Maternal immunologic diseases such as idiopathic thrombocytopenic purpura, systemic lupus erythematosus, myasthenia gravis, and Graves disease, all of which are mediated by immunoglobulin G autoantibodies that can cross the placenta, frequently cause transient illness in the newborn. Maternal autoantibodies to the folate receptor are associated with neural tube defects (NTDs), whereas maternal immunologic sensitization to fetal antigens may be associated with neonatal alloimmune hepatitis and neonatal alloimmune thrombocytopenia (NAIT).

Untreated metabolic disorders such as maternal phenylketonuria (PKU) results in miscarriage, congenital cardiac malformations, and injury to the brain of a nonphenylketonuric heterozygous fetus. Women whose PKU is well controlled before conception can avoid these complications and have a normal newborn.

Medication and Teratogen Exposure

Kristen R. Suhrie, Sammy M. Tabbah
When an infant or child has a congenital malformation or is developmentally delayed, the parents often wrongly blame themselves and attribute the child's problems to events that occurred during pregnancy. Because benign infections occur, and several nonteratogenic drugs are often taken during many pregnancies, the pediatrician must evaluate the presumed viral infections and the drugs ingested to help parents understand their child's birth defect. The causes of approximately 40% of congenital malformations are unknown. Although only relatively few agents are recognized to be teratogenic in humans, new agents continue to be identified. An excellent internet-based resource known as Reprotox (reprotox.org) provides comprehensive and routinely updated summaries on drugs and other potentially teratogenic agents in pregnancy. Overall, only 10% of anomalies are caused by recognizable teratogens (see Chapter 128). The time of exposure that is most likely to cause injury is usually during organogenesis at <60 days of gestation. Specific agents produce predictable lesions. Some agents have a dose or threshold effect, below which no alterations in growth, function, or structure occur. Genetic variables such as the presence of specific enzymes may metabolize a benign agent into a more toxic, teratogenic form (e.g., phenytoin conversion to its epoxide). In many circumstances the same agent and dose may not consistently produce the lesion.

Reduced enzyme activity of the folate methylation pathway, particularly the formation of 5-methyltetrahydrofolate, may be responsible for NTDs or other birth defects. The common thermolabile mutation of 5,10-methylene tetrahydrofolate reductase may be one of the enzymes responsible. Folate supplementation for all pregnant women (by direct fortification of cereal grains, which is mandatory in the United States), and oral folic acid tablets taken during organogenesis may overcome this genetic enzyme defect, thus reducing the incidence of NTDs and perhaps other birth defects.

The U.S. Food and Drug Administration (FDA) classifies drugs into 5 pregnancy risk categories. Category A drugs pose no risk on the basis of evidence from controlled human studies. For category B drugs, either no risk has been shown in animal studies but no adequate studies have been done in humans, or some risk has been shown in animal studies but these results are not confirmed by human studies. For category C drugs, either definite risk has been shown in animal studies but no adequate human studies have been performed, or no data are available from either animal or human studies. Category D includes drugs with some risk but with a benefit that may exceed that risk for the treated life-threatening condition, such as streptomycin for tuberculosis. Category X is
for drugs that are contraindicated in pregnancy on the basis of animal and human evidence and for which the risk exceeds the benefits.

The use of medications or herbal remedies during pregnancy is potentially harmful to the fetus. Consumption of medications occurs during the majority of pregnancies. The average mother has taken 4 drugs other than vitamins or iron during pregnancy. Almost 40% of pregnant women receive a drug for which human safety during pregnancy has not been established (category C pregnancy risk). Moreover, many women are exposed to potential reproductive toxins, such as occupational, environmental, or household chemicals, including solvents, pesticides, and hair products. The effects of drugs taken by the mother vary considerably, especially in relation to the time in pregnancy when they are taken and the fetal genotype for drug-metabolizing enzymes.

**Miscarriage** or **congenital malformations** result from the maternal ingestion of teratogenic drugs during the period of organogenesis. Maternal medications taken later, particularly during the last few weeks of gestation or during labor, tend to affect the function of specific organs or enzyme systems, and these adversely affect the neonate rather than the fetus (Tables 115.5 and 115.6). The effects of drugs may be evident immediately in the delivery room or later in the neonatal period, or they may be delayed even longer. The administration of diethylstilbestrol during pregnancy, for instance, increased the risk for vaginal adenocarcinoma in female offspring in the 2nd or 3rd decade of life.

