear causal relationship between infrastructure provision and economic performance.
- Vague definition of “infrastructure” making the quantitative analysis speculative.
- Policy variables that are too short-term to be consistent with relevant infrastructure variables.
- Isolation of factors influencing macroeconomic performance: where transport to soft infrastructure operates in the context of legal, educational (human capital), and business institutions, and in terms of national defense priorities.
- Different methodologies applied to different datasets, resulting in implications that are attributed to imprecise quantitative estimation.

Further, earlier studies did not consider the spatial interactions among units across different geographic locations. These early analyses assumed the existence of spatial homogeneity. Further, as the geographic scale of the research area changes, estimated impacts change as well. Based on a meta-analysis of a large number of studies discussing highway infrastructure and the economy, Shatz, Kitchens, and Rosenbloom (2011) indicate that the effects of highway infrastructure on economic output vary when different levels of data are applied. They concluded that studies tended to find higher rates of return and strong productivity effects of highway infrastructure at the national scale than at the state and substate scale.

Spatial economic theory

The assessment of infrastructure impact on regional development has involved the application of spatial economic theory, which considers the nature of spatial dependence and heterogeneity. Munnell and Cook (1990) pointed out that the impact of infrastructure on regional development became smaller as the geographic focus narrowed. She believed that this was due to the effects of leakages from infrastructure investment that could not be captured at a small geographic scale. Although such a hypothesis may not be fully accurate, as indicated by Boarnet (1998), it does suggest that the spatial dimension has an influence on the estimated impact and should not be ignored.

LeSage and Pace (2009) emphasize that traditional econometrics have largely neglected the spatial/geographic dimension of sample data. When data has geographic information, two issues arise due to the violation of the Gauss–Markov assumptions. The first one is spatial dependence between observations, and the second is spatial heterogeneity. Without considering these spatial issues, any estimation may be statistically biased.
Thanks to the development of spatial econometric techniques by Jean Paelinck, Luc Anselin, James LeSage, Paul Elhorst, and many other regional scientists, a number of empirical analyses with spatial considerations have been carried out. One of the compelling functions of spatial econometrics is to allow for measuring spatial spillover effects. This refers to the situation in which the input in one sector or region influences changes in neighboring economies through trade linkages and market relationships. Infrastructure is likely to have a spillover effect on regional development because the benefits generated from infrastructure improvement would not be confined to the specific region where the improvement occurred. This hypothesis has been empirically tested in various spatial models (Holtz-Eakin and Schwartz 1996; Kelejian and Robinson 1997; Cohen and Morrison Paul 2003). As yet, there is no consistent conclusion on whether or the degree to which spillover effects of infrastructure are positive and significant.

Boarnet (1998) constructed a spatial lag model to evaluate the spatial effects of public transport infrastructure in Californian counties. He found a negative spatial effect for the Californian road system, due to migration. Holtz-Eakin and Schwartz (1996) found that highway stocks do not have substantial spillover effects on private productivity. Kelejian and Robinson’s study (1997) found that the results are quite sensitive to model specification.

On the other hand, positive spillover effects of transportation infrastructure have been found (Cohen and Morrison Paul 2003). Cohen and Morrison Paul conducted a series of studies aimed at the benefits of airport, highway, and port investments accruing to the US manufacturing sector. They apply cost functions with considerations of spatial autocorrelation adjustments to data from 1982 through 1996. In their analysis, positive and significant spatial autocorrelation parameters were obtained, which they concluded are indications of positive spillover effects. However, in terms of ports, they found that the elasticity of the shadow value of a neighbor’s port improvement with respect to their own state’s port infrastructure was negative and significant.

A brief overview of the literature on infrastructure and regional development suggests that the conclusions are not consistent, given that different data, methods, regions, and periods are employed in each analysis.

General equilibrium theory

According to the neoclassical and spatial economic theories, impact assessment of infrastructure on regional development is conducted under the assumption of partial equilibrium. The linkages between economic output and infrastructure input are assessed only from the supply side by assuming the demand of infrastructure remains constant during any specific period of investigation. Clearly, the outcome of economic impact is only partial since the impact caused by the change of demand is not captured under such a theoretical framework. Practically, the impact of infrastructure on travelers’ welfare measured by levels of utility cannot be adequately measured under a partial equilibrium analysis alone. In order to achieve a comprehensive regional development impact evaluation of infrastructure investment on both the supply and demand sides, a general equilibrium theoretical framework is required.

A computable general equilibrium (CGE) model developed by Johansen in the 1960s enables impact analysis with a consideration of both demand and supply. The theoretical framework relies on the Walras–Arrow–Debreu theory of general equilibrium with modern modifications and extensions allowing for imperfect
markets. Because CGE provides a clear linkage between the microeconomic structure and the macroeconomic environment, the model can be used to not only describe the interrelationship among multiple industrial sectors and markets, but also to assess direct and indirect effects from the change of public policy on various kinds of economic variable, such as output, employment, prices, income, and welfare (Chen and Haynes 2014).

The applications of CGE in evaluating the impact of infrastructure on regional development are abundant. Depending on the stages of infrastructure provision, impacts can be evaluated differently. For instance, the short-term impact of infrastructure investment (such as job creation and demand for raw materials) can be measured by examining linkages of the infrastructure sector with other economic agents, including consumers, producers, and government. On the other hand, the long-term impact of infrastructure (such as a reduction of transportation costs due to network improvements) can be evaluated by examining the variation of trade margins among different regions. Because the impact can be measured under a general equilibrium among multiple geographic regions, this modeling structure is often called spatial CGE or SCGE, but is in reality an interregional CGE model.

In recent decades, different types of SCGE models were established to evaluate the impact of infrastructure investment policies. For instance, Miyagi (2006) evaluates the impact of infrastructure in Japan in relation to the accessibility change using SCGE. In his model, the impact on regional development was measured through a reduction of congestion due to a specialized infrastructure investment (Miyagi 2006). Another SCGE analysis applied to transportation infrastructure evaluation was conducted by Goce-Dakila and Mizokami (2007) with a focus on the Philippines. They established an SCGE model with consideration of five subregions and found that technological improvement in land transport has the highest impact on output.

Haddad and Hewings (2005) assess the regional impact of changes in Brazilian road transportation infrastructure by applying a multiregional CGE model. By introducing non-constant returns and non-iceberg transportation costs, they find asymmetric impacts of transportation investment on the spatial economy of Brazil.

In addition, there are a few different types of SCGE models developed for the regional impact assessment of infrastructure. For instance, CGEurope is another SCGE model developed by Bröcker (1998) with a primary use of spatial analysis in the distribution of welfare effects linked to changes in accessibility within and between regions. The MONASH model developed by Dixon and Rimmer (2000) is another widely used multiregional and multisectoral dynamic CGE model that can be used to assess the impact of infrastructure on regional development. Their model allows for different choices of levels of sectoral and regional disaggregation, and infrastructure such as transportation can be treated as a marginal sector where costs are imposed on the purchase price of goods in trade and services.

Major issues

One should note that the understanding of infrastructure and regional development is still limited despite the development of modern techniques of economic modeling. Given the existence of issues of equity, causality, geographic scale, and different types of spillover effect, further research is needed.

Equity of investment

One major concern of infrastructure policy is the equity impact of investment both in terms
of geographic locality and types of infrastructure. Despite the fact that the primary goal for many national governments is to promote equal opportunities for economic development among subnational regions through improved infrastructure systems, some studies have found that sometimes the effects of infrastructure investment can produce the opposite outcomes. For example, the original objective of the Japanese Shinkansen high-speed rail network was to reduce regional disparity. The actual outcome was not as expected. Factors such as labor forces were found to be more moveable than expected. One consequence was that urban metropolitan areas continued to agglomerate, leaving other regions behind and underdeveloped. Therefore, how to invest in infrastructure wisely so as to reduce regional disparity continues to be a challenge for decision-makers.

The issue of equity also exists when decisions have to be made on how to allocate funding between different types of infrastructure. For instance, roads are the dominant mode of infrastructure in the United States. Studies confirm that highway infrastructure contributes the most to regional economic development from all modes of public infrastructure, including airports, ports, and public railways. Given the economic impact of highways and the level of existing capital stock, the question is whether new public financial resource should still be allocated equally to different modes, and how that relates to the efficiency consequences of infrastructure investment.

Causality

The nature of the causal relationship between infrastructure and regional development is another critical issue for impact assessment. This issue is sometimes known as the endogeneity problem. Infrastructure investment enhances the connectivity of regional transportation networks, which subsequently facilitates both freight and passenger movement through the reduction of transportation costs. On the other hand, the improvement of economic performance may, as a result, lead to an increase in demand for both freight and passenger transport and thus require more investment for infrastructure improvement. Such results are also referred to as a reflection of latent demand. Failure to appropriately address the endogeneity issue may jeopardize the outcome and interpretation of impact investigation and lead to erroneous policy implications.

Geographic scale

Since an impact assessment of infrastructure on regional development needs to be conducted at a specific geographic scale depending on the research objectives, how to choose the right geographic scale becomes a sensitive issue. As noted above, the variation in impact assessment with respect to scale has been discussed extensively by Shatz, Kitchens, and Rosenbloom (2011). Studies using national rather than state-level or substate-level data were more likely to find a positive and significant relationship between infrastructure and economic outcomes. One reason for these differences is the observation unit’s spatial stability, as there is a tendency for highway infrastructure to reallocate economic activity. Therefore, negative spillover effects are more likely to be found at a smaller geographic scale. On the other hand, a national-level assessment may be more likely to capture geographically distant (and often positive) spillovers (Shatz, Kitchens, and Rosenbloom 2011).

The sensitivity of the scale of analysis also relates to methodologies for spillover estimation. To effectively account for the spillover effects of infrastructure, spatial econometric techniques are usually adopted. Boarnet (1998) found a negative
spatial lag effect for the Californian road system on economic output at the county level. However, based on a different analytical scale, Jiwat-tanakulpaisarn et al. (2009) found a completely different answer across the interstate highway system: that growth in roadway density had positive spillover effects on state employment growth.

Overall, the tradeoff between geographic scale of analysis and interpretation of results are issues that deserve significant attention in the assessment of infrastructure impacts on regional economic development. While the assessment may be easier to implement at the aggregated level (such as the national level or state level) given data availability, the assessment becomes challenging at the disaggregated level (especially at the Metropolitan Statistical Area (MSA) or county level) as data is usually not available and capital stock has to be estimated. As a result, it should be noted that as the data being estimated move away from the “ideal,” so does the level of confidence in the results. Hence it is important for any user to carefully review and assess such geographic disaggregation for the level of confidence needed.

Global versus local spillover effects

The spatial spillover effects on regional development from infrastructure facilities have been widely observed in empirical studies. But how to measure these effects appropriately and accurately is still challenging. One of the main reasons for this is due to lack of sufficient information to determine the impact scale of infrastructure. This directly relates to the robustness of impact estimation given the sensitivity of spatial modeling specifications. Some studies consider only local spillover effects but, as infrastructure networks provide accessibility and connectivity from one region to adjacent regions, therefore the impact on regional development involves not only neighbors, but high-order neighbors (neighbors to the neighbors, neighbors to the neighbors of the neighbors, and so on).

However, in other cases, the influence of infrastructure on high-order neighbors’ regional development may exist and/or may decline with distance: for instance, when highway congestion occurs, the behavior of commuters in different regions is affected, given that feedback or endogenous interaction effects are present (LeSage 2014). As a result, the congestion of highway infrastructure may have global spillover effects on regional development despite the fact that the magnitude of the effect decays as the distance to the core increases.

How to choose the appropriate spatial spillover effects for an infrastructure’s regional impact assessment is fundamental. Although spatial modeling techniques and application principles have been extensively discussed (LeSage 2014), given the uncertainty of data availability and different theoretical foundations being applied, challenges confronting assessment of the impact of infrastructure on regional development remain.

Infrastructure plays a vital role in structuring the relative spatial connectivity of place. Infrastructure systems tend to be immobile but facilitate numerous mobilities which, at their core, provide the mechanisms and context through which modern life functions. They enable the process of time-space compression and shape the relational networks through which localities are articulated within broader social, economic, political, and environmental systems. They expedite technological transformations and sociospatial change, and foster new spatial imaginaries. The Internet, for instance, is celebrated as the backbone of a new era of connectivity and progress. Yet, while the “information age” is premised on the idea of uninterrupted digital flows and circulation, such discourses render other infrastructure systems mundane and overlook inequalities in access and processes of uneven development.

Infrastructure is usually understood in physical terms. Technical, or hard, infrastructures are physical systems consisting of material elements—highways, pipelines, power stations, cables, energy grids, airports, fiber optics, sewers—that mediate resource flows. Transportation, water, energy, trade, and telecommunications networks materially connect more or less distant places by facilitating various social processes and relations across space. The development of technical infrastructure systems plays a vital role in the development of territorial units from cities to nation-states. At the same time, by supporting processes of globalization via telecommunications and trade innovations (such as containerization and intermodalism), technical infrastructure provides an important means to challenge the construction of places as bounded, internally organized, territorial units.

Variations in the density and concentration of technical infrastructures spur distinct patterns of uneven geographical development. Infrastructure systems can invoke distinct environmental and social problems, from local events (oil spills, water pollution) to global crises (climate change); however, the transformative potential of engineered systems also provides the potential to realize new spatial fixes. Infrastructure megaprojects, as material and symbolic spaces, have been closely associated with programs of modernization. They often function as a means, and context, for sustainable development while, in the wake of the 2008–2009 global financial crisis, infrastructure investment has emerged as a key policy tool to reinvigorate local and national economies.

Infrastructure may also be understood through the production and operation of social relations. Social, or soft, infrastructure consists of the formal institutions and informal practices employed by various actors (individuals, households, etc.) that structure the capacities of people in place. The relative “thickness” of social networks strongly influences the practices and experiences of everyday life. Social infrastructures, for example, public services or utilities, may be provided by governmental agencies. They may also be forged by a diverse array of actors operating at multiple scales—from small-scale cooperatives to transnational organizations—when the state is unable or unwilling to provide them. Simone (2004) directly ties the concept of infrastructure to
people’s activities in cities by foregrounding the economic collaborations between marginalized residents in Johannesburg. Examining the case of urban markets, he frames practices of “cooking, reciting, selling, loading and unloading, fighting, praying, relaxing, pounding, and buying … on stages too cramped, too deteriorated, too clogged with waste, history, energy, and sweat to sustain all of them” as providing the concrete acts and context through which the city is reproduced (Simone 2004, 426). In this context, people’s networks and rules, which are dynamically invoked and reinforced, form the infrastructure conditioning social practice.

Entering the twenty-first century, the nature and focus of geographic inquiry shifted alongside a broader reappraisal of infrastructure studies across the social sciences. Geographic engagement with infrastructure, particularly those in the sphere of transportation geography, has strong roots in the discipline’s quantitative turn. Systematic approaches to the mapping and measurement of spatial processes developed through the 1950s and 1960s helped establish geography as a science and enabled geographers to inform public policy and investments decisions. Despite a long-standing interest in social justice issues within geography, infrastructure systems consequently tended to be relegated to the apolitical domain of engineers and technocrats (see Furlong 2010; Graham 2010). Over the past decade, a groundswell of critical analyses – drawing on a diverse amalgam of theoretical frameworks – has focused on examining how infrastructure profoundly shapes the production, experience, governance, and transformation of social relations. Work conducted under the rubric of the politics of infrastructure, techno-natures, urban metabolism, and the sociotechnical city have encouraged a reconsideration of geographic engagements, spurred, in no small part, by a reinvigorated commitment to “[open] up the ‘black box’ of urban infrastructure to explore the ways in which infrastructures, cities and nation states are produced and transformed together” (McFarlane and Rutherford 2008, 364).

In contrast to scholars in other disciplines – for example, science and technology studies, which concentrates on the technological or engineered aspects of infrastructure systems – geographic scholarship has tended to foreground social, political, and economic factors to demonstrate, empirically and conceptually, that infrastructure systems are not isolated, apolitical, static, or stable entities. Inequalities in access and mobility produce distinct power relations and articulations of uneven development that position them as central objects of social struggle. Developments like urban growth and shrinkage or public budgetary crises can challenge traditional forms of infrastructure provision and require new technical or social solutions. Moreover, scholarship influenced by the new mobilities paradigm challenges normative understandings of infrastructure stability by drawing attention to how, at a microscale, infrastructure may be characterized by dynamism and change. Seemingly fixed, material objects are constantly being modified and refashioned in subtle ways: streets are repaved, buildings painted, grass mowed.

Poststructural approaches, notably drawing from actor-network theory and cyborg studies, have attempted to conceptually collapse the distinction between the human body and technological networks. Infrastructures are conceived as a series of interconnecting unconscious life-support systems that make urban life possible. For instance, the modern home – with its provisions of light, heat, and water and telecommunications networks – is a normalized yet essential exoskeleton that blurs the distinction between the organic and the technological. Shifting scale, the hybrid urbanization embodied within the cyborg city produces urban space as
an inseparable fusion of the social and technical. Marxist scholars have engaged such normalization as a mode of fetishism that obfuscates the social relations that underpin the production of infrastructure systems. Scholars utilizing assemblage theory have further problematized notions of agency by focusing analytical attention on sociomaterial interaction. Assemblage theory constructs infrastructure systems as bringing together and organizing multiple human and nonhuman relationships in a manner that distributes agency beyond the human actants involved. Bennett (2005), for example, interprets the 2003 North American blackout as a moment of crisis rooted in the specific arrangement of flows, users, commodities, production processes, lifestyles, profit motives, and electron streams bundled in the specific infrastructural constellation of the East Coast electric grid.

Splintering urbanism

The form, function, and governance of infrastructure networks vary across geographical and historical contexts. Graham and Marvin’s (2001) “splintering urbanism” thesis has proved a highly influential analytical framework to conceptualize broad transformations in the production and management of sociotechnical systems. Between 1850 and 1960, urbanization, especially in advanced capitalist countries, catalyzed a movement from piecemeal and fragmented infrastructure provision toward an emphasis on the centralized and standardized systems that underpinned the modern networked city. The intersection of modernist aesthetics and technology promoted rationality and order in the production of urban space. Infrastructure systems served as both functional, material networks and symbolic representational spaces that spurred dreams of mobility, modernity, and circulation. The modern infrastructural ideal, as a decidedly Western construct, was buttressed by an ideological belief in the positive social transformative capacity of networked technologies. The ascension of modern theories and practices of urban planning helped codify new ways of thinking about and shaping cities and their sociotechnical relations. Government support for near-universal access to infrastructure networks across urban, regional, and national space was vital to the extension of the networked technologies that facilitated new forms of mass production and consumption. The Fordist New Deal is commonly accepted to be the nadir of technological modernism in the United States, with the machine emerging as a motif for both industrial production and social organization.

Across the globe, postwar modernization programs were characterized, and defined, by standardized modern infrastructures; from highways and high-rise residential tower blocks to vast electric, water, and sewage grids. However, the ascension of the modern infrastructural ideal fostered a concomitant critique of dehumanizing and alienating impacts of technological modernism. By the early 1970s, social critiques regarding the lived experience of high modernism, perhaps most influentially in the writings and activism of Jane Jacobs, undermined the development of infrastructural networks as idealized technological-engineered systems. As the long postwar capitalist boom subsided, governments struggled to invest the constant inputs of capital and labor required to maintain modern infrastructure networks which consequently became vulnerable to protracted fiscal crises and physical decay into the 1980s.

Processes of political and economic restructuring following the crisis of Fordism directly impacted the planning, management, and governance of infrastructure systems. Planning rationales that legitimized the construction of modern integrated infrastructure systems were undermined by increased technical specialization.
and a gradual shift in attention from concerns regarding built form and mechanic metaphors to administrative, legal, and social issues. Under the auspices of neoliberalism, the logics of infrastructure provision have shifted from the modern ideal of public provision and universal access to collectively distributed services, toward the valorization of individual choice and atomized mobility, in a manner that obscures the continued reliance on public infrastructures that enables such mobility. In lieu of nationally scaled spatial fixes, local governance units have taken on increasing responsibility for developing the urban infrastructures necessary to support growth in their own territorial jurisdictions. Infrastructure restructuring, in terms of both material networks and their governance regimes, has provided a lens to reveal both the processes of deterritorialization associated with globalization and the rise of the “network society,” and the modes of reterritorialization through which new scalar relations are produced.

A key mechanism here is the cleaving, or secession, of infrastructure elements from collective public systems. Publicly managed infrastructures have been increasingly splintered through processes of deregulation and privatization (Graham and Marvin 2001). The unbundling of existing infrastructure networks establishes premium network spaces (e.g., toll roads, privatized express rail links) that are integrated into selective global political economic frameworks through specialized development funds, financial tools, and public–private (P3) partnerships. Material, political, and economic relations foster new topological geographies that tie together a privileged archipelago of elite global nodes reformulated in a manner that constructs and reinforces sociospatial relations. In an era of free trade, just-in-spatial production, and globalized supply-chain networks, the production of premium infrastructure networks enables localities to create competitive advantages while erecting barriers to entry for their competitors. City-regions that are able to construct world-class infrastructure, develop multimodal transportation centers, and lower transportation costs greatly strengthen their competitive position in the international economy. Consequently, several planning scholars now consider strategic investment in infrastructure as presenting a new spatial planning paradigm, with urban infrastructure planning held as a potentially visionary yet pragmatic tool for planners.

Local units of governments have subsequently adjusted how they perceive and utilize their infrastructure assets. As austerity regimes limit the public capital available to invest in public infrastructure, a major trend in local urban policy has been the financialization of infrastructure networks; either through engaging in (P3) partnerships or through selling them off outright. Technical infrastructure has acted as an experimental testing ground for P3 funding arrangements. A common form of P3 arrangement enables governments to lease the operation of such infrastructure to a private company over a limited time frame for a lump sum payment while retaining ownership of the physical systems. The City of Chicago has exemplified such strategic unbundling through landmark leasing arrangements for the Chicago Skyway and municipal parking meters. A broad global trend is emerging in which the public ownership and local management of technical infrastructure is usurped by supranational governance regimes, whereby infrastructure systems are privately owned by global companies and regulated by local actors.

Critics of P3 arrangements point to the dangers associated with local governments’ reliance on increasingly risky financial arrangements and security-backed speculation. The production, financing, and regulation of urban infrastructures
produced through supranational governance deepens the multifaceted and multiscalar connectivity of places, but in doing so opens local struggles over collective consumption amenities to the disciplinary logic of private capital. Moreover, unbundling has profound implications for class struggle and environmental justice by engendering differential access to infrastructure networks. New articulations of uneven geographic development intensify sociospatial polarization with metropolitan space. Places that are physically bypassed by globally privileged networks suffer from limited material and social connectivity and are often discursively framed as corridors that require traversing rather than as spaces of habitation (see Young, Wood, and Keil 2011).

Disruptions, crises, and consequences

Investigations into the political production and transformative capacity of infrastructure systems have pointed to a central paradox. While infrastructure systems are essential to our everyday lives, their ubiquity renders them invisible, as normalized, and taken for granted. Oftentimes it is only once systems break down, fail, or are disrupted that their materialities, roles, geographies, and social functions are revealed (see Graham 2010). This is the case for both technical and social infrastructure. Differing infrastructure systems are themselves fused together in complex and inter-dependent relationships. Consequently, a crisis arising at a specific point may quickly spread through other infrastructures and networked places. Crises can be place-based. Natural disasters may strike specific locales, as when Hurricane Katrina hit New Orleans in 2005, or localized fat deposits in city sewers may cripple basic sanitations systems. They can also be distinctly reticulated. Disruptions to transnational mobility caused by the spread of the SARS (severe acute respiratory syndrome) and H1N1 (swine flu) viruses through global air networks revealed how infrastructure-based crises cascade between places. Increases in the visibility of infrastructural failures mean infrastructure disruptions – from the challenges of climate change to the threat of Internet worms and identity theft – can become ingrained as a normalized expectation within modern society. Moreover, infrastructure networks have emerged as a mechanism for political insurgency, whether in the form of infrastructural terrorism (most notably in the case of the September 11, 2001, attacks in New York and Washington, DC), Anonymous attacking governmental websites, or First Nations protesters in Ontario blocking major highways to gain visibility for their cause. Many recent state interventions around infrastructure networks have therefore been marked by a concern with securitization and surveillance. Infrastructure disruptions are experienced differentially across geographical and social contexts. In advanced capitalist countries, infrastructure tends to be normalized until large-scale crises viscerally insert them into political and economic mechanisms. By contrast, infrastructure disruptions tend to be foregrounded for precarious social groups whose lack of access or relative disconnectivity leads everyday life to revolve around a constant struggle to obtain adequate water, food, sanitation, and mobility. Several scholars have illustrated that the epochal shift between the modern networked city and the unbundling neoliberal city region has unfurled in uneven geographically and historically unstable patterns, and continues to do so (see Coutard 2008). Critics drawing on evidence from cities in the developing world demonstrate that the construction and implementation of the modern infrastructural ideal was far from universal. Rather, standardized networks developed unevenly and exhibited
significant geographic variations within and across national contexts. Historical analyses also complicate simple narratives of the bundling and unbundling logic of infrastructure networks by disclosing an ambivalent relationship between standardized service provision and increased levels of urban integration and the complex relationship between publicly owned networks and the driving role of private interests in infrastructure construction (see Coutard 2008).

Despite, or even because of, their technical and fiscal vulnerabilities, infrastructures are not only vital in demarcating the practical possibilities of governance regimes but also crucial in defining the ideological parameters of political discourse (Gandy 2005). For instance, as splintering urbanism is the product of strategic coalitions within multiscalar governance regimes, unbundling processes are open to social contestation and political intervention. Flexible networks and creative investment strategies can open possibilities for future urban growth and development. As an unstable and multistage process, infrastructure splintering fosters fissures in which new modes of social and spatial justice, as well as collective action, can emerge. Network splintering may cleave off premium network space, but differentiated service provision within public networks enables institutional and financial capacity to better serve marginalized users and urban inhabitants. Contestation over infrastructure production and a rescaled territorial politics of collective provision can animate political movements centered on class struggle at broader spatial scales, as seen in the mobilization of the Los Angeles Bus Riders Union. The struggle between global forces controlling commodified networks and attempts to democratize infrastructure systems will likely form an increasingly central component of urban, national, and international politics.

There is considerable scope for conceptual and applied geographic research to probe the limits and possibilities of political movements around a politics of infrastructure, particularly at the interdisciplinary nexus of political economy and ecology, critical urban studies, and security studies. While much of this research may center on major societal shifts and moments of crisis, significant conceptual and political insights can also be revealed by uncovering the everyday adaptability and transformations of infrastructure, including stressing the role of mediating technologies in influencing infrastructure provision and adaptability. The elaboration of multiple scalar perspectives offers a productive avenue to further examine infrastructure’s role in shaping the governance practices, progressive development frameworks, and the spatial processes conditioning contemporary social relations and everyday life (see Furlong 2010; McFarlane and Rutherford 2008).

Innovation and regional development

Chun Yang
Hong Kong Baptist University, China

Over the past decades, innovation-driven growth has become a major driver of development dynamics in both advanced and emerging economies. Innovation is considered a core growth driver in knowledge-based economies and a subject for wide-ranging policy efforts. It is also regarded as a socially and spatially embedded interactive learning process that cannot be understood independently of its specific national/regional institutional and cultural contexts. Since the 1990s, the geography of innovation has become an important field of research in economic geography. The renewed interest in the relationship between innovation and regional development has arisen due to the performance of a few highly innovative industries such as the Silicon Valley electronics cluster in southern California, Emilia-Romagna in Italy, the science-based industrial cluster around Cambridge, England, the Hsinchu Science Park in Taiwan, and Zhongguancun technology hub in Beijing, China.

Regions have become key actors shaping the generation and diffusion of new knowledge in the global economy. Policymakers increasingly recognize the role that regions play in cultivating, attracting, and retaining innovative people and firms. The main challenge for regional innovation policies is to ensure a favorable environment for the diffusion of innovations and for entrepreneurship and business growth. In order to understand the relationships between innovation and regional development, this entry will start by defining and measuring innovation. Then the scales and spaces of innovation over the last few decades will be explored. Particular emphasis is put on the evolution of innovation systems approaches. An investigation of empirical experiences of innovation and regional development in developed countries and emerging economies, particularly China, will follow. A summary and agenda for future research is presented in the conclusion.

Defining and measuring innovation

The earliest conceptual exploration of the role of innovation in economic development is the Schumpeterian theory of entrepreneurial innovation. To Schumpeterians, innovation can be regarded as the creative destruction of the old economic system and its replacement by the successful introduction to the market of new combinations of materials and forces. Five types of innovation were identified, including new products, new methods of production, new sources of supply, the exploitation of new markets, and new ways to organize business. Following Schumpeter, Porter put more emphasis on the first two types of innovation, calling them “technology innovation.” Technology innovation is regarded as an effort “to create competitive advantage by perceiving or discovering new and better ways of competing in an industry and bringing them to market” (Porter 1990, 45).

According to the OECD innovation strategy (OECD 2010), innovation is defined as
the implementation of a new or significantly improved product (goods or service) or process, a new marketing method, or a new organizational method in business practices, workplace organization, or external relations. All innovation must contain a degree of novelty. Innovation rarely occurs in isolation. It is a highly interactive process of collaboration that is increasingly international, involving a growing and diverse network of stakeholders, institutions, and users. Innovation involves the successful implementation of a new product, service, or process. Distinguishing between product and process innovations is a problem because one often leads to the other. One firm’s new product is another firm’s new process, and vice versa. New processes can allow new products to be developed, while the mass production of successful new products often requires process innovation. Also, new products, when they are consumed either as factor inputs or intermediate goods, can contribute to changes in the way other products are produced.

We may make a distinction between narrow and broad dimensions of a system of innovation. The narrow definition includes organizations and institutions involved in searching and exploring, such as Research and Development (R&D) departments, technological institutes, and universities. The broad definition includes all parts and aspects of the economic structure and institutional setup affecting learning as well as searching and exploring. To this end, innovation capability can be assessed using the input and output measures of the innovation system. The input measures are usually represented by indicators such as the amount of R&D investment and the number of researchers in R&D, whereas output measures are reflected by indicators such as patents, high-tech/service exports, and academic output like publications in scientific and technical journals. Despite skepticism, the number of patents granted has been accepted as the most appropriate output measure. Other output indicators, such as those tracking R&D inputs, paper citations, and new product announcements, can be adopted.

Evolution of innovation systems approaches

The way innovation yields “new” developments takes two forms. The first form is most manifest in nascent, high-tech (sub)sectors and knowledge-intensive services. It is often associated with a more linear and technologically oriented view of innovation. In the second form, innovation as new to the region refers to the process in which “local” firms absorb new knowledge and practices from elsewhere, to tailor their products and services better to a wider market area. Such a broader, more entrepreneurial definition of innovation tends toward a system perspective, emphasizing the importance of the mutual interaction of many actors. Over the past decades, the “innovation systems” approach and its three perspectives, namely national innovation systems (NIS), sectoral innovation systems (SIS), and regional innovation systems (RIS), have been developed and adopted by many researchers as conceptual frameworks to analyze innovation in different contexts. Systems are defined as a set of interrelated components which share a common boundary and work toward a common purpose. The systemic approach to innovation highlights the fact that innovation is an interactive process that requires intensive cooperation between firms and agents (such as universities and public research facilities, technology centers, educational establishments, financing institutions, industry associations, and government agencies and bodies).
National innovation systems (NIS)
The national innovation system (NIS) was the first application of the concept to gain widespread recognition. Christopher Freeman and Bengt-Ake Lundvall trace the roots of the approach back to Friedrich List’s concept of national systems of production which took into account the importance of a wide range of national institutions (Freeman 1987; Lundvall 1992). The first contemporary use of the term is found in Freeman’s study of technological change in the Japanese economy. Freeman defined national systems of innovation as “the network of institutions in the public and private sectors whose interactions initiate, import, modify and diffuse new technologies” (Freeman 1987). He underlined the roles of four key components in driving the innovative performance of Japanese firms: government policy, corporate R&D, the education and training system, and the industrial structure of the Japanese economy. Lundvall used the concept to analyze interactions between firms and knowledge institutions in the innovation process. Refining the concept, Lundvall pointed to the interactive nature of the learning process that exists between producers and users of new technology and defined it as being “constituted by elements and relationships which interact in the production, diffusion and use of new, and economically useful, knowledge and that a national system encompasses either located within or rooted inside the borders of a nation state” (Lundvall 1992, 2). A third application of the national innovation system concept is provided in the collaborative study of innovation across 15 nations edited by Richard Nelson (1993). Nelson argued that the use of the concept of “system” to analyze the innovative performance of firms and nations drew attention to the role of a “set of institutional actors that, together, play the major role in influencing innovative performance” (Nelson 1993, 349).

Technological and sectoral innovation systems (SIS)
In a series of case studies in different sectors of the Swedish economy – factory automation, electronics, materials technology, and pharmaceuticals – researchers led by Bo Carlsson identified a distinctive technological dimension that grounded the firms involved in their national or regional contexts. A concept of a technological system was developed and defined as a network of agents interacting in a specific technology area under a particular institutional infrastructure to generate, diffuse, and utilize technology. Technological systems are defined in terms of knowledge or competence flows rather than flows of ordinary goods and services (Carlsson and Stankiewicz 1991). A closely related approach is the idea of a sectoral system of innovation developed by Franco Malerba and others. A sectoral system of innovation is defined as “that system (group) of firms active in developing and making a sector’s product and in generating and utilizing a sector’s technologies; such a system of firms is related in two different ways: through processes of interaction and cooperation in artifact-technology development and through processes of competition and selection in innovative and market actions” (Breschi and Malerba 1997, 131). The primary focus of the SIS approach is on the competitive relationships among firms, with specific reference to the selection environment for firms and their products. The SIS approach is open about the spatial boundaries of the innovation system; the actual boundaries of the system emerge from the specific conditions of the sector under investigation.
Regional innovation systems (RIS)

An extension of the NIS concept, the regional innovation systems (RIS) perspective has been recognized as the most appropriate scale for understanding the dynamics and organizing policy interventions for regional catch-up in the global economy (Cooke, Uranga, and Etxenbarria 1997). This approach identified institutions at the regional level that contribute to industrial innovation as the “regional innovation system,” partly in response to the spread of globalization and increased attention to the importance of geographical proximity for innovation. The governance of regional innovation systems involves a mix of public and private organizations, and their norms, rules, routines, and conventions. These organizations can include research institutes, industry associations and chambers of commerce, financial services providers, technology transfer agencies, public sector development agencies, and regional government, especially in more decentralized systems (Asheim and Gertler 2005).

The systemic dimension of RIS results from the coupling of three subsystems (Cooke, Uranga, and Etxenbarria 1997) leading to the synergy effects of enhanced regional innovation capacities. The first subsystem of finance refers to the availability of regional budgets and capacities to control and manage regional infrastructures. The cultural setting of regions constitutes the second subsystem and defines the milieu within which knowledge networks are embedded. Interactive learning is identified as the third subsystem and represents the core element of RIS as new knowledge is created and exploited. By defining more or less favorable conditions for these subsystems, the RIS approach became popular in the formulation of regional innovation policies. Two key dimensions of innovative activities have been identified in the RIS approach, namely the governance structure and the business structure.

The governance dimension focused on the modes of regional technology transfer as well as modes of governance: grassroots, network, and dirigiste. The business innovative dimension was characterized by the prevailing set of relations among firms in the global economy. This dimension concerns the role of leading firms in the regional economy, the tendency of firms to obtain R&D from in-house activities as opposed to public research institutions, and the innovative milieu within which firms operate. There is no best-practice or one-size-fits-all model of RIS. Instead, tailor-made policy measures adapted to specific regional arrangements are required (Todtling and Trippl 2005).

Despite the proliferation of the RIS approach in the literature, Asheim, Lawton, and Oughton (2011) argued that much of the empirical work dealt with well-functioning, successful regional economies and innovation in high-tech sectors, and should be supplemented with further theoretical and empirical analysis of “less successful” systems and of innovation in more traditional industries. Moreover, most studies are conducted from “a static perspective, while questions in relation to where RIS initially emerge, and why and how RIS and the advantages associated to them change over time are largely ignored” (Tel Wal and Boschma 2011, 923). The extent of knowledge transfer does not depend exclusively on geographic proximity but also on firms’ capabilities, absorptive capacity, and ability to renew their capabilities over time.

Global innovation networks

Although the system approach is very helpful in understanding the internal structure and the evolution of innovation in a specific country/region, it has been criticized for lacking consideration of relationships with key actors outside of the system and for a poor understanding of the
dynamics of the innovation system (Humphrey and Schmitz 2002). Despite a rich stream of research covering OECD and developing countries, the innovation systems approach has been criticized for its weakness in understanding the role of external linkages, its depiction of only a part of the story, and its weakness in dealing with the dynamics of innovation systems. As Hotz-Hart (2000, 444) put it, “systems of innovation are increasingly complex and intertwined, with regional, national, and international levels of integration of innovating activities.” The study of spaces of innovation needs to be more oriented toward exploring the linkages and interrelationships between and across these various spatial levels of scales from the “regional/local” through to the “global” (Bunnell and Coe 2001, 577). Fromhold-Eisebith (2007) called for a “master of scales” to integrate global, national, and regional innovation processes.