CNS, Central nervous system; G6PD, glucose-6-phosphate dehydrogenase; IUGR, intrauterine growth restriction; SSRI, selective serotonin reuptake inhibitor.

Often the risk of controlling maternal disease must be balanced with the risk
of possible complications in the fetus. Most women with epilepsy have normal fetuses. Nonetheless, several commonly used antiepileptic drugs are associated with congenital malformations. Infants exposed to valproic acid may have multiple anomalies, including NTDs, hypospadias, facial anomalies, cardiac anomalies, and limb defects. In addition, they have lower developmental index scores than unexposed infants and infants exposed to other common antiepileptic drugs.

Moderate or high alcohol intake (≥7 drinks/wk or ≥3 drinks on multiple occasions) is a risk for fetal alcohol syndrome. The exposed fetuses are at risk for growth failure, central nervous system abnormalities, cognitive defects, and behavioral problems. It must be emphasized, however, that there is no known dose-response threshold for fetal alcohol exposure; therefore pregnant women should be counseled toward complete abstinence. Smoking during pregnancy is associated with IUGR and facial clefts.

Chronic heroin (opioid) use throughout pregnancy is associated with an increased risk of fetal growth restriction, placental abruption, stillbirth, preterm birth, and intrauterine passage of meconium. Opiates readily cross the placenta; therefore these effects are postulated to be related to cyclic fetal opiate withdrawal. Furthermore, the lifestyle issues surrounding opioid abuse, including lack of or late entry into prenatal care, place the mother at higher risk of adverse pregnancy outcome. Therefore, opioid maintenance therapy with either methadone or buprenorphine is recommended for opioid-dependent pregnant women to prevent complications of illicit opioid use and narcotic withdrawal, encourage prenatal care and drug treatment, reduce criminal activity, and avoid risks to the patient of associating with a drug culture.

Neonatal abstinence syndrome (NAS) occurs in the setting of opioid maintenance treatment or illicit drug use; thus opiate maintenance therapy is not preventive in this regard. Methadone is considered first-line therapy for treatment of opioid dependence in pregnancy; buprenorphine is an acceptable alternative in the appropriately selected patient. There is no established, dose-response relationship between methadone or buprenorphine and risk/severity of NAS, so the lowest effective dose to eliminate maternal cravings/withdrawal is recommended. Methadone is associated with a lower birthweight than buprenorphine. Both medications have a similar rate of NAS requiring treatment (approximately 50%); however, the use of antenatal buprenorphine has been associated with significantly lower dosages of morphine to treat NAS and significantly shorter NAS-related hospital stays than methadone. For these
reasons, buprenorphine may be preferred under certain circumstances.

The specific mechanism of action is known or postulated for very few teratogens. **Warfarin**, a vitamin K antagonist used for anticoagulation, prevents the carboxylation of γ-carboxyglutamic acid, which is a component of osteocalcin and other vitamin K–dependent bone proteins. The teratogenic effect of warfarin on developing cartilage, especially nasal cartilage, appears to be avoided if the pregnant woman's anticoagulation treatment is switched from warfarin to heparin for the period between weeks 6 and 12 of gestation. However, the risk of intracranial hemorrhage is maintained with exposure throughout pregnancy. For these reasons, **low-molecular-weight heparin** is the preferred anticoagulant when treating pregnant women.

**Hypothyroidism** in the fetus may be caused by maternal ingestion of an excessive amount of iodide or propylthiouracil; each interferes with the conversion of inorganic to organic iodides. Furthermore, there is an interaction between genetic factors and susceptibility to certain drugs or environmental toxins. Phenytoin teratogenesis, for example, may be mediated by genetic differences in the enzymatic production of epoxide metabolites. Polymorphisms of genes encoding enzymes that metabolize the polycyclic aromatic hydrocarbons in cigarette smoke influence the growth-restricting effects of smoking on the fetus.

Recognition of teratogenic potential from a variety of sources offers the opportunity to prevent related birth defects. If a pregnant woman is informed of the potentially harmful effects of alcohol, tobacco, and illicit drugs on her unborn infant, she may be motivated to avoid consumption of these substances during pregnancy. A woman with insulin-dependent diabetes mellitus may significantly decrease her risk for having a child with birth defects by achieving good control of her disease before conception. Lastly, in view of the limits of current knowledge regarding the fetal effects of maternal medication use, drugs and herbal agents should only be prescribed during pregnancy after carefully weighing the maternal benefit against the risk of fetal harm.

Radiation

*R Kristen R. Suhrie, Sammy M. Tabbah*
See also Chapter 736.

Accidental exposure of a pregnant woman to radiation is a common cause for anxiety about whether her fetus will have genetic abnormalities or birth defects. It is unlikely that exposure to diagnostic radiation will cause gene mutations; no increase in genetic abnormalities has been identified in the offspring exposed as unborn fetuses to the atomic bomb explosions in Japan in 1945.

A more realistic concern is whether the exposed human fetus will show birth defects or a higher incidence of malignancy. The background fetal radiation exposure in a given pregnancy is approximately 0.1 rad. The estimated radiation dose for most radiographs is <0.1 rad and for most CT scans <5 rad (maximum recommended radiation exposure in pregnancy). Imaging studies with high radiation exposure (e.g., CT scans) can be modified to ensure that radiation doses are kept as low as possible. Thus, single diagnostic studies do not result in radiation doses high enough to affect the embryo or fetus. Pregnancy termination should not be recommended only on the basis of diagnostic radiation exposure. Most of the evidence suggests that usual fetal radiation exposure does not increase the risk of childhood leukemia and other cancers; although some sources suggest that a 1-2 rad fetal radiation exposure may confer a 1.5-2–fold increased risk of childhood leukemia, which has a background risk of 1 in 3,000. Before implantation (0-2 wk postconception), radiation doses of 5-10 rad may result in miscarriage. At 2-8 wk gestation, doses in excess of 20 rad have been associated with congenital anomalies and fetal growth restriction. Severe intellectual disabilities can occur with exposures of ≥25 rad before 25 wk gestation. The available data suggest no harmful fetal effect of diagnostic MRI or US, which do not involve radiation.

Bibliography

Brent RL. Saving lives and changing family histories: appropriate counseling of pregnant women and men and women of reproductive age, concerning the risk of diagnostic radiation exposures during and before pregnancy. Am J
Diagnostic procedures are used to identify fetal diseases when direct fetal treatment is possible, to better direct neonatal care, when a decision is made to deliver a viable but premature infant to avoid intrauterine fetal demise, or when pregnancy termination is being considered. Fetal assessment is also indicated in a broader context when the family, medical, or reproductive history of the mother suggests the presence of a high-risk pregnancy or a high-risk fetus (see Chapters 114 and 115.3).

Various methods are used for identifying fetal disease (see Table 115.1). Fetal US imaging may detect fetal growth abnormalities (by previously outlined biometric measurements) or fetal malformations (Fig. 115.7). Serial determinations of growth velocity and the head-to-abdomen circumference ratio enhance the ability to detect IUGR. Real-time US may identify placental abnormalities (abruptio placentae, placenta previa) and fetal anomalies such as hydrocephalus, NTDs, duodenal atresia, diaphragmatic hernia, renal agenesis, bladder outlet obstruction, congenital heart disease, limb abnormalities, sacrococcygeal teratoma, cystic hygroma, omphalocele, gastroschisis, and hydrops (Table 115.7).
FIG. 115.7  Assessment of fetal anatomy. A, Overall view of the uterus at 24 wk showing a longitudinal section of the fetus and an anterior placenta. B, Transverse section at the level of the lateral ventricle at 18 wk showing (on the right) prominent anterior horns of the lateral ventricles on either side of the midline echo of the falx. C, Cross section of the umbilical cord showing that the lumen of the umbilical vein is much wider than that of the 2 umbilical arteries. D, Four-chambered view of the heart at 18 wk with equal-sized atria. E(i), Normal male genitals near term. E(ii), Hydrocele outlining a testicle within the scrotum projecting into a normal-size pocket of amniotic fluid at 38 wk. Approximately 2% of male infants after birth have clinical evidence of a hydrocele that is often bilateral, not to be confused with subcutaneous edema occurring during vaginal breech birth. F, Section of a thigh near term showing thick subcutaneous tissue (4.6 mm between markers) above the femur of a fetus with macrosomia. G, Fetal face viewed from below, showing (from right to left) the nose, alveolar margin, and chin at 20 wk. (From Special investigative procedures. In Beischer NA, Mackay EV, Colditz PB, editors: Obstetrics and the newborn, ed 3, Philadelphia, 1997, Saunders.)