To address these weaknesses, researchers have proposed to integrate trans-local linkages into territorially bounded innovation systems and have analyzed catch-up in innovation capability, taking into account changes in technological regimes and the global economic environment. The global value chain (GVC) (Gereffi, Humphrey, and Sturgeon 2005) and global production network (GPN) (Coe et al. 2004) approaches have emphasized how firms have been instrumental in transferring technology, particularly tacit knowledge, to local companies. However, studies have indicated that interfirm networks have a limited impact on innovation capability as measured either by the number of patents, the product novelty, or impact. The relationship between GVCs and innovation systems is nonlinear. The 2000s has witnessed the emergence of global innovation networks (GINs). The traditional process of innovation in centralized corporate R&D departments has given way to GINs (complex and multilayered “networks of networks” that involve both global corporations and “local” companies), which integrate geographically dispersed engineering and product development activities.

Changing spaces and scales of innovation

Learning regions

The notion of “learning regions” is one of a family of concepts known as territorial innovation models (TIMs) that evolved from the late 1970s onwards. Although there are several definitions and perspectives, most scholars consider learning regions as a regional innovation strategy in which a broad set of innovation-related regional actors are strongly but flexibly connected with each other. The founding fathers of the concept of learning regions as distinctive TIMs in their own right were Storper (1993), Florida (1995), Asheim (1996), and Morgan (1997). Richard Florida (1995) is credited with the term “learning region.” He argued that in these new circumstances, networks would be the dominant organizational mode of production, and that the world economy would see the rise of global networks of companies but these companies would be dependent on the key knowledge assets of their home regions. These home regions (especially as the home base of headquarters and R&D functions of transnational corporations (TNCs)) would provide the underlying environment and infrastructure for the generation of ideas and learning and knowledge transfer. Also in the United States, Michael Storper (1993) sought to explain the emergence of new “worlds of production” or new forms of production organization emerging with the growth of a knowledge-based economy. Storper considered three empirical cases: design-intensive or craft-based industries in northeast and central Italy; the Paris fashion clothing industry and
the Île-de-France high-technology aerospace, electronics, and nuclear energy industries; and California high-tech districts concentrating on electronics and aerospace. He found that within the industrial sectors in these particular places technological learning could be seen as a social process that was heavily influenced by the conventions, culture, and informal institutions of local networks, which he called “untraded interdependencies.” Asheim’s (1996) study in Norway focused on the nature of successful learning in particular places. Like Florida (1995) and Storper (1993), he argued that in a knowledge-based economy networks are the key organizational form facilitating technological learning, and that agglomeration provides advantages with regard both to the formation of local networks and consequential learning.

In addition to informal arrangements, Asheim (1996) argued that learning regions required a formal institutional setup. These formal institutions for learning and innovation were what distinguished a learning region from an industrial district. In a learning region geographically concentrated learning networks, territorially embedded conventions, and formal institutions, including a regional innovation policy and support organizations, work together as part of a coherent system. However, the introduction of a requirement for formal institutions to stimulate learning made Asheim’s (1996) view much more akin to the concept of a regional innovation system than a learning region. This more policy-oriented approach to learning regions was developed in Wales by Morgan (1997). In Wales, one of the United Kingdom’s less-favored regions (LFRs), Morgan (1997) confronted the failure of the United Kingdom and Europe to close the gap between rich and poor regions on the basis of traditional regional economic policy. Morgan (1997) linked innovation to economic development and regarded it as an instrument to further social welfare. This gave the learning region a policy agenda in addition to its theoretical one. He argued that innovation was an interactive process influenced by a variety of institutions and conventions, which constitutes its “social capital.”

Recently, critical voices have started to challenge the notion of learning regions (Hassink 2007; Cooke 2002). In particular, its “fuzziness,” normative character, strong overlap with other concepts, and squeezed position between national innovation systems and global production networks have been criticized (Hassink 2007). In a study of innovative firms in the south-east of England, Simmie (1999) found that they learned as much from national and international networks as they did from their local regional networks. Cooke (2002) argues that the learning region is likely to last as a policy framework because of asymmetries rather than equality in local collaborations using different forms of economically valuable knowledge. Hudson (1999) argues that the social and structural constraints imposed by the capitalist system of production set the limits of what is possible. He argues that the prospect of generating convergence between different regions on the basis of a policy focus on learning is unlikely to succeed in the face of the forces driving uneven economic development.

Open innovation and proximity

Since 2000, literature on innovation has turned to consider the boundaries of the regional innovation system, and, in particular, has examined the issue of linkages to organizations outside the region. For instance, Bathelt, Malmberg, and Maskell (2004) argue that local and global linkages can coexist in a context where local interactions create a “buzz” that adds to local innovation processes, while channels of communications or “pipelines” to actors outside the region
are developed in order to access knowledge that is external to the region. New regional advantage in a global economy is generated by combining local buzz with global pipelines for knowledge circulation, within as well as beyond local territories (Bathelt, Malmberg, and Maskell 2004). Pipelines could be constructed either by bringing embedded knowledge in the form of mobile professionals into cluster communities or by sending local entrepreneurs outside to learn in global knowledge networks. Learning from foreign direct investments, transnational entrepreneurs, and global buyers in value chains is in line with the former type of pipeline formation. The concept of open innovation defined as “the use of purposive inflows and outflows of knowledge to accelerate internal innovation and expand the markets for external use of innovation” (Chesbrough 2003) and its impacts on regional development have aroused wide attention among researchers and practitioners.

Cooke (2002) argues that open innovation is one of the challenges that underline the importance for global competitiveness of regional innovation systems and clusters within them. Open innovation in networks of universities, research institutes, industry, government, and financiers leads to the transformation of dynamic knowledge networking capabilities into a regional capability. So, regional knowledge capabilities are rooted in open innovation. Cooke uses biotechnology as an example, but finds evidence that “open innovation” from knowledge-capable regional clusters can be seen in other sectors as well: the automotive sector, information and communication technology (ICT), and electronics and media. Open innovation is still a relatively new model and there are many areas for future research. The focus of open innovation research has been on global networks, but the potential impact on regional development is enormous. In parallel with the emergence of “open innovation,” the concept of a global innovation system/network is proposed, indicating the inadequacy of traditional notions of the innovation system, which focused solely on local or national processes and tended to ignore the international dimension of innovation systems.

Along with the popularity of open innovation, there has been increasing interest in the notion of proximity in the context of economic growth in general and innovation in particular (Boschma 2005). When analyzing the logic and dynamics of innovation, four functions of proximity have been identified. First, being close to each other helps companies to develop an efficient division of labor and coordinate their actions with a core of specialized suppliers and partners. Second, there are externalities of proximity available to all within a region. Third, there is evidence that when companies in the same industry are located close to each other it forces them to innovate. Fourth, and more importantly, proximity is associated with knowledge spillovers and mutual learning. Boschma (2005) has argued, however, that geographical proximity per se is neither a necessary nor a sufficient condition for learning. Therefore, when discussing the roles of proximity and distance in innovation policy, there is a critical dilemma. On the one hand, as most modern innovation policies and technology centers and science parks recognize, there is a need for a mechanism for enhancing physical, social, and cognitive proximity between the relevant actors in the innovation process. On the other hand, innovation policy must include mechanisms for enhancing social and cognitive diversity, the openness of innovation networks, and the ability of an innovation network to connect itself to the wider national and global knowledge base: that is, mechanisms for ensuring sufficient distance between the actors. Obviously, the central challenge for regional innovation policies is not to maximize proximity, but to create an efficient

balance between the contradictory purposes of enhancing proximity and distance.

Seven central dimensions of distance and proximity, as well as their relevance to innovation, are summarized in Table 1. The extent to which manufacturing companies have moved production activities from advanced economies to offshore locations has raised concerns that R&D and manufacturing know-how will follow and be “lost.” Even for industries in which innovation and production are tightly linked, companies do not automatically relocate R&D to their offshore production sites. For instance, makers of mobile phones and other consumer electronics products need to engage with dozens of parts suppliers that cluster around the Asian production sites, but Apple continues to come up with its innovative iPhone designs in California.

Innovation and regional development: divergent trajectories

Innovation and regional development in developed countries

Innovation is not uniformly distributed across geographical landscapes. Innovation clusters have emerged as places with dense webs of interconnected technology companies, customers, and suppliers. Improving a cluster’s chance of flourishing are factors such as liberal immigration laws and venture capital financing.
Since the end of the 1970s, industrial districts have been studied in Italy (Dunford 1996), more widely in Europe, and in North America (Saxenian 1994), not only because of their capacity to compete in international markets, but also because they have turned out to be significant wellsprings of product and process innovations. This issue has been studied by numerous scholars and schools through various perspectives, among which are the innovative milieu and “collective learning” approach, the regional innovation systems approach, the Italian school of industrial districts, the California school of economic geography, and the regional economists’ tradition of localized knowledge spillovers. It is argued that all these different streams overlap with respect to the mechanisms associated with the formation of innovation networks, including market relationships, social ties, and policy-driven relations. First, networks have been considered a significant channel for the diffusion of knowledge and for the generation of inter-organizational innovations in regions and subregional areas. The diffusion of knowledge through local market linkages is facilitated by the geographical proximity of firms and other organizations, which eases the transfer of tacit knowledge and promotes innovation accordingly. Second, what really seems to make a difference in regions and subregional areas is networks originating from nonmarket relationships and stemming from the regional, cultural, and social proximity of entrepreneurs and workers. Storper (1993) considers “social ties” a dimension of “untraded interdependencies,” while Saxenian (1994) considers them a driver of the way engineers interact with each other in the high-tech cluster of Silicon Valley. Third, besides spontaneous processes of collective innovation related to the presence of market and/or social networks, scholars have emphasized the importance of public institutions and policies in fostering the formation of innovation networks at the regional and subregional levels. All these studies have helped generate an incredibly rich and descriptive account of regional and subregional innovation networks – although rarely named as such.

Silicon Valley has been widely regarded as a successful model of innovation-driven regional development. Saxenian (1994), in her comparative study of Silicon Valley and the Boston area, analyzed the role of regional inter-organizational networks in making regions innovative, emphasizing the role of regional culture, identity, and human capital. She argues that the Silicon Valley pioneers created a decentralized system characterized by open information flows and learning between firms and between firms and regional universities (for example, Stanford University) with the ability to respond rapidly to changing markets by very quickly putting together people with different backgrounds and starting new companies. The cultural dimension also shows up in a willingness to experiment and take risks in the relatively flat organizational hierarchies, in the informality of work styles, and in occupational mobility. Although Saxenian did not use the term “open innovation,” she describes how Silicon Valley firms were successful by competing intensely while collaborating in informal and formal ways with one another and with regional universities to learn about fast-changing markets and technologies. As Saxenian (1994, 156) said, “the openness of this partnership ensured that the design and manufacturing innovations that it produced would diffuse rapidly throughout the region and the industry.” Interfirm supplier networks reinforced the regional advantage of Silicon Valley as an attractive location for innovative companies. Another benefit of open innovation derives from the maintenance of open boundaries to benefit from global connections and cultural diversity. Silicon Valley’s immigrant entrepreneurs and engineers also contribute to
maintaining open boundaries. They not only bring cultural diversity, but also connect Silicon Valley to Taiwan and India through informal social and professional ties and formal corporate alliances and partnerships, thereby facilitating flows of capital, skills, and technology.

Innovation and regional development in emerging economies: insights from China

Cities all over the world have tried to replicate the success of Silicon Valley. Of them, Beijing has emerged as a serious contender. Beijing, China’s political and cultural capital, has seen dramatic growth in recent years. In 2011, Chinese venture capital firms invested US$13 billion, half as much as their US counterparts, 30% of this in Beijing (Figure 1). Beijing hosts rare concentrations of wealth and some 70 institutions of higher learning, including China’s best computer science departments. Beijing produces what few other places can – giant, fast-growing tech companies, such as Baidu (worth $31 billion in 2014), Lenovo, and smartphone maker Xiaomi, which sold handsets worth $2 billion in 2013. China’s government has set in motion ambitious plans to break into high-tech and electronics manufacturing. In the 1980s it opened the Zhongguancun technology hub in Beijing, taking Silicon Valley as its inspiration (Zhou 2008).

Prior to the 1980s, China had an NIS similar to other centrally planned economies such as the Soviet Union and India, characterized by the complete separation of research activities, education, and manufacturing activities, with the first
two in public research institutes (PRIs) and universities, and the last in state-owned enterprises (SOEs), respectively. Since the start of reform and opening up in 1978, the Chinese government has started to actively transform this Soviet model, especially by emphasizing the co-location of research and manufacturing. The government has used both carrots and stick to pull and push R&D institutes to adapt to a market environment and to conduct R&D that has direct or indirect industrial applications. For instance, while it reduced institutional funding for PRIs in order to push them to conduct more market-oriented R&D through industries and universities, it also offered financial incentives to commercialize R&D results, especially through the 1988 Torch Program, a national science and technology program specifically targeting high-tech industrialization. The government also promoted organizational transformation by advocating the merger of some R&D institutes with enterprises in 1987 and reforming established R&D institutes into entities with economic functions, such as production and consultancy centers, from the 1990s.

Continuous reform has transformed the pre-reform government-led model of innovation. Firms have been reorganized and acquired R&D and marketing functions, and their innovation capability has increased notably. An enterprise-led and market-based technological innovation system has not yet been well established because SOEs, rather than private enterprises, dominate the national R&D landscape in China. The technology landscape in China is certainly highly uneven, with considerable differences in endowments, cultures, and institutions, varying positions in state strategies, and a variety of linkages with the global economy, resulting in distinctive patterns of innovative regions and cities.

In Zhongguancun in Beijing, China’s Silicon Valley and the most innovative region, the influence of actors in the regional systems of innovation (that is, the central and local state, TNCs, local firms, and research institutions), wax and wane, and each is challenged by others and by the changing political and institutional environment. Shanghai’s regional innovation systems have benefited from global linkages and recent TNC R&D centers. In Shenzhen, the contribution of universities and research institutes to technological innovation is relatively minimal compared to Beijing, which is a national scientific hub with a number of prestigious universities and institutes. Accessible venture capital from Hong Kong, the completeness of the ICT industrial value chain, and active private entrepreneurship have been cited as the basis of the prosperity of domestic high-tech firms in Shenzhen.

The East Asian model based on the postwar experiences of Japan and the four “tigers,” that is, South Korea, Taiwan, Hong Kong, and Singapore, has found limited applicability in post-reform China. In its simplest form, in the East Asian model, export-driven industries are the chief and superior vehicle for industrial competitiveness and technological upgrading. Over the last two decades, however, empirical experience in China has challenged this model. There is a growing recognition that internal dynamics such as the roles of the state, domestic markets, and the resources and strategies of indigenous companies are indispensable determinants of the success of technological upgrading.

The major findings of studies of innovation and regional development in China can be summarized as follows. First, FDI and export-oriented industry have an indirect effect on innovation development in China. Firms or regions with strong internal R&D capacity can absorb external knowledge and benefit from FDI-related technological innovation.
Second, China’s hierarchical science and technology system has a heavier imprint on the map of knowledge creation than the location of industry or foreign investment. However, China’s public institutions play only a limited role in creating and disseminating knowledge to industry, although a knowledge transfer network is gradually emerging. Third, China’s heavily export-oriented regions have been pursuing policies or strategies to move up the value chain since the 1990s, both at the enterprise and local state level. So far only a few successful indigenous companies have established dominant roles in regional innovative networks (e.g., Huawei, ZTE, BYD, and Tencent). While the innovativeness of these companies is not widely shared by other enterprises in the region, the trajectory toward more technology-driven and international collaboration is definitely on the way.

A comparison of the importance of indigenous and foreign innovation efforts in China indicates that the major drivers of the technological frontier are domestic firms in low- and medium-technology industries, and foreign-invested firms in the high-technology sector. The R&D activities of foreign-invested firms have not had significant positive effects on the technical transformation of local firms. Similarly, subcontracting will not necessarily improve the ICT suppliers’ technology innovation in China. Moreover, overdependence on subcontracting for the global market and global contractors will impede technological innovation in China (Sun et al. 2013). Negative correlations between technological investment and regional specialization in export-oriented industries are found for ICT firms in Beijing, Shanghai-Suzhou, and Shenzhen-Dongguan regions. ICT firms in Beijing, the most domestic-oriented region, perform better than those in the other three regions. The empirical experience of Shanghai’s Zhangjiang high-tech park shows that both a developmental state and entrepreneurship play key roles in the governance of innovation in China. In the initial stage, the municipal government is more crucial, but integration into global knowledge flows is more important in the later stage. Interestingly, in Shenzhen, heavy investment in R&D seems to belong exclusively to Chinese indigenous companies, while multinational companies, especially those from Hong Kong or Taiwan, have hardly participated. Despite the massive and intensive production linkages, firms in the Shenzhen ICT industrial cluster show weak innovative performance. Most local firms gain technological knowledge from internal R&D activities instead of external technology. Companies such as Huawei started with import substitution practices, but as they build up their internal R&D capability and invest heavily abroad, they are turning themselves into truly China-based transnational corporations and global lead firms in their respective GPNs and GINs.

In post-reform China, the state’s role in innovation systems has changed dramatically over time and space. Since the mid-2000s, Chinese leaders have realized that core technologies failed to come along with foreign equipment purchases or foreign investment flows. This recognition is reflected in the seminal document entitled “Guidelines for the Implementation of the National Medium- and Long-term Programme for Science and Technology Development (2006–2020)” (MLP hereafter) (China Science and Technology Newsletter 2006). As a grand blueprint for science and technology development designed to bring about the renaissance of the Chinese nation, the MLP defines indigenous innovation as enhancing original innovation through co-innovation and re-innovation based on the assimilation of imported technologies. Indigenous innovation
is planned to turn the Chinese economy into a technology powerhouse by 2020 and a global leader by 2050. Fu and Gong (2011) argued that the term “indigenous” (zizhu), which literally means self-direction, is problematic. As a matter of fact, it does not mean that technology has to originate in China or that the participation of TNCs is excluded. Policies are designed to boost indigenous R&D efforts and encourage domestic enterprises to exercise more strategic control in their technological interactions with foreign parties. The ongoing campaign for technological upgrading in response to the paradigm shift in innovation policies in China has two aspects. One is to foster technological innovation in the export-oriented production networks of TNCs, which have relocated their production activities, but with limited engagements in R&D in China. The other is to develop indigenous innovation through the technological upgrading of domestic firms, fostered by a paradigm shift in innovation strategy envisaging the state-initiated coupling of domestic firms and global leading TNCs (Yang 2014). The indigenous innovation strategy has been implemented since 2006. Prior to the onset of the 2008 global financial crisis, the Chinese state had already pushed Chinese enterprises to alter the nature of their relationships/positions in GPNs, with the explicit goals of technological upgrading and greater independence from TNCs, but full implementation of this new strategy did not start until 2009 in the wake of the global financial crisis.

The financial crisis provided stronger reasons for the Chinese government to adopt an aggressive innovation strategy. R&D funding in China reached a historically high level of 1.7% of gross domestic product (GDP) in 2009, surging from 0.8% in 2001. Efforts have been taken to assess the impact of changing state innovation policies on the transformation of NISs. In practice, indigenous innovation has been recognized as a viable strategy to foster technological upgrading in selected Chinese cities and sectors. In 2010, seven strategic emerging industries (SEIs) were selected by the central government to be technology intensive, and to achieve technological breakthroughs in a short period of time. These sectors are energy-saving and environmental protection, new information technology, biology, advanced equipment manufacturing, new energy, advanced materials, and new energy vehicles (Table 2). These SEIs, regarded as knowledge- and technology-intensive industries with less resource consumption, are expected to foster the technological upgrading of domestic firms. Local government authorities, such as the Guangdong provincial and Shenzhen municipal governments, announced similar SEIs to replace the low value-added, labor-intensive, environment-polluting and high energy consumption industries primarily invested in by TNCs from Hong Kong and Taiwan (Yang 2014). “Transition from production to innovation” through developing state-designated SEIs has been listed on policy agendas at various levels of government in China.

Innovation policies and regional development in the globalizing world: the research agenda

Innovation is nowadays considered a highly interactive and systemic process. In the globalized, post-Fordist knowledge economy, the relationship between innovation and regional development has become a central avenue of inquiry for scholars in a range of disciplines, particularly economic geography. The increasing mobility of production factors from 1990 to 2010 has radically changed the scale and space of innovation. The quality and performance of RISs depends to a high degree on
the knowledge interactions within and beyond their regions. The regional dimension is essential for innovation. This is partly due to its content but also to the social embeddedness of regional economic relations. But regional systems or networks are not self-contained and self-sufficient entities. The relational view has to be extended. Trans-regional innovation is an essential element of innovation potential. Many empirical studies show that RISs are highly open systems and that international or global knowledge links are often vital. Regional systems that have been and are still developing along trajectories of cumulative innovation and knowledge find themselves part of a multiscalar system.

Scholars dissatisfied with existing approaches to the study of innovation networks have in recent years proposed a methodological shift. Key findings of the literature and directions for future research include the following.

1 Understanding innovation networks. Scholars have investigated the structural properties of innovation networks within and across regional clusters and have found that different types of network structure may also lead to different types of reward (and constraint) for its members. Innovation-related knowledge is diffused in a rather structured, selective, and uneven way within industrial clusters and is thus not pervasive or collective, as presumed by conventional theories – leaving a number of firms isolated from the local knowledge network, even when they are located nearby or have established other types of business linkages with nearby firms.

2 Analyzing the relationship between network position and firm characteristics. The analysis of the structural properties of networks reveals that actors are not equally positioned within a network. The position of actors in a network is associated with the innovative performance of firms or with other firm-level characteristics.

3 Comparing different networks. Social network analysis permits the comparison of different types of network formed by the same set of actors. It helps to illuminate what type of network (for example market, friendship, professional) is most likely to

transmit knowledge relevant to innovative results.

4 Analyzing network evolution over time. A key innovative step has to do with the study of innovation network evolution over time. While previous studies have taken a historical or descriptive perspective, recent research has explored whether network analysis could offer an alternative view. Because of the lack of longitudinal network data at the regional level, scholars have so far primarily used co-inventor networks based on patent data. Very few data exist, however, on the evolution of informal networks. This line of research is certainly one of the most promising.

Policy actors at various levels (local, regional, national, and supranational) are integral elements of innovation systems. Increasingly, we observe a system of multilevel governance. Three main and interdependent policy foci are needed to help enhance and improve a region’s innovation capability: policies aimed at tackling weaknesses and inadequacies in regional “fundamentals”; those aimed at enhancing external economies associated with the region’s existing and potential industries and clusters; and those aimed at improving the adaptive capability of a region’s economic asset base and fundamentals (firms, industries, workers, institutions, infrastructures, governance arrangements, and so on). Different regional authorities may be expected to assign different relative emphases to these groups of policy initiatives, but, in almost all regions, policies will be needed on all three fronts.

The global recession that began in 2008 suggests that the innovations of the second half of the twentieth century may not be a model for the twenty-first century. Technology innovation will not end, but both are likely to be subject to a more “managed” policy environment, with government support.

Input–output analysis

Dazhong Cheng  
*Fudan University, China*

Peter W. Daniels  
*University of Birmingham, UK*

Input–output analysis is one of the most widely applied analytical frameworks in economics. Its fundamental purpose is to analyze the interdependence of various industries or sectors in an economy, such as agriculture, manufacturing, or services. The original idea for input–output analysis can be traced as far back as the early work of a British physician and Oxford professor, William Petty, in the mid-seventeenth century. The first historic breakthrough was made by a Russian-born US economist, Wassily W. Leontief (1906–1999), in the late 1930s, for which he received the Nobel Prize in Economic Science in 1973 (Miller and Blair 2009).

Two pillars of input–output analysis

Over the past eight decades, the evolution of input–output analysis has been based upon two major pillars: theoretical foundation and data construction. Therefore, some studies may be purely theoretical, exploring the formal relationships that can be derived under various assumptions from sets of equations; other studies may be purely descriptive and dependent upon the construction of input–output tables; others will incorporate a mixture of both empirical data and theoretical relationships in an attempt to explain or predict actual interdependence between industries or sectors (Christ 1955).

The theoretical foundation of input–output analysis, or the input–output model, is viewed by Leontief as a general equilibrium theory. In its most basic form, an input–output model consists of a system of \( n \) linear equations with \( n \) unknowns which form a matrix that can be readily used to represent the mathematical structure of the model. An essential condition for empirical input–output analysis is the input–output table, which was first used by the French economist François Quesnay in *Tableau Économique* (Kuczynski and Meek 1972). Input–output analysis became a widely used tool of economic analysis after a standardized system of economic accounts built around input–output concepts was developed, initially by Leontief (1941) and then by Richard Stone (1961), who was awarded the Nobel Prize in Economic Science in 1984 (Miller and Blair 2009).

The basic structure of an input–output table records the flows of goods or services from each sector (as a producer or seller) to each of the other sectors or itself (as consumers or purchasers) (Table 1). The distinction commonly made in input–output analysis is between the production of goods and services and their utilization, as reflected in the four quadrants of the input–output table. Quadrant I shows the intermediate transactions; that is, the flows of goods and services that are both produced and consumed in the process of current production. Quadrant II shows the sales by the producing industries to final uses such as private consumption, government consumption, fixed capital formation, and net exports. Quadrants I and

II together allocate the total output of each industry in the economy. Quadrant III shows the primary (factor) inputs that are required by each producing industry; these constitute the gross value added (including employee compensation, depreciation of capital, and indirect business taxes) in each industry. Quadrants I and III combined show the total inputs used for production by each industry in the economy. Quadrant IV records two equivalent measures of gross domestic product (GDP), one derived from expenditure components, and the other from value-added components.

Recent major developments in input–output analysis

The widespread availability of high-speed modern computers has made input–output analysis more comprehensive and practical. Among the most important advances are the improved implementation of computable general equilibrium (CGE) models and the ability to continually update and expand input–output tables. CGE models use the input–output model as a benchmark for working with actual economic data to estimate how an economy might react to changes in policy, advances in technology, or other external factors. So far, there are two versions of mathematical programming and optimization software suitable for CGE modeling and analysis: the general algebraic modeling system (GAMS) (see www.gams.com/) and the general equilibrium modeling package (GEMPACK) (see www.copsmodels.com/gempack.htm).

There have been two important developments in the use of input–output tables in recent decades. First, since 1936, when Leontief first presented US interindustry transactions tables for 1919 and 1929, an increasing number of countries and regions around the world have been routinely constructing input–output tables. Two crucial advances can be identified in the evolution of these national-level input–output tables. One is the compilation of regional and multiregional input–output (or MRIO) tables, which provide the basis for impact analysis and examining the interconnections between different regions within a country. The other is the construction of noncompetitive import type input–output (or noncompetitive IO) tables. In these tables, domestically produced intermediate inputs and imported intermediate inputs are treated separately, as they are presumed to be poor substitutes for each other. If the inputs imported by a country are differentiated further by country of origin, it is possible to trace its external economic and trade relationship with other countries (of which more below).

Second, as more and more countries have become engaged with the process of globalization, industrial linkages now reach well beyond national borders and it has become more difficult for the conventional national-level input–output tables to capture the details of global industrial and value chains. Therefore, various attempts to harmonize input–output tables for different countries and to construct international input–output tables are ongoing. Examples include the Asian IDE-JETRO tables compiled by the Institute of Developing Economies and Japan External Trade Organization (Inomata and Okamoto 2015), the GTAP tables constructed by Purdue University (see https://www.gtap.agecon.purdue.edu/), and the recently released World Input–Output Database (WIOD), which covers 27 countries of the European Union and 13 other major countries in the world for the period from 1995 to 2011. The latter attempts to analyze the effects of globalization on trade patterns, environmental pressures, and socioeconomic development (see www.wiod.org/new_site/data.htm) (Timmer 2012). In contrast to a national input–output table, a world
INPUT-OUTPUT ANALYSIS

input–output table traces flows of products or services for both intermediate and final use that are divided into those that are produced domestically and those that are imported (see Table 2).

An application of input–output analysis to producer services

In contrast to consumer services, producer services enter the production process of other manufacturing and services firms as an input (Grubel and Walker 1989; Stibora and de Vaal 1995). Firms can obtain producer services via two channels: in-house provision and/or market transactions. The former reflects the specialized division of labor inside the producers or firms, and thus the internal resource allocation and industrial linkages directed by firms’ decisions. Unfortunately, these types of producer services cannot be captured by input–output tables in the System of National Accounts (SNA) and will frequently be grouped according to firms’ main business (e.g., manufacturing). The latter, market-driven group reflects the specialization of, and division of labor between, different firms in the market, and hence the resource allocation and industrial linkages based on market competition. These types of producer services are captured in the SNA input–output tables, with the number of such records increasing as the outsourcing and marketization of producer services, a natural evolution of specialized division of labor and resource allocation from inside the firm to the market, continues.

However, from a statistical perspective it is difficult to distinguish between producer services and consumer services; activities such as banking or transport not only fulfill intermediate demand but also meet the needs of final consumers, even though individual firms may emphasize the provision of services to one group or the other. As a result, research that uses an arbitrary classification of producer services cannot accurately detail their status, their role, and their contribution to a national economy. In order to circumvent such problems, some researchers have turned to input–output analysis (Khayum 1995; Windrum and Tomlinson 1999; Cheng and Daniels 2014).

By way of illustration, two examples are presented here. First, the output of any one specific service sector must be classified into two parts: output consumed by final users and output that will be used by firms as an input. The ratio of the former part in the output is the consumer services ratio, while the latter part (\( SI/SO = \text{services input/services output} \)) is the producer services ratio. This identifies the extent to which a specific service-sector category is a producer service. A large producer services ratio means that more of the output of a specific service sector is being used as input to other parts of the economy; this suggests that the sector is more like a producer service. If the ratio is low for a specific service sector, it is considered to be functioning more like a consumer service. As a general rule, a ratio of 50% or above is considered the threshold for judging whether a service activity can be characterized as a producer service. Data for the USA (Table 3) show that the sectors with a producer services ratio averaging 50% or more are research and development (R&D) (about 90%), other business activities (about 80%, including knowledge-intensive business services (KIBS) such as consulting, design, legal services, etc.), transport and storage (70%), post and telecommunications (over 60%), and finance and insurance (above 55%). The remaining sectors with values below 50% are more closely aligned with consumer services. For China in the mid-2000s (see Table 3) six activities have more than 60% of their output used as producer services: wholesale and retail trade and repairs, hotels and restaurants,

transport and storage, post and telecommunications, finance and insurance, and other business activities. The comparison suggests that although R&D behaves more as a producer service in the United States, in China it is more akin to a consumer service, along with real estate activities, education, and health and social work. On the other hand, wholesale and retail trade and repairs and hotels and restaurants in China act more as producer than consumer services.

Input–output analysis is also used to compute two linkage coefficients: the backward linkage coefficient ($BL_j$)

$$BL_j = \left( \frac{1}{n} \sum_{i=1}^{n} b_{ij} \right) / \left[ \frac{1}{n} \left( \sum_{i=1}^{n} \sum_{j=1}^{n} b_{ij} \right) \right]$$ (1)

and the forward linkage coefficient ($FL_i$)

$$FL_i = \left( \frac{1}{n} \sum_{j=1}^{n} b_{ij} \right) / \left[ \frac{1}{n} \left( \sum_{i=1}^{n} \sum_{j=1}^{n} b_{ij} \right) \right]$$ (2)

(from the Leontief inversion matrix $B = (b_{ij})_{n \times n} = (I - A)^{-1}$, the Leontief complete consumption coefficients $b_{ij}$ can be obtained, where $A$ is an input coefficient matrix based on Quadrant I in Table 1 and $I$ is an identity matrix). The first coefficient measures the backward economic linkage of one specific sector $j$ to the rest of the economy; that is, when the output of sector $j$ (e.g. transport services) increases by 1 unit, how much of the increased demand from sector $j$ (as a purchaser) will rely on (upstream) sectors (e.g. transport vehicles) whose outputs are used as inputs to production in sector $j$? The greater the value of this coefficient, the stronger the pulling power of sector $j$ on the rest of the economy. The second coefficient measures the forward economic linkage of one specific sector $i$ to other sectors; that is, when the output in every sector of the economy increases by 1 unit, how much of the increased demand from these (downstream) sectors will depend on sector $i$ (as a seller) (e.g. transport services)? The greater this coefficient, the higher the pressure of demand experienced by sector $i$.

Indeed, there has been considerable literature arguing about the linkage measures and offering numerous suggestions for differing definitions and refinements of them (Beyers 1976; Miller and Blair 2009). Our aim here is just to introduce the simplest forms of these measures and in particular to show how they are derived from information in the IO table.

It is common for the same kind of services (e.g. transport services) to be used as both upstream and downstream services. Referring again to Table 3, in the mid-2000s, R&D, other business activities, education, and health and social work have larger backward linkage coefficients in China than in the USA. However, the backward linkage coefficients of real estate activities and finance and insurance are obviously much smaller (only 0.57 and 0.74, respectively) in China. The values of the forward linkage coefficients for wholesale and retail trade and repairs, transport and storage, and other business activities in China are greater than 1, while the values for the other sectors are much lower; five scored less than 0.5 in the mid-2000s. In the USA, the forward linkage coefficient for R&D was well above 1.7 from the early 2000s, approximately four times the equivalent value for China. Indeed, almost all the service sectors in China, except hotels and restaurants and transport and storage, have much smaller forward linkage coefficients.

The fact that every sector of the economy in China depends to a significant degree on hotels and restaurants and on transport and storage again confirms that these services are utilized more as producer services and have therefore performed a key role in industrialization. Once again, the forward linkage coefficient for real estate activities

INPUT-OUTPUT ANALYSIS

in China is less than 0.5 and is just one-third of the equivalent USA value. It is clear that Chinese real estate activities cannot exert strong pulling or pushing powers on the rest of the economy: this sector functions independently from (or is not strongly connected to) the rest of the economy since both linkage coefficients are well below 1.

To sum up, subject to the availability of suitable and reliable data, an input–output analysis can greatly improve our understanding of the development and contribution of producer services to economic change and restructuring, especially at the national scale but also at the global scale as the appropriate models for analysis begin to be introduced.

Institutions and development

Anthony Bebbington
Clark University, USA
University of Manchester, UK

Institutions, institutions everywhere – and we’re still not satisfied

A city in South America, early 2015, and the author is interviewing a senior international economic journalist about their take on extractive industries and development. The journalist, who is simultaneously of a social democratic and neoliberal inclination, says something along the lines of: “Of course, the social scientists are right when they say it’s all a problem of institutions. But this doesn’t help very much. I can’t help feeling that this is their trade and that they should be able to say rather more than just that.”

In a short sentence, the journalist summarizes the problem of institutionalist thinking about development: that a typical response is “Yes, of course institutions matter, but so what?”

The idea of an institution is difficult to pin down. The term is used to refer to formal organizations at scales ranging from the World Trade Organization through to panchayats; recognized sets of rules that guide practices in such a way that the rules are reproduced, for instance the institution of marriage; and sets of practices that become so routinized that they imply the existence of sets of rules that actors follow, for instance the institution of the gift. In these meanings – albeit very different – the constant is a reference to stability, reproduction, and acceptance, and to rules that govern behavior whether through the exercise of force or the command of legitimacy. But institutions also change, often profoundly: think again of the institution of marriage, for instance, which has changed profoundly in modern history and continues to do so. So institutions are stable, but they are also not stable.

Another binary that institutions seem able to bridge is the formal and the informal. Laws, constitutions, tax codes, property – these can all be highly formal, tangible institutions, the rules underlying which can be pulled off a shelf and perused (at least in modern economies). However, systems of reciprocity, moneylending, or “corruption” can equally be based on rules of which participants are quite aware, but these institutions are in no way formal: there is nothing written down or formally adjudicated, and there are no rule books on the shelf. And then, in some sort of liminal space between the formal and informal are institutions such as systems of indigenous or religious law which may be only partially formalized and only partially recognized by the state, and which are completely binding for those who recognize them and adamantly rejected by others who do not.

This expansiveness of the term “institution” leads some to find relatively little use in the concept, but it also reflects a broad-based recognition that explanations of social phenomena cannot wholly rely either on the purported motivations of individual actors or on the power of overwhelming structures. The concept of institution gets at the idea that there is something
between structures (such as the logic of capitalist development) and human actions (such as those of rational microentrepreneurs or motivated development workers) that influences outcomes. The recurring interest in institutions also reflects the desire to intervene in development processes in pursuit of different outcomes. Whether authors call for tighter financial regulation, state oversight of enterprises, more stringent tax codes, government decentralization, more opportunities for popular participation, ways of making budgets transparent, indigenous autonomy in local government, or the liberalization of capital markets – these are all calls for forms of intervention to change the rules and make these new sets of rules binding. In short, they are calls to change institutions and reflect a belief, stated or not, that a change of institutions might just change development outcomes.

Institutions and development

The importance of institutions in explaining development outcomes and processes became one of the more important themes in development theory and policy from the 1990s onward. A milestone text in this regard was Douglass North’s *Institutions, Institutional Change and Economic Performance* which understood institutions as “the rules of the game or more formally, the humanly devised constraints that shape human interaction” (North 1990, 3) and argued that these rules of the game are the primary determinant of the degree and quality of economic performance. The reasons for the rapid rise of these institutionalist arguments are many. While one reason might, of course, be the general power and persuasiveness of the argument itself, Ben Fine (1999) suggested instead that the idea of institutions became so popular because it was a way of being able to recognize that markets do not function perfectly without having to return to discussions of the developmental state. Rather than rebuilding states reduced by structural adjustment and other neoliberalizing reforms, the institutional argument led to an emphasis on property, contracts, and information asymmetries. Whether this was the reason or not, the institutional turn became apparent in many development agencies as well as in the literature – and it is certainly the case that development economists and rational choice political scientists were at the fore of this intellectual innovation.

One ongoing debate among macro-economists has been whether institutions (understood primarily as enforceable contracts) or geography (understood primarily as location and resource endowments) are the prime explainer of overall development performance. While authors such as Dani Rodrik emphasized that “institutions rule” (Rodrik, Subramanian, and Trebbi 2004), others in the camp of Jeffrey Sachs (2003) argued instead that location, distance from the sea, and other basic locational characteristics were ultimately more important. A variant in this discussion has been the turn to historical institutions on the part of some development economists and political scientists who have sought an explanation of divergent forms of development in the nature of colonial institutions of property and exclusion (Acemoglu, Johnson, and Robinson 2001).

Another avenue toward the institutional question has been the long historical debate on the relationships between state, market, and civil society. This debate was fueled by, inter alia, the increasing interest in nongovernmental and community-based organizations in certain aspects of development (in particular local development and natural resource management). Typically such discussions have come to the view that the quality of development hinges not on the absolute prioritization of one or other of these
sectors, but instead on the nature of the relations between them, or in other terms how they “govern” each other, be this through relationships of regulation or of complementarity. The focus on governance always tracks back to “getting the institutions right” and also establishing relationships that will bring such “good” institutions into being and sustain them. One particular favorite has been to establish institutions that enhance transparency: of the many venues in which this can be seen, the Extractive Industries Transparency Initiative (EITI) and the Open Government Partnership are just two examples.

Another domain in which these questions of complementarity, regulation, and institutional design have been explored has been that of financial services – both formal and microfinancial. The debate on institutions for regulation of the formal sector has taken on renewed vigor since the financial crises of the last two decades, while the discussion of microfinance has been a cornerstone in development thinking and intervention for at least three decades now. Early microfinance discussions focused rather more on the establishment of alternative institutional forms for delivering credit to very poor people who otherwise did not have access to such financial services. These discussions tried to understand the formal and informal rules that made Grameen such a success, as well as the formal and informal rules that underpinned emerging models such as the increasingly popular “village banks.” These ideas were then taken up by an increasing number of nongovernmental organizations (NGOs) and donor agencies as they each rolled out models for the delivery of microfinance as a vehicle of poverty reduction, economic empowerment, and enterprise development. As time went on, however, discussions began to consider the types of institutional arrangement that would be needed to provide additional financial services, such as savings accounts, insurance, and money transfers; and, at the same time, the formal banking sector began to look at these experiences, and to see the lower parts of the pyramid, if not the bottom, as a potential market. The effect of these developments was that the microfinance discussion was steadily taken toward the state–market–civil society framework. The questions became: What sort of rules would need to be in place to allow formal banks and NGOs to collaborate, to ensure that village banks or NGOs that began deposit schemes would be good guardians of people’s savings (and did not run off with them), and to bring the microfinance sector into the sphere of regulation like the formal financial services?

A further strand of institutionalism that has been especially influential in development theory and practice is that stemming from Elinor Ostrom’s (1990) work on institutions for collective action. Originating in an effort to understand the institutional arrangements under which common pool resources could be managed collectively in ways that avoided the “tragedy of the commons,” this work led to a far broader framework for understanding the institutional arrangements that would lead to more sustainable and inclusive management of resources such as forests or irrigation systems, that could facilitate the joint provision of services through the combined action of government and civil society, and that could promote what became known in World Bank parlance as “community driven development.” If the line of analysis reflected by the work of Rodrik, Acemoglu, Johnson, Robinson, and others was concerned above all to discern the institutional explanations of variation in macro-economic development, Ostrom’s approach (since continued by scholars such as Arun Agrawal, Krister Andersson, and others) was instead interested in explaining institutional sources of variation in local and resource specific development as well as in
identifying the “design principles” under which such development might be more “successful.” Within development geography, this work on institutions for local natural resource governance has been perhaps most influential in efforts to understand the dynamics surrounding protected area management and co-management, as well as use and management of forest and forest margins.

For many geographers these approaches to institutional explanations of trajectories of development have felt excessively formalistic, requiring a degree of simplification (in order to define variables and indicators that can be compared across cases) and emphasis on design principles that sit awkwardly with concerns for context and place specificity. Indeed, the discipline has made only limited contributions to theories of the relationships between institutions and development. It is probably economic geography, and in particular those parts of the subdiscipline most closely related to economics and regional science, where most has been contributed to more theoretical debates about institutions (Storper 2013). The primary concern of this work has been to understand the institutional conditions underlying the emergence of vibrant regional economies and industrial clusters, with a particular emphasis on OECD (Organisation for Economic Co-operation and Development) economies.

Institutions and development geographies

Institutional theory has been dominated by the work of economists, political scientists, management theorists, and some social theorists. While this literature has, by and large, treated institutions aspatially, there are many senses in which the relationships between institutions and development need to be understood geographically.

First, while the rules constituting some institutions may exist aspatially (e.g., tax rules, or rules governing access to social protection programs), their effects are very much spatially differentiated. Second, to the extent that institutions only exist when they are practiced, the geography of their practice may well be highly uneven across space. Rules governing environmental standards may exist nationally, but their enforcement will vary across space as a consequence of the spatially uneven presence of the state or other bodies that oversee the application of such rules. Third, one institution may interact with other institutions in ways that vary across space. Continuing with the earlier example of environmental standards, enforcement of formal governance institutions may vary depending on the geographies of corporate responsibility (leading some companies to take up environmental rules more willingly than others) or the geographies of corruption (in which some subnational authorities are more resistant to corruption, and thus more likely to enforce standards, than others).

A fourth reason for being spatially explicit in the discussion of institutions relates to the very ways in which the nation-state is understood. Thus, while sets of rules may exist at a national level, the state (or indeed other actors) may establish areas of exception in which these rules do not apply, because of state policy (which may, for different reasons, suspend human rights and environmental or tax institutions in certain spaces in the name of national interest, security, or the like), because of the geographies of insurgency (determining areas in which some state rules cannot be applied but others can), or because of geographies of crime which can also displace the rule of law as well as a swath of other institutions. Perhaps the more general observation here is that the presence of the state (as a bundle of institutions) varies across space to the extent that the rules that underlie the state are practiced
unevenly across space. Indeed, in some sense the project of nation-state building is one of trying to extend its institutions across territory in ways that are increasingly similar. The converse situation is one of institutional patchiness and, at an extreme (which characterizes very many countries), the coexistence across “national” territory of differentially governed fiefdoms (as, for instance, where parts of “national” territory are instead governed by insurgent groups, companies, mafias, paramilitaries, or large property owners).

**Explaining institutions and their change**

Let us return to the lament of the economic journalist in the introduction. While existing institutional arrangements might be critiqued, and alternatives called for, such commentaries beg two questions. First, if existing arrangements are undesirable or suboptimal, why do they exist in the first place? Second, what does this explanation of current institutional arrangements imply for the processes through which they might change? There are no generic answers to such questions, and answers may likely vary depending on the type and scale of institutions in question. However, some general observations can be made.

While existing institutional arrangements might be understood as reflecting dominant interests, such an observation neither identifies what those dominant interests are, nor the indicators that prove that they are indeed “dominant.” Perhaps most importantly, the observation itself does not establish the mechanisms through which interest groups were able to secure such arrangements and render them sufficiently stable and respected such that they could be deemed “institutions.” Two relatively recent and influential efforts to develop such a line of analysis have come from the team of Daron Acemoglu and James Robinson (2012), and from the political economist Mushtaq Khan (2010). Acemoglu and Robinson pose the macro-developmental question of “why nations fail” and argue that those nations that do indeed fail tend to be characterized by “exclusive” economic and political institutions that allow wealth accumulation through the control of rents, exclude many in society from property rights and market access, limit political participation, lead to discretionary application of the rule of law, and prevent access for the majority to authority and government. This argument is very similar to North, Wallis, and Weingast’s (2009) who distinguish between limited-access and open-access orders, the former being much more exclusive in how access to political power is organized. Acemoglu and Robinson (2012) explain the general structure of institutional arrangements in a society in terms of “political equilibria” that are understood as the set of political and economic institutions that are compatible with the balance of power between groups. In a similar vein, Khan (2010, 20) argues that the determinants of institutional arrangements have to be found in the “political settlement” on which society is founded, understood as “the interdependent combination of a structure of power and institutions at the level of a society that is mutually ‘compatible’ and also ‘sustainable’ in terms of economic and political viability.” These settlements, according to Khan, constitute a sort of agreement regarding how power will be exercised to enforce rules governing access to political authority and the distribution of benefits in society.

These approaches imply that actually existing institutions can only be understood in terms of the way in which political and social power are exercised in a given country. (Indeed, the focus of these approaches is on the national level, though the arguments could easily be taken to a subnational level, raising the interesting question
as to how subnational and national settlements interact with and constitute each other.) This is an important counterpoint to what can often be design- and blueprint-oriented approaches to institutional change, because the implication is that, in addition to design (because, of course, design still matters), sociopolitical relationships and incentives must also be such as to favor a given institutional change. This might seem like an obvious observation: however, it is an important one, not least because much development intervention has paid relatively little attention to understanding the real world of political power when devising institutional changes — helping to explain, perhaps, why so much development “fails.” Moreover, while this emphasis on political power may, again, seem obvious to geographers, these contributions force the very difficult questions of how the nature, structure, distribution, and exercise of sociopolitical power is actually organized. This is not an idle task, and indeed contributions such as these have elicited significant work in some development organizations seeking to address the “political drivers” of development and state formation (see, e.g., www.effectivestates.org).

While these frameworks offer important insights, they say much less about the cultural politics that underpin particular institutional arrangements. Different institutions become dominant not only because of the political interests to which Khan, Acemoglu, and Robinson draw attention, but also because of the ideas and narratives that make those institutions seem acceptable and appropriate. The emergence of the institutions that underlay the neoliberal economic reforms characterizing the period since the 1980s was itself facilitated by the rise of certain ideas and arguments, themselves elaborated and broadcast by networks of intellectuals, think tanks, and journalists. Similarly the institutional changes fostered by progressive governments in Latin America since the 2000s have also depended on the crafting of arguments regarding resource nationalism, sovereignty, and the role of the state. The importance of such narratives in stabilizing social order is, among other things, one of the lessons of poststructural approaches to government and Gramscian approaches to hegemony. While such literatures are not typically associated with thinking about institutions, they contribute a lot to understanding how certain rules of the game become dominant. More familiar analysts of institutional change say something similar: “the politics of ideas is intrinsic rather than epiphenomenal to the processes of coalition formation that underpin institutional change” (Hall 2009, 212).

These insights into how institutions become dominant also help explain how they might change, with consequences for patterns of development. First, institutions can change as a result of the emergence of actors with what Khan would call “holding power,” the ability to upset existing political settlements. This can occur at different scales. At a national level, Boix showed how the steady emergence and consolidation of a professionalized middle class in Franco’s Spain slowly but surely asserted its growing influence on the development trajectory of that country, ultimately helping to take it toward democratic transition and economic development. Subnationally, institutions governing forest control and access (for instance) can change over the course of time as movements of forest dwellers (indigenous or otherwise) have become stronger; examples range from Chipko in South Asia, through to rubber tappers and indigenous organizations in Latin America. That said, these institutions can also change in ways that are less than inclusive or sustainable as small- or large-scale loggers become more organized, as drug-funded networks become consolidated, or as new industrial interests emerge (e.g.,
hydrocarbon industries concerned to access oil deposits located in forested protected areas).

Second, institutions can change under the influence of external pressures, albeit generally when also aligned with particular domestic interests. The institutional transformations in Mexico and Central America that have derived from free trade agreements with the United States clearly reflected the exercise of US power, albeit with the clear support of certain domestic interest groups also. These institutional changes in everything from environmental governance to trade tariffs and laws governing capital flows rewrote the rules of the game in ways that have left profound imprints on patterns of development in the region. As another example, the World Bank and the Canadian government have clearly influenced the rewriting of mineral codes in many countries. And, in a more progressive sense, the United Nations and other external bodies have also influenced human rights codes.

Third, institutions can change under the influence of new narratives. The importance of narrative and ideas in regulating social life and social organization has been an insight of post-structural and Gramscian approaches in social movement theory and political ecology, as well as of work on the role of epistemic communities in policy processes. There are many examples of this within development studies and practice. To return to an earlier example, the general spread of microfinance institutions was assisted by a whole narrative-building machine that assembled academics, development observers, Muhammad Yunus (the spokespeople for NGOs such as BRAC), and others to craft an argument that finance should be thought of differently, and that there was no reason that poor people could not be disciplined subjects of banking services. The emergence of joint and community forest management institutions has been in some sense an effect of the combined demands of forest user organizations and an international epistemic community working on community forestry. In a similar sense, the growth of participatory institutions, while clearly owing much to the demands of strong and party politically articulated social movements (as in the case of participatory budgeting in Brazil) also has to be understood as an effect of the emergence of a global movement around participation and development combining ideologues (ranging from Robert Chambers to Orlando Fals Borda). Experiments in gender-based budgeting (to name but one) similarly reflect the combination of domestic feminisms and international epistemic communities in gender and development. And, finally, the slow emergence of institution regulating for prior consultation of large-scale investment projects with indigenous peoples reflects the crafting of domestic arguments about indigeneity, race, and rights, as well as the global pressure of movements organizing around the same issue and of dedicated bodies and activists within the UN system. The emergence and consolidation of certain sets of institutions over others depends, then, on the circulation and persuasiveness of narratives endorsing these institutions.

One of the implications of such observations is that institutional change will rarely occur just because a donor agency or a government wishes to introduce new institutions. Instead the change will occur when these underlying conditions are favorable to change. Of course, donors (say) may still introduce change – but the success of such change depends on how far proposed changes align with the broader political context, and the degree to which the changes are assumed by other social actors. Agencies that take a far longer approach to institutional change would first work on strengthening the political influence and legitimacy of certain actors such that they have the political power to subsequently be “insurrectionary” drivers of institutional change.
(to use Mahoney and Thelen’s (2009) term). There is no doubt that some actors have indeed followed such a strategy in the past – building first the political infrastructure for institutional changes before then introducing these changes and determining their details. Reminding us that there is nothing necessarily progressive about such a strategy, this approach was, for instance, the idea that lay behind US foreign policy during the 1980s and 1990s to support conservative forces in Central America (incumbent governments, business groups, factions of the military, counterrevolutionary groups). Only by enhancing the power of such groups were certain institutional changes in the organization of production, trade, ownership, taxation, and so on possible. However, supporting such groups alone would not itself have been sufficient to secure the institutional changes that the United States wished to promote. The detailed work on institutional reform also had to be done. The support offered by other actors to pro-democratic forces during periods of dictatorship in Chile, for instance, was a similar strategy – a strategy of building the political foundations of institutional change as a necessary but not sufficient precursor of such change – just pulling in an ideologically different direction.

Even though the definition of “institution” can often remain slippery, there is now much convergence around the idea that the nature of institutions is a critical determinant of the quality of development. This institutional turn then begs the questions implied by the journalist at the beginning of this entry: Where will “better” institutions come from? What will drive their emergence? And what will they look like? These questions take the discussion of development back to social and political terrains that are familiar to geographers – but which require very careful and disaggregated forms of analysis.

Interdisciplinarity and geography

Louise J. Bracken
Durham University, UK

Calls for interdisciplinary approaches to real-world, complex problems are becoming increasingly common, especially in research concerning the natural environment. The rationale behind such calls is to bring quality research from different disciplines together to overcome increasing specialization. Geography is regarded by many as a discipline, but it involves very different trainings for practitioners in human and physical aspects. Thus the issues surrounding geographers with different backgrounds working together are analogous to those around interdisciplinary working between the physical and social sciences. This entry initially reflects on what interdisciplinary working is and why researchers enjoy undertaking such research. It then considers a number of themes that are central to undertaking interdisciplinary research: the role of language, the importance of framing, and the inclusion of stakeholders in interdisciplinary research.

What is interdisciplinarity?

The term “interdisciplinary” has multiple meanings, “from simple borrowings and methodological thickening to theoretical enrichment” (Klein 1996, 153). Some have therefore suggested that “interdisciplinarity is best understood not as one thing but as a variety of different ways of bridging and confronting the prevailing disciplinary approaches” (Huutoniemi et al. 2010, 80). The appropriateness of interdisciplinary research is based on the premise that its associated collaboration and networking will produce innovative concepts and methods to answer complex research questions that are beyond the expertise of individual disciplines (Bruce et al. 2004). At the outset, it is important to clarify what is meant by the terms “discipline” and “interdisciplinarity.” A discipline is a branch of learning or scholarly instruction which is defined by institutional boundaries constructed by the needs of teaching, funding, administration, and professional development. The perceived boundaries of a discipline may change over time. Students are prepared for work within a discipline by an appropriate and specific training. As Dewsbury and Naylor state, “disciplines themselves are the outcome of ‘a variety of practices whose conceptual identities were the outcomes of local patterns of training and socialization’” (2002, 255).

Interdisciplinarity is a collective term encompassing all forms of scientific collaboration where the field of a single discipline is transgressed (Balsiger 2004). Interdisciplinarity is therefore about creating something new by crossing boundaries between academic disciplines or schools of thought, as new needs and thinking across them emerge (Bracken and Oughton 2006). Figure 1 presents a simple representation of the differences between discipline-based research, multidisciplinary, interdisciplinary, and transdisciplinary research. During discipline-based research disciplines bring their own trainings, understandings, and perspectives to a research issue/topic. There is no interaction between the
disciplines (Figure 1a). In a multidisciplinary approach, research continues to be undertaken within distinct disciplines around a certain theme or topic, but ideas and outputs are then brought together to relate to the research topic (Figure 1b). Outputs are thus joined and thought about together, but methods and perspectives are not integrated. An interdisciplinary research approach demands interaction between the trainings, expertise, and perspectives between disciplines. Thus the research topic sits at the intersection of a range of disciplines (Figure 1c).

Thus an integrated understanding and approach to the research topic is established. Transdisciplinary research is similar to interdisciplinary research but with the addition that those who are affected by the issues with which it is concerned, or who have a stake in the issue, are involved in the research (Figure 1d). Transdisciplinary research has come to symbolize a broad shift in research agendas toward an emphasis on utility (Bracken, Bulkeley, and Whitman 2015). This approach is based on the understanding that there are many equally legitimate sources of

Figure 1 Differences between (a) discipline-based research, (b) multidisciplinary research; (c) interdisciplinary research; and (d) transdisciplinary research.
knowledge and evidence that need to be drawn on to inform the management of environmental problems (Wynne 2003; Petts 2007).

Achieving good interdisciplinary research is not necessarily straightforward. It is well recognized that interdisciplinary practice is challenging because of differences in epistemologies, knowledges, and methods (Evans and Marvin 2004); different ways of formulating research questions (Oughton and Bracken 2009); differences in the nature of communication (oral and written) (Bracken and Oughton 2006); and differing attitudes within and between disciplines as to the importance of interdisciplinarity (Lowe and Phillipson 2009). These challenges can be exacerbated by expert knowledge becoming segmented and bureaucratized and compounded by the fact that science and technology are often grounded in the philosophy of reductionism, which tries to simplify and prise apart complex, real-world problems into manageable chunks of discipline-specific research (Balsiger 2004). With the increasing appreciation of difficulties and barriers to undertaking interdisciplinary research, publications have recognized and highlighted practice for successful collaboration. Key suggestions are: (i) longer start-up phases of projects to promote cohesion and to learn to value contributions from other disciplines; (ii) development of projects which satisfy complex societal problems; (iii) effective and experienced management of interdisciplinary teams; (iv) flexibility of researchers involved in conducting the research; and (v) understanding the ways of thought and language of others (Bracken and Oughton 2006). Of central importance is learning to work with the messiness of complex real-world problems rather than trying to simplify them (Donaldson, Ward, and Bradley 2010).

Boundaries can be both intellectual and administrative, and exist at a variety of scales. Often tension exists around these boundaries.

For instance, geography as a discipline is composed of two very different approaches, social science and physical science, which map onto very different ways of working. Interdisciplinarity can thus unfold within a single department of geography as well as between other departments (Bracken and Oughton 2006). Administrative practices can also influence the ways in which disciplines are encouraged to come together to undertake research. For instance, the Research Exercise Framework in the United Kingdom has tended to encourage departments to have a strong disciplinary core. Against such a backdrop, publishing and reaching out beyond high-profile geography journals in talking to interdisciplinary audiences becomes challenging.

Why do interdisciplinary research?

Oughton and Bracken (2009) found that academics leading funded interdisciplinary projects were keen to undertake this type of research to “give something back” and/or to “make a difference” (emphasis original). In their paper Oughton and Bracken (2009) were referring to applied research rather than coproduced knowledge. Justifications for undertaking interdisciplinary research were implicitly grounded in the notion that, by including the needs of others, it is somehow more valuable. Successful projects were able to identify and support the processes that allowed the communication and negotiation that is necessary, not just for the initial framing of a research funding proposal, but were able to maintain negotiation throughout the research (Oughton and Bracken 2009). Self-awareness, continual reflexivity, and a willingness to be questioned by others were essential to this process. It is vital to acknowledge the continued role of reframing. This is especially important for projects collecting data across the social and
natural sciences because it is difficult to map different epistemologies and methods successfully. Although hard, this is rewarding and may lead to new and exciting knowledges. Oughton and Bracken (2009) found three different, although not mutually exclusive, routes to undertaking interdisciplinary research: first, through collaboration with people from different disciplines, where researchers remained centered within their own area of expertise but were willing to engage with and to trust the expertise of others; second, through reading adventurously and developing understandings that allowed researchers to work critically with others in different disciplines, but without more formal collaboration; and, finally, by undertaking training in a completely new area or field, with some of those interviewed taking high-level qualifications in multiple fields of expertise. These three routes were supported by specific practices, such as working with physical objects (e.g., models), visiting places to experience how interdisciplinary research is practiced, and serendipity.

The role of language in conducting interdisciplinary research

Language may determine the positionality of the researcher, the way in which the research question is framed, the translation of the “field” to the academy, and the development of the theoretical context (e.g., Mirowski 1994). To try to improve practice in interdisciplinary research, previous work has tried to understand the ways in which we use language and how it may help or hinder our understanding of each other and of our respective disciplines. This work has been concerned with the contemporary, multiple meanings and uses of words in practice. Bracken and Oughton (2006) identified three distinct issues: registers of speech termed “dialects” and “metaphor” and the process of articulation (see Bracken and Oughton (2006) for case studies of instances where different perspectives on the meaning of words can lead to problems for common understanding).

_Dialects_ represent the difference between everyday use of a word and specialist, disciplinary use of a word (Bracken and Oughton 2006). Dialects are also produced by the same word having slightly different meanings within different disciplines (Bruce _et al._ 2004), which may also be different from their everyday meaning. Words which are in everyday use tend to be those that cause the most difficulty for the unwary interdisciplinary scientist. These misunderstandings may be exacerbated by the fact that academics are unlikely to question the meaning of a word with which they are already familiar. The conversation may be well developed before it becomes apparent that a particular word has a specific disciplinary interpretation as well as its everyday use. This situation is bound to lead to frustration for those coming together from different academic specialisms to undertake interdisciplinary research.

The second aspect of language is _metaphor_. The use of metaphors is common in everyday discourse and is embedded in our language; we rarely think about them or are aware that we use them. When working within disciplinary teams we tend to have common metaphors on which we draw to express and explain ideas. For good interdisciplinary practice we need to be aware of the times at which we move into separated speech communities and when the form of metaphor being used may be misinterpreted (Bracken and Oughton 2006).

The final aspect of language highlighted by Bracken and Oughton (2006) differs from the first two in that it is a process rather than a register of speech. _Articulation_ involves deconstructing
one’s own disciplinary knowledge in conjunction with those of other disciplines in order to understand the building blocks and thereby reconstruct a common understanding. The idea of articulation is particularly stimulating and an accurate description of the very active discussions involved in framing and undertaking interdisciplinary research. Slightly different definitions of the same word can highlight alternative starting points in terms of thinking about the research, related to disciplinary backgrounds. Breaking these down and developing a shared, common understanding creates a more powerful platform from which to develop a project. One aspect of this way of working is to define a whole that is greater than the sum of its parts. A second aspect can also emerge through the process. Each member of the team is constantly tested in their assumptions and perceptions, and while the process is difficult and time-consuming it can be rewarding and result in a much stronger basis from which to develop research (Bracken and Oughton 2006).

Framing

The use and role of language can be important in developing the frame by making sure people from different disciplinary backgrounds understand each other, but also by enabling new knowledges to be produced from which to develop a frame. Framing encompasses the processes of identifying and bounding the area of research. Few studies have explored practices of framing, although there are some guidelines for good practice (e.g., Mostert and Raadgever 2008). Distinctions have been made between framing and sense-making with the term “sense-making” being used to stress the internal, self-conscious process of developing a coherent account of what is going on, while framing emphasizes the external, strategic process of creating specific meaning in line with political interest (Fiss and Hirsch 2005). Others do not distinguish between the two because they see both as being an integral part of the framing process (Oughton and Bracken 2009).

There is a considerable amount to be learned about the negotiations behind successful framings and the factors that affect them that may be of use to the researcher embarking on interdisciplinary research. Within traditional disciplinary ways of working, the framing of the research question often arises directly from previous research or is left as implicit. The process of framing the research is not explicitly defined because it is accepted, or habitual, within a school of thinking which shares an ontology and epistemology. Hence the research process tends to follow an established pattern and is concerned with limiting a distinct experiment or investigation rather than placing it in a context (Oughton and Bracken 2009). Explicit negotiations associated with framing in this context need not be extensive and may be minimal. This is not to say that framing undermines the integrity of the research, but it may be that it is just not necessary. In the case of an interdisciplinary project none of this process can be taken for granted. Extra negotiation and uncertainties surround working in a research project that takes place outside and across disciplinary boundaries. By exploring the activity of framing across a number of different projects, it is possible to identify a range of features that support and shape the successful initiation and continuity of the research process (Oughton and Bracken 2009).

Many of the ways and processes of developing interdisciplinary research projects are no different from the initiation of ideas in disciplinary projects, but what is very different is the negotiation that is involved in developing the frame. Oughton and Bracken (2009) proposed two core
INTERDISCIPLINARITY AND GEOGRAPHY

elements to framing: identifying the research focus and determining the common objects with respect to scale, place, and time, and identifying the research team. The team may exist before the idea or may be brought together in line with the research question. Hence, researchers affect the research question and the research question determines who is drawn in as a researcher. One aspect of the process that interviewees commented on explicitly was that the iterative and negotiated natures of developing the research project which may well mean withdrawing a particular contribution, perspective, or person from the project should their input no longer seem relevant – in this case, the frame.

There is also a third element to developing the frame of research that is especially relevant to undertaking research around risk: the problem itself and letting the problem exist as a frame (Bracken 2012). This element of framing is therefore about letting those who live with an issue challenge the ways in which it is framed in our research. Allowing those who matter to speak back may not simply involve “normal conversations” with, for example, those who live with flooding, but conversations with a much wider set of “things,” both animate and inanimate, that constitute and formulate the problem that is of interest. Gaining input from others to help frame and shape research can occur in a range of ways. These range from stakeholders raising an issue which sparks an idea with researchers, to knowledge being coproduced with stakeholders (see the discussion on transdisciplinary research in the next section for further discussion of the role of coproduction in interdisciplinary research).

What came out strongly from the work of Oughton and Bracken (2009) was not just the amount and intricacy of debate that was necessary at the outset of establishing an interdisciplinary research project, but the continued negotiation that was demanded throughout the lifetime of the research. This is because the act of researching, or coming to know, a particular framing becomes, in itself, something that unsettles that framing in a similar way; this is termed “knowledge shifts.” It also emerged that researchers found it important to recognize that interdisciplinary projects are iterative because they are drawing on a number of different disciplines and that the research may be particularly complex and liable to fail in some aspect. One therefore has to be ready to change to ensure an outcome, especially with the involvement of stakeholders who are often looking to the research to solve immediate problems (Oughton and Bracken 2009). Researchers found it important to understand what others were saying and meaning to be able to negotiate the developing frame; thus the explicit use of language was important.

**Transdisciplinary research: the inclusion of stakeholders**

Few studies have tried to understand what stakeholders feel about being involved in research and how academics could work differently to develop more successful transdisciplinary practices. Such research is vital to developing more sustainable transdisciplinary research through greater reflections on the relationships between “science” and the “public,” as suggested by Irwin and Wynne (2003, 7). Bracken, Bulkeley, and Whitman (2015) initiated a study with a variety of different types of stakeholder (nonacademic expert and the wider public) involved in academic research in a range of ways: as subjects in focus groups and members of competency groups through to inclusion in participatory
action research, advisory panels, and work shadowing schemes. The research demonstrated that stakeholders have multiple interests and reasons for getting involved in academic research, although a desire to acquire new knowledge, either for its own sake or around a particular issue, was pertinent to all participants. A common thread that united stakeholders was that they all advocated a research process that is open, based on dialogue, flexible and where there are multiple measures of success.

A number of authors have raised the issue of “stakeholder fatigue” in participatory research and suggested that it can be due in part to the ephemeral nature of knowledge and poor communication within research projects (Du Toit and Pollard 2008; Holman 2013). Bracken, Bulkeley, and Whitman (2015) found that participants in their study confirmed that they would continue to take part in academic research if they found it interesting and relevant to their needs. Thus stakeholder fatigue may be lessened, and more sustainable participation maintained, if academic projects engage and communicate more effectively with stakeholders. To this end it is essential that there is flexibility in research project design and/or the research process to enable thoughts, ideas, and suggestions from stakeholders to be incorporated from conception to outputs within projects (Bracken, Bulkeley, and Whitman 2015). It was also clear that stakeholders valued and appreciated the debated and contested nature of the knowledges produced in their projects. This led to their gaining a better understanding of other people’s perspectives (both from each other and from academics), which were then applied, either through professional and/or personal routes, in their own contexts. Consequently, transdisciplinary working can counteract the “exclusionary and socially disengaged policy tradition characterized by invocation of the objective authority of scientific expertise” (Irwin, Elgaard, and Jones 2012, 128). Nonacademic experts and the wider public had similar experiences of being involved in academic research and both gained substantial knowledge and enjoyment. This is an important finding because the wider public is not often included in transdisciplinary research, only scientists and practitioners (e.g., Lang et al. 2012; Jolibert and Wesselink 2012).

The aspect that varied most between stakeholders was the benefits from being involved in academic research. Phillipson et al. (2011) noted that there was a positive impact on research relevance and quality, but the impact on stakeholder practices or knowledge seemed slight. In contrast, Bracken, Bulkeley, and Whitman (2015) demonstrate that the impacts on stakeholders can be significant. All stakeholders valued the increased stock of brokered knowledge that was gained through the coproduction process and suggested that this had made a difference to them even without giving an explicit impact or change to their daily ways of working (practice). In other words, the process itself was of value to them independent of any specific outcomes – a finding that questions those who argue for the ephemeral nature of coproduced knowledges (i.e., Holman 2013). Participants felt a personal pride at being involved in their respective research projects, even if something concrete had not been attained, although as mentioned earlier, the new networks and brokered knowledge were judged to be incredibly valuable to participants. Another important finding was the value of the “intangible impacts” on stakeholders of being involved in participatory research. These ranged from increased personal confidence, learning the languages of other stakeholders, to their continued engagement once researchers had completed their studies (Bracken, Bulkeley, and Whitman 2015).
INTERDISCIPLINARITY AND GEOGRAPHY

Both nonacademic experts and the public feel strongly that their judgments and values should be regarded as an integral part of the research process, as proposed by Macnaghten and Chilvers (2012). Furthermore, flexibility, openness, and the iterative development of projects enable stakeholders to contribute to the coproduction of knowledge and to enjoy being part of the research process (Bracken, Bulkeley, and Whitman 2015). This, they argue, may challenge previously published research where legitimacy has been used in reference to determining whether a stakeholder holds the “right” type of knowledge and experience to bring to transdisciplinary research (Lang et al. 2012).

While such approaches support the inclusion of stakeholders at the outset of the research process to shape projects, it remains the role of academics to determine which stakeholders hold “relevant” knowledges or expertises to be invited into the research (Lang et al. 2012). Such approaches maintain the authority of scientific knowledges and expertise while continuing to marginalize or even ignore the judgments and values of the wider public, based as these are in what might be termed more “local knowledges.”

Summary

The defining characteristic of interdisciplinary research is that it involves the integration of two or more academic disciplines into one activity such as a research project. Interdisciplinarity is thus about creating something new by thinking and working across boundaries. This can include working with stakeholders to coproduce knowledge, as in transdisciplinary research, or remaining within academia, as in interdisciplinary research. Interdisciplinary and transdisciplinary working are often necessary to explore real-world issues that do not fall within the bounds of a single discipline. There are many pitfalls to be avoided, but these can be pre-empted and sensible project planning can be used to develop successful interdisciplinary ways of working. Micropolitics plays a significant role in the ability to practice good interdisciplinary work and this is reflected in the ways in which certain kinds of language become used and in terms of how projects become framed. The notional hierarchies of disciplines, the personal ambitions and competitiveness of colleagues, not to mention the implicit and long-standing issues of power surrounding gender relations all play an important part in determining interactions within a research team. Understanding the role of language in interdisciplinarity is not going to solve these problems—it does, however, offer a route to making them visible. Sharing and exploring a speech community involves transparency. There is nothing to hide behind if one is sincerely translating one’s work for others and is simultaneously engaged in actively listening to their contributions. This process involves becoming vulnerable and thus open to the misuse of power. Good interdisciplinary work, therefore, is not possible without mutual trust and respect. Recognizing the roles of dialects, metaphor, and articulation is a move toward creating a new space for interdisciplinary intellectual engagement. Related to this crucial use of language is the way in which interdisciplinary research is framed.

Individuals tend to have a strong predisposition to work across disciplinary boundaries and an openness to collaborate with others. Successful projects are able to identify and support the processes that allow the communication and negotiation that are necessary, not just for the initial framing of a research funding proposal but as the project progresses. Self-awareness and continual reflexivity and a willingness to be questioned by others are essential to this process.
It is vital to acknowledge the continued role of reframing. This is especially important for projects collecting data across the social and natural sciences because it is difficult to map different epistemologies and methods successfully. Subprojects which may encounter problems when underway should, therefore, not be written off but negotiated so that they can be reframed. Although hard, this is a rewarding exercise and may lead to new and exciting knowledges. What is required for the successful framing of a research project is the coordination of the different perspectives to reveal the problem thus making it open to research.

Critical to the coproduction mode of transdisciplinary research is maintaining flexibility within the research process both in framing how the research is conducted and in the meaning of what constitutes “success.” Negotiation and working iteratively can help both stakeholders and researchers expand their knowledges about an issue, understand each other’s views, and hence reach a common understanding (although not necessarily agreement). Embracing the idea that knowledge is multiple and as likely to be held by community-based stakeholders or professionals as by academics is critical to the development of such dialogues. Transdisciplinary research is thus highly relevant, and should be a foundation of impact assessments of academic research.

Geography and geographers are well placed to undertake inter- and transdisciplinary research. A wealth of good practice and successful interdisciplinary research projects involving geographers already exists. We should learn from these success stories, take stock of studies that can help us refine interdisciplinary research practice, open our minds to being challenged from other disciplines, and embrace the multiple sources of knowledge that can assist us in developing high-quality, novel, and useful research. Most of all, we should have fun and enjoy challenging boundaries – undertaking inter- and transdisciplinary research is one way of doing this.

Maps produced on paper present their information visually. Cartographers designing for static maps communicate by making marks on a page, arranged in some way that the spatial relationships among the marks correspond to the spatial relationships of the objects in the real (or imagined) world. Apart from the mental processes of knowledge construction, readers interpret a paper map passively, able to interact with it only very little, possibly rotating it in their hands in order to aid in navigation, or folding it in order to limit the view (or fit it on a table).

Digital maps, on the other hand, can vary significantly in the ways that information is presented to users and in the ways users may interact with the displays. Digital map-makers now must consider not only the design of the marks on the page (e.g., the screen, still very important) but also the design of the myriad ways that the map can be manipulated and used. In this sense, cartographers are now user interface designers – while in the past their primary concern was an appropriate and intuitive graphical display of geographic information, today, cartographers must examine the diverse uses, and diverse users, of the maps they create, and design appropriate and intuitive interfaces that connect the user and the map (and thus the information contained within the map).

The term “mapping” is used in a noncartographic sense in human–computer interaction to refer to any encoding of user input (like a mouse-click) to an action on the computer (like moving from one web page to another), or any encoding of a piece of information (like a news item) to a stimulus (like a hyperlink on the screen). Now that digital maps are much more than passive visual representations of geographic data, with capabilities for both dynamic, customizable display and detailed, multifaceted interaction, it is useful to think of the cartographic process in this broader sense as well – actions of the user can be mapped to a reaction by the computer (a double-click will zoom the map’s scale), and geoinformation can be mapped to a mark on the screen (a church’s location is represented as a point in the pixel space of the display). It should thus not be surprising that cartographers are keenly interested in interface design as a means of efficiently connecting users of digital geoinformation to that information and the meanings and interpretation of it.

However, despite the possibilities afforded by digital geographic representation, the user interfaces for digital mapping environments have changed very little in the last thirty or so years. Digital maps owe much to the so-called WIMP (windows, icons, menus, pointers) interface, popularized in computers like the Apple Macintosh in the 1980s. As is the case with most computing environments in use today, digital maps rely on input from point-and-click computer mice (or, more recently, touchpads) and display their output via graphical windows that display visual plan–views of the Earth. This does not have to be the case, however. Research efforts in human–computer interaction (HCI), virtualization, and geographic visualization have all experimented with alternative and multiple modalities.
of digital map user interfaces that employ senses and cognitive channels that complement or even replace traditional interface modalities.

Vision and mapping conventions

In many ways, static maps themselves can be considered user interfaces: they are the intermediaries between a user and information, enabling users to understand a complex world through graphical symbols, conventions, and metaphors. Computer user interfaces (like the Windows desktop or the “home screen” of a smartphone) are abstractions of complex computational information: rather than typing commands and reading machine languages, users are allowed to interact with computers graphically and rely on metaphors such as folders, hierarchies, and slider bars to make sense of, and influence, the inner workings of the computer. Maps – even those created on clay tablets – do the same thing: maps are an abstraction of a complex world, simplified and generalized to their “essences,” at least according to cultural cartographic conventions.

While conventions of representation are useful to create and conform to a common language of information communication, they can also serve to restrict information to that which is expected or traditional. A classic example of a cartographic convention is that north is “up” on static maps; more subtle is the convention that elements of the environment that are culturally significant (such as courthouses or shopping malls) are shown at the expense of those that are deemed less important. But an even more fundamental convention on maps is that the Earth is represented visually.

This convention is very logical for the purposes of maps when they were simply static representations of Earth. Vision is the dominant mode of processing spatial information, as our vision is spatial – though we focus on only one point as we use our eyes, we can sense both breadth (using our peripheral vision) and depth (using our binocular vision). The transformation of the 2-D (or “2½-D,” if surface undulations are considered) surface of the Earth onto a 2-D sheet of paper is natural and intuitive, and represents a way of organizing the world that appears to be culturally universal (Blaut et al. 2003).

However, the dominance of the use of vision can lead to both cognitive mismatches (if a user is not trained in those conventions, or if the conventions are context-dependent) and constraints on the types of data that can be represented. Spatial descriptions that can be measured and quantified, for example, are privileged on a map, relative to a nonspatial story passed down through generations, that is also keenly important in the understanding of a place. In HCI, this has been called “blinkering” (after the “blinkers” on a racehorse that inhibit its view to only what is straight ahead (Nelson 1990)).

Additionally, vision is not always the most appropriate sense for representation of the use or the user of the map. Of course, those that have various forms of vision impairment must use alternate modalities to understand information but, perhaps less obviously, those whose eyes are engaged elsewhere – like soldiers on the battlefield, surgeons in the operating room, or even drivers of a car – would likely benefit from a “mapping” that allows for communication using modes other than vision.

Nontraditional modalities for cartographic interfaces

Humans naturally use multiple senses, or modalities, to communicate with each other and interact with the world. As we communicate, we speak, listen, watch our audience, often gesticulate, raise our eyebrows and scrunch our
noses, supplement our speech with sketches, and so on. When we observe phenomena in our environment to make sense of the world, we make connections among our senses to recognize or learn (looks like a duck, walks like a duck, quacks like a duck, etc.).

However, many of the aspects of the environment that are traditionally difficult to map are those that are experienced with senses other than vision. Most maps, for example, are relatively devoid of emotion, and it has always been challenging to represent (or emphasize) place over space on maps. Emotion is influenced by not only sights but also sounds, tastes, smells, and (literally) feelings, and a natural “mapping” of emotion and place should probably include at least some of these alternate modalities. Fortunately, the technology associated with digital mapping has opened possibilities for doing just this.

Interface input modalities

Map interface modalities (as with most types of interfaces) can be separated into different general kinds of uses: input and output. In terms of paper maps, output modalities consist of the map itself and the visual encoding of information of the marks on the page, whereas input modalities of paper maps are essentially nonexistent. As maps have become more interactive, it is these input modalities that have been borrowed and adapted from the realm of human–computer interaction, and that represent a great deal of innovation in the representation of geographic information.

Most digital maps receive input from the manipulation of a computer mouse and, to a lesser extent, through keyboard entry (typing in an address in an online map, for example). The operation of a computer mouse is a remnant of the popular graphical user interfaces (GUIs) of the 1980s. Prior to the mouse, one of the most notable experiments in user interface design was, coincidentally, demonstrated using a map. The “Put–that–there” system, developed by a team at MIT (Bolt 1980), included an entire “media room” with a wall-sized color map panel. The user would sit in a chair and point to the panel and issue verbal commands, to which the computer would respond. This is an early example of both gestural and voice modalities for interface input. Using a limited set of recognized active verbs (e.g., “create,” “move,” “put”) and pronouns (“that,” “this”) along with natural pointing gestures, the user could interact with shapes on a base map.

As there are multiple modalities (speech and gesture) working in concert with one another in this scenario, this style of interface is known as multimodal (Oviatt 2002). Speech input requires software processing of natural language, and for the computer to recognize and parse the semantic meaning of the commands. As we know when speaking on the telephone, this task is made difficult without communication clues given by visual cues of gesturing, gaze, and other natural behavior. Because, as is true in natural language, context and semantic clues to human verbal communication can be better understood when multiple modes are utilized, multimodal interfaces can accept input from parallel streams (for example, both voice and gesture).

Multimodal fusion like this was demonstrated in a crisis-management mapping scenario through the use of an environment called DAVE_G (Sharma et al. 2003). In that project, designers created a system in which multiple individuals would collaborate with a large-scale display that would respond intuitively and quickly to gesturing and verbal commands. The use of multimodal interactions here was considered important because the gesture and voice recognition supported the time-sensitive
and multi-user nature of the problem-solving scenarios.

Input to visualization systems through gestures and voice requires hardware as well as software to map the inputs to virtual interactions. Microphones (and headsets) are the most obvious of these input devices that would supplement or supplant the computer mouse for voice commands. For gestural input, there are several varieties. The wired (or “data”) glove can capture physical data such as finger bending or motion tracking. These are, not surprisingly, used in virtual reality systems where the user is immersed in a virtual environment (and not seated at a desk). Head and motion tracking devices can also use a video camera (mounted near the actual visual display) to observe infrared light emitted by markers worn by the user. These have become very popular in the gaming community. Other game system devices can also be used for gesture input, such as “Wiimotes” or joysticks that combine kinetic input with optical sensors and accelerometers. The Wiimote, for example, can be used to control applications with keyboard shortcuts, like Google Earth, quite easily.

Appearing at about the same time as gesture-based game controllers and systems were mobile devices such as smartphones and tablet computers that represented the first significant departure in about thirty years from the mouse point-and-click computer interface in wide use. Early mobile devices such as the Palm required a stylus to substitute for the mouse, with the point-and-click interaction very similar to that of a desktop computer. Now, the mobile device accepts gestural input such as swiping, shaking, rotating, pinching, and spreading. Additionally, the devices feature speech recognition and interpretation (through Siri, for example) and, in the case of wearable devices like Google Glass, require speech interaction. The rules for these interactions are still being developed (and have led HCI designers to call for standardization (Norman and Nielsen 2010)) but these devices surely will continue to demonstrate the utility of alternative modes of interface input and manipulation.

Interface output modalities

Prior to the advent of digital technology, nonvisual forms of geographic representation primarily included auditory abstractions, such as oral storytelling through language and song. Composers of so-called “tone poem” music popular in the nineteenth century intentionally represented place through nonverbal music; Bedrich Smetana’s “Die Moldau/Ma Vlast,” for example, evokes a soundscape of folk music and whitewater rapids to represent a river in Bohemia.

In addition to representations of geography that are designed for the ears, haptic representations, which rely on the sense of touch, have been developed, primarily for the visually impaired. So-called “tactile diagrams” are vacuum-formed raised surfaces similar to (and in some cases using) Braille. A significant impetus for nonvisual means of cartographic presentation is accessibility for the visually impaired; there is a long-standing subgroup of the International Cartographic Association (ICA) on Maps and Graphics for the Blind and Partially Sighted. Rice et al. (2005) and Griffin (2001) provide comprehensive reviews of haptic maps; efforts to represent geographic information to the disabled highlight the importance of alternative interface modalities for diverse users of geoinformation.

Cartographers have long used (and debated the use of) the “visual variables” presented by Bertin (1983) to guide the encoding of information to graphic marks on a map. Griffin (2001) draws parallels for encoding types of geographic data to
haptic variables, first classifying haptic sensations into “tactile,” perceived when skin comes in contact with an object, and “kinesthetic,” which are those stimulated by motion of the skin or body. A virtualized map displaying weather could feel physically colder in colder regions, and this would be represented as the tactile variable of temperature. Alternatively, a map of slope could encode steepness by the relative resistance provided by a computer mouse as it is (kinesthetically) moved around the map.

Computers can afford the opportunity to represent data sonically as well as visually. This is probably the most common alternate modality employed by map-makers, primarily because the hardware for creating sound (loudspeakers and an audio card) is now ubiquitous. Krygier (1994) categorized abstract sounds that might be produced by a computer into their appropriate cartographic use. The abstract sound variables, as he called them, included the basic building blocks of music: pitch, loudness, timbre, attack and decay, and register, among others. Such musical primitives are shown to adequately represent geographic variables of various levels of measurement (timbre for nominal data, pitch and loudness for ratio data, for example) and, as such, they are useful for bivariate or multivariate maps, as Fisher (1994) used them in representing uncertainty with sound. Rice et al. (2005) used sound in connection with haptic devices to create a “haptic soundscape” environment for the visually impaired.

Music – comprising higher-order structuring of the primitives Kyrgier described – holds potential for conveying emotion (as in the score of a film) as well as quantitative information. As such, sound and other modalities may be appropriate for conveying aspects of geographic reality that visual displays struggle to represent. The dynamic maps of Caquard et al. (2008) explore the use of such cinematic devices, supplementing maps with nonabstract sounds such as political speeches, airplane engines, and natural sounds. Sound plays a significant role in their studies, as spoken language, scores, songs, and sound effects play significant roles in film.

These alternative and multiple modalities are of course important for accessibility of geographic information to diverse users, such as those with visual impairment. But alternate modalities – in particular sound – can be important and effective for diverse uses of maps as well. User interface designers have, over the last two decades or so, explored the use of sound to make systems useful to individuals whose “eyes and hands are busy.” GPS receivers – which are being used in cars with the same purpose as road maps and atlases in the past – now feature verbal turn-by-turn instructions for easily distracted drivers.

Multimodal interfaces open new cognitive channels for humans to readily absorb information, as we do in our everyday environments. Digital maps are not unique in their potential for improvement using representation and interaction methods that more closely replicate the way we communicate with each other and understand the world. However, because cartographers have for centuries been tasked with abstracting complex information into useable and useful forms, they both contribute to and are informed by research and innovation in human–computer interaction, including the use of nontraditional interface modalities.

**INTERFACE MODALITIES**

**Further reading**

The Intergovernmental Panel on Climate Change (IPCC) was officially constituted during its first meeting in November 1988, convened in Geneva by its two sponsoring bodies, the World Meteorological Organization (WMO) and the United Nations Environment Programme (UNEP). It received its United Nations mandate through a Special Resolution of the 70th Plenary Meeting of the UN General Assembly, passed on December 6, 1988. The IPCC has published five full-scale assessments to date: in 1990 (the First Assessment Report: AR1), 1996 (AR2), 2001 (AR3), 2007 (AR4), and 2014 (AR5).

On each occasion the assessment of scientific knowledge has been organized around three Working Groups (WGs), which have retained broadly similar scope: the physical science of the climate system (WG1); the impacts of climate change on ecosystems and society and options for adaptation (WG2); and the economics and technological options for mitigation (WG3). In addition to these periodic assessments, nine “special reports” on more narrowly defined issues have been produced by the IPCC, the most recent being in 2012 on managing the risks of extreme events and disasters. IPCC reports have been influential for national and international policy development and in 2007 the Panel received, jointly, the Nobel Peace Prize for “its effort to build up and disseminate greater knowledge about man-made climate change and to lay the foundations for the measures that are needed to counteract such change.” During 2010 the governance of the IPCC came under significant public and political scrutiny owing to a small number of errors in AR4 (WG2), most notably about the future melt rate of Himalayan glaciers. The United Nations secretary-general commissioned the Inter-Academy Council (IAC) to conduct an independent investigation into the errors, an investigation which made wide-ranging recommendations for adjusting the governance and assessment procedures of the IPCC (IAC 2010).

Origins and mandate

The origins of the IPCC can be traced back to the growing number of scientific and political discussions in the 1980s about the extent of human influence on the climate system (Agrawala 1998). In 1985, an international meeting of climate and environmental scientists was convened by WMO/UNEP/ICSU (International Council of Scientific Unions) at Villach in Austria, which presented the case for more comprehensive international knowledge assessments of climate change. Rather than concede too much influence in this process to environmental nongovernmental organizations (NGOs), the US government in particular argued for
such assessments to operate under an intergovernmental mandate. Several events in the late 1980s converged to catalyze the formation of the IPCC as a new institution for global knowledge assessment about climate change. These included the growing capabilities of climate modeling and Earth system science through which climate was conceived as a global system, the rise of global environmental politics throughout the 1980s, and the success of the 1987 Montreal Protocol on Substances that Deplete the Ozone Layer. The end of the Cold War in 1989/1990 was also influential in spurring a new optimistic mood of political internationalism.

The IPCC was officially constituted during its first meeting in Geneva in November 1988. The UN Mandate to the IPCC was to “coordinate scientific assessments of the magnitude, timing and potential environmental and socio-economic impact of climate change and realistic response strategies.” Scientific understanding of climate change was to embrace both natural and human causes of change, but to distinguish between their effects where possible. It was to accomplish this task by recruiting international experts who would assess and synthesize peer reviewed literature, generating knowledge which would fall short of offering policy recommendations or advice. The distinction between science and policy thus implied has been an ongoing source of tension and reflection for the IPCC.

**Governance and learning**

The IPCC has evolved its own rules of governance and its own protocols for knowledge assessment, partly in response to external events and criticisms. The Panel is governed by a Bureau of around 30 officials and experts, elected by the IPCC Plenary in which each member state of the United Nations has a vote. The Plenary also elects the overall chair (and a co-chair) of the IPCC and the chairs (and co-chairs) of the three Working Groups. To date there have been four IPCC chairs: Bert Bolin (a Swedish biogeochemist who chaired AR1 and AR2), Robert Watson (a British atmospheric chemist who chaired AR3), Rajendra Pachauri (an Indian economist who chaired AR4 and AR5), and Hoesung Lee (a South Korean economist who is chairing AR6). In association with chapter lead authors, the IPCC Plenary also approves, line-by-line, the Summary for Policymakers of each WG Report. This approval process of the headline messages of each assessment cycle affords the IPCC’s conclusions the distinctive status of joint ownership between governments and scientists. The Bureau has responsibility for agreeing to the Working Group structures and the outline scope of each chapter. Together with the WG chairs and co-chairs, the Bureau filters nominations for lead authors and agrees to the final list of experts to be invited to convene and coordinate each chapter writing team.

The formal knowledge assessment work of the IPCC is governed by strict rules of procedure. These have undergone three major revisions, in 1993 (after AR1), in 1999 (after AR2), and again in 2010 (after AR4). The changes adopted in 1999 were made to accommodate more diverse regional sources of knowledge for the regionally focused chapters of WG2, but also were partly a response to a controversy which erupted in 1996 around the wording of Chapter 8 (“Detection of climate change and attribution of causes”) in WG1 of AR2 (see Lahsen 1999). The changes made in 1999 included: the introduction of independent review editors to oversee the peer review process; the adoption of formal rules for the making of an IPCC Synthesis Report (a single, shorter report drawn from across the three Working Groups); and the clarification of
circumstances under which non-peer reviewed (“grey”) literature would be acceptable as a primary source of knowledge.

It was the use of some of these latter sources in the WG2 Report of AR4 which provoked another major controversy and which led to a further round of procedural and governance revisions. In January 2010, shortly after the inconclusive meeting of the United Nations Framework Convention on Climate Change (UNFCCC) at Copenhagen (COP15) and after the release of controversial emails originating from the University of East Anglia, it emerged that a statement in the 2007 Report about the imminent melting of Himalayan glaciers was erroneous. This was traced back to a non-peer reviewed source and to poor review editing. The IPCC had no mechanism in place for the correction of errors and the IPCC leadership handled poorly the ensuing crisis of authority. The entire AR4 Report was placed under critical scrutiny and other minor errors and ambiguities were discovered. The United Nations secretary-general and the chair of the IPCC invited the IAC, a multinational organization representing the world’s science academies, to conduct an independent review of the IPCC processes and procedures.

These recommendations included, inter alia, establishing an Executive Committee and director; making the selection of experts a more transparent and rigorous process; clarifying the use of non-peer reviewed material; strengthening the role of review editors; and developing an effective communication strategy. The episode was a test of the leadership and transparency of the IPCC and of its peer review system for making reliable public knowledge about climate change. The credibility of many climate change policies continues to rely on the scientific authority of the IPCC, which in turn is grounded as much in trust as in truth (Beck 2011).

**Disciplinary and geographical expertise**

The mandate given to the IPCC by the United Nations was wide-ranging: to assess global knowledge about climate change and its potential implications for society. The scope and significance of this mandate means that who is selected to serve as an “expert” on the Panel becomes a matter of public interest: Which knowledge disciplines are favored by the IPCC? What is the geographical representation of the Panel’s experts?

Reflecting its origins in the meteorological and environmental sciences, the IPCC has been much more heavily influenced by natural science disciplines than by the social sciences or the humanities. In AR3 (2001) for example, only about 12% of the 8500 citations to peer reviewed journal articles were from social science literature (and of these about one-third were from economics). Although there was a modest broadening of disciplinary experts in AR5, the IPCC remains heavily skewed towards assessing knowledge of the physical climate system and ecological impacts, rather than knowledge about human beliefs and values with respect to causes, consequences, and responses to climate change. This has been referred to as the “IPCC fallacy” and social scientists have sought to understand the epistemological, institutional, and political reasons why the social science and humanities disciplines have been marginalized by the IPCC. Yearley (2009) argues that climate science is currently constructed through assigning the (interpretative) social sciences a specific role – a subsidiary one. “The institutional assumption of the IPCC is that the most relevant social science is economics” (401), thus marginalizing knowledge about climate change which emerges from disciplines such as anthropology, social psychology, communication science, philosophy, and history.
The IPCC has also faced criticism that its expert authors are drawn disproportionately (about 75%) from North America and Europe and disproportionately (about 60%) from Anglophone cultures. Up to and including AR4, 45% of the 193 nations of the world had never had an expert author selected for any IPCC author team in one of the four major assessments (Ho-Lem, Zerriffi, and Kandlikar 2011). The consequences of this uneven geography of IPCC expertise are significant, politically as much as epistemically. The IPCC experts who have constructed development scenarios, who have differentiated the value of human lives, and who have conceived of tropical forests as “empty spaces” for carbon sequestration – all examples of controversies from IPCC assessments – have therefore been drawn from a relatively small cohort of nations. In 1991, the then chairman of the IPCC, Bert Bolin, remarked: “Right now, many countries, especially developing countries, simply do not trust assessments in which their scientists and policymakers have not participated. Don’t you think credibility demands global representation?” (cited in Schneider 1991, 25).

Consensus, risk, and uncertainty

From its first assessment report onward the IPCC has been explicit about seeking to generate a “scientific consensus” about how climate is changing and especially about the extent of human influence on the climate system. Consensus-building in fact serves several different goals. For example, seeking consensus can be as much about building a community identity – what scholars refer to as an “epistemic community” – as it is about seeking the “truth.” Nevertheless, the IPCC’s drive for consensual knowledge claims has been a source of both strength and vulnerability. On the one hand, IPCC consensus-making has been largely driven by the desire to communicate climate science coherently to a wide spectrum of policy users – to construct authoritative globally agreed knowledge for use by governments in their development of policy. On the other hand, without a careful explanation of what consensus means, and without a full and careful exploration of uncertainties and disagreements among experts, the IPCC is vulnerable to criticisms of premature foreclosure of scientific discovery or of silencing dissent.

Consensus-making can also lead to the criticism of the IPCC being too conservative and of encouraging “scientific reticence.” Some have argued, for example, that the IPCC AR4 has been too conservative in reaching its consensus estimates about the range of future possible sea level rise. Given the broad acceptance that humans do now exert a significant influence on the climate system, it may be that governments would find it more useful were the IPCC to focus more on areas of disagreement and uncertainty than on consensus.

Within the IPCC, consensus-making is often an exercise in collective judgment drawing upon subjective (or Bayesian) probabilities in areas of uncertain or incomplete knowledge. To increase the rigor with which the IPCC reached and communicated its consensus, official uncertainty guidelines were introduced in 2000 as part of AR3. Three uncertainty schemes were adopted, all of which relied upon Bayesian forms of reasoning and judgment: a likelihood scale (from “virtually certain” to “exceptionally unlikely”), a confidence scale (from “very low” to “very high”), and a level-of-understanding matrix (“level of agreement” versus “amount of evidence”). The aim of these guidelines was to introduce a consistent methodology for uncertainty communication across the different IPCC Working Groups, yet the guidelines have
been difficult to police. Different Working Groups, familiar and comfortable with different epistemic traditions, construct and communicate uncertainty in different ways. This creates possibilities for confusion and misunderstanding, not just among policymakers and the public, but among IPCC experts themselves. One of the recommendations made by the IAC in 2010 was for the IPCC to be much clearer in explaining the processes whereby it attaches different levels of confidence to its headline conclusions.

Equally important is how the uncertainties reflected in the IPCC’s knowledge claims are understood in nonexpert public and political settings. Expressions such as “likely” or “extremely likely,” or claims of “high” or “low confidence” in certain knowledge statements, mean something very specific in expert IPCC terms. Yet the vernacular interpretation of such phrasing varies across audiences and cultures. Studies have shown how different forms of uncertainty communication used by the IPCC – for example uncertainties deriving from model differences versus disagreements between experts – alter the level of trust among lay audiences of the veracity of the IPCC’s claims. Work has also shown the effect of cultural differences on message reception; for example, Chinese and British citizens attach different intuitive probabilities to expressions such as “likely” or “unlikely.”

Wider influence and impact

There is little doubt that the IPCC has had a significant influence on climate change knowledge, on public discourse about climate change, and on climate policy development. On the other hand, scholars disagree about the exact reasons for this influence and whether it has always been for the best. Knowledge that is claimed by its producers to have universal authority is received and interpreted very differently in different political and cultural settings (Jasanoff 2010). Revealing the local and situated characteristics of climate change knowledge thus becomes central for understanding both the acceptance and the resistance that is shown towards the knowledge claims of the IPCC. There is also concern that the sheer size of full IPCC assessments (over 5000 pages in AR5) makes its product too unwieldy and cumbersome; an alternative arrangement of much shorter and more regular assessments is favored by some.

The IPCC has helped to fashion and consolidate a global climate change epistemic community. Thousands of scientists from across a hundred countries have served as lead authors and tens of thousands of experts from most countries in the world have participated in the reviewing process. The impact of this IPCC epistemic community has been examined from a number of different regional perspectives – for example, Brazil, France, China – with some concluding that IPCC knowledge “travels well.” Others, however, have identified some of the problems with the circulation of IPCC knowledge and warn against the “epistemological hegemony” of the IPCC. There remains considerable detailed empirical work to be done around the world about exactly where, how, and why the practices of climate change knowledge production developed by the IPCC have altered scientific practice, in the biogeophysical sciences and social sciences as well as in the design of interdisciplinary research.

The IPCC has also gained visibility in public spaces as the authoritative voice of climate change knowledge – “the privileged speaker and discursive leader” – a visibility enhanced through being awarded the 2007 Nobel Peace Prize. The “boundary work” between science and policy that the IPCC performs has also
legitimized the scientific vocabulary that businesses and NGOs have been able to deploy in public spaces. With regard to the impact of the IPCC on policy development, opinions become more polarized. The IPCC has operated under the rubric of being “policy relevant but not policy prescriptive” (i.e., policy neutral). Its work has underpinned the adoption by many political actors of “two degrees” of warming as being the definition of dangerous climate change and therefore the ultimate goal of international climate policy. On the other hand, Pielke (2007) argues that the IPCC has failed in its role as an “honest broker” and has moved towards being an “issue advocate,” or even on some occasions a “stealth issue advocate.”

The authority, credibility, and reflexivity of the IPCC have become matters of much debate. Some point to the successive adjustments of the IPCC governance system as a sign of institutional learning. They point to how the IPCC has become a benchmark and role model for newer forms of global knowledge assessment in domains such as biodiversity and desertification. Other critics, however, have pointed out the need to remain vigilant of the ways in which international knowledge institutions like the IPCC gain power and influence in international policy deliberations, while being less than open or democratically accountable in their own modes of operation. Writing in 1997 about the future status and impact of the IPCC, Shackley concluded his commentary by noting: “Of particular concern is whether the IPCC can make its knowledge more socially relevant and trusted by bridging the gulf which exists between scientific experts and on-the-ground decision-makers and members of the public” (Shackley 1997, 174). This question of the IPCC – relating to participation, trust, governance, and policy advocacy – remains as important today as it did in the late 1990s.

Intermediaries facilitate the transmission of services between two parties, acting as a conduit between supplier and consumer. They play a dynamic role in shaping the geography and regulation of the economies and labor markets in which they are embedded. Product market intermediaries include actors such as accounting or advertising firms, mortgage or insurance brokers, or financial or legal consultants that offer producer services. Labor market intermediaries (LMIs), the focus of this entry, are similar to product market intermediaries in their function and geography, but because their “product” is labor they play a unique role in mediating the relationship between capital and labor.

Labor market intermediaries facilitate and regulate the matching of workers to employers, acting as brokers that influence and sometimes control the negotiation process between the two parties. LMIs comprise a diverse array of entities including labor recruiters and temporary staffing agencies, executive search firms or headhunters, public employment offices, labor unions, state regulatory bodies, criminal records providers, some training/educational institutions, and online job boards or search engines. They can be public or private, require voluntary or compulsory membership, and fall along a spectrum from formal and established to informal and less “legitimate” operations. Research has shown that, while private, for-profit intermediaries increasingly drive market development and shape employment norms, public and membership-based intermediaries tend to arise more often in response to changing employment conditions.

Intermediaries redress and capitalize on information asymmetries. Where there is a cultural, linguistic, or significant geographic distance between employers and workers, LMIs use the competitive advantage of their information about and access to employers or labor pools to reduce the friction and costs associated with job matching. For employers, they provide a supply of prescreened, just-in-time workers. For job-seekers, they offer immediate, often short-term, employment with no investment in a job search. Beyond job matching, LMIs shape labor market dynamics in fundamental ways by mobilizing workers and impacting labor agency, shaping compensation levels, mitigating and displacing risk (generally onto workers), and contributing to production and social network building (see Benner, Leete, and Pastor 2007). The triangular relationship between intermediaries and the employers or workers who contract them is not merely aimed at cost reduction but is also shaped by, and in turns shapes, nonmarket social relations.

The role of intermediaries is a relatively under-studied area in economic and labor geographies. However, since the 1990s scholars have begun to place greater emphasis on labor as an agent actively creating and shaping economic geographies – and concomitantly have begun exploring the impact of LMIs on labor mobility and agency. Furthermore, since the mid-1970s, economic restructuring and intensified global economic
integration have created the conditions for significant expansion of LMIs, which have thus received increased attention from geographers in recent years.

Economic restructuring and labor flexibility

The recent expansion of labor market intermediaries should be considered within the context of economic restructuring and globalization. The period since the 1970s has been characterized by massive changes in labor markets and employment relations. Neoliberal deregulation and public and corporate policies promoting labor flexibility have made labor markets increasingly competitive and volatile in recent decades. As the demand for more flexible, contractual, individualized, and temporary labor has increased, intermediaries have emerged as a significant industry.

Most economic geography research on the industry has focused on temporary employment agencies, and particularly those servicing low-skilled industry sectors, where the largest growth has been. Though initially associated closely with clerical and sales work, these agencies have also become important employers for blue-collar workers in production and transportation. The temporary employment industry accounted for an increasingly large share of job creation in the 1990s, especially in the United States, the United Kingdom, Canada, countries in continental Europe, and Japan. Scholars tracing the evolution of temporary staffing agencies in many “developed” countries have noted a shift as public institutions that traditionally performed job-matching functions have been replaced by private, for-profit agents. In fact, the International Labor Organization now recognizes the temporary staffing industry as a necessary fixture in the twenty-first-century labor market.

Research has highlighted how the temporary staffing industry not only benefits from an increased demand for temporary employment but is also a promoter and orchestrator of it. By delivering just-in-time labor on a contingent basis, the industry reinforces the demand for it. As Peck and Theodore (2001) note, temporary employment agencies “actively shape the growth in contingent labor through their role in labor-market intermediation, by selling employers the cost-cutting and labor-controlling virtues of workforce flexibility while mobilizing contingent workers and brokering connections to employers” (p. 477). LMIs are active agents in marketing their labor pools, and some scholars have argued that the availability of workers through temporary employment agencies in fact encourages employers to pursue high turnover, low skill-investment human resources strategies. Though LMIs often represent themselves as neutral intermediators, researchers argue that their very presence contributes to the formalization of contingent work as a feature of flexible labor markets.

Labor market regulation and segmentation

Temporary employment agencies typically operate on extremely tight profit margins and absorb much of the risk (on behalf of employers) associated with fluctuations in labor demand and the uncertainties associated with hiring and managing a more flexible and contingent workforce. While there are organizational strategies for mitigating such risk (such as geographical expansion or diversification of services), the most common strategy is to pass it on to workers. In so doing, LMIs play an increasingly significant role in the regulation and segmentation of labor markets.

Some scholars studying LMIs discuss labor flexibility as a post-Fordist strategy for increasing
capital accumulation and labor control. There are many reasons companies may choose to hire an intermediary – for cost reduction, as part of internal restructuring, or because of changes in the nature of production or the regulatory environment. Regardless of the reason, though, by contracting LMIs employers externalize and minimize their costs, risks, and responsibilities (including obligations to workers). Researchers have shown that outsourcing to temporary employment agencies directly regulates workers by subjecting them to a dual layer of management – to overlapping systems of sanctions imposed by both the intermediary and the contracting employer.

Temporary employment agencies also indirectly regulate labor through implied worker substitution. While they are able to mobilize unemployed and underemployed sectors of the population, more often than not it has been for precarious positions with lower wages and fewer benefits. The absence of regular, secure jobs has rendered many workers dependent on temporary employment and the LMIs that provide it. This has led to intensified competition within the contingent labor sector, especially in low-skilled occupational sectors, where workers are often viewed as substitutable. LMI practices that contribute to the individualization and precarity of work also inhibit collective action and weaken trade unions. Anecdotal evidence suggests that some firms use temporary help agencies to illegally screen out potential union organizers. In addition to engendering a dependent, highly substitutable, and reliably contingent and compliant labor supply, the possibility of employee substitution implicitly threatens relatively more secure “core” labor as well.

LMIs such as temporary employment agencies also shape assumptions about which sectors of the labor pool constitute the contingent workforce. They act as gatekeepers, regulating entry to the labor market through worker recruitment, screening, and placement. Research has shown that these activities have consequences for labor market segmentation. Employment agencies have a financial incentive to comply with stated, implicit, and anticipated employer demands and preferences, and as such they tend to reproduce and entrench discriminatory hiring practices. The activities of LMIs route workers into particular kinds of work – in terms of wage rates, industry sectors, and occupations (for example, women into clerical work). This in turn naturalizes and institutionalizes gendered and racialized ideas about who belongs in what kind of work.

In fact, some LMIs differentiate themselves by associating with particular segments of the labor market, defining their market niche in terms of an industry sector or the ethnic makeup of their labor pool. Geographers have also noted that the location of an agency’s primary labor pool – especially at the local, urban scale – is often seen as implicit coding for certain social characteristics, such as socioeconomic status, presumed employability, and race. Peck and Theodore (2001), for example, found that employment agencies specializing in ethnic segments of the labor market, tied to particular neighborhoods in Chicago, reinforced historic race-structured hiring regimes that effectively excluded many African American workers, even from low-wage temporary work. The presence and practices of LMIs in many cases contributes to intensified patterns of exclusion and inequalities, both socially and spatially, in already segmented labor markets.

Globalization, labor mobility and agency

As transnational companies have expanded as part of global economic integration, producer services have followed, and LMIs have expanded
INTERMEDIARIES

and diversified. The viability of LMIs is to some extent predicated on a spatial mismatch between employers and jobseekers, one that has only intensified through globalization. While the demand for more flexible labor and the increased presence of LMIs has meant increased precarity and vulnerability for some, it has resulted in enhanced mobility for others. Knowledge-based economies compete for increasingly mobile global talent. LMIs such as headhunters and executive search firms can directly contribute to career and salary advancement, particularly for workers in specialized or high-skilled, elite labor markets. Some larger employment firms differentiate themselves within the LMI industry by catering specifically to these workers.

Geographers have noted a polarization within the industry itself in recent years, made evident, for example, in the locational strategies of major agencies. The spatial agglomeration of agencies can be indicative of their echelon in the industry. Whereas employment agencies placing low-skilled or “lower-end” labor will often co-locate with their primary labor pools, research has found that those catering to more high-skilled, elite workers or companies in search of such workers tend to locate themselves in the same corporate milieu as their clients – distancing themselves physically and perceptually from less established or “shadier” parts of the industry.

The LMI industry has not only pushed upward into new occupational sectors but also outward into new markets. Globalization of the industry has occurred for two primary reasons. For one, more countries have opened up their economies and deregulated their labor markets, which has created the conditions for LMIs to expand. Second, scholars point out that the very presence of established LMIs acts as an indicator to the multinational companies that might contract them that an economy is stable and worthy of investment. Thus the industry both results from and contributes to the ongoing restructuring and (neo)liberalization of labor markets and the wider globalization process. Research has documented how European and US-based multinational LMIs, in particular, have been active agents in the liberalization of labor markets in countries such as Italy, Spain, Germany, and Japan and are increasingly capitalizing on emerging markets in places such as Mexico, China, India, and Brazil (Ward 2004; Peck, Theodore, and Ward 2005). As these agencies expand transnationally, their staff, offices, and labor pools are dispersed geographically and they are run in a decentralized fashion. Local markets limit the extent to which agencies can simply implement business models developed in their home markets. While the industry itself may be globalizing, the information and services offered by LMIs remain highly territorially embedded and local in nature.

As LMIs have expanded transnationally, so too have their services, and profit-seeking intermediaries increasingly facilitate and organize the transnational movement of workers. As migratory movements become established, the need for specialized information and services arises and a “migration industry” emerges, especially in the context of weak social networks. This industry encompasses a range of actors including LMIs such as labor recruiters, brokers, and smugglers. LMIs specializing in migration help solidify transnational migrant networks, organize migrant emigration and subsequent return, and facilitate job placement and local integration. Some are formal businesses with established reputations, but there are a myriad of other intermediaries who operate informally, and the industry is frequently characterized by fraudulent, exploitative, and illegal practices.

Most migrant workers who find work through intermediaries use informal agents, and are thus more likely to be charged exorbitant
recruitment-related fees and to experience coercion and forced labor. Indeed, for-profit employment agencies are in a position to exploit precisely the information asymmetry they are hired to resolve – to use their informational advantage to exploit rather than assist their clients. As a consequence, governments in both sending and receiving countries are increasingly instituting measures to regulate the migration industry, either by establishing highly regulated licensing and monitoring regimes for the private recruitment industry or by offering alternative forms of public assistance.

Some countries are becoming more directly involved in the management of labor migration – to the point that some scholars argue that states themselves are acting as labor brokers. The Philippines, for example, actively encourages and regulates the emigration of its nationals as foreign workers to reap the benefits of remittances and transnational connections abroad. Though criticized by some, this approach is often held as a model for other sending countries that wish to develop their overseas employment potential. States that are hesitant to become involved in the organization and regulation of labor migration may indirectly encourage the proliferation of commercial recruitment. In the absence of governmental regulation, employers or workers must rely on the integrity of the LMI they contract, and, more often than not, vulnerable migrant workers are the ones who suffer abuses at the hands of unscrupulous intermediaries.

Intermediaries are playing an increasingly significant role in assisting migrants crossing national borders, often in the context of restrictive immigration policy regimes, and this has important implications for labor mobility and agency. LMIs figure as gatekeepers, granting or limiting access to workers and routing them to particular destinations and positions based on factors such as their race or ethnicity, gender, language ability, and nationality. They offer some workers the flexibility and enhanced mobility required to compete globally, and they can facilitate opportunities that improve the wellbeing of workers with few assets other than their labor. At the same time, a reliance on intermediaries may introduce additional barriers for some workers, limiting their access to global labor markets and constraining their mobility and employment opportunities. While the impact of LMI use on individual workers may be varied, however, research has shown that their effect on labor organizing and trade unions is undoubtedly deleterious. Temporary employment arrangements inhibit collective action, and at the transnational scale workers are further fragmented, arguably making political efforts to organize and build solidarity more difficult. In this vein, some geographers have called for more in-depth research on the impact of LMIs on labor agency, with specific attention to how transnational connections might in fact open up new opportunities for labor organizing and worker rights and protection.

Though intermediaries represent a growing institutional presence in the organization of labor markets at a range of geographic scales, research on them is still limited. The currently fragmented and partial view of intermediaries results in part from challenges associated with their oftentimes elusive and transitory nature, and future studies may need to adopt innovative data-gathering and methodological approaches to capture a more comprehensive picture. Within economic and labor geographies, attention has tended to focus on LMIs in North America and Western Europe, and on temporary staffing agencies in particular. In migration research, the commercialization of migration and involvement of LMIs in transnational labor movements remains one of the most understudied topics. Future studies
on intermediaries should draw on both these literatures, and might examine the role of LMIs in the restructuring of labor markets, in the changing nature of employment relations, and in reinforcing or challenging existing inequalities of labor market access. As a topic of study, the role of labor market intermediaries is not just of theoretical import, but also has significant implications both for policymaking and for the development of new and alternative strategies of labor organization.

Description and purpose

The society furthers geographical studies, organizes public activities to develop theoretical and applied knowledge, and initiate consultation and applied scientific studies for public and private sectors. It is a scientific and educational nonprofit association that aims to promote cooperation and understanding among its members, working with geographers from Gulf Arab countries, and associates from other countries.

To achieve these goals the society establishes beneficial partnerships with community-based organizations active in the Gulf society as well as with government institutions and non-profit organizations, the private sector, and geological survey and environmental preservation bodies, among others.

Journals or major publication series

Almajalah Aljografiyah Alkhleejiah (The Gulf Geographical Journal)

Current activities or projects

Regular scientific meetings are held – the next (fifth) meeting will be held in Salalah in the Sultanate of Oman in 2016. Scientific trips are organized. Previous trips were to the State of Qatar and Oman. The society publishes The Gulf Geographical Journal as well as a book, The Geography of GCC Countries.

Brief history

Geographical departments have existed in Gulf universities for almost 40 years. The first was created at Kuwait University with additional departments established since in other Gulf universities. Hundreds of students have graduated from these programs. Some graduates work in scientific, governmental, and private institutions; a number hold prominent positions in their countries; and some have become well known for their work, for example, Professor Abdullah Al-Ghunaim from Kuwait. One of the most important goals of the association is to bring together specialists and interested geographers in the GCC countries within an institutional framework. It has had a prominent role in the reunification of geographers in scientific meetings of academic and nonacademic activities. The association also realized its objective of writing a book on the “Geographical Cooperation Council (GCC)” from a unity and common fate perspective. The association is involved with geography departments’ students in universities by introducing and training them on academic and social activities as well as participating in academic and cultural cooperation agreements with the Saudi Commission for Tourism and Antiquities.

International: Association of Geographical Societies in Europe (EUGEO)

Founded: 1997
Location of headquarters: Utrecht, Netherlands
Website: www.eugeo.eu
Membership: 24 (as of 2014)
President: Henk Ottens
Contact: hfl.ottens@gmail.com

Description and purpose

The aim of EUGEO is to represent its members at European level and to coordinate and initiate joint activities of the members to advance research and education on the geography of Europe and to promote the discipline of geography of Europe. EUGEO has members from 21 countries. EUGEO also functions as a network and a forum for strengthening the position and operations of its member organizations, in particular for activities with a European dimension.

Current activities or projects

EUGEO organizes a biannual congress entitled The Geography of Europe and Geography in Europe. Congresses have been held in Amsterdam (2007), Bratislava (2009), London (2011), and Rome (2013). Coming congresses are planned in Budapest (2015) and Brussels (2017). The association organizes a yearly seminar on “Improving the State of Geography in Europe” in combination with the yearly General Assembly meeting. EUGEO cooperates with EUROGEO and IGU in a roadmap project to strengthen the position of geography education in Europe (and worldwide). EUGEO participates in European projects in which geography education and/or research is a theme.

Brief history

EUGEO was formed on the initiative of the Italian Geographical Society (Società Geographica Italiana, SGI). In 1994 representatives of geographical societies in the European Union gathered in Rome at the headquarters of SGI, Villa Celimontana (the “home of geography”) and decided to establish an association. The idea was to encourage and enhance greater collaboration between the independent scholarly European geographical societies, associations, and institutes, each of them having a community of geographers from a nation or region in a EU member state as their membership.

The first president of EUGEO was Henri Nicolaï of the Société Royale Belge de Géographie (Royal Belgian Geographical Society) and the first secretary-general was Armando Montanari of the Italian Geographical Society. Henri Nicolaï was followed by Christian Vandermotten, also from the Belgian Geographical Society, and Armando Montanari was followed by Rita Gardner of the Royal Geographical Society (with IBG). In December 2009, Henk Ottens of the Royal Dutch Geographical Society was elected president. Massimiliano Tabusi (SGI) became secretary-general in 2012. Christian Vandermotten and Zoltán Kovács of the Hungarian Geographical Society MFT were elected as executive committee members. EUGEO now welcomes societies from all nations in Europe as members.

International division of labor

Kean Fan Lim  
University of Nottingham, UK

For much of the eighteenth to mid-twentieth centuries, commodity production within the global economy took on distinct geographic patterns. Manufactured goods and producer services were largely built and assembled in industrialized economies such as the United Kingdom, France, and the Netherlands. Many of these products were traded with other industrialized economies and surpluses were sold to nonindustrialized economies, many of them colonies. Raw materials and agricultural products were in turn extracted from these nonindustrialized economies, giving rise to a phenomenon known as the “old” international division of labor. The very notion of international division exemplifies an apriori conception of economic production and consumption as intrinsically transnational. It exemplifies, specifically, an apriori conception of labor power interdependence between different parts of the world.

This interdependence changed during the mid- to late 1970s as firms in industrialized economies embarked on vertical disintegration and relocated production processes – particularly labor-intensive manufacturing – to developing economies. In a highly influential book, The New International Division of Labour, the German social scientists Folker Fröbel, Jürgen Heinrichs, and Otto Kreye (1980) outline key tenets of this process, now widely known as the “new international division of labor” (hereafter NIDL). To Fröbel, Heinrichs, and Kreye (1980, 45), NIDL is a tendency which:

1. undermines the traditional bisection of the world into a few industrialized countries on one hand, and a great majority of developing countries integrated into the world economy solely as raw material producers on the other; and
2. compels the increasing subdivision of manufacturing processes into a number of partial operations at different industrial sites throughout the world.

From a longue durée perspective of world economic history, NIDL is not exactly novel. As the renowned economic historian Andre Gunder Frank (1977, 2096) puts it, the accelerated and profound transformation in the international division of labor (and of production and work processes) during the 1970s re-expresses a cyclical crisis of profit realization in the same way that earlier crises precipitated changes in the production process. However, there were at least three new features that distinguished NIDL from earlier historical changes in the international division of labor:

1. The geographical extent of the “division” was much wider after the mid-1970s, with manufacturing activities spreading to Central and Latin America, East and Southeast Asia, and parts of Africa.
2. The intensity and range of transnational economic activities increased as more multinational corporations (MNCs) were formed in the 1970s compared to a century earlier.
INTERNATIONAL DIVISION OF LABOR

This phenomenon can be largely attributed to improvements in “space-shrinking” transport and communications technologies, which enhanced the coordination of production and distribution processes by corporate headquarters, as well as MNCs’ ability to raise financial capital through expanding capital markets in the industrialized world following the collapse of the Bretton Woods monetary system in the early 1970s (Murray 1971; Aglietta 1982). As Emmanuel (1975, 36) puts it, there existed by the mid-1970s “a relative mobility of [financial] capital, sufficient to give rise to a tendency for the world-wide equalization of the rate of profit, and a relative immobility of labour allowing considerable predetermined disparities in the wage rates of various countries.”

A massive and growing pool of low-skilled or unskilled laborers became available for employment in many parts of the world, in part as an outcome of improving agricultural technologies, in part as a result of weak or failed domestic industrialization. To Harvey (1999/1982, 436), “Beneath all of the nuanced shifts in the international division of labour, in technology and organization and in the distribution of productive forces, lies a basic Marxian proposition: the accumulation of capital is increase of the proletariat” (emphasis original). Put another way, NIDL was correlated positively with the expansion of wage laborers at the global scale.

NIDL was a combination of these three features. Crucially, its emergence was enabled in large part by the “crisis” of Fordism. Fordism refers to a regime of accumulation first implemented in the United States and then expanded in varying degrees to Western Europe, Canada, and Australia. It is characterized by the mass production and consumption of standardized goods, high wages, and relatively fixed currency exchange rates which facilitated international trade. To keep the Fordist regime running, labor unions fought to keep wages high and growing, which would putatively translate to expanded consumption as well as stable fiscal revenues for the state, while the state took responsibility for providing collective goods such as domestic infrastructure, health care, and education and for overseeing stable fiscal and monetary policies. By the mid-1970s, it became apparent that the Fordist regime was becoming increasingly strained as profit rates declined. Large corporations in those economies consequently began exploring production and market opportunities elsewhere around the world. This phenomenon corresponded with FDI-friendly or import substitution policies in “host destinations,” which in turn encouraged offshoring and produced modern-day transnational corporations (TNCs) and global production networks.

Economic geographers were quick to analyze the causes and differentiated geographical impacts of NIDL. Initial research probed these causes by examining firms’ strategies vis-à-vis the Fordist structural crisis in the so-called core group of industrialized economies (see Wallerstein’s (1974) discussion of core–periphery dynamics). Quite what triggered such systemic distress remains moot: the primary issue is whether demand- or supply-side factors, or a combination of both, contributed to the dismantlement of Fordism. To Doreen Massey (1978), market contraction was a major trigger of growing deindustrialization within several major industrial sectors in the United Kingdom. This in turn highlighted the limits of trade and labor market protectionism that undergirded the Fordist system. Once product markets began to open, the onslaught of competition – much of
which emerged from firms within other “core” economies, notably Germany and Japan – caused many domestic firms to explore alternative production methods and strategies to remain in business. Alain Lipietz construes this supply-side factor as a major cause of NIDL:

Unlike the thirties crisis, however, it is essentially due not to the tendency of supply to exceed popular demand, but to the fact that insufficient surplus-value results from a growing mass of invested capital. For capital in general (not, of course, for each individual capitalist), the problem is not so much to find markets as to drive up the rate of exploitation. And that has been the case since the late sixties. (1982, 36; emphasis original)

The underlying issue, however, was more intricate than simple cost reduction or increased exploitation. To Schoenberger (1988, 261), the nature of interfirm competition during the Fordist era planted the seeds for NIDL: “uncontrolled product competition is incompatible with Fordist production techniques,” which were astute at churning out standardized models in huge numbers to capture economies of scale. Similarly,

excessive price competition is incompatible with maintaining the mass-consumption base. In general, the system relies on the maintenance of an orderly oligopoly that will support stability in terms both of products and of prices while competition is channelled into such areas as superficial product differentiation, advertising, and distribution. (Schoenberger 1988, 261)

The effect, as Schoenberger shows, was in fact so significant as to trigger a “cultural crisis of the firm,” wherein an “entire ensemble of material practices, social relations, and ways of thinking, and the material and social assets tied up in them, were invalidated” (1997, 224; emphasis added). From this perspective, NIDL precipitated industrialized economies’ variegated adoption of industrial deregulation: with more open markets and increasing competition, the Fordist accumulation system could not cope. While it was not a prescribed policy panacea, NIDL was the result of this nascent shift in economic governance.

Perhaps more crucially, firms’ strategies to develop transnational production networks are intimately connected to concrete state policies within multiple economies that created fresh conditions for capital to flow internationally. Empirical research has demonstrated that developing countries were not passive actors in shaping MNCs’ location strategies, nor were their industrialization strategies predicated on an ecumenical blueprint sourced from the “center”; the wholesale imitation of Fordism, notably the establishment of high wages for semi- or low-skilled workers, did not occur at all. New markets also emerged outside the “center,” first in so-called newly industrializing economies like South Korea and Taiwan, and then in emerging economies such as China, India, Russia, Brazil, and Mexico. Even within the “core,” common markets were formed in what is now known as the European Union and North American Free Trade Area (NAFTA). These findings provided a much-needed refinement to the NIDL thesis, which is often critiqued as describing a unidirectional and mechanistic transfer of labor-intensive, lower-order economic activities from industrialized countries to developing countries in order to achieve cost savings; they show how the international division of labor is driven as much by place-specific political objectives as by the profit motive.

Environmental Information
Systems Africa
(EIS-AFRICA)

Founded: 2000
Location of headquarters: Pretoria, South Africa
Website: www.eis-africa.org
Membership: 93 (as of October 2014)
Executive Director: Sives Govender
Contact: sgovender@eis-africa.org,
sives.govender@gmail.com

Description and purpose

EIS-AFRICA is a membership-based organization created by African experts to advance Africa’s development goals through more effective access and use of geospatial information, science, and technology. EIS-AFRICA has been incorporated as an association under Section 21 of the South African Companies Act (Act 61, 1973) and registered as a nonprofit association in the Republic of South Africa since 2000. The organization is governed by an elected board of directors (from its members) and is audited annually by Grant Thornton. EIS-AFRICA’s daily activities are undertaken by a secretariat which is managed by a board-elected executive director.

EIS-AFRICA’s vision is an African society where geospatial information for sustainable development is readily available and easily accessible and its mission is to be recognized by its strategic partners, clients, and the public as a legitimate and leading organization developing African capacity to generate, use, manage, and disseminate geospatial information, science, and technology to enrich policy debate and support decision-making for the wellbeing of Africa’s people.

Journals or major publication series

Current activities or projects

EIS-AFRICA publishes a monthly electronic newsletter which is received by over 5000 contacts from 108 countries in the world and hosts the biennial AfricaGIS conference and exhibition. EIS-AFRICA has contributed to publishing of selected papers from its conferences to a special IJAGR–AfricaGIS journal edition.

EIS-AFRICA contributed to the studies on the determination of fundamental geospatial datasets for Africa which was published by the UNECA. EIS-AFRICA is key contributor to GSDI, ISO TC 211, and UN–GGIM.

EIS-AFRICA in collaboration with the American Association of Geographers (AAG) hosted a Global Connections and Exchange 2014 Youth TechCamp: My Community, Our Earth Program (MyCoE) during July 2014 where 10 American and 40 South African high school students learnt about geography, mapping, and environment management (http://www.aag.org/cs/my_community_our_earth/mycoe_
Brief history

EIS-AFRICA has been promoting the use of geospatial information, science, and technology for sustainability on the continent since the early 1990s (first as the EIS program for sub-Saharan Africa, then EIS-AFRICA).

The organization was a key partner in developing the National Environmental Action Plans which are known today as State of the Environment Reports and was an early adopter of GIS technologies. EIS-AFRICA has acted on behalf of the Africa geospatial community to engage with global, multinational agencies to access spatial information, training and software to increase its capacity, and competency to better manage our environment.

EIS-AFRICA sits on various UN, global associations, continental, and intergovernmental meetings advising on how geography and geographic information is a key infrastructural requirement in better managing our environment for a sustainable future. EIS-AFRICA has also been involved in hosting many capacity building activities ranging from the AfricaGIS conference and exhibition (first held in 1993) to many national training events.

EIS-AFRICA’s network includes participants from all 54 African nations as well as all the leading regional and subregional organizations, national mapping agencies, and many universities. EIS-AFRICA’s membership program allows its members free membership to the American Association of Geographers and the organization have also just established a facility to host the newly formed South African Geography Teachers Association which will be expanded to a continent-wide group.

EUROGEO is a European scientific society, which aims to develop, support, and promote policies and actions designed to advance the status of geography; establish and promote cross-border cooperation; promote education and training in geography from a European perspective; and represent nationally and internationally the views of its members.

The association supports geographers in their jobs and careers, promoting good practice and cooperating with agencies such as the European Union, Council of Europe, European Commission, UNEP, and other relevant organizations.

To meet these aims, the association operates in relevant European policy areas and organizes events and activities for its members, the most significant of which is the EUROGEO annual conference.

The main research and development projects of the association are: iGuess 2 (www.iguess.eu), a project for the creation and implementation of European training courses on the use of geographic information systems; SPACIT (www.spatialcitizenship.org/), a teacher training project on issues of citizenship and spatial thinking; PiriReis (http://pirireis.dicle.edu.tr), a transfer of innovation project to create and develop an association of geographers in Turkey; I-Use: Statistics in Education (http://i-use.eu), a project promoting the use of statistics in education; Geocapabilities (www.geocapabilities.org), examining powerful knowledge and teachers as curriculum leaders; and Geoskills Plus (www.geoskillsplus.eu), a transfer of innovation project bridging the gap between universities and vocational training with employers.

EUROGEO is a consortium partner in a new “Science in Society” research project called “Sea Change,” which aims to raise awareness of the importance of understanding the oceans.

EUROGEO has helped establish, as founder members, a number of innovative networks.
INTERNATIONAL: EUROPEAN ASSOCIATION OF GEOGRAPHERS (EUROGEO)

in Europe, such as the European Citizen Science Association and the European Alliance of Social Science and Humanities Research (EASSH). EUROGEO is also a stakeholder in the UNEP EyeonEarth, “Geo for All,” and Smart City Learning initiatives. The association has developed active working links, not only with national and international associations in Europe, but all over the world.

Brief history

EUROGEO was established in 1979 as an association of national associations, with strong support from the European Commission. National bodies in Europe were networked together to form the European Standing Conference of Geography Teacher’s Associations (ESCGTA) and to represent the views and opinions of geographers in different European countries. They met every 2 years and published a bulletin called EUROGEO.

As Europe grew, organizations from other countries became members and the association took the name of its bulletin: EUROGEO: the European Network of Geography Teachers’ Associations.

In 1987, in recognition of its activities, the association was granted official consultative status to the Council of Europe, making it one of the first to be awarded this position. Since 2003 EUROGEO has been a full participant of the Council of Europe, being the voice of geography and geographers there, actively lobbying politicians and their advisors on themes such as climate change, landscape convention, migration, borders, energy, human rights, and citizenship education.

Following reform in 2009, EUROGEO became a membership organization allowing individuals and institutions with an interest in geography, its theory, and methods to become involved.

The association is an international nonprofit organization (INGO) incorporated under the name EUROGEO: the European Association of Geographers by the provisions of Title III of the Belgian law of June 27, 1921.

International: Instituto Panamericano de Geografía e Historia (IPGH) (Pan American Institute of Geography and History)

Founded: 1928  
Location of headquarters: Mexico City  
Website: www.ipgh.org  
Membership: 21 member states and 4 permanent observers  
Secretary General: Rodrigo Barriga-Vargas  
Contact: secretariageneral@ipgh.org

Description and purpose

The main purposes of the IPGH are to encourage, coordinate, and publicize cartographical, geographical, historical, and geophysical studies, as well as other related scientific studies of interest to the Americas; to promote and coordinate scientific and technical development, research, relations among institutions and specialists, studies and training in cartography, geography, geophysics, and history; and to promote and stimulate cooperation among the specialized institutions of the Americas and international organizations in its four fields of activity.

Journals or major publication series

Revista Cartográfica  
Revista Geográfica  
Revista Geofísica  
Revista de Historia de América  
Revista de Arqueología Americana  
Boletín de Antropología Americana

Current activities or projects

Through its commissions, IPGH offers a wide range of courses, workshops, and conferences directed at specialists and professionals in the areas of interest of the institute, and in general to other professionals interested in those fields.

Through its Commission on Cartography the institute develops important projects in the areas of: fundamental geospatial data (SIRGAS, fundamental data, geographic names, aeronautic and hydrographic charts); institutional strengthening and technical cooperation (geospatial data infrastructure); thematic applications (geospatial information for the prevention and mitigation of disasters, information for planning and decision-making); standards (positioning, digital cartography, data exchange).

In the field of geography, the Commission on Geography is developing projects on urbanization and environmental impacts, geographic information systems, regional development, intermediate cities and quality of life, and teaching and professional training.

The Commission on History develops projects on archaeology, anthropology, folklore, bibliography and archives, economic, political, social history, and history of the ideas.

The Commission on Geophysics supports projects on seismology, vulcanology, meteorology, atmospheric physics, geomagnetism, aeronomy, physical oceanography, gravimetry, and environmental geophysics.
Brief history

The General Assembly is the supreme organ of the IPGH and determines the institute’s scientific, administrative, and financial policies. The Directing Council is the Pan American organ of the IPGH that is entrusted with the functions of the General Assembly during the intervals between meetings of the latter. Meeting of Officers is the organ that directs and coordinates the institute’s activities between the meetings of the Directing Council. The General Secretariat is the IPGH’s central and permanent organ responsible for administration, coordination of organ activities, providing the necessary assistance for the proper functioning of said organs, execution of the tasks entrusted to it, and ensuring compliance of the agreements adopted for the smooth functioning of the IPGH. The secretary general represents the IPGH. The Commissions are the organs entrusted with promoting the scientific and technical development of their respective fields of action in the member states. They are also responsible for coordinating, encouraging, and supervising projects and other agreements involving research approved by the General Assembly or the Directing Council. There are four commissions: Cartography, Geography, History, and Geophysics, which are subdivided into committees and working groups. The National Sections are entities established by each member state, whose role is to fulfill the objectives of the IPGH in the sphere of their respective countries.

International: International Geographical Union (IGU)/Union Géographique International (UGI)

Founded: 1922
Location of headquarters: Cape Town, South Africa
Website: www.igu-online.org
Membership: 75 (as of 2014)
President: Vladimir Kolossov
Contact: vladimir.kolossov@gmail.com

Description and purpose

The International Geographical Union (IGU) is an international, nongovernmental, professional organization devoted to the development of the discipline of geography. The purpose of the IGU are primarily to promote geography through initiating and coordinating geographical research and teaching in all countries of the world. Its work is conducted through the instruments of its national committees, commissions, and task forces. The IGU hosts the International Geographical Congress every four years and also promotes regional conferences and other meetings that further the objectives of the union. The IGU also facilitates the participation of geographers in the global community of scientists through its formal affiliation as a member union within both the International Council for Science (ICSU) and the International Social Science Council (ISSC).

Journals or major publication series

Current activities or projects

International Year of Global Understanding: Thinking globally and acting appropriately locally presupposes global understanding. This initiative by the International Geographical Union aims to bridge the awareness gap between local acts and global effects. It will achieve this aim through research, education, and information. Ultimately, the International Year of Global Understanding will encourage everyone to make daily decisions in the light of global challenges.

IGU “Journals Project”: There are many journals globally that deal with the broader discipline of geography. In recent years the domination of major publishing houses in the scientific journal market has become much stronger and it is clear that many geographical journals are published that have a much lower profile and yet could provide a very valuable resource for geographers – researchers and teachers alike – in particular national or regional contexts. It was for this reason that the IGU embarked on a project to establish a searchable global database of geographical periodicals. Follow the link from the IGU homepage at www.igu-online.org.

Our Sustainable Cities (“OurSus”): This project is based on the idea that, despite their different sizes, location, and functions, all cities are facing similar challenges in terms of sustainable
features, such as green R&D, environment-friendly consumption, green campaigns, challenges, and education, and so forth. In 2013 the project had a full double Internet infrastructure, in English and Chinese (www.oursus.org and zh.oursus.org).

**Brief history**

The IGU was formally established in Brussels in 1922. However, the history of international meetings of geographers is much longer. The first of a series of congresses met in 1871 in Antwerp. Since its early days the union has consisted of three major components: a general assembly of the delegates appointed by the member countries which meets at the time of the congress and is the highest authority of the union; an executive committee which consists of a president, eight vice-presidents and a secretary-general and treasurer; commissions and study groups which continue their work between general assembly meetings. The working languages of the union are English and French. Recent International Geographical Congresses have been held in Tunis (2008) and Cologne (2012) and the next one is scheduled for Beijing in 2016.

ICA supports and recognizes cartographers and GIScientists around the globe through its commissions and working groups (www.
icaci.org/commissions), the International Cartographic Conferences (www.icaci.org/icc), several publication channels, cartographic exhibitions and displays, children map drawing competition, research agenda and research grants, awards, outreach programs, and the close cooperation with sister societies in the Joint Board of Geoinformation Societies (JBGIS) as well as with international bodies such as the United Nations.

**Brief history**

ICA was founded on June 9, 1959, in Bern, Switzerland. The first general assembly was held in Paris in 1961, that is also when the statutes were accepted. Later conferences have been held around the world from India (Delhi, 1968) to South Africa (Durban, 2003), from Italy (Stresa, 1970) to Mexico (Morelia, 1987), from Australia (Perth, 1984) to China (Beijing, 2001) and in many other locations.

The international nature of ICA activity has also been reflected by the work of its commissions and working groups over many decades, under the leadership of many different people, and in many different places. These organizations have addressed the full range of scientific, technical, and social research which is the mark of ICA activity.

Throughout its 50-year history, ICA has brought together researchers, government mapping agencies, commercial cartographic publishers, software developers, educators, earth and environmental scientists, and those with a passion for maps. The cartographic world has changed significantly since 1959, while the role and impact of ICA has been steadfast.

International: Southeast Asian Geography Association (SEAGA)

Founded: 1990
Location of headquarters: Singapore
Website: www.seaga.info
President: Chew Hung Chang
Contact: seaga@nie.edu.sg

Description and purpose

The Southeast Asian Geography Association (SEAGA) is a scientific and educational society set up in 1990 by a group of geographers. Its members share interests in the theory, methods, and practice of geography and geographic education. SEAGA’s vision is to be an association that will raise the profile of Southeast Asian geography and geographers. The key mission is to promote and disseminate geographic research, promote geographic education, and develop a global network of geographers interested in the Southeast Asian region.

Journals or major publication series

A list of publications can be found on the association’s website at www.seaga.info/publications

Current activities or projects

The association organizes a biennial conference, regular international forums, and other workshops hosted in different ASEAN countries which provide a platform for sharing research findings in geography and related area with a focus on Southeast Asia.

SEAGA places a strong focus on geography education within the conferences, often supported by a sizable contingent of geography teachers, as well as university lecturers and professors who have a keen interest in geography education.

SEAGA Publishes an eNewsletter twice a year as well as proceedings of the meetings. Occasional special issues of journals, book chapters, and books arising from meetings are also encouraged.

Brief history

The founding president of the association was Professor Goh Kim Chuan. From 1990 to 2005 he was instrumental in encouraging and assisting geography departments in the region to host SEAGA’s biennial international conferences. To date they have been held in Brunei, Indonesia, Malaysia, Thailand, Singapore, Philippines, Vietnam, and Cambodia. The events also allow geographers to connect with each other and enhance cooperation in joint research, student fieldwork, or even staff exchange.

The association has been formally registered with Singapore’s Registrar of Societies since 2006. The secretariat for the executive committee of SEAGA is hosted at the Humanities and Social Studies Education Academic Group of the National Institute of Education, Nanyang Technological University, Singapore.

One aspect SEAGA has been encouraging is to make the conferences accessible to geography
teachers and graduate students in each of the host countries either through their direct participation in sharing their research findings or having a complementary one-day workshop on some aspects of the teaching of topics in geography. In this way, the association hopes to improve and revitalize the status of geography in the region.

International: The International Association of Chinese Professionals in Geographic Information Science (CPGIS)

Founded: 1992
Location of headquarters: Ann Arbor, MI
Website: https://cpgis.org
Membership: 1450 (as of September 21, 2015)
President: Mei-Po Kwan
Contact: http://meipokwan.org

Description and purpose

The CPGIS is a non-profit organization committed to promote research, education, and entrepreneurship in geographic information science and technology. Its members include scholars, researchers, students, and employees of businesses and government from over 30 countries. The CPGIS seeks to: promote members’ professional development through collaboration; promote intellectual exchange in GIS and related sciences and technologies between Chinese GIS professionals abroad and those in China; provide a channel for interaction and collaboration between its members and other GIS professionals; and promote education of geographic information sciences at all levels around the world.

Journals or major publication series

- Annals of GIS, www.tandfonline.com/loi/tagi20#.VgAY55eguDk
- The CPGIS Book Series

Current activities or projects

The CPGIS organizes an international conference on GIS (Geoinformatics) annually in various countries. It edits a peer-reviewed academic journal (Annals of GIS). It maintains a website (www.cpgis.org) and a listserv (CPGIS-L@listserv.buffalo.edu) with over 1400 subscribers. The CPGIS also organizes a wide range of GIS-related workshops, initiates various projects to promote GIS in both the public and private sectors, particularly in China, and encourages young scholars to be involved in its various activities (e.g., Health GIS Workshops, Go Home Professional Workshops, and Young Scholar Summer Workshops). It recognizes the accomplishments of Chinese professionals in GIS through various awards: Excellence in Service, Distinguished Scholar, and student paper competition awards.

Brief history

In the summer of 1992, a group of students led by Hui Lin and Yuemin Ding organized an international conference at SUNY-Buffalo and founded The Association of Chinese Professionals in Geographic Information Systems - Abroad (CPGIS). To reflect its growing visibility in the international community and the rapid expansion of the field, the CPGIS changed its name to The International Association of Chinese Professionals in Geographic Information Science (CPGIS) in October 2001. Since its establishment in 1992, the CPGIS has grown into a mature and vibrant association with active members from over thirty countries around the world. It edits its official journal (Annals of GIS), organizes annually the Geoinformatics international conference, the annual Young Scholars Summer Workshops, Go Home Professional Workshops, and many other
INTERNATIONAL

activities. The CPGIS is a unique organization through which Chinese students, scholars, and professionals in GIS can develop their social networks, leadership, and professional careers. The CPGIS is governed by an elected president and an elected board of directors. Its many programs and activities are organized with the assistance of other appointed officers and committees. A group of regional officers and directors help coordinate its members in the United Kingdom, Germany, Japan, Australia, and other countries.

Internationalization

Patrik Ström
University of Gothenburg, Sweden

Internationalization of business activities occurs when a firm starts to trade or make investments in new host markets abroad. Before, internationalization often meant sending goods to markets overseas or establishing a production plant in another country. Today, technological advances enable firms within advanced production and producer services to supply distant markets through the Internet and telecommunication. A physical presence in the markets abroad is no longer the only way of internationalizing business activities. A producer service firm can supply a market overseas with services without having a physical base. It can receive and supply services through secure Internet channels. The firm may alternatively send a consultant abroad to supply the service or establish an office abroad. This new form of internationalization has also enabled service firms from emerging markets to supply their services over long distances to customers in mature markets.

The outcome of internationalization is evident at many levels of geographical and locational analysis. Its effects are evident in the study of the macro-economy, where trade and foreign direct investment connect places to each other, in the micro-level study of firms and in studies of how the internationalization process has developed and been implemented over time. The fundamental aspects of internationalization will first be considered in relation to the approaches used in economics. The analysis is then deepened by incorporating a more spatial perspective. This will illustrate the important connection between economic geography and international business in an attempt to uncover and explain the reasons why firms engage in internationalization. It also illustrates the complexity that exists in the internationalization of producer services. The entry concludes with a summary of new ways of exploring internationalization from the viewpoint of the speed with which it can occur and the growing involvement of companies from emerging markets. This is an aspect of the study of internationalization that requires further theoretical development.

Classic approaches

The more modern explanations of international trade require an appreciation of the concept of comparative advantage which states that a country should specialize in producing and exporting only those goods and services that it can produce more efficiently than other goods and services, which should in turn be imported. Using the fundamental parts of the Heckscher–Ohlin theory, Krugman (1994) adds other explanatory reasons for international trade that are overlooked in traditional trade theory. Trade arises not only from differences in factor endowments between countries but also because of the inherent advantages of specialization. The Krugman approach also puts more stress on the important factors of arbitrariness and increasing returns. The more dissimilar the factor endowments of two countries, the more important are the comparative advantages. If factor endowments are similar, there is a good potential for...
INTERNATIONALIZATION

intraindustry trade. Thus, interindustry trade reflects natural comparative advantage while intraindustry trade reflects acquired comparative advantage. The parts and components required by large companies for the assembly of final products such as vehicles or laptops are usually produced at diverse locations in order to minimize production costs. It is product complexity together with the increased production of intermediate goods that opens the way for intraindustry trade.

Technological development itself can generate temporary comparative advantages. In the United States, transistors and integrated circuits gave manufacturers a valuable headstart but this soon disappeared when other countries such as Japan imitated the technology. Typically, the most industrialized countries export the most technologically intensive products and import more standardized products. This follows the principles of the so-called product life cycle theory, in which location and internationalization are related to the cost of production (Vernon 1966). Finally, transportation costs and environmental standards are also important determinants of international trade; for example, decreasing transport costs for automobiles have facilitated long-distance international trade.

Global shifts and spatial division of labor

On the basis of the transformational power of the economy, Dicken (2011) states that earlier theories of the changing economic situation in the world have been too static. He argues that it is organizational and institutional forces that create shifts in the international economy. Comparative advantage is not simply a given. Rather, it is a process created and recreated as a consequence of human action that is reflected in such things as the variations in trade policy between countries or in levels of innovation and technological development. Countries must try to sustain their competitive advantage and firms must keep up with technology in order not to lose ground. These are the considerations that largely explain why firms tend to reorganize their international operations. They have mainly been used to understand the internationalization of manufacturing, but may also be applicable to the changes taking place within the service economy and its tendency to outperform the manufacturing sector in terms of contributions to GDP and employment. The recent rapid restructuring of economies from manufacturing to services in both mature and emerging markets has been characterized as the second global shift (Bryson 2007). It has been spurred by the second unbundling of globalization, that is, the radical lowering of data and other transmission costs as a result of information and communications technology (ICT) (Baldwin 2014). This has resulted, for example, in changes to trade patterns and to global value chains in East Asia whereby trade in goods has been displaced by trade in tasks. Competition in low-value-added services that can also be traded is fierce, but competition is increasing in high-value-added subsectors of the service industry, where the content of the services provided in the international market has a strong impact on the competitive advantage of a product or service. As the combination of manufacturing and services becomes even more important for how and where the value added in production is generated, it has further impacts on the internationalization of trade and foreign direct investment (FDI) (Daniels 2012).

Cultural considerations are evident for all kinds of international transactions, but in the case of service industries they may be an absolute barrier. Such barriers have their greatest impact on verbal and media-based services, but standardized and highly technological services may
be exceptions to this general rule. These services can be found in various back-office activities handling, for example, financial transactions. Specialized services that are essential in global value chains are more often delivered through face-to-face interactions; such internationalization is thus more dependent on people. A further factor is risk in general, such as that associated with political situations, insurance requirements, financial probity, or adaptation to unfamiliar legal systems. It is argued that these barriers, or risks, may be greater for service firms than for goods-producing firms involved in internationalization. The sheer complexity of undertaking international operations that span several countries or continents also poses new challenges for operational management. In general, firms located in major metropolitan areas are more likely to be confronted with various internationalization opportunities. Firms in more peripheral areas also show an interest in working internationally, but their opportunities are more limited.

In relation to the classification and conceptual difficulties associated with service trade, empirical findings show that the direct contribution of services to national exports is growing slowly and that the pattern of trade is highly concentrated. Instead, it may be useful to acknowledge and nurture the indirect contribution of services to overall national export activity. Service support for many of the manufacturing sectors enhances total export competitiveness. Specialized services then become embodied in the goods and services exported to a specific country or out into the world market. In the case of services, because of their intangible character, FDI in the form of mergers and acquisitions seems to be more important than greenfield investments and there is a need to locate at specific places in order to be recognized as a serious service provider. Investment shifts in the economy due to variations in labor costs are not a new phenomenon. Much of the evolutionary character of international economic development has been a result of increasing wage levels. As wage levels rise in the developed world, more production is located in the developing countries. This trend is said by some to have raised the capital and knowledge content of products produced in emerging markets (Alvstam, Dolles, and Ström 2014). Since the mid-1990s the rise of emerging market multinationals has started the repositioning of competition in the global market. The impact is clearly visible in the changing pattern of trade and FDI flows, and it has also helped to refine conceptual understanding of how these firms internationalize.

Internationalization theory and the firm

The study of company internationalization can be divided into two main research approaches: economic theory and behavioral theory (Dunning and Lundan 2008; Vahlne and Johanson 2013). The purely economic viewpoint originates from classical trade theory which is based on comparative advantage. Over time, theories such as transaction cost economics have been developed to interpret and explain the complex international business environment. Most of the research has focused on the manufacturing sector, but more recently there have been attempts to explain the growing trade and internationalization activity within the service sector.

There has also been a tradition within internationalization theory of adopting a more behavioral approach. After decades of analyzing internationalization, mainly from the economic viewpoint (see Vernon 1966), international business research entered a new era following the work of Johanson and Vahlne (1977). The so-called stage theories of the Uppsala School,
which are based on the role of proximity, psychic distance, and experiential knowledge, have greatly helped to advance the theoretical development of the behavioral approach. Its significance has also been tested, analyzed, and further extended. However, a basic problem with stage theory is the nature of the conceptual framework and its relatively modest empirical foundations. The early studies were based on only a few case studies of multinational Swedish manufacturing companies. These have since been extended in terms of geographical coverage and through the broader coverage of different industries. These concerns have also been alleviated to some extent by incorporating network theory into the research (Vahlne and Johanson 2013) so that the dynamic dimension and speed of the internationalization process are examined in relation to the difficulties arising from foreignness and outsidership in distant markets. This implies that it is not the distance and cultural aspects that necessarily have a strong influence on the possibility of internationalizing operations, but rather that a firm is able to access business networks at new international locations. These aspects are highly important for the internationalization of producer services.

International business and location

Research on international business (IB) takes into account many different aspects of the firm and its environment. The focus is on the firm and its international operations, with special reference to the organization, strategic aspects, and knowledge transfer. The relationship between strategic aspects and location is seen as a key issue for a satisfactory explanation of internationalization (Buckley and Gauri 2004).

In early IB research, Hymer’s (1976) objective was to explain the reasons for rather than the operations of a multinational corporation (MNC). However, the contributions made by Vernon (1966) regarding cycles and trade/antitrade FDI seem to equate with a more normative explanation of the internationalization process. Since these early studies, the complexity of the global economy has created a need for theories that develop an understanding of competition between firms. The technological environment or technological accumulation possibilities are important for shaping the pattern of international operations, where technological abilities and research and development (R&D) constitute competitive advantage to a greater extent in complex global value chains. These are aspects that clearly relate to the discussions in economic geography about firm clusters and national innovation systems. This can be seen as an increasing interest for including location in management-related sciences since, traditionally, location factors have received limited attention in the IB literature. However, Dunning was a forerunner among those placing more emphasis on the role of location and location-bound assets. This connects to the debate within economic geography about the development of clusters with special characteristics and the way in which locational advantages can be created by regional innovation systems. That locational configuration in itself can be an ownership-specific advantage adds another perspective to IB research and the value of the ownership, location, and internalization (OLI) configuration.

Locational configuration, such as regional innovation systems, lies within the range of governmental influence, which means that a business-oriented approach is necessary to create and sustain innovative clusters that can both stimulate the growth of new companies and attract existing MNCs. This issue is of great importance in the field of economic geography because of the changing landscape of
industrial production and the way in which high knowledge content services are put forward as new engines of regional development and where regional innovation systems help to facilitate the attraction of regions or cities for international firms. These are very important locational aspects in driving the internationalization of producer services. The most essential resource is the competence and experience of existing and potential employees; they are most likely to be found in urban areas with a strong service economy orientation in different places in the international market.

Combining research on the managerial aspects of internationalization and localization with the more descriptively or conceptually oriented research undertaken by economic geographers is a useful way forward (Ström and Wahlqvist 2010). The internationalization of manufacturing and service firms needs to be explained with reference to both the locational and the managerial perspectives. The strategic perspective seems to miss the subnational locational dimension that relates to the advantages of agglomeration, proximity, and global connectedness. These are described as pipelines of communication. The possibility for firms to utilize the specific advantages of regional innovation systems to enhance their internationalization is essential in explaining why some regions and not others have a strong position within global production chains (Ström and Wahlqvist 2010). These complex value-adding networks have become the cornerstone of internationalization for the production of both goods and services (Beyers 2012).

Even if firms today are operating on a global stage, the aspects of location that facilitate internationalization have not diminished. Derived from economic geography theory, research on innovation shows at least three characteristics: (i) there is a need for a reduction of technical and economic uncertainty over time; (ii) interactions with outside parties are necessary; and (iii) face-to-face contact is still important which means there remains a need for business travel even if information technology has reduced the friction of distance. These three characteristics underpin the ongoing importance of industrial clusters or agglomerations of various kinds. If the diffusion of knowledge, ideas, or good business practice, for example, is easy, globalization is said to override locally confined innovation processes. If the diffusion process is difficult and involves expensive transaction costs, localized innovation processes are still of great importance and will eventually have an impact on the internationalization processes of firms, not least their geography.

Rate of internationalization and emerging market multinationals

Since the mid-1990s the rate of internationalization has changed drastically. In the early studies of how firms internationalized, the process usually extended over several years. Today firms can become international in an instant, thanks mainly to the possibilities offered by a combination of increasingly sophisticated telecommunications and the Internet. Rather than being a later step in firm development, some firms have internationalization on the agenda right at the start of operations. This “born global” phenomenon enables firms to become international using connections they have established with partners around the world. It often coincides with the entrepreneurial aspects of how to expand a firm over extended geographies and to markets with large cultural differences.

The last two decades have also witnessed another phenomenon in relation to internationalization. Whereas firms from mature and the
most advanced economies were the first to take advantage of their competitive strengths to venture into foreign markets, firms from emerging market economies in Asia and Latin America are also now rapidly expanding their geographical reach to both developing and developed markets (Ramamurti and Singh 2009). These emerging market multinationals have become serious competitors to many of the most established firms in the mature economies. Technological possibilities have also enabled firms from emerging markets to compete in high-end producer services. Information technology services are one example where firms from India have established a strong presence on the international market, by using back-office functions in the domestic market for supplying services to customers in Europe and North America.

Several emerging market firms have also established themselves as the largest players in their respective industries. From the perspective of traditional internationalization theory, they have become internationalized from a position of disadvantage. Their only advantage was seen as the low cost structure for the production of goods and services, but recently these firms have moved in to high-value-added activities such as advanced production networks and high knowledge content services. Some have also tried to leapfrog into internationalization by acquiring well-known and respected corporate brands. Examples include the takeover by Lenovo of IBM’s laptop business and the takeover by Geely of Sweden’s iconic Volvo Car Corporation.

Internationalization has become the backbone for connecting business locations around the world. Economic integration has enabled regions to increase their value-adding possibilities. Complex regional and global production networks have managed to reduce costs and allowed more complex divisions of labor, which now makes up a larger share of service activities. Internationalization is difficult to understand unless studies of the spatial dynamics that drive location patterns are combined with strategy-oriented studies of how and why firms internationalize in a service-dominated economy. As global markets become ever more intertwined, the study of internationalization will develop further. Apart from examining how firms can now find their way into international markets in an instant, it is also necessary to better understand how firms from emerging markets are capturing distant markets in both mature and developing economies so effectively. Technology has helped to shrink the world and to increase the speed of service delivery across markets. It has enabled new forms of internationalization. This calls for further cross-disciplinary studies that combine the economics, political economy, spatial dynamics and configuration, and firm-level location strategies that together shape the internationalization of services and manufacturing.

INTERNATIONALIZATION

“The Internet changes everything” was the over-the-top mantra of the 1990s dot-com boom, easily critiqued in light of the subsequent bust in the early 2000s. Twenty years later, a similar refrain can be heard from the top executives of technology corporations like Google and Facebook and seen in initiatives to apply information and communication technologies to everything from the complex problem of international development to more mundane matters like catching a cab or finding a parking spot. While not wishing to characterize such simplistic sloganeering as truly visionary, it is important to recognize that there are now few corners of our social, economic, and political structures (at least in the industrialized world) that remain untouched by the Internet and its associated technologies. Computer networks, powerful digital devices, and integrated databases are now deeply embedded in the products and daily practices of the global economy.

This entry reviews this complex intertwining of information technologies and the more conventional material geographies of the global economy. We seek to provide some answers to the questions of how the geographies of global capitalism have shaped the Internet and how the Internet has reshaped the geographies of global capitalism. Clearly it is not enough to simply assert that everything (or nothing) has changed; instead we must understand the nature of changes in the space economy, how these changes came about, where and to whom power and wealth has shifted, and how new products, organizations, and spaces in the global economy are emerging thanks to the availability of the Internet and digital technologies.

The informational infrastructures of the global economy

During the commercialization and rapid diffusion of the Internet in the early 1990s, techno-utopian visions abounded: workforces freed from the constraints of co-presence by the power of telecommuting; the decline of cities as agglomeration economies became less relevant; and, most famously, the “death of distance” as the Internet provided constant connectivity (cf. Cairncross 1997). These visions were, at their core, technologically determinist, predicting uniform and massive upheaval in long-standing social and spatial structures with little regard to the complex ways the Internet could be put to work in the economy. Not surprisingly, the reality that emerged was much different and considerably more complex than these simplistic visions.

A key reason behind this is that the Internet is grounded in particular places through the massive, albeit often unseen, network of material infrastructure necessary to support its existence, from fiber-optic cables spanning the continents.
and oceans to so-called server farms located in peripheral locations, which house all of the data we generate and store “in the cloud.” Despite widespread visions of ubiquitous connectivity, access to the Internet has remained stubbornly uneven, from the local scale to the national and supernational scales, due to the “splintering” effect engendered by Internet infrastructures (Graham and Marvin 2001; Malecki 2002). This splintering has meant that rather than the predicted universal access to the Internet, some places (particularly urban areas) have become quite well connected, while other nearby places remain practically off the map.

The tendency for informational infrastructures to cluster together in relatively dense places has ultimately meant that the geography of the Internet has often reinforced existing patterns of urbanization and agglomeration, rather than overturning them. Using a range of metrics – from bandwidth measures, points of presence, and domain name registrations, among other things – early geographers of the Internet demonstrated that the then-emerging information economy was not somehow separate from other sectors of the economy and their geographic influences (Townsend 2001; Zook 2000). This work highlighted the importance both of a handful of key “global cities” like New York which were at the center of the global network, and of long-standing national powers, such as the United States. Although the United States retains a powerful place within the landscape of Internet connectivity and governance, its centrality has diminished somewhat in more recent years. For example, it was recently announced that the US Commerce Department would cede its control over the Internet Corporation for Assigned Names and Numbers (ICANN), the body responsible for governing the domain name registration system, to the international community.

As has been the case with the United States’ role, these patterns of continuity, however, have also been accompanied by reconfiguration of urban hierarchies tied to Internet infrastructure. Some cities, such as Washington, DC, San Francisco, and Seattle, have benefited economically during the last two decades due to their positioning as transoceanic cable landings (Townsend 2001). While New York remains the most significant city in this respect, due largely to its direct connections with Europe, these other cities have encroached on the status of America’s more conventional global cities such as Chicago and Los Angeles. The groundedness of this infrastructure in particular places, however, also leads to potential for disruptions. While targeted terrorist attacks on critical infrastructure (Roberts, Secor, and Zook 2012) or disruptions to global financial markets caused by earthquakes or other natural disasters tend to preoccupy some, much more straightforward and mundane disruptions are also possible. For example, the ability of the Egyptian government to simply “switch off” the country’s Internet during the Arab Spring protests in 2011 due to the centralization of the country’s global connections in a single government-owned building, or the case of a Georgian woman scavenging for copper who sliced through a cable and disconnected 90% of Armenia’s Internet, highlight the importance of these material manifestations to this supposedly virtual domain or global capitalism.

Infrastructure alone is rarely enough as the immaterial knowledge infrastructures present in urban centers – often built around existing industries or capabilities – have also proven key in the reordering of these economic hierarchies. For example, Zook (2000) has shown that places like San Francisco and the Bay Area in California, Provo, Utah, Portland, Oregon, Austin, Texas, and Las Vegas, Nevada, emerged as relatively specialized centers of Internet content.
production, while a handful of cities in Florida have become well known for their specialization in the Internet adult industry. While the reasons behind this clustering are complex and many – indeed, not all places can develop such clusters – these particular urban nodes have succeeded by leveraging existing local economic activities such as software development and gambling onto the Internet. More contemporary data show that specific slices of informational activity are concentrated unevenly and sometimes in somewhat unexpected ways. A case in point is that the Tokyo metropolitan region retains its centrality in terms of user-generated Google Maps content, but has been surpassed, along with New York and London, by Jakarta, Indonesia, in tweeting activity. So while the particular places privileged by the Internet’s geography may not accord precisely with rankings of global cities or other expectations about the distribution of economic power and resources, larger scale social and economic processes, such as geographically uneven development, have been intensified by the Internet, rather than eliminated.

Digital commodities and consumption channels

While the Internet has contributed to the restructuring of global urban hierarchies, perhaps the greatest impact has been on the (re)organization of the economy. This is most evident in creating space for new kinds of products and services which are either wholly digital or which rely upon the Internet to facilitate the consumption of particular offline goods or services. This includes digital versions of previously material items such as music or movies, and inherently digital commodities for use in gaming or virtual worlds like Second Life and World of Warcraft, as well as novel services like eBay or AirBnB, which redirect consumption patterns, or social media platforms focused on the production, capture, and exchange of user-generated information.

A commonality across new digital products is that the Internet has made it ever more difficult to exclude access to them; perfect copies can easily be made and distributed for simultaneous use by multiple individuals across great distances. While more conventional business models of the twentieth century were predicated on the excludability and rivalrous nature of consumer products, the Internet has largely turned digitized products, such as music, into both a nonexclusive and nonrivalrous good (cf. Leyshon 2001). This has led to significant disputes over intellectual property rights with a spiraling set of technologies and counter-technologies competing to permit or prevent copyright holders from making digital commodities into excludable and rivalrous goods. In parallel, new businesses, such as Google and Spotify, have emerged in which consumers no longer pay directly for digital products with money, but do so by forfeiting the right to data about themselves and their online interactions, which is then used to serve targeted advertisements to these potential consumers. The growing importance of social data as a product for resale has led to a growth in user-generated content through websites like Facebook, Twitter, Flickr, and Instagram, which all are free for users, but which for commercial viability also rely on the sale of data generated by these users to third parties.

In addition to new digital products, the Internet has engendered novel ways of channeling consumption through a range of digital services. Though the aforementioned social media platforms have been important commercial actors in their own right, other platforms attempt to more directly tie the virtual world of the Internet and social media to the material world, especially
INTERNET AND GLOBAL CAPITALISM

through consumption. While Google Maps provides spatial search and wayfinding services, its algorithms also have the potential to “re-route” users to particular kinds of locations based on a number of more-or-less opaque factors, perhaps leaving some places undiscovered by anyone without deep, place-based knowledge (Zook and Graham 2007). Similarly, Foursquare provides social and monetary incentives for individuals to record and annotate their daily spatial practices of consumption, such as the offer of a discount for habitually “checking-in” at one’s favorite coffee shop. One important recent development is Facebook’s purchase of Oculus VR, a maker of virtual reality headsets most commonly used for gaming. This investment of $2 billion is indicative of the importance of linking these virtual experiences and interactions to the material world and everyday life. As Facebook notes in their press release about acquiring Oculus, “virtual reality technology is a strong candidate to emerge as the next social and communications platform,” highlighting the centrality of digital mediation to consumption in the economy.

The impact of the Internet on consumption is not limited to these highly visible examples, however. Indeed, online retail, or “e-tailing” as it was referred to in its early manifestations, is transformational precisely in so far as it has receded from our view and seamlessly melded into the daily routines of so many individuals. From online travel websites such as Expedia and Priceline to multipurpose retailing websites such as Amazon, consumers now have easy access to a wide variety of products via quick shipping options. Brick and mortar stores remain, but online consumption channels are solidly established in our economies. Moreover, some of these channels have introduced new ways of widely distributing material products at reduced volumes making smaller scale operations commercially viable. This can be seen in the growth of new sales channels such as the craft website Etsy, in which artists and artisans can access new and distant markets, or AirBnB, which allows one to rent out one’s home as if it were a hotel room. In short, the Internet has enabled a range of new products, services, and pathways for consumption to emerge within the economy.

Internet-enabled changes in labor geographies

Alongside these new products and services have come important changes in the practices and geographies of labor. Initially, the preoccupation with the Internet’s effects on work and labor tended to focus on two key ideas. First was the notion that the introduction of new ICTs would necessarily lead to the deskilling of labor and loss of jobs, as computers automated many routine tasks performed by unskilled information processing workers. The second important idea was the now somewhat mundane notion of “telecommuting” or the ability of workers to work from home due to the remote accessibility enabled by an Internet connection. In other words, the Internet was expected to render co-presence obsolete, as companies and workers alike could save time and money, avoiding lengthy commutes, unnecessary capital outlays for office space, or other things by communicating online. While there has been deskilling and telecommuting, the Internet’s effects on labor and its geographies are much more complex. New forms and definitions of labor have emerged alongside deskilling, while spatial practices of labor have evolved to take advantage of these emerging forms of work and organization.

One of the key shifts associated with Internet-enabled labor practices has been the emergence of crowdsourcing, or a kind of
“volunteered” labor associated with the production of user-generated content without financial compensation. Ritzer and Jurgenson (2010) identify this process as the rise of “prosumption” on the Internet, or the increasing tendency for production and consumption of online information to be indistinguishable, occurring simultaneously. They argue that this process is characterized not only by free labor and free products, but also by an economy of abundance, rather than scarcity. They point to the potential for prosumption to act as an alternative to conventional capitalist social relations, especially around the control of exploitation of labor by capital. Rey (2012) furthers this argument, likening Facebook to Marx’s factories as the key site of exploitation under informational capitalism, whereby capitalists extract surplus value from the unpaid labor of Facebook users.

While the prevalence of unpaid labor is increasingly important for an economy where information is a primary commodity, the Internet also has allowed for the expansion of systems of paid informational labor outside of more conventional employment relationships. One of the key examples of this is the rise of “microwork,” such as that offered by Amazon’s Mechanical Turk service. This platform connects employers with workers for short-term information processing tasks, such as identifying typos in a sentence or comparing the objects in a set of images, which tend to pay just one or two cents per task. Despite the low average pay of $2.30 an hour – enabled by Amazon’s classification of workers as independent contractors – 15% of the Mechanical Turk workers living in the United States (which accounted for 56% of the global Mechanical Turk workforce in 2009) rely upon this income “sometimes or always” in order “to make basic ends meet” (Ross et al. 2010).

Alongside informational microwork, there is the process of offshoring, or the outsourcing of jobs from developed economies to developing countries in order to profit from decreased labor costs and lower burdens of government regulation. While often discussed in terms of manufacturing employment, a number of informational occupations, including call centers and customer service, also have been affected (Gereffi 2006). While offshoring of routine and even skilled informational jobs is ongoing, Zook and Samers (2010) argue that the geographies of outsourcing are also taking the form of “nearshoring,” “onshoring,” or “homeshoring,” indications that although the Internet can allow for coordination and communication across great distances, social relations remain incredibly place bound, whether by language or cultural similarities, affecting a business’s wellbeing. For instance, countries such as India, the Philippines, and South Africa have all emerged as key localities for call center outsourcing catering to English-speaking countries, while Spanish-speaking call centers tend to locate in Latin America, and German-language call centers in Turkey.

In short, it is important to embed these changes within broader histories and cultural specificities that create a significant amount of internal differentiation between places. While the reduction in labor costs remains an important consideration for firms wishing to outsource any type of job, there is no single set of criteria by which these decisions are made, with different locations offering a variety of advantages depending on their particular relationships with other spatially distant locations. Similarly, just as no places are affected in the same way by these structural changes, the kinds of changes wrought by the Internet do not apply equally to all kinds of labor. While some jobs have been entirely automated by computers, outsourced to other countries or continents, or broken into a series of microtasks, other opportunities have emerged, particularly for what Castells (1996)
characterizes as self-programmable labor, where workers are able to quickly adapt to volatile employment opportunities.

New forms of manufacturing in the Internet era

The influence of the Internet on labor practices is not confined to the use and dissemination of information. The Internet also has important impacts on how material goods are produced. From robotics to computer-aided design (CAD), enabling designs to be produced in one location and easily transferred to computer numerical control (CNC) tools in another, the Internet has altered the kinds of work performed in manufacturing material goods, providing an important role for information processing and transfer even in this sector. CNC systems are central to flexible manufacturing, permitting the creation of “reconfigurable manufacturing systems” which “allow adding, removing, or modifying specific process capabilities, controls, software, or machine structure to adjust production capacity in response to changing market demands or technologies” (Mehrabi, Ulsoy, and Koren 2000, 404).

These techniques of flexible manufacturing have further evolved with the growth of 3-D printing technologies in which solid objects based on CAD specifications are created by precisely depositing material – often a plastic but potentially metals or other materials – in a series of layers, a feature that is particularly useful in prototyping. While traditional mass production techniques produce lower cost (and generally higher quality) products, 3-D printing is beginning to be used by a range of corporations and likely will become even more useful as the technology advances to include the ability to print electrical circuits directly into objects.

While the high costs of 3-D printing remain its greatest challenge, some business scholars highlight its potential to support a range of “mobile manufacturing” strategies (Stillström and Jackson 2007, 188). For example, the start-up company Mebotics has developed a desktop system which is marketed as “the world’s first machine shop in a box.” One of the founders of the company sketches out a scenario of being in a remote location but needing a spare part; access to a 3-D printing system and the Internet would allow the user to acquire printing specifications and create a replacement part. Proponents of 3-D printing, moreover, argue that normal consumers, even with access to standard retail outlets, will eventually find it economical to print out a range of simple consumer products using open-source CAD files for objects at online repositories.

The necessity of CAD files (open source or proprietary) highlights ongoing concerns about intellectual property that are associated with the Internet. Just as the music industry lost the ability to monetize product through physical media (records, CDs) as digital files enabled perfect copies of music, manufactured goods could face the same threat. Once CAD source files are available on the Internet, then anyone with a 3-D printer could create a material copy. One could easily imagine groups of activists creating high quality CAD files of desirable (yet proprietary) goods – jewelry, silverware, and so on – and making them available via bit torrent systems – much in the same way that copyrighted videos are currently shared – to create open (albeit illegal) production of material goods. This potential strikes directly at a range of design and creativity-based economies and economic development policies; if design-intensive items can be scanned and available to anyone to download, this potentially threatens the value
that designers and corporations can capture (as in the recording industry).

**Transformation of finance and logistics**

The Internet has been equally important in introducing new spatial and organizational dynamics into service industries such as finance and logistics. While one focuses on money flows and the other on material goods, both are fundamentally dependent on the flows of information through the material infrastructures of the Internet.

**Finance**

In many ways, the financial sector has been the area of the economy most fundamentally impacted by the growth of the Internet and other digital technologies. Indeed, it was the intertwining of the Internet and finance that led to early pronouncements of the “end of geography,” (O’Brien 1992). Not only has finance grown to become one of the most important parts of the global economy, but it also has begun to shift away from its historical function of providing capital investments for new business or trade ventures. The financial sector has increasingly focused on the trading of a range of complex financial instruments or derivatives that are loosely, if at all, connected to material assets or the competitive prospects of a given firm.

The Internet and associated information technologies underlie many of these new products and practices, as they could simply not exist to any meaningful extent without computers and standardized global communication networks. Like the Internet’s intertwining in other processes, the importance of these technologies is often hidden from view for all but those experts who experience these practices directly. For example, one of the key mechanisms contributing to the 2008 financial crisis were instruments known as collateralized debt obligations (CDOs), which combined hundreds of income streams deriving from hundreds or thousands of home mortgages. Each income stream did not represent an entire mortgage but instead was a slice or tranche of the payment prorated in various ways. More expensive tranches were drawn from lower risk mortgages and/or were guaranteed first payment rights. The goal and claim of makers of these CDOs was that this provided a reliable way to mitigate risk, but events quickly proved that complexity was no barrier to financial hazard. While dividing, bundling, and sharing risk is a long-standing and important practice within the financial sector, the sheer magnitude of these practices associated with the mortgage crisis was only possible with digital technologies that are seemingly able to make risk disappear.

The financial industry has also developed new practices that fundamentally rely on the Internet. For example, during the past 20 years trading at stock exchanges has shifted from actual trading floors to server farms in which computer algorithms conduct tens of thousands of trades every second. This phenomenon, known as high-frequency trading (HFT), works to compress time–space at very small scales (milliseconds and microns) to construct informational advantages vis-à-vis other traders. One of the key techniques used in HFT is to identify small price differences in pricing for the same or similar stocks in different (and physically distant) trading venues. With this information, trading algorithms execute buy and sell orders across hundreds of kilometers via an increasingly sophisticated array of networks. This has involved the laying of new fiber–optic networks between major trading centers, such as between Chicago and New York, as well as setting up a series of microwave and laser transmitters, simply in order...
to ensure that an HFT buy or sell order arrives a few thousandths of a second before those of one’s competitors (MacKenzie et al. 2012).

While HFT tends to be out of view for most individuals, a more common way that the Internet has influenced finance is through the emergence of virtual currencies associated with virtual worlds and online social networks, such as Linden Dollars in Second Life or the attempt to create a completely decentralized currency, Bitcoin. While these currencies currently suffer from issues of stability, liquidity, and uncertainty of legal obligations, they offer an intriguing glimpse of what may be possible in a global information economy in which software and networks allow global collections of users (versus states or large financial firms) to literally create money. Equally interesting are the political values associated with these currencies; in the case of Bitcoin a type of algorithmic libertarianism poses behind a stance of apolitical objectivism. Whether the specific Bitcoin project succeeds or not is less relevant than the individualization of empowerment – the ability to design or manipulate software (either directly or via proxy) – that allows some individual actors to undertake political and economic projects at scales and scopes that previously were not possible. In short, the power of the networked individual is a fundamental characteristic of global capitalism in the age of the Internet.

Logistics and global production networks

The virtual spaces of the Internet have become more and more intertwined with the flow of material goods around the globe. Just as the near-instantaneous global information flow has allowed for high-frequency trading and other new financial products, these same informational infrastructures are put to use in tracking and changing the way material products move through space on a global scale (Coe, Dicken, and Hess 2008).

While spatial structures in the economy have long been driven by transportation networks and population, new IT-enabled logistics has allowed for new forms of competitive advantage for firms and localities across the globe, with firms increasingly outsourcing their logistics operations to specialized third-party logistics providers who concentrate on the collection and analysis of information about products, rather than on their design and manufacture. Rather than focusing on building competitive advantage solely within the production process, new logistics services allow firms to reduce the cost of moving goods and maintaining inventory, as pioneered by the just-in-time manufacturing systems of Toyota, or the cross-docking restocking of the American retail chain Walmart.

With easily accessible information and the ability to reroute flows of goods relatively easily, inputs for products or final goods can be “stored in transit” rather than warehoused, thus reducing the necessary capital outlays for production or retail stocks. The augmentation of these material products and the vehicles on which they move with radio-frequency identification (RFID) chips and global positioning systems (GPS) receivers allow for individualized tracking of products, even across great distances. This facilitates the further spatial extension of supply chains, as important factors such as trust and tacit knowledge become codified through digital information. It has been argued that contemporary Internet-enabled logistics services represent an unprecedented merging of transportation and information industries, making the movement of material goods through space a virtual phenomenon as much as a material one (Aoyama and Ratick 2007).

The digital augmentation of supply chains can also be produced through new forms of
infrastructural systems. Space-constrained ports can use their knowledge of distanced supply chains to better manage the flow of goods in and out of the port, increasing the efficiency of transportation. As one IBM promotional video on the baggage handling system at Amsterdam Airport states, “We can’t make the airport bigger. The physical footprint is limited by highways, cities and villages. We must make more capacity available by making the system smarter … the intelligent software creates space where there was no space before.” Although couched in advertising rhetoric, this quote is indicative of the broader trend of using information flows to overcome the constraints of existing physical infrastructures.

While the use of the Internet in managing supply chains has stretched economic relations across greater social and spatial distances, it has not eliminated the massive inequalities that exist within the global economy. For example, Graham (2011) has shown that despite the expectations for the Internet disintermediating supply chains, that is, allowing for more direct relationships between producers and consumers, evidence suggests that there is little change in the organization of many sectors, at least not in such a way as to alter more macro-level development outcomes. Moreover, examining small-scale manufacturers in Tanzania (which enjoy widespread use of information and communication technologies), Murphy (2013) shows that the benefits of these technologies tend to accrue primarily to extra-local actors who are already situated in dominant positions relative to local-scale businesspeople. That is, the Internet may offer the means for economic exploitation of marginal places and places in the information age, even as it opens up significant opportunities for others (Ya’u 2004). Even the production of commodities emblematic of the information economy, such as the iPhone, tends to reinforce these patterns.

While the iPhone’s supply chain is truly global, with manufacture of the phone alone stretching across China, South Korea, and Germany, most of the value produced in the process of creating the several-hundred-dollar device is captured by designers located at Apple’s headquarters in California, not by workers assembling the devices. So while Internet-enabled logistics are reshaping parts of the sociospatial system, this seems to have done little to alter the fundamental economic structures that influence everyday life in the Global South (Carmody 2012).

Conclusion

The Internet has undoubtedly played an important role in the evolution of global capitalism over the last two decades. While the changes are significant, they are best characterized as a reconfiguration or intensification of existing structures and processes, rather than a wholesale creation of new forms of economic organization that are somehow qualitatively distinct from previous eras. The examples outlined here highlight the complex and contradictory role of the Internet in reconfiguring flows of products, labor, and capital in the global economy. New products and consumption channels have emerged just as labor and production practices have evolved in response to the availability of the Internet, bridging the seeming divide between the virtual and material.

The Internet has facilitated new uses for old spaces and enabled new forms of capital investment, from fiber-optic cable infrastructure to high-frequency trading to the commodification of personal data. Ultimately, the sociospatial reconfigurations of the global economy wrought by global networks of information technologies are remolding the terrain on which capitalism operates. While this has brought many changes
INTERNET AND GLOBAL CAPITALISM

to our everyday lives and to the processes through which the economy is constructed, capitalism remains the dominant form of economic organization worldwide, even in the age of the Internet and notwithstanding the notion that the Internet supposedly changes “everything.”

Interoperability of representations

Boyan Brodaric
Geological Survey of Canada

Interoperability is an essential requirement in complex digital environments where multiple geographical information sources must work together. For example, an online hotel booking system might require a mapping component to work with payment and reservation systems, and the mapping component itself might access a variety of online sources to contextualize the location, such as nearby tourist attractions, restaurants, or other amenities. Often these components are distributed geographically, are heterogeneous in their deployed technologies, data structures, and data content, and are managed autonomously by distinct agents with diverse goals, policies, rules, and regulations. These differences must be overcome in order for the systems to work together cohesively and become interoperable.

Interoperability defined

Interoperability is defined variously. All definitions include the notion of diverse autonomous entities working together to achieve some common goal in a particular setting. Working together in this sense requires some or all of the following: cooperation, compatibility, unification, coupling, sharing, exchange, negotiation, and communication (Manso and Wachowicz 2009). It also usually carries a quality connotation, as in working together smoothly rather than laboriously. The definitions also vary as to whether interoperability is (i) a measure of how well entities work together in the attainment of a common goal (e.g., less or more interoperable), (ii) a state-of-affairs describing a working functional relationship between entities (e.g., several components continuously interacting to read and analyze environmental conditions), or (iii) a similar ability hosted by participating entities (e.g., being able to understand a specific, often standardized, language or to exchange specific data). The challenge common to these various orientations involves overcoming differences, that is, heterogeneities, among the interacting entities to ensure their unified functioning. Indeed, heterogeneity is an essential characteristic of the ecosystem composed of the interacting entities: without heterogeneity they could clearly interoperate without further effort. The interacting entities could be natural or artificial, such as humans or machines, respectively, making interoperability per se a very broad notion. An interoperability example among humans is a teleconference, which could prove challenging due to the use of different languages, and to the need to avoid speaking at the same time. An example of machine interoperability involves the integration of multiple distributed heterogeneous datasets, or the synchronized operation of diverse software running on different machines.

Geographical interoperability occurs when the attainment of a common goal requires interaction with geographical entities — these are entities that occupy some space, or unfold in it, such as landforms, buildings, or earthquakes. The occupied space need not be physical — it
might be, for example, abstract, emotional, social, or representational (e.g., digital) – but it is necessarily structured such that pertinent entities can occupy locations in the space and partake in relations or actions within it. Geographical interoperability in this sense can be more complex than interoperability between nonspatial entities, say financial accounts, due to the wider range of heterogeneity resulting from the additional spatial aspects. Examples of geographical interoperability are numerous, and include such things as the use of multiple blueprints to construct an edifice, the coupling of air traffic or road systems, or any other environment in which spatial aspects influence the interaction of the entities. By far the most prevalent form is information interoperability: the working together of digital representations of geographical entities that typically reside in various kinds of geospatial databases, geographical information systems (GIS), or web pages.

Frameworks for interoperability
(i) – general

Frameworks for interoperability, including geographical information interoperability, are numerous and follow from the various definitions of interoperability (Manso and Wachowicz 2009). Each is typically portrayed as a stack of stratified and nested levels. Thus measurement, or “maturity,” stacks distinguish levels according to how well entities, typically organizations, function together or adapt to changes in computational environments. States-of-affairs stacks delineate levels according to relationships between types of components, such as the existence or degree of connectivity between databases or software. Ability stacks differentiate levels according to the type of transformation required to align entities, such as syntactic or semantic transformation. However, an apparent shortcoming of these and other stacks is their lack of a comprehensive theoretical framework. In contrast, a broader approach depicts interoperability as a communication process, in which messages are necessarily exchanged between entities (Brodeur et al. 2003). This reliance on message passing is not limited to information interoperability singularly, as it applies to all forms of interoperability: fundamentally, in this paradigm, entities could not interoperate without communicating, and this implies the transmission of messages and the shared use of some common language.

Why representations?

Representations are at the core of interoperability in the communication paradigm, not only due to the messages passed between interoperating entities, which are in fact representations external to the entities, but also due to the internal representations of these messages maintained by senders and receivers: it is the sender’s internal representation that is encoded into an external message, which is then decoded into the receiver’s internal representation. In general, two types of messages are exchanged: (i) control messages that influence how entities interoperate, such as error messages or requests for data or software, and (ii) content messages containing actual subject matter, such as geographical data or software. For example, a teleconference participant can signal a desire to speak by coughing or asking permission, and can then supply relevant discourse in one language or another. Analogously, an information system in a federated data network might use Representational State Transfer (RESTful) principles for exchanging messages, and might require data content to be structured as objects and vectors.
As becomes quickly evident, the main obstacle to interoperability in this paradigm is the meaning challenge: whether receivers can decode a message to understand the sender’s intended meaning, given the almost inevitable variability among representations. Achieving understanding requires, at a minimum, communicators to share an external representation, which enables them to encode and decode a common language that is rich enough to transmit the intended meaning. This becomes more complex when the number of communicators increases, as it almost invariably amplifies the number of distinct internal and external representations within the communication community. The effect of this increase is significant: it can exponentially increase the total number of decodings within a community, in order to enable a member to dialog with any other member. It can also increase the chances of having severe differences between representations, such as different languages deployed by telecom participants, or different communication interfaces and data structures deployed by interacting information systems. Overcoming the meaning challenge, in general, then devolves to the problem of overcoming differences, or heterogeneity, between representations by translating one representation to another, ideally with minimum meaning loss.

Frameworks for interoperability (ii) – theoretical

A significant advantage of the communication paradigm for interoperability is its theoretical foundation, namely semiotics. Semiotics provides not only a theory for describing the representation and interaction of messages – called signs – but also enables description of the heterogeneities inherent in sign interaction. At its core is the structure of a sign, which is dominated by Peirce’s formulation in the context of information interoperability. A sign has four components: (i) an object that is being represented, (ii) a symbol, which is an external representation of the object, (iii) a concept, that is an internal representation, and interpretation, of the object and symbol, and (iv) an agent that hosts the internal representation, and that either produced or consumed (interpreted) the external representation. A unit of meaning then consists of the four-way relationship between these components, such that a particular symbol stands for a particular object as produced/consumed via a certain concept by a specific agent. It is often depicted as a triangle consisting of object, symbol, and concept nodes, with the agent placed nearby.

The sign, as a semiotic unit of meaning, is further delineated by Morris (1938) into the three semiotic dimensions of syntax, semantics, and pragmatics. Syntax refers to the relation between a sign and its symbol, and encompasses the formal structure of a sign, such as the grammar of a language or structure of a message. Semantics refers to the relation between a sign and the object being represented, and encompasses the conceptual and referential structure of a sign, for example, as famously noted by Frege, that “morning star” and “evening star” are different signs, hence meanings, referring to the planet Venus. Pragmatics refers to the relation between sign and agent, and encompasses contextual aspects such as how signs are created and used, and their related effects – for example, the varied interpretations of some body gestures among cultures, or the context-dependent interpretations of natural language indexical terms such as “it” or “them.” Understanding, that is, decoding, a message can subsequently be achieved by the progressive understanding of its syntax, semantics, and pragmatics, as widely noted by linguists – though some cognitive linguists blur the line between semantics and pragmatics,
particularly for human communication. As a side effect, the three semiotic dimensions are then also often viewed as broad categories for associated heterogeneities.

For example, consider an information integration use-case in which an online system, for example, for hotel reservation, is merging information about a specific geographic location from the DBpedia and GeoNames web databases. Syntax differences occur when the structure of messages vary for the same information, due to inherent differences in the external languages, that is, HTML (Hypertext Markup Language) and RDF/XML (Resource Description Framework/Extensible Markup Language). Semantic differences occur when the content of the messages varies – for example, when each has unique properties not included in the other, such as a ‘photo collection’ (DBpedia) or a list of ‘nearby features’ (GeoNames). Pragmatic differences are also apparent, as the HTML format is primarily intended for use by web browsers, but the RDF/XML format is largely geared for use by reasoning engines. To overcome these differences, the online system must create its own internal sign, typically a composite of the external signs normalized to a preferred option along each semiotic dimension.

More generally, while the example just described above illustrates a blending scenario, in which an agent consumes and amalgamates multiple signs, it equally applies to communication scenarios in which an agent consumes or produces a single sign, or acts as a producer of many signs for external consumption. Heterogeneities in all three semiotic dimensions can, and regularly do, then exist for the sign blending and communication scenarios, because in both scenarios the agent is transforming signs either to or from internal representations.

The three semiotic dimensions (syntax, semantics, and pragmatics) and two sign interaction scenarios (blending and communication) also apply to the other major information interoperability use-case of software orchestration. This use-case includes any processing environment in which software components are coupled to attain a specific goal. It requires agents, such as GIS, to coordinate actions by exchanging control messages, the most significant of which conform to declarative templates, called signatures, describing interfaces to the actions. Heterogeneity exists between the internal representation of the message-producing agent, who is requesting the action, and the external signature of the message-consuming agent, who is carrying out the action. Syntax heterogeneity is then related to the language and structure of the signature, semantic heterogeneity is related to the concepts inherent in the signature, and pragmatic heterogeneity is related to the information required to enable the software components to function together, such as the sequence and validity of connections and the reactions to monitored events, as well as the criteria for overall fitness for use. The orchestration use-case clearly exemplifies the communication scenario, as control messages are sent to and from a producer, and can also exemplify the blending scenario: though control messages are rarely integrated into one composite message, even if arriving simultaneously, signatures often do refer to information inputs that might in fact require blending from multiple sources prior to processing by the receiving agent.

Frameworks for interoperability (iii) – geographical information

Prominent frameworks for information interoperability, or related information system design,
include the Semantic Web (Horrocks et al. 2005), database interoperability (Sheth 1999), simulation interoperability (Tolk, Diallo, and Turnitsa 2007), and computational semiotics (Stamper et al. 2000). As shown in Figure 1, these frameworks are organized into nested ability stacks, in which the semiotic dimensions are further subdivided within the syntax and pragmatic layers, and a new bottom layer is universally added, here called systems following the database interoperability stack. While domain-neutral, all these stacks can be applied to geographical information interoperability – for example, the database interoperability stack has been applied to GIS interoperability (Bishr 1998; Sheth 1999), the simulation interoperability stack has been adapted as a framework for Spatial Data Infrastructures (SDIs) (Manso, Wachowicz, and Bernabé 2009), and the Semantic Web stack has been implicitly applied to geospatial Linked Data (Kuhn, Kauppinen, and Janowicz 2014).

**Systems**

Semiotically, systems can be seen as the relationship between a message (sign) and the media carrying it, though this distinction is an artifact of later information theory and not part of original semiotic formulations. In information interoperability, media encompasses both the hardware and the software infrastructure required for message passing. For instance, in the Semantic Web stack it generally refers to all aspects of web infrastructure, and significantly to the universal resource identifier (URI), which is required to identify and possibly navigate to a web-based entity called a resource; it also includes the alphabet used to encode URIs, and the hyper-text transfer protocol (HTTP) for transmitting messages. In the database and simulation stacks it refers to computing foundations, such as operating systems or database management systems, including specific GIS. In computational semiotics the physical and empirical nature of the media is emphasized: the physics subdivision
INTEROPERABILITY OF REPRESENTATIONS

refers to the physical aspect of the media, such as hardware infrastructure, including connectivity, while empirics refers to how signals are organized within the physical media, including tendencies such as entropy. As in the Semantic Web, the latter includes the organization of signal patterns into alphabets, though it is possible to argue that the abstract identity of a character belongs to the syntax layer, while its digital encoding as a specific character set, or as a digital pulse in a communication channel, belongs to the system level. Regardless, alignment of systems between entities is required for their interoperation – for example, different operating systems and character encodings, or perhaps even the different size constraints imposed by GIS on the representation of geometry types, such as the maximum number of nodes or storage limits for a line or polygon.

Syntax

Syntax refers to components of the language used to encode a message, including the words, the grammar, and possibly the alphabet. Semiotically, this is understood as the relation between a message (sign) and its symbol. Syntaxes can be abstract or concrete; for example, RDF has an abstract grammar consisting of subject–predicate–object triples arranged in nested graphs, and concrete syntaxes such as RDF/XML, N3 (Notation3), or others, that variously encode the abstract grammar. Syntax heterogeneities then concern differences in abstract or concrete language aspects. In geographical information interoperability, they further encompass iconic languages, for example, to overcome differences in cartographic presentations.

In the geographical domain, iconic standards have been developed by various communities, such as in transportation, facilities, geology, ecology, or soils, to normalize the presentation of specific geographical entities. Likewise, the Open Geospatial Consortium (OGC) and International Standards Organization (ISO) standards bodies have developed the textual Geographical Markup Language (GML), an application of XML for the standard encoding of geographical entities. Similarly, the Semantic Web stack includes standard XML applications such as RDF/XML and Web Ontology Language (OWL). For query languages, the Semantic Web community widely uses SPARQL (SPARQL protocol and RDF query language), while its geospatial extension is GeoSPARQL. In terms of interfaces for online software components – that is, web services – the Semantic Web community is increasingly migrating to RESTful principles, which reuse a simple syntax for web operations, while the OGC and ISO provide a fixed terminology for all its web service interfaces, and is selectively adding RESTful versions. Note the Semantic Web and data interoperability stacks exclude configuration aspects, which are found instead at the structure level.

Structure

Structure refers to the configuration of the parts of a message. Semiotically, message structure is known as the syntagmatic relation between the elements of a message, associated primarily with the semiotic tradition of Saussure. It is explicitly differentiated in the database interoperability and Semantic Web stacks, and merged with syntax in the remaining stacks. The database interoperability stack differentiates meta, conceptual, logical, and physical schemas, following database design principles, such that interoperability requires alignment over each schema type. Meta-schemas define the components in a schema, such as entities and relations, conceptual schemas adapt a meta-schema and describe a domain in a technology-neutral manner, logical schemas
adapt a conceptual model according to a specific technologic style, and physical schemas adapt a logical model to a specific technologic system. Structural heterogeneity evident in physical encodings can thus be the result of differences in any of the related schemas – this can be seen as heterogeneity in propositional structure. Another category of structural heterogeneity consists of differences in spatial structure, such as varied representations for the geometric shape or geographic location of a geographical entity.

In support of geographic data interoperability, the OGC and ISO have developed a meta-schema as well as frameworks for logical and physical schema, but lack formal mechanisms for conceptual schemas. The meta-schema describes the structure of a geographic feature type (General Feature Model, ISO 19110), which can be implemented in an ad hoc conceptual schema and/or in GML to enable development of a logical and physical schema within a domain, such as in geology (GeoSciML), hydrology (WaterML), and city infrastructure (CityML), and across domains, such as Observations & Measurements (O&M) and metadata. In contrast, the Semantic Web relinquishes predefined and fixed schemas altogether. Feature descriptions in the Semantic Web can evolve over time and vary across different manifestations at the same time, as well as be linked to a normative-type definition. This flexibility is particularly useful in open environments, such as the web, where structure is inherently unpredictable. It is less desirable in closed environments, where a predictable and consistent structure is often preferred, such as in some scientific data transfer scenarios, or in urgent care or emergency response situations, where, for example, missing information could be crucial and sequence could play a role. These drawbacks are overcome in the Semantic Web via the semantic and pragmatic levels, where ontologies can regulate message content, and practice conventions can guide usage and other structural aspects such as sequence.

The OGC and ISO also provide a standard fixed structure for each web service interface. Key web services include those that access data such as maps (web mapping service), features (web feature service), fields (web coverage service), observations (sensor observation service), and metadata (catalog service), and that invoke geospatial processing software (web processing service). Each web service is self-descriptive, allowing the discovery of supported functional components and representational schema. The structure of these OGC web service interfaces diverges from the Web Service Description Language (WDSL) industry standard, which has been used by many non-geospatial web services, and from the recently popular RESTful principles, used particularly for simple applications where the structure of response data can be relatively easily determined without formal self-description. However, a lack of canonical mechanisms for self-description in the response can be a deterrent to interoperability when the response structure is complex and not readily discernible.

Semantics

Semantics refers to the meaning inherent in the content of a message. In terms of semiotics, it can be understood as the relation between a message (sign) and an object. Classical semantics is divided into extensional and intensional varieties. In extensional semantics, meaning is referential, and focuses on the relation between symbol and object: an agent interprets a message by directly referring to the objects it represents. For example, an extensional interpretation of “lake” (a symbol) is the collection of all lakes in a domain (some objects), where a domain consists
INTEROPERABILITY OF REPRESENTATIONS

of the entities of interest, such as the geographical features found in a geographic area or in a particular GIS. Extensional collections are called models, or extensions. In classical extensional semantics, the extension of a name, or literal constant, such as “Lake Ontario,” is the collection of all lakes with that name. The extension of an n-ary relation predicate is the collection of actual n-ary relations in the domain; for example, Lake Ontario might be in the extension of the unary “lake” predicate, and the pair Lake Ontario and Niagara River might be in the extension for the “flows-into” binary predicate. Lastly, the extension of a propositional sentence is a truth value: the extension of “Ontario is a lake” is true if Lake Ontario exists in the domain. However, associating semantic meaning with extensions can be problematic in several respects, for example, with nonextensional symbols that are difficult to match to a reference, such as those concerned with necessity, agent beliefs, and hypothetical and abstract entities. Also, most notably, an extension can be shared by messages with different meanings; for example, “cold lake” and “deep lake” could refer to the same collection of lakes in a domain, causing them to be interpreted as having identical meaning in extensional semantics.

To overcome these and other problems, intensional semantics focus on properties rather than extensions: “cold lake” and “deep lake” then differ because they carry different properties, which comprise their intensions. Intensional semantics can in this way be seen to focus on the semiotic relation between concept (i.e., intension) and object. Classical intensional semantics accomplishes this by making extensions relative to possible states-of-affairs (worlds) or their fragments (situations) in some domain. Thus if “cold lake” and “deep lake” have different extensions in some possible world or situation, such as in a distinct GIS as is conceivably the case, then their intensions are different. However, this says very little about the nature of an intension, particularly regarding its metaphysical status and the properties that comprise its content.

- Metaphysically, intensions in cognitive semantics are viewed as agent-dependent internal constructs that can be shared to a point, in the sense that very similar constructs can be built internally by agents when they possess similar cognitive hardware and undergo similar experiences. In contrast, in realist semantics, intensions are agent-independent invariants in reality, so-called universals, unmediated by agents but perceived similarly because they exist invariably in reality: for example, scientific laws that are discovered and verified independently by scientists.

- In terms of content, classical intensions are functions that return an extension for some symbol, relative to a specific world or situation. In effect, they serve as a meaning waypoint in the path from symbol to object, and this mediated path serves as an intensional interpretation of the symbol. They are typically fleshed out, in this tradition, using necessary and sufficient truth conditions, and associated reasoning mechanisms. Necessary conditions are true for every member of the extension, while sufficient conditions allow an entity to be placed into an extension. For example, an Aristotelean approach to intensions involves specifying a genus and differentiating conditions – for example, ‘lake’ and ‘river’ intensions might possess a necessary and sufficient condition consisting of the ‘water body’ intension as their genus, and different ranges of ratios for surface width to length as their differentiating conditions. Thus, the symbols ‘Lake Ontario’ and ‘Niagara River’ can be placed into the...
‘lake’ and ‘river’ extensions, respectively, due to their widths and lengths and because they are members of the water body extension.

Following Guarino, a computational ontology (henceforth ontology) is then a digital artifact that externally expresses a collection of intensions in some machine-readable language (Guarino, Oberle, and Staab 2009). Its contents are often influenced by ideas from philosophical ontology, which is the study of what exists. Note the two are very different: the former is a digital artifact used for computing, and the latter is a discipline of study. An ontology is also distinguished from a conceptualization by their diverse expressions: the former is externally expressed, while the latter is not externally expressed, but is an artifact of some metaphysical commitment such as an internal agent representation or invariant in reality (possibly internally represented by an agent). However, the two are linked when an ontology is defined as the external expression of such a conceptualization. It is then possible for an ontology to vary from the conceptualization that it is expressing: a good ontology will have an extension proximal to that of the conceptualization, and a bad one will have one that is distant. Factors such as the selection of the domain, expressivity of the language, and detail of expression will all govern this proximity. Ontologies in practice can then take many forms; for example, conceptual models for various schema, as well as glossaries, data dictionaries, vocabularies, and thesauri, might be considered ontologies in some sense, in addition to the logical theories so prominent in the Semantic Web. Opinions vary as to which of these forms are, and are not, an ontology, and how they differ from an ontology, with the criteria typically including the degree of language expressivity, the generality of the intensions, and their run-time availability.

Ontologies also vary in generality, prominently stratified by Guarino into foundational, domain, and application variants (Guarino 1998): foundational ontologies apply across all domains and include concepts such as physical object or process; domain ontologies apply within a specific domain (e.g., the “lake” concept could be applied in a geographical or hydrological domain, but perhaps not in the domain of financial management); finally, application ontologies apply in specific situations, such as the concepts referenced in a particular GIS (e.g., “deep lakes in Ontario”). Somewhat orthogonal to this stratification are ontology design patterns (ODP); these are essentially self-contained ontology fragments or replicable patterns, from any level of generality. ODP are primarily concerned with ontology modularity to minimize the complexity of the fragment or pattern, as well as minimize their dependence on other ontologies while maximizing re-use.

Interoperability with intensional semantics clearly exemplifies the communication paradigm for interoperability, because understanding the meaning of a message involves translating the ontologies between the sender or receiver of a message (their internal representation) and the message itself (an external representation). Translation of ontologies typically requires the following steps.

- **Semantic enrichment** involves attaching an ontology to an artifact, such as to some data, a GIS database schema, or a web service signature. This can involve discovering the ontology, if unspecified, using a variety of data-driven or knowledge-driven methods.
- **Semantic matching** involves determining the similarity between concepts in ontologies, to identify equivalences and differences, and expressing these as a mapping in some language. As with semantic enrichment, there
exist many methods for semantic matching in the geographical domain, including lexical, statistical, and knowledge-driven, as well as a variety of mapping languages to capture similarities and differences.

- **Semantic integration** involves combining ontologies, once matched, into a unified conceptualization and representation, again using a variety of approaches, such as the use of a bridge ontology to connect diverse ontologies, or the use of a common ontology that is specialized by the diverse ontologies.

Geographical information interoperability benefits from both intensional and extensional aspects, primarily because geographical location can provide a useful extensional reference for semantic matching. For example, while distinguishing a cold lake from a deep lake primarily requires knowledge of intensions, matching the “lake” concept in one data source with a “lake” concept in another could be aided by their extensions: if similarly located objects with some shared properties exist in both extensions, then the intensions are likely similar in comparable contexts. More generally, extensions can provide facts that help to assess the logical consistency of an ontology and its implied inferences.

Intensional semantics, as realized in logic-based ontologies, does however have shortcomings related to meaning representation, and thus interoperability. In particular, the necessary and sufficient conditions used to represent concepts in logic-based ontologies crisply determine whether an entity is a member of an extension, or not. In contrast, prototypical concepts do not have crisp boundaries as extension membership could be graded: some entities might be better examples of a concept than others. For example, a robin is a better example of a “bird” than a penguin, because flying is central, though not necessary nor sufficient, to the bird concept: not all birds fly, and not all that flies is a bird. Many geographical concepts have been shown to be prototypical in this sense, such as “mountain” or “lake.” This has motivated a variety of representations of prototypical concepts in the geographical domain, most notably building on Gardenfors’s (2000) theory of conceptual spaces, in which concepts are represented as portions of a space constructed from quality dimensions such as height or size, and where similarity to a prototype (a location in the space) can be measured. The key role of spatiality in such representations is further reflected in semantic reference systems (SRS), which use spatiality as a metaphor for an overarching theory for geographical semantics: effectively, if concepts are prototypical and thus spatial constructs, then a theory for their representation and manipulation can be formulated analogous to SRS (Kuhn and Raubal 2003). Various connections have been proposed between concepts as spatial constructs and traditional logic-based semantics, and these constitute a promising direction for semantics in geographical information interoperability.

In open geospatial standards, the OGC and ISO provide basic support for semantics. Geospatial feature types, such as definitions for road or river, comprise concepts that are formed by instantiating the OGC meta-schema. Each in turn can then serve as a coarse definition for a feature-type manifestation in a conceptual, logical, or physical schema, without, however, being linked to these schemas in any standard way. As a result, features in data streams, such as specific roads, cannot canonically refer to their type definitions within the data stream, which hinders interoperability. Likewise, categorical values in a data stream cannot also canonically link to a definition, though various physical schema are adopting best practices to achieve this, such as linking to simple knowledge organization system (SKOS) thesauri. Geospatial standards are
increasingly exploring Semantic Web approaches to overcome this obstacle, mainly because types and instances are tightly coupled therein, and moderately expressive languages such as RDF and OWL enable richer type definitions.

Semantic heterogeneities take many forms. As semantics is the relation between sign and object, semantic heterogeneities can be characterized as variations in the sign relations along the path to an object. Because intensional semantics emphasize the role of concepts along this path, then related heterogeneities involve concept relations within a sign, specifically the concept–symbol, concept–object, and concept–concept relations. Variations in the concept–symbol relation include polysemy and synonymy: polysemy occurs when a symbol has diverse intensions, such as “wood” meaning either ‘a piece of tree’ or ‘a collection of trees,’ and synonymy occurs when diverse symbols share an intension, such as when the English “lake” and French “lac” terms both refer to a common ‘lake’ concept. This type of heterogeneity is predominantly the focus of ethnophysiographic studies, which examine the relation between concepts and symbols in different human cultures and languages. Variations in the concept–object relation involve classification heterogeneity: an object can be diversely classified, such as a water body classified as a ‘lake’ or ‘pond,’ while an intension can variously classify objects in diverse databases, for example, a specific water body might be included in the extension for ‘lake’ in one domain, but not in another, due to differences in the description of the water body in the domains. Variations in the concept–concept relation occur when the same meaning has different intensions, such as “lake” defined with different width–length conditions in different ontologies. This also encompasses intensional differences due to variation in the underlying spatial structures associated with prototypes, conceptual spaces, and SRS. Lastly, extensional semantic heterogeneities involve the symbol–object, or reference, relation: a symbol might refer to diverse objects, such as “London” referring to a city either in Canada or in the United Kingdom, and an object might be a reference for various symbols, such as London referred to as “the location of the 2012 Summer Olympics” or “the capital city of England.”

Pragmatics

Pragmatics is defined semiotically as the relation between a message and an agent: how an agent creates or uses a message, or the effects of the message on the agent or others. These aspects are seen as contextual, because they are not part of the message itself, but they control action and reaction related to the message. For example, the concept of ‘recreational lake’ might not vary intensionally among agents, that is, its semantics are uniform, but whether a lake can be used recreationally, and thus be interoperable within that context, varies according to things such as agents’ pollution policies, seasonal restrictions, or even the occurrence of specific obstacles such as low water levels or debris congestion. In other cases, intensions might vary due to experience, such as when varying evidence causes scientists to create different intensions about the same geographical entity (Brodaric 2007) – as a result, experientialists see the semantics and pragmatics distinction as vague, because intensions and experience are so intermingled. Notwithstanding this ambiguity, pragmatic context is generally seen as helping determine, for example, whether a certain lake is included, or not, in response to a query for recreation locations near a hotel, by taking into account contextual details.

Pragmatic heterogeneities include differences in the creation, use, and effect dimensions. Creation differences include various provenances for a geographical entity, such as the diverse intensions developed by distinct geoscientists.
Use differences recognize, for example, that a lake might have various purposes in different databases, such as recreation, water supply, or transportation, and that some uses are more fitting than others for certain states-of-affairs. Effect differences include potential or actual impacts associated with an entity, such as differences in the flood plain associated with a lake.

Pragmatics is categorized variously in the interoperability stacks. One categorization delineates pragmatic context into intensional or extensional types: prescriptive constraints are intensional, such as policies and regulations, while restrictive states-of-affairs are extensional. The simulation interoperability stack uses this distinction to delineate pragmatic and dynamic levels: the former is about awareness of possible actions, such as workflows, and the latter is about adjusting actions dynamically in reaction to a running state-of-affairs. Note this stack is capped with a conceptual level that seems more aligned with semantics as described above. Another categorization delineates pragmatics according to agent action or interaction: action constraints guide agent behavior, such as a workflow plan, while social interchange among agents guides interaction constraints, such as the creation of policies or regulations. The computational semiotics stack uses this distinction to delineate the pragmatic and social levels, while the data interoperability stack focuses on agent interaction, primarily in terms of reaching consensus about data access policies such as security. In contrast, the Semantic Web stack uses a mix of categories: the proof level is extensional, providing provenance about some resource or action, while the trust level involves agent interaction as it concerns evaluation of one agent’s resource or action by another agent.

Pragmatic constraints in geographical information interoperability exemplify many of these distinctions. The more prominent examples include trust evaluation of OGC web services used to display maps online (extensional); the specification of domain-specific best practices for the use of certain standard geospatial web services, for example, sensor observation services for hydrology, and standards to describe the creation, supply, and use of specific datasets (intensional and interaction); critical investigations on the effect that institutional policy and behavior have on interoperability within SDIs (intensional and interaction); and the effect of individual observers on the development of shared geoscientific concepts (extensional and interaction).

Architectures for geographical information interoperability

An interoperability architecture is a plan that describes how computational components function cooperatively to achieve an intended goal. The plan includes a strategy and technical design that both constrains and guides the selection of components, as well as their arrangements. In this sense, it is a specialized version of the broader notion of enterprise architecture, used to describe the design of any major information system. Frameworks for an enterprise architecture are usually composed of multiple dimensions, which denote multiple perspectives on the system (e.g., the Zachman framework). A frequently included dimension is level of technicality, which usually grades from detailed technical details to inherent abstract concepts and their motivating requirements. A conceptual architecture then refers to a system design at the level of broad abstractions – it is general and applicable to a wide variety of situations. In contrast, other technical levels increasingly become more specific, ultimately ending at an implementation plan for a particular system. While large data sharing initiatives, such as national...
and international SDIs, have variously developed multi-perspective architectures for their specific environments, research efforts in geospatial information interoperability have been largely focused on developing conceptual architectures. In these efforts, conceptual architectures can be described using a mixture of approaches, including component-based, which specifies major components and their roles; layer-based, which categorizes components according to the type of usage (Heitmann et al. 2014); and structure-based, which describes the various approaches to connecting components.

**Component-based architectures**

Typical constituents of the component-based approach are shown in Table 1. These consist of functional components and knowledge artifacts. Functional components are system elements that undertake specific actions related to data and metadata, queries, and workflows. In general, requests to the interoperability system are structured as queries, which can retrieve data from multiple sources and possibly select and invoke workflows, using metadata to help find, evaluate, and select the required components. Knowledge artifacts are declarative representations from various levels of interoperability, and consist of (i) schemas for data, queries, or interfaces to executable codes, (ii) ontologies, (iii) mappings involving schemas and ontologies, and (iv) workflows, which document a plan for the coordinated running of executable codes. It is noteworthy that these components are universally applicable to the three major approaches to geospatial information interoperability: database interoperability, SDIs, and Linked Data.

**Layer-based architectures**

Unlike component-based architectures, which are oriented around specific technical resources, layer-based approaches organize resources into strata containing components with similar roles or functions, and which interact with adjacent strata in similar ways. This is most evident in online geospatial computing environments, where prominent client–server, service-oriented, and Web-Oriented Architectures (WOAs) have led to two-layer and three-layer information interoperability architectures.

The client–server architecture is a distributed computing model in which computing tasks are variously segmented between resource requesters (clients) and resource providers (servers). The server layer mainly provides resources such as geospatial data or executable codes, and the client layer requests these resources and further processes and displays them, typically using web browsers controlled by humans. This architecture is considered tightly coupled, because access to server resources is largely platform-specific (including vendor-specific), causing clients to be primarily constructed for specific platforms. In terms of interoperability, functional components for storage, cache, access, and update are server responsibilities, while display components are uniquely client responsibilities; the remaining functional components are then variously carried out by either server or client, resulting in an exponential number of potential solutions as each platform creates a solution for every other platform.

In contrast, Service-Oriented Architectures (SOAs) are loosely coupled. They introduce middleware between server and client that is platform-neutral and often standardized, thus easing communications across platforms. This leads to a three-layer model in which data and code resources comprise the lowest layer, connecting middleware comprises the middle layer, and presentation mechanisms comprise the top layer. Often the middle layer is further subdivided according to specific roles, for
## Interoperability of Representations

Table 1 Components of geospatial interoperability architectures.

<table>
<thead>
<tr>
<th>Functional component</th>
<th>Purpose</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>Data or metadata</strong></td>
<td></td>
</tr>
<tr>
<td>Store</td>
<td>Persistently stores data or metadata (e.g., in a geospatial database). Metadata can include descriptions of data, services, and knowledge artifacts, locations of all functional components, and data summaries such as aggregated statistics, value ranges, most recent additions, etc.</td>
</tr>
<tr>
<td>Cache</td>
<td>Optimized copy of one or more stores, typically maintained locally near some of the remaining functional components to increase efficiency of access.</td>
</tr>
<tr>
<td>Access</td>
<td>External machine interface to data stores and caches, for manipulating data.</td>
</tr>
<tr>
<td>Update</td>
<td>Refreshes data caches by harvesting from data stores.</td>
</tr>
<tr>
<td>Discovery</td>
<td>Finds components in the network, most significantly stores and knowledge artifacts, using pre-existing metadata or via dynamic exploration of a network.</td>
</tr>
<tr>
<td>Translation</td>
<td>Translates data described by schemas and ontologies, using mappings and metadata; performs semantic enrichment, matching, and integration as required.</td>
</tr>
<tr>
<td>Integration</td>
<td>Unites data from multiple sources into a single whole; includes uniting geographical features and relations that share identity.</td>
</tr>
<tr>
<td>Distribution</td>
<td>Returns translated and integrated data to a requester.</td>
</tr>
<tr>
<td>Mediator</td>
<td>Brokers data queries (requests) and responses, invoking other functions.</td>
</tr>
<tr>
<td>Display</td>
<td>Displays returned data, e.g., in a web browser, typically to a human user.</td>
</tr>
<tr>
<td><strong>Query</strong></td>
<td></td>
</tr>
<tr>
<td>Display</td>
<td>User interface for constructing queries, often using a common public ontology and query language.</td>

</table>
example, to differentiate functions supporting data translation and search. Component interactions follow the publish–find–bind strategy, in which server resources are published as metadata, then discovered by clients who request resources from servers. In the geospatial community, the OGC has developed standard web-based service definitions for the access functional components, enabling platform-neutral pathways to online geospatial data and executable code. While web services are often deployed for the remaining applicable functional components, they have not yet been standardized and can vary by system.

WOAs extend SOAs, to a large degree by following RESTful principles. Key aspects include the adoption of standard web functions in the interface to a web service, for example, HTTP GET, PUT, POST, and DELETE; a standardized identifier for a resource that can be dereferenced, that is, the URI; and a standard web transport protocol, that is, HTTP. In essence, WOA web resources are accessed over HTTP via a standard web function operating on a URI. WOA is thus resource-centric in contrast to SOA’s function-centric approach, though WOA does not alter the three-layer interoperability model, as services are still prominent. In terms of geospatial interoperability, the main advantage of the WOA approach is mainly pragmatic, as the relative simplicity and uniformity of the WOA approach typically make services easier to implement in a web environment, particularly for uncomplicated applications, such as the simple retrieval of a geographic feature from a GIS. WOA can thus be seen as primarily advancing pragmatic interoperability. However, this pragmatic gain might be questionable when complex interfaces to resources are required, for example, in some scientific computing environments.

Structure-based architectures

In central/distributed architectures, functional components can be variously arranged within an interoperability network. The storage components usually comprise the resources being networked, and as such they differ variously in their distribution, heterogeneity, and autonomy. The remaining functional components then support interoperability among such resources. These remaining components can be arranged in various degrees of centrality and aggregation. A key component is the mediator, which effectively acts as a virtual node in the network, providing an interface to a subnetwork of resources by brokering requests and responses targeted at these resources. Mediators can be arranged centrally, in clusters over distinct subnetworks, or uniquely for each resource in peer-to-peer networks, and they can also be nested. These variations can result in complex arrangements whereby mediators are parts of one or more subnetworks. The remaining components can optionally be logically co-located (aggregated) with a mediator. For example, metadata, cache, update, discovery, segregation, distribution, and integration components are typically logically co-located with a mediator as their contents and functions usually span its subnetwork, while access and translation components are often logically, and physically, co-located with each resource in the subnetwork, as they are resource-specific.

Monistic/pluralistic architectures refer to the multiplicity of knowledge artifacts present in a network or subnetwork, specifically ontologies and/or schemas. This, in effect, reflects the degree of artifact standardization imposed on a (sub)network and the number of mappings required within it, which influences the placement of mediators and translators. In a monistic approach, a single normative ontology and/or schema is exposed by a (sub)network,
such that the ontologies and schemas of its resources are translated to and from these norms, requiring a mapping for each translation. In contrast, a pluralistic approach exposes multiple knowledge artifacts for a (sub)network, thus requiring an increased number of mappings for each combination of resource and artifact. Monistic approaches are favored in static knowledge environments, where ontologies and schemas are well known and do not change, while pluralistic approaches are favored in dynamic environments where such artifacts are not well known or are subject to change, due to the addition of heterogeneous resources to the network, or due to knowledge evolution within the network.

Static/dynamic architectures refer to a style of network governed by the degree of internal change, that is, by how frequently and intensely resources are added, deleted, or modified. For example, some SDIs are relatively static in practice, in that major resources are typically known beforehand and do not join or leave the network regularly – this requires significant a priori network design to characterize such resources and allow fixed components to be built around them. In contrast, some sensor networks can be highly dynamic, as sensors move in and out of the system frequently, so the presence of specific resources cannot be predicted. This architectural aspect also refers to the degree of change in knowledge artifacts. Linked Data is a good example of a dynamic environment, inasmuch as knowledge can change rapidly within its web-based resources. Consequently, they need not be annotated beforehand with schemas and ontologies, and indeed rapid or severe change might preclude this, requiring these artifacts to be discovered on the fly to the degree possible. Architectures in highly dynamic environments thus cannot anticipate the presence of specific resources, must adapt to changes, and might require substantial exploratory discovery mechanisms.

Approaches to geographical information interoperability

Significant approaches to geographical information interoperability follow major advances in computing, most notably the early rise of database systems and their geospatial manifestations, GIS, followed by the rise of the web with SOA fueling SDIs and, lately, WOA powering Linked Data.

Spatial database interoperability

Early, largely pre-web, geographical information interoperability was file-based and exhibited structure interoperability: specific GIS transformed foreign schema, in various syntaxes, into their own proprietary structure and syntax. Semantics and pragmatics were largely not supported. In essence, a static, monistic, distributed peer-to-peer architecture was deployed, using file-based media transfer. Subsequent research into schemas for geographical features enabled a centralized approach with an intermediary common schema that could be deployed in stand-alone software, for example FME (Feature Manipulation Engine). Database techniques that deployed common schema via dynamic mapping of views were largely absent among GIS, or played a minor role, as they became overtaken by SOA approaches.

Spatial data infrastructures

A SDI is a network of online geospatial data resources, as well as associated policies, agreements, standards, and people, that interoperate to share data. SDI resources are typically
INTEROPERABILITY OF REPRESENTATIONS

distributed across one or more jurisdictions, such as municipalities, states, or countries. Notable SDIs include NSDI (USA), GeoConnections (Canada), INSPIRE (Europe), and GEOSS (Global). SDIs are founded on the SOA, and related geospatial standards developed by the OGC and ISO, with support for all interoperability levels, albeit with ongoing developments in semantics. Functional components defined by the OGC are restricted to geospatial data and metadata storage, discovery, and access, as well as executable code execution, and schemas are by far the primary knowledge artifact. Although OGC/ISO standards enable either central or distributed approaches, SDIs typically adopt a central approach to metadata functional components, and a distributed approach to data components. Likewise, a monistic approach is favored for knowledge artifacts, via the development of normative schemas for particular domains. SDIs vary widely in terms of a static versus dynamic approach to overall network structure, and they are slowly following the gradual migration of geospatial standards to WOAs and related technologies.

Linked Data

Linked Data is an approach to connect data on the web, such that the data, its definition in the form of a type description, and its connection to related data are made explicit and easily accessible using web-based mechanisms. For example, data about “Lake Ontario” can be obtained by following links within and between the online DBpedia and GeoNames databases, each of which are further linked to a type definition for “lake.” Traversal of such links is in contrast to the navigation of web pages, which is a means of viewing representations of the data, such as a map of a specific lake. Linked Data is thus explicitly aligned with semiotic principles by inherently distinguishing an object (data about a geospatial entity), its representation (a web page), and its conceptualization (a type definition). It is also founded on four technical principles (Bizer, Heath, and Berners-Lee 2009): (i) use of URIs to identify any web entity, (ii) URIs able to be dereferenced via web mechanisms, (iii) dereferencing supplies information using Semantic Web approaches, such as RDF, OWL, and SPARQL, and (iv) connectivity between resources is promoted. As Linked Data adopts the Semantic Web interoperability stack, it addresses all interoperability levels, though omits structure, shifting structural issues to the semantic and pragmatic layers (Kuhn, Kauppinen, and Janowicz 2014). It also adopts the WOA, with its RESTful principles, and leverages the full range of architectural components, minus schemas. Data and metadata components were initially typically centralized in RDF databases, but are becoming more distributed with an increasing number of RDF data providers. Linked Data also takes strongly pluralistic and dynamic architectural approaches, to reflect the diversity and rapid change of web resources, including the geospatial. Outstanding challenges in the context of geographical information interoperability include things such as adaptation to structurally rigid data, and raster data, appropriate level of granularity for linking (e.g., a raster pixel or a sensor measurement?), integration with legacy systems and architectures, and linking software, not just data.

References

The term “areal interpolation” was first coined in Goodchild and Lam (1980) to denote the problem of transforming data defined in one set of areal units to another, where the two sets of boundaries do not coincide (Lam 1980, 1983, 2009). The areal interpolation problem occurs when there is a need to incorporate different types of areal data defined in different administrative or political boundaries into a single platform for analysis. An example commonly found in geospatial analysis is to interpolate the socioeconomic variables (such as number of people or housing units) defined originally in census units into other administrative units, such as traffic zones or school districts, for integrated modeling. In areal interpolation terminology, the original areal units where data are available are called source zones, whereas the units into which the data are transformed are called target zones.

The ability to integrate data from one set of areal units to another set is crucial to many types of inquiry where disparate data defined in different forms are required. With the rapid development of geospatial technology and increased need for multidisciplinary integrated analysis, areal interpolation has become an indispensable tool in making many applications possible. Since 1980, there have been steady theoretical and methodological developments in the topic, and new forms of applications of areal interpolation are multiple. Areal interpolation is now a core body of knowledge and technology in geographic information science. This entry first explains the concept of areal interpolation and the basic methods for areal interpolation, then is followed by a summary of its latest developments and an illustration of two very different applications of areal interpolation. The entry concludes with remarks on future development.

Classification of areal interpolation methods

In a broader sense, the areal interpolation problem is a variant of the spatial interpolation problem. Spatial interpolation refers to the procedure of using a set of sample locations with known values to estimate values at other locations. Spatial interpolation includes two main forms: point and areal interpolation. Point interpolation deals with data collectable at a point, such as elevation or temperature readings, whereas areal interpolation deals with data aggregated according to some boundary delineations, such as census tracts or police precincts. Point interpolation has been frequently used to create isolines (lines of equal values), such as contours in topographic maps, and many point interpolation algorithms had already been developed prior to 1980. Point interpolation methods can further be categorized into two groups: exact or approximate (Table 1). Exact methods will retain the original sample point values after interpolation, whereas approximate methods do not guarantee the preservation of the original sample point values.
values and generally include a certain degree of smoothing. Some well-known examples in the exact method category are distance-weighting and kriging, whereas trend-surface and Fourier models are representatives in the category of approximate methods. The choice of an appropriate point interpolation method depends on the type of attribute to be interpolated, the accuracy of the sample points, the type of the underlying surface, and the computational resources required. In all cases, the fundamental issue associated with every interpolation method is that an assumption is made about the underlying surface for interpolation and that assumption may or may not be true.

The discussion of point interpolation and the general concept of spatial interpolation is very relevant to understanding the principle of areal interpolation and its historical, intellectual, and technical developments. Before 1980, the areal interpolation procedure was seldom applied and the only approach available was to mimic point interpolation by reducing the areal data into points. Hence, the “pre-1980” approach would generally start by overlaying a grid mesh on the source zones and assigning a control point (usually the centroid of the areal unit) to represent each source zone. A point interpolation method is applied to estimate the value at each cell. Then, the estimates of the cells are summed or averaged according to the new target-zone boundaries to produce the final target-zone estimates. In this approach, the major variations among the various methods are the different point interpolation methods used in estimating the grid point values. This approach was termed the “point-based areal interpolation approach” because it utilizes points in the interpolation process. A major problem of this point-based approach is that no matter how accurate the point interpolation method is, the approach does not guarantee the preservation of the original source-zone values. This property, called the volume-preserving property, was considered a vital property for accurate areal interpolation. Subsequent empirical tests demonstrated unequivocally that areal interpolation methods that have the volume-preserving property (preserving the original source-zone

INTERPOLATION: AREAL
values) are far more accurate than those generated by non-volume-preserving methods (Lam 1980, 1983).

The volume-preserving property

The first two methods developed for volume-preserving areal interpolation are the areal weighting and pycnophylactic methods (Goodchild and Lam 1980; Lam 1980; Tobler 1979). The areal weighting method superimposes the target zones on the source zones, and their areas of intersection are used to derive weights to distribute source zone values proportionally into target zones. In equation form, an estimate of target zone \( t \) is obtained by:

\[
V_t = \sum_s U_s a_{ts} / \sigma_s
\]  

(1)

where \( V_t \) is the target zone \( t \) estimate, \( U_s \) is the value of source zone \( s \) intersecting target zone \( t \), \( \sigma_s \) is the source zone area, and \( a_{ts} \) is the area of intersection between target zone \( t \) and source zone \( s \). The areal weighting method is intuitively simple. The method uses the source zone itself as unit of operation instead of reducing them into points; hence, it is considered a type of area-based areal interpolation. The method by nature preserves the original source zone values, and therefore it is a volume-preserving method. The method assumes spatial homogeneity within each source zone. The higher the spatial homogeneity of the attribute (i.e., evenly distributed) within each source zone, the more accurate the resultant target zone estimates. Unlike the pycnophylactic method discussed next, no smoothing across source-zone boundaries is enforced.

The pycnophylactic interpolation method was originally developed by Tobler (1979) for isopleth mapping. Lam (1980) incorporated the method for areal interpolation by adding the last step of re-aggregating the grid cells into new target-zone estimates. In Tobler’s terminology, pycnophylactic means volume-preserving. The method starts by overlaying a mesh of grids on the source zones and assigning the same mean value to those grid cells belonging to the same source zone. The cell values are then modified iteratively according to two criteria: smoothing and volume-preserving. The smoothing condition is applied by replacing the cell value with the average of its four neighbors. The volume-preserving condition is enforced by comparing the sum of all cell values within a source zone with its original source-zone value in each iteration and adjusting the cell values by either increasing or decreasing them. Let \( U_s \) be the value of source zone \( s \), \( \sigma_s \) the area of source zone \( s \), \( Z_{ij} \) the value in cell \( ij \), and \( \alpha \) the area of a cell. Also, set \( q_{ij}^s \) as 1 if \( ij \) is in zone \( s \); otherwise set it at 0. The pycnophylactic conditions include:

\[
\sum_{ij} (\alpha Z_{ij} q_{ij}^s) = U_s, \quad \sum_{ij} \alpha q_{ij}^s = \sigma_s, \quad \text{and} \quad \sum_s q_{ij}^s = 1
\]  

(2)

Unlike the areal weighting method, the spatial homogeneity assumption is no longer required in the pycnophylactic method. Instead, the method assumes the existence of a smooth surface that takes into account the effects of adjacent source zones. This smoothing assumption, however, may or may not hold true in real-world applications. An empirical test conducted using hypothetical surfaces generated from a fractal algorithm showed that the performance of both volume-preserving methods was far better than that of the non-volume-preserving methods, and that within the group of volume-preserving methods, the areal weighting method performed slightly better than the pycnophylactic method (Lam 1980). In a nutshell, these two volume-preserving methods can be considered as the two ends of a continuum between a
very discrete and a maximally smooth surface. There should be some real-world cases where reliable interpolation occurs somewhere along the continuum for the whole or parts of the study area. Areal interpolation with ancillary data, subsequently developed after the 1980s, is designed to provide this additional information to produce better estimates.

Areal interpolation with ancillary data

With ancillary data, the accuracy of areal interpolation can be substantially improved, because the incorporation of ancillary data can effectively remove the need for an assumption about the underlying surface or reduce the error resulted from imposing a faulty assumption. The most commonly used ancillary data are land-use–land-cover data derived from remote sensing images. Other types of ancillary data, such as geological layers, road networks, and land parcels, have also been used. Since 1980, improvements of areal interpolation methods have been centered on how to incorporate additional data layers to make the target-zone estimates more accurate.

Areal interpolation with ancillary data is also called “intelligent” areal interpolation (Cromley, Hanink, and Bentley 2012). Ancillary data such as land cover categories are called “control” variables. Areal interpolation with additional control variables is very similar to the principle of dasymetric mapping, a mapping technique designed to reflect within-zone variations. Dasymetric maps use line symbols to depict the spatial distribution of attributes that are defined in areal units. Unlike choropleth mapping, where variables are mapped following the areal unit boundaries, dasymetric mapping uses additional control variables to identify variations within zones and depicts the spatial variation using a set of isolines on top of the areal unit boundaries.

Three groups of intelligent areal interpolation methods can be distinguished. The simplest one is the binary dasymetric method. In this method, control variables, such as land-cover data, are used to identify locations where certain attribute would not exist. For example, in estimating the population number for target zones, if a source zone has a large body of water, it can be assumed that the water area does not have population. Therefore, instead of using the total area of the source zone to derive the weights in areal weighting interpolation, only the area minus the water body is used.

The expectation/maximization (EM) algorithm is used to refine the basic dasymetric method by producing better estimates of subsurface zone values given the ancillary data. The EM method was developed originally to solve the problem of missing data. The method uses two steps. The expectation (E) step calculates the conditional expectation of the subsurface zone value given the total source zone value and the ancillary variable, whereas the maximization (M) step fits the model by maximum likelihood. These two steps are repeated until the algorithm converges. The method can be generalized for different types of ancillary data, including both continuous and categorical types.

The third group of intelligent areal interpolation methods utilizes statistical techniques such as regression to derive functional relationships between the ancillary data and the attribute to be estimated. For example, different land-cover categories are likely to have different population density ratios. Thus, a large part of subsequent research has been on perfecting the regression method to achieve higher accuracy in target-zone estimates. The standard ordinary least squares (OLS) method was first experimented with. However, it was soon discovered
that the ordinary least squares method has several problems: (i) ordinary regression models normally have an intercept, which means that population could still exist even when all the independent variables are zero; (ii) ordinary regression models can lead to negative regression coefficients, which could lead to negative target-zone estimates; (iii) regression coefficients developed for the entire study region may not apply to different parts of the study region.

Several approaches have been developed to address part or all of the three issues related to the ordinary least squares method. The first problem of intercept can be corrected by forcing the regression line through the zero origin, an option that is available in most statistical software. To address the second problem of ensuring no negative values, a number of methods can be used, ranging from simply adding a scalar to offset the negative values to the use of the spatial error model, Poisson regression, and quadratic programming optimization techniques to ensure no negative values. The third problem of heterogeneous substudy area estimates can be overcome by using hybrid models for different parts of the study area. Recently, the quantile regression model has been suggested as an efficient method that can resolve all three issues. Quantile regression minimizes the sum of absolute deviations about the regression line, as opposed to minimizing the sum of squared deviations in ordinary least squares regression. The technique is complex, as it requires linear programming. Furthermore, an empirical study comparing quantile regression with other areal interpolation methods showed that not much accuracy was gained by using this method, making the second-highest accurate but much simpler method, the binary dasymetric method, a viable choice for most areal interpolation (Cromley, Hanink, and Bentley 2012).

Areal interpolation in practice

Two diverse applications of areal interpolation are selected for illustration here: the national historical geographic information system project (Schroeder and Van Riper 2013) and the carbon dioxide emissions estimation project (Shu, Lam, and Reams 2010).

The national historical geographic information system (NHGIS) project, together with a follow-up project called the integrated spatio-temporal aggregate data series (ISTADS), aims to produce a web-based access system that provides summary statistics and boundary data for US census from 1790 to the present (Schroeder and Van Riper 2013). A major task of the project was to standardize the geographic units across censuses, which changed from time to time. Areal interpolation was the main technique to link the historical census data to the present.

The project first used a method called target-density weighting (TDW) for areal interpolation, which is more accurate than simple areal weighting. The target-density weighting method assumes the same proportional distribution of an attribute between two time periods and utilizes the proportional information from one time period to allocate source-zone values to target zones for another time period. For example, to allocate a 1980s tract population to two intersecting target 1970 tracts, if one of the 1970 tracts had twice the population density as the other in 1970, then the same 2:1 ratio was used to allocate the population in 1980 (Schroeder and Van Riper 2013).

However, such method may produce large errors, especially when the assumption of constant data distribution ratio through time is not true. To improve interpolation accuracy, researchers in the project have recently developed a new method, called the geographically weighted expectation-maximization (GWEM).
INTERPOLATION: AREAL

The new method combines both the EM method and the geographically weighted (GW) regression. The EM step provides a framework for incorporating proper constraints on data distribution, whereas the GW step allows an estimation of data distribution to vary spatially. An assessment of the GWEM method based on a study using a land-use–land-cover dataset to interpolate 1980 US census tract pairs showed that the target-density weighting method generally outperforms GWEM, but a combined GWEM-TDW method improves estimates substantially (Schroeder and Van Riper 2013). Given the importance of producing reliable historical census data that will be used by many, it warrants the use of a complex interpolation procedure such as GWEM-TDW to gain higher interpolation accuracy.

A relatively new application of areal interpolation is the downscaling of broad model estimates into fine-scale cell estimates for a variety of environmental applications. For example, detailed estimates of carbon dioxide (CO₂) emissions at fine spatial scales are useful to both modelers and decision-makers who are faced with the problem of global warming and climate change. Shu, Lam, and Reams (2010) demonstrated the use of the volume-preserving principle in downscaling carbon dioxide (CO₂) emissions from transportation from the county-scale to a 1-km² grid cell for the entire state of Louisiana, USA. The volume-preserving interpolation (VPI) method, together with the distance-decay principle, were used to derive emission weights for each grid based on its proximity to highways, roads, railroads, waterways, and airports. The total CO₂ emission value summed from the grids within a county was made to be equal to the original county-level estimate, thus enforcing the volume-preserving property. The distance-decay principle is similar to the use of ancillary data for intelligent areal interpolation. The results revealed a more realistic spatial pattern of CO₂ emission from transportation, which can be used to identify the emission “hot spots.” The fine-scale grid values can be used to integrate with other attributes for further analysis and modeling.

Future directions

The concept and techniques of areal interpolation, and its underlying volume-preserving property, is considered a contribution originated from geography, cartography, and geographic information science, as opposed to many other methods that are borrowed from other disciplines. Although there are always errors involved in the interpolation estimates, recent methodological advances in areal interpolation have substantially reduced the errors, making it an indispensable tool for many applications. However, unlike kriging or other point interpolation techniques, areal interpolation remains an “elite” technology that is difficult to access and use by the general scientific community. In the short run, two future research directions are obvious. First, building a software module for the various options of areal interpolation and making it accessible would be very useful to many different applications. Second, an error estimation module such as Monte Carlo simulation is needed to help generate confidence limits of target-zone estimates. These two steps will help propel the field, not just areal interpolation, from academic scientific investigations to practical decision-making.

Interpolation: kriging

Changshan Wu
University of Wisconsin–Milwaukee, USA

Kriging represents a group of geostatistics-based interpolation techniques that attempt to give an optimal estimate of the value of a variable on a surface. Kriging was initially developed in the 1960s by Matheron (1963, 1973) based on the theory of regionalized variables, which was, in turn, an extension of the methods employed by David Krige in the mining industry of South Africa (Cressie 1993). Similar to other spatial interpolation methods, such as spatial average and inverse distance weighting, kriging is a distance weighting technique. The major difference between kriging and other distance weighting techniques lies in how the weights are decided. Techniques such as spatial average and inverse distance weighting employ expert knowledge to decide the range of spatial autocorrelation and the rate of distance decay, while kriging examines this through analyzing the spatial structure of the control point data.

Steps of kriging

The basis of kriging is to estimate the weights assigned to each control point, and this is implemented using three consecutive steps: (i) deriving the experimental variogram through examining the spatial variation in the control point data, (ii) fitting the experimental variogram into a mathematical model using a regular mathematical function, and (iii) interpolating the variable value of a particular location through solving a least squares function. These three steps can be summarized as follows.

Step 1: Deriving the experimental variogram through examining the spatial variation in the control point data. The objective of this step is to examine the patterns of spatial variation (spatial dependence) within the control points. That is, for every two points, it calculates the squares of the differences between them, and examines whether two nearer points have similar values, and two further points have significantly different values. The formula of estimating the experimental variogram is shown in equation 1, where \( \hat{\gamma}(d) \) is the experimental variogram with a lag of \( d \), \( \Delta \) is the lag width, \( z_i \) and \( z_j \) are the values of points \( i \) and \( j \), and \( d_{ij} \) is the distance between points \( i \) and \( j \).

\[
\hat{\gamma}(d) = \frac{1}{2n(d)} \sum_{d_{ij} = d - \Delta/2}^{d_{ij} = d + \Delta/2} (z_i - z_j)^2
\]

Step 2: Fitting the experimental variogram into a mathematical model. With the experimental variogram, numerous theoretical mathematical models, such as linear, spherical, exponential, Gaussian, and circular, and so on, can be employed to fit it. A number of variogram fitting techniques have been developed in the literature, including ordinary least squares, weighted least squares, maximum likelihood, and so on; the weighted least squares technique detailed by Cressie (1985) has been widely employed. With the fitted mathematical function, several essential parameters, including nugget, range, and...
INTERPOLATION: KRIGING

sill, can be obtained (see Figure 1). Specifically, nugget represents the variance at zero distance, which is also considered as measurement error or the uncertainty of the attribute values. Range indicates the distance with which the variogram begins to level off; therefore, it is also considered as the range of spatial autocorrelation, and for the purpose of interpolation, any points beyond the distance of range should not be considered. Lastly, sill is the constant value of semivariance beyond the range.

Step 3: Interpolating the value of a variable at a particular location through solving a least squares function. With the variogram function obtained, the next and final step is to determine the weight of each sampling point. The interpolation can be expressed as in equation 2.

\[ \hat{z}_s = \sum_{i=1}^{n} w_i z_i \quad (2) \]

As an unbiased estimation, kriging requires that the mean of the estimated value is equal to the mean of the “true” variable, that is, \( E(\hat{z}_s) = (z) \), and the variance of the estimated error should be minimized (see equation 3).

\[
\begin{align*}
\text{Minimize } & \ E\{[\hat{z}_s - z_s]^2\} \\
= & \ 2 \sum_{i=1}^{n} w_i \gamma(d_{is}) - \sum_{i=1}^{n} \sum_{j=1}^{n} w_i w_j \gamma(d_{ij}) \\
\text{Subject to } & \sum_{i=1}^{n} w_i = 1 \quad (3)
\end{align*}
\]

As a constrained linear optimization problem, it can be solved using the Lagrangian relaxation technique, and the resultant weights, as well as a Lagrangian multiplier \( \lambda \), form a system with \( n + 1 \) linear equations with \( n + 1 \) variables (equation 4), where \( w_i \) represents the weight of each sampling point \( i \), \( \gamma(d_{ij}) \) is the variogram value with the distance from point \( i \) to point \( j \), and \( \lambda \) is the Lagrangian multiplier. With the derived \( w_i \), the attribute value at point \( s \) can be estimated through applying equation 2.

\[
\begin{align*}
& w_1 \gamma(d_{11}) + w_2 \gamma(d_{12}) + \ldots + w_n \gamma(d_{1n}) + \lambda = \gamma(d_{1s}) \\
& \vdots \\
& w_1 \gamma(d_{ns}) + w_2 \gamma(d_{ns}) + \ldots + w_n \gamma(d_{nn}) + \lambda = \gamma(d_{ns}) \\
& w_1 + w_2 + \ldots + w_n = 1 \quad (4)
\end{align*}
\]

Variations of kriging

Ordinary kriging, as introduced above, assumes that a constant mean exists for the underlying surface, and an interpolation can be implemented through only considering spatial dependence.

Variations of kriging

**Figure 1** An example of fitting an experimental variogram using a spherical model.
If there is drift in the underlying surface, however, universal kriging, which includes a trend surface analysis and ordinary kriging, needs to be applied. Other variations of kriging include indicator kriging (interpolate a binary variable) and cokriging (with two or more variables) (Cressie 1993).

Advantages and disadvantages of kriging for interpolation

An obvious advantage of kriging is that it employs the control point data to estimate the range and extent of spatial autocorrelation. That is, through constructing the variogram, it chooses the function, weights, and neighborhood for spatial interpolation. It is a statistically rigorous method, and the estimate is considered as unbiased. Moreover, kriging allows the estimation errors to be quantified using the derived variogram, the spatial pattern of the samples, and the weights.

Major disadvantages of kriging include the computation cost. Kriging is an especially complicated interpolation technique, and its every step is computationally intensive. With a large number of control points, the inversion of a large matrix is essentially burdensome, even with state-of-the-art computation powers. Second, as a statistical technique, kriging requires a large number of control points to be statistically rigorous. For an accurate estimation and modeling of the variogram, in particular, a large number of point pairs are necessary. Finally, although kriging is considered an automatic technique, human interventions are still necessary, and some arbitrary choices (e.g., distance band number and lag interval, model choices, etc.) might have a significant impact on the interpolation results.

SEE ALSO: Geostatistics; Interpolation: inverse-distance weighting; Spatial weights

References

The inverse-distance weighting (IDW) method is one of many spatial interpolation methods found in the literature (Bailey and Gatrell 1995), and it is very popular among geographic information system (GIS) users as the tool is easy to use, and the concept is relatively straightforward. The general concept of spatial interpolation can be explained by referring to Figure 1, in which elevations (in meters) of selected locations (part of the Shenandoah National Park in Virginia, USA) are available and shown, but the elevations of most part of the covered region are unknown. The basic objective of spatial interpolation is to estimate the value (in this case, the elevation) of a location where there are no data available using data that are available in other locations. In other words, the method interpolates a value for a location from values found around that location. By extension, if the method can estimate the value of a given location, it can estimate values for all locations in the study region. Thus, the ultimate result from spatial interpolation is often a surface in raster format (grid cells), providing interpolated values for all locations covered in the study area.

However, spatial interpolation should be explained in the context of spatial sampling (Stehman and Overton 1996). Most phenomena are spatially continuous; that is, theoretically, a measurement of these phenomena can be taken at any given location. However, different types of spatially continuous phenomena can vary over space in dramatically different manners. Some vary relatively continuous without big jumps and many physical phenomena can serve as such examples: temperature, barometric pressure, elevation, and ultraviolet light intensity. Measurements of this type of phenomenon usually change gradually in natural landscapes (with some exceptions), but may have abrupt or sharp changes in certain human-modified landscapes, such as the drop in elevation by several hundred meters from the edge of a skyscraper to just a few centimeters away from the building. However, many human-oriented phenomena vary more dramatically over space, partly due to the spatially discrete nature of human populations, and partly due to the artifact of how measurements are reported over space. Theoretically, we can measure population density around a “neighborhood” at every location, but the density may change relatively discretely as people are counted or not counted within the “neighborhood,” regardless of how a neighborhood is defined. Whether the phenomenon changes relatively gradually or discretely over space, the first law of geography is still valid in most cases: all things are related but closer things are more related (Tobler 1970). Thus, locations within the vicinity should have similar values. Therefore, taking a measurement from every location, which is impossible theoretically and practically, may not be necessary. We can just take measurements from selected locations (spatial sampling), hoping that these measurements from selected locations can provide an accurate overall description of the spatial distribution or pattern of the phenomenon.
INTERPOLATION: INVERSE-DISTANCE WEIGHTING

Although remote-sensing technology provides a means to capture spatially continuous phenomena in the form of a raster surface, measurements from selected locations are still quite common. Such sample data are often not sufficient to provide a visual depiction of the spatial variation of the phenomenon, such as the elevation example depicted in Figure 1. On the other hand, a surface describing the variation of the phenomenon is often preferred for visualization, analysis, and modeling. Then spatial interpolation techniques are employed to “fill in the holes (values)” between sampled locations. Sometimes, the sampled locations or points may be representative locations of regions rather than the actual sampled locations. That is, measurements may be taken within each region, and the summary of the measurements is assigned to the representative location, such as the geometric centroid of the polygon representing the region. In general, inputs of spatial interpolation are measurements in interval-ratio scales sampled from point locations, and estimates in interval-ratio scales are computed for unsampled locations. However, specific types of spatial interpolation, such as indicator kriging, can be used to provide estimates in categorical scale.

The general objective of spatial interpolation is to estimate the values in locations that have not been sampled based upon values in sampled locations. Let \( a(s_i) \) be the value of a random variable \( a \) in location \( s_i \), which may be represented by a Cartesian coordinate pair of \((x, y)\). In other words, values of \( a \) are location-dependent. Then, formally, spatial interpolation is to estimate the value of \( a \) in unsampled location \( s_0 \) (e.g., Figure 1) such that the predicted value:

\[
\hat{a}(s_0) = \sum_{i=1}^{n} \lambda_i a(s_i)
\]

where \( \lambda_i \) is the weight for location \( s_i \), and \( n \) points have been sampled for the value of \( a \). The weight \( \lambda_i \) should be smaller than or at most equal to 1, indicating how values in sampled locations \( s_i \) are used to predict the value of \( a(s_0) \). Different spatial interpolation methods vary in the way in which the weights are determined, and IDW provides a specific way to determine the weights in equation 1.

Two general approaches have been used in the literature to determine the weights. The statistical or geostatistical approach operates under the premise that the weights should be determined according to how the sampled values are spatially autocorrelated. To evaluate the magnitude of spatial autocorrelation in the sampled data, a variogram needs to be constructed showing the variation between observed values (semivariances) relative to their spatial separation (distance or spatial lag). If the phenomenon follows the first law of geography well, then semivariances of sampled values for closer pairs of locations
should be smaller than the semivariances for farther pairs. A mathematical function fitting the empirical variogram will provide a set of weights to be applied to values for sampled locations given their distances from the unsampled location. Kriging is a spatial interpolation method using the geostatistical approach. Many types of kriging have been developed and different kriging methods are needed for various situations and different assumptions (Bailey and Gatrell 1995; Lloyd 2010).

Different from the geostatistical approach where the weights are determined empirically by the spatial structure of the sampled values, weights of the deterministic approach are determined independent of the characteristics of the sampled data, but based upon certain premises about the relationships between values in sampled locations and estimates in unsampled locations. For instance, when estimating the value \( a \) in location \( s_0 \) (i.e., \( a(s_0) \)) in Figure 1, a logical estimate will be 461, the value from the nearest sampled location, if no other information is provided or used. In other words, unsampled locations will be assigned the values of the nearest sampled location, and the resultant value surface will consist of stepped flat surfaces with a blocky structure, exhibiting a configuration similar to the Thiessen polygons, in which boundaries assign locations to the nearest points or neighbors (Lloyd 2010; O’Sullivan and Unwin 2010). In this case, the weights \( \lambda_i \) for all sampled locations are set to zero, except that the weight for the nearest sampled location is set to 1.

Using the nearest sampled value as the estimate is a “winner-takes-it-all” strategy, as values of other sampled locations are completely ignored. On the other hand, IDW takes all sample values into the estimation but, logically, values in sampled locations nearer should be considered more while values in farther away locations should be considered less. In other words, IDW considers only the distance between the sampled and unsampled locations, and weights are determined under the premise that they should be inversely related to distance. If \( s_i \) is farther away from an unsampled location \( s_0 \) than another sampled location \( s_j \), then the sampled value \( a(s_i) \) should be weighted less than \( a(s_j) \) merely because \( s_i \) is farther away from \( s_0 \) than from \( s_j \). Therefore, a simple specification of the weight can be \( 1/d_{i0} \) for the sampled location \( s_i \), where \( d_{i0} \) is the distance between \( s_0 \) and \( s_i \), assuming that the inverse relationship is strictly proportional to distance.

Two additional conditions should be considered in determining the weights. While the general notion that the weight should be inversely related to distance is understandable, the exact relationship still needs to be determined: whether it is directly proportional or not. To accommodate this flexibility, the weight can be specified as \( 1/d_{i0}^\alpha \) or simply \( d_{i0}^{-\alpha} \) where \( \alpha \geq 0 \). The inclusion of \( \alpha \) as a power function can accommodate various degrees of inverse distance relationship. Figure 2 shows the change in weight with increasing distance when \( \alpha \) takes on different reasonable values. In general, weights decrease with increasing distances (i.e., sampled locations farther away from the unsampled location \( s_0 \)), but such distance-decay effect is more substantial when \( \alpha \) becomes larger. When \( \alpha = 0 \), increasing distance from the unsampled location has no impact on the weight. According to the spatial interaction literature, a distance-decay parameter of 2 is applicable to many phenomena based upon many empirical studies (Fotheringham and O’Kelly 1989).

However, if \( \alpha = 1 \), then the estimated value of the unsampled location will be the sum of all sampled values: not a desirable outcome. In fact, the estimate will still be extremely large even if \( \alpha \) does not equal 1. The problem is that we have not imposed a condition on how much we should take in total across all sampled values to
derive the estimate. Ideally, the sum of all weights for an estimate should equal 1 such that a fraction of each sampled value is used to derive the estimate. In other words, \( \sum_{i}^{n} \lambda_i = 1 \). This is the second condition to be considered in modifying the simple \( 1/d_{i0} \) weight. IDW is essentially a spatial averaging method through which an estimate draws on a fraction of each neighboring value. Thus, to ensure that weights sum to 1, we have to standardize the weights such that:

\[
\lambda_i = \frac{d_{i0}^{-\alpha}}{\sum_{j=1}^{n} d_{j0}^{-\alpha}}
\]

(2)

where all terms were defined above. However, a special condition is when \( s_i = s_0, \lambda_i = 0 \) for all \( i \neq 0 \), but \( \lambda_i = 1 \) when \( i = 0 \). This condition means that when estimating values for location \( s_i \), the sampled or observed value for location \( s_i \) will be used. If this special treatment is not invoked, then \( d_{00} = 0 \), creating a weight of 0 and thus the sampled value will be discarded in deriving the estimate for location \( s_i \). That will not be a logical way to handle the situation, as the estimated value should take on the observed value. Therefore, the estimated value for \( s_i \) is \( a(s_i) \), the observed value, and thus IDW is an exact interpolator.

Besides determining the value of the distance-decay parameter \( \alpha \), another parameter to be determined in performing an IDW interpolation is to determine the size of neighborhoods within which sampled values will be used to estimate the value of an unsampled location. Theoretically, the \( n \) in equation 1 can be the number of all sampled locations. But if the study area is relatively large, it may be pointless to include sampled values that are far away as their contributions to the estimate may be negligible. Therefore, it is also an efficiency consideration by limiting the number of sampled values to be included in determining an estimate. At least two approaches can be used to make such a decision. A spatial approach is to define a neighborhood of a given size around each unsampled location. Typically, a distance from the unsampled location is chosen to define a circular neighborhood within which all sampled values will be included in the interpolation process. All unsampled locations will use the same size to define their neighborhoods. Another approach is simply to determine the number of sampled values nearest to the unsampled location to be included in the interpolation. In this case, areas of neighborhoods for different estimates will not be the same because the distributions of sampled locations usually vary across unsampled locations.

Both the choice of neighborhood size, regardless of how it is defined, and the distance-decay parameter will affect the results of the IDW procedure. In general, the smaller the neighborhoods (by area or number of sampled locations included) the more sensitively the estimates will respond to local variations of sampled values, as only sampled values closer to unsampled locations are included, and closer values will have more weighting. Using larger neighborhoods leads to more observed values.
The four maps in Figure 3 are interpolated elevation surfaces using data reported in Figure 1. Figure 3a uses a relatively small $\alpha$ (0.5) and the 15 nearest sampled values (out of 24). As a result, the elevation surface is relatively smooth with the two peaks around the sampled locations of 507 and 596 m. In general, the slopes are relatively smooth mainly because of the small distance-decay parameter. The map in Figure 3b uses the same small $\alpha$ (0.5), but only the eight nearest sampled values. As a result, boundaries defining areas with similar elevation levels have quite irregular shapes as the distributions of nearest neighbors are also quite irregular. Figure 3c uses a larger $\alpha$ (2.0) and also the 15 nearest sampled values. Compared to the two maps using a smaller $\alpha$, the larger
distance-decay factor here increased the influence from the local values, and thus quite a few local peaks emerged. The final map (Figure 3d) also uses a small $\alpha$ (0.5), but the search for sampled values used an approximately 1 km circular neighborhood around each location. Thus, boundaries of some elevation regions are artificially circular.

The maps in Figure 3 show one important characteristic of the IDW spatial interpolation method. As the term *interpolate* implies inserting something in between, the IDW method, as for most interpolation methods, cannot estimate values beyond the edges of the sampled region. The spatial extent of the four maps in Figure 3 is essentially the minimum bounding rectangle of all the sampled locations. Values beyond the rectangle have to be estimated through extrapolation, which IDW cannot offer. In other words, in the context of using spatial sampling to generate a continuous surface, the extent of the sampled locations determines the spatial limits of the interpolated surface.

Figure 3 also shows a potentially alarming issue, not so much about the conceptual formulation of IDW but more about the algorithmic implementation of the method. In addition to being a weighted spatial averaging method, IDW is also an exact interpolator, as discussed above. While checking how well all observed values match up with the predicted values may take some effort, checking the predicted values against the overall observed minimum (218 m) and maximum (596 m) elevations is relatively straightforward. No maps except Figure 3c include the minimum and maximum elevations on the elevation classes, contrary to the exact interpolator claim that estimated values at the sampled locations should equal the observed values. This seeming inconsistency is the artifact of the rendering or data model adopted in GIS, as the raster cells have relatively low resolutions such that the minimum and maximum values, like all observed values, are smoothed or averaged by the neighboring predicted values when generating the raster maps.

IDW is only one of many deterministic methods. A popular alternative to IDW among deterministic methods is using spline functions. There are many types of spline and related functions (Lloyd 2010). The general idea is that these are relatively smooth mathematical functions that can be used to fit smooth surfaces between sampled values. Such spline function fittings may estimate values beyond the range of the sampled values, overcoming one of the limitations of IDW. Another limitation of the general IDW interpolation concept is the use of one distance-decay parameter for the entire region, assuming that the magnitude of the distance-decay effect is uniform spatially. However, Lu and Wong (2008) suggested that in areas where sampled values are relatively dense $\alpha$ should be smaller, drawing sampled values from farther away, while for less-dense areas $\alpha$ should be larger, putting more weight on close-by sampled values. Such local adjustments of the distance-decay parameter are implemented in the adaptive IDW method, borrowing ideas from the adaptive kernel density estimation method. However, implementing such adaptive methods in GIS is still challenging. As IDW is a popular choice among geographers, Lu and Wong (2008) offer some guidelines about when IDW or kriging should be used.

Intersectionality recognizes the multiple axes of social structural difference in individuals, and groups, and the ways in which these differences combine to advantage or disadvantage individuals and groups in different contexts. Intersectionality is a significant advance over one-dimensional identity politics. It has transformed theory, methodology, and teaching around social and spatial issues of human difference and disadvantage in women’s studies and other feminist endeavors, including feminist geography.

Juridical activist and scholar Kimberlé Crenshaw recognizes Anna Julia Cooper’s work in her own development of the idea of intersectionality. Cooper was a leading intellectual of the late nineteenth century, a period during which questions concerning who could speak for whom around issues of race and class were important. A widely respected black man named Martin R. Delany was known to claim that when he entered any gathering, the entire race [sic] entered with him. He intended that, in his person, he stood for all black Americans. Cooper disagreed: “Only the Black Woman [sic] can say ’when and where I enter, in the quiet, undisputed dignity of my womanhood, without violence …., then and there the whole Negro race enters with me’” (Cooper 1886). Cooper’s counter-statement illustrates her understanding of black women’s intersectional position as more disadvantaged, or “below” that of black men.

Cooper’s commitment to the most oppressed Americans informed her view that effective solutions to human problems must elevate the most disadvantaged. Cooper’s concern for black girls, in particular, birthed her realization that women and – under reconstruction – girls were more vulnerable than boys, even within what she described as the Negro [sic] community. In her analysis of the structural oppression of black women, Cooper recognized intersectionality (although she did not name it as such): black and female, which is both more disadvantaged under many conditions than either black or female (alone), yet which is not additive or separable under most circumstances.

The Combahee River Collective was next to formally articulate an intersectional ethos (see Patricia Hill Collins (2000) The Social Construction of Black Feminist Thought for many others who did so). Based in New York, this group of black women coalesced in the mid-1970s around political, ethical, and social concerns that arose from their lives. Chief among these were members’ experiences in civil rights groups, where they were frequently discriminated against as women by black men, and in feminist groups, where they were frequently discriminated against as blacks by white women. Both Cooper and the Collective recognized that work relations, or class, were a significant dimension of their oppression.

Kimberlé Crenshaw is currently the theorist most associated with intersectionality. She
explored the mistreatment of black women complainants in legal cases concerning workplace discrimination and rape, and in the inadequate remedies for battered women of color. Her investigations show why remedies for “women” must explicitly seek redress for those at the intersections of structural oppression such as race and class, or race and gender. Among her findings were that when solutions for women are developed based on the needs of women who are white and middle class, only they will be well served. For example, Crenshaw learned that rape crisis center clients in underserved areas may have needs for food and shelter that, in the clients’ eyes, must be met before they will accept assistance with the aftermath of having been raped. White, middle-class clients are less likely to have these needs.

The concept of intersectionality has been developed from American black women’s experiences of neglect in politics, law, social policy, and life, and these experiences and subsequent analyses arise from a variety of times and places. What all have in common is that black women have labored in them, disadvantaged by being female within groups of black women and men, by being black within groups of white and black women, and often through their relationship to the means of production as workers.

Crenshaw’s work launched intersectionality into the mainstream. Almost inevitably, a concept’s move from scholarly deployments to writing for a general audience is accompanied by simplification. In addition, intersectionality’s grounding in standpoint theory clashed with some poststructural theories that, among other things, declared the death of categories. So, while Cooper’s, Crenshaw’s, and the Combahee River Collective’s formulations were grounded in their experiences and those of women whose lives they sought to improve, in 2009 Ms. Magazine published an article which said, in essence, that by applying intersectionality to their own lives, all students in women’s studies classes could understand it (Thornton Dill 2012, 27). By 2012, this statement had found its way into a popular textbook.

To be fair, the same essay (written by a prominent black feminist) presented a nuanced, if only weakly political, view of intersectionality. But it stripped intersectionality of its roots, and thus its power, by suggesting that students’ immediate grasp of the concept was adequate. Intersectionality was born from and is intended to improve the lives of women who, in Crenshaw’s words, are “on the bottom” (Crenshaw 2000, 218). She offers this analogy:

Imagine a basement which contains all people who are disadvantaged on the basis of race, sex, class, sexual preference, age and/or physical ability. These people are stacked – feet standing on shoulders – with those on the bottom being disadvantaged by the full array of factors, up to the very top, where the heads of all those disadvantaged by a singular factor brush up against the ceiling. Their ceiling is actually the floor above which only those who are not disadvantaged in any way reside. In efforts to correct some aspects of domination, those above the ceiling admit from the basement only those who can say that “but for” the ceiling, they too would be in the upper room. A hatch is developed through which those placed immediately below can crawl. Yet this hatch is generally available only to those who – due to the singularity of their burden and their otherwise privileged position relative to those below – are in the position to crawl through. Those who are multiply burdened are generally left below (Crenshaw 2000, 218–219).

In other words, while intersectionality can illuminate the life of each student in the women’s studies classroom most American classrooms are not filled with black women. Those with “singular” burdens, including straight white women, white gay men, and black men, are not
who intersectionality is for, in an analytical or political sense. Nonetheless, all can benefit from analyses and politics that build on intersectional understandings of oppression.

Those for whom intersectionality is intended have been the subjects of research in a variety of fields. In geography, for example, the concept has been taken up largely by feminist geographers to illuminate investigations into water access in Bangladesh, the experiences of deaf people in Britain, and gender and work studies in Canada. Recent and exciting scholarship concerns immigration, transnationalism, and nation-states. Indeed, there has been an explosion in empirical work informed by intersectionality in the past decade and case studies may well be the methodology for which intersectionality offers the most. Intersectionality is also informing theory as well as offering important new empirical knowledge. Scholars have pursued theoretical questions including: What happens when intersectionality clashes with poststructuralism? And, how can intersectionality’s power be realized through a conversation among its strongest proponents (Roshanravan 2013)? Answers to these and other questions highlight how crucial it is to ground intersectional analyses in the histories and geographies through which feminist standpoints are achieved.

Over a century after its appearance on the American scene, intersectionality has become ubiquitous within women’s studies and within feminist analyses in other disciplines, including geography. A large measure of its appeal is its power to shed light on differences within groups such as women, and its potential to aid in coalition building. Its ongoing salience lies in its utility for case-study research, especially where case studies can inform larger quantitative analyses that may usefully inform policy. Keeping intersectionality focused on those most disadvantaged, as called for by the women of color who developed it, will be key.

INTERSECTIONALITY

Interviews

Fernando J. Bosco
San Diego State University, USA

Interviewing is one of the most commonly used methods for gathering information about people, their lives, and the places, landscapes, and environments they occupy. In an interview, the collection of data occurs by inviting individuals at a set time and place to answer questions and/or have a conversation with a researcher, with a specific research goal in mind. As commonly used in contemporary geographic research, the goal of interviewing is to probe an issue in-depth to gain access to the meanings that people attribute to different experiences in different contexts and to understand the reasons people do what they do. Interviewing is a people-oriented research methodology; the focus is often on social relationships and human actions in specific contexts. Geographers have adopted interviewing as a method for research in a range of settings and scales, from the urban to the rural, the city to the neighborhood, the village to the agricultural field, the mundane to the exotic, the home to the workplace. The outcomes of an interview are often rich, detailed, and multilayered data (Valentine 2005). Depending on the research project, the outcomes of the interview might be preserved in textual, sound, or visual forms – or a combination of these. During an interview, researchers record, in different forms, either the entire conversation or key points and ideas discussed. It is not uncommon for participants to raise issues during an interview that researchers may not have anticipated. Thus researchers often write additional notes and reflections immediately after an interview to provide an additional layer of context and content. The objective is to have access to all the information collected at a later time so that it can be analyzed as primary data to help answer specific questions in a research project.

Interviews have generally been associated with several different systematic branches of human geography – such as cultural, urban, and feminist geographies. However, this method has been increasingly used by geographers pursuing all kinds of investigations in almost all branches of the discipline. For example, interviews play a central role in more recently emerged areas of specialization, such as in children and family geographies or in participatory GIScience where they are used together with other people-oriented methods of data collection. It is also a method increasingly used in geographic studies of human–environment interactions. Regardless of the topic or area of investigation, many geographers today see interviews as belonging to a shared set of fieldwork and data collection practices that involve questioning and having purposeful conversations with people. The nature, format, and outcomes of such questions and conversations are dependent on the research design guiding the investigation. Thus, interviews range from the formal to the informal; they include conversations of varying length that are based on structured or semi-structured questions and prompts or can follow an unstructured format that leads to more participatory and intimate contacts between researchers and research subjects.
Interviews and geographic thought

Interviews have a relatively long history as a geographic method of data collection – an even longer history if one interprets interviewing in a broader sense. Some scholars have made connections between geography and interviewing all the way back to classic Greek travel accounts, arguing that certain descriptions of places and people likely were informed by conversations rather than by direct field observations. Similarly, vestiges of early forms of interviewing can be traced back to the European ages of navigation and exploration during the sixteenth, seventeenth, and eighteenth centuries. However, what is clear is that this early form of interviewing was supplemental to fieldwork and not a direct, purposeful, and planned method of data collection as it is today (Cloke et al. 2004).