Real-time US also facilitates performance of needle-guided procedures (i.e. cordocentesis) and the BPP by imaging fetal breathing, body movements, tone, and amniotic fluid volume (see Table 115.2). Doppler velocimetry assesses fetal
arterial blood flow (vascular resistance) (see Figs. 115.4 and 115.5). Fetal MRI is used to better define abnormalities detected on US and to help with prognostication (see Fig. 115.1).

**Amniocentesis**, the transabdominal withdrawal of amniotic fluid during pregnancy for diagnostic purposes (see Table 115.1), is a common obstetric procedure. It is frequently performed to evaluate for infection. It is also done for genetic indications, usually between the 15th and 20th wk of gestation, with results available as soon as 24-48 hr for fluorescence in situ hybridization (FISH) testing and 2-3 wk for microarray testing. The most common indication for genetic amniocentesis is **advanced maternal age**; the risk for chromosome abnormality at term at age 21 yr is 1 : 525, vs 1 : 6 at age 49 yr. ACOG recommends that all pregnant women be offered amniocentesis to evaluate further for an underlying genetic condition such as Down syndrome. Analysis of amniotic fluid may also help in identifying NTDs (elevation of α-fetoprotein [AFP] and presence of acetylcholinesterase). Additionally, families with a known genetic syndrome may be offered prenatal genetic testing from amniotic fluid or amniocytes obtained via amniocentesis or CVS.

**Chorionic villus sampling (CVS)** is performed in the first trimester, either transvaginally or transabdominally. The sample obtained is placental in origin, which can sometimes be problematic because aneuploidy may be present in the placenta and not the fetus, a condition known as **confined placental mosaicism**, which can give a false-positive rate as high as 3%. Furthermore, CVS may be associated with a slightly higher risk of fetal loss than amniocentesis.

Amniocentesis can be carried out with little discomfort to the mother. Procedure-related complications are relatively rare, and many can be avoided by using a US-guided approach. These risks include direct damage to the fetus, placental puncture and bleeding with secondary damage to the fetus, stimulation of uterine contraction and premature labor, chorioamnionitis, maternal sensitization to fetal blood, and pregnancy loss. Best available data indicate that the pregnancy loss rate associated with amniocentesis is 1 : 500-900 procedures. Amniocentesis is not recommended before 14 wk of gestation because this has been associated with a higher risk of pregnancy loss, ruptured membranes, and clubfoot.

**Cordocentesis**, or percutaneous umbilical blood sampling (PUBS), is used to diagnose fetal hematologic abnormalities, genetic disorders, infections, and fetal acidosis (see Table 115.1). Under direct US visualization, a long needle is passed into the umbilical vein at its entrance to the placenta or in a free loop of
Transfusion or administration of drugs can be performed through the umbilical vein (Table 115.8). The predominant indication for this procedure is for confirmation of fetal anemia (in Rh isoimmunization) or thrombocytopenia (NAIT), with subsequent transfusion of packed red blood cells or platelets into the umbilical venous circulation.

EXIT, Ex utero intrapartum treatment; IVIG, intravenous immune globulin; (?), possible but not proved efficacy.

**Aneuploidy screening** is offered to pregnant women in the first trimester or at midgestation to evaluate the risk for common aneuploidies such as Down syndrome (trisomy 21), trisomy 18, trisomy 13, and congenital malformations (e.g., abdominal wall or neural tube defects) known to cause elevations of various markers. A combination of these biochemical markers (including AFP, inhibin A, estriol, pregnancy-associated plasma protein A, β–human chorionic gonadotropin [hCG]) and US increases the positive predictive value (PPV) of these screening tests. Fetal DNA in maternal plasma and fetal cells circulating in maternal blood are potential noninvasive sources of material for prenatal genetic
testing. This testing, however, is not diagnostic, and a positive test requires either amniocentesis or postnatal analysis to confirm the diagnosis. Nonetheless, fetal karyotyping by analysis of fetal DNA in maternal plasma is another screening test that is very sensitive for the detection of Down syndrome, with a higher PPV than any other prenatal screening test for Down syndrome. Currently, however, the use of this technology is only advocated in pregnancies deemed at high risk for aneuploidy.

**Treatment and Prevention of Fetal Disease**

*Kristen R. Suhrrie, Sammy M. Tabbah*

See also [Chapter 116](#).

Management of a fetal disease depends on coordinated advances in diagnostic accuracy and knowledge of the disease's natural history; an understanding of fetal nutrition, pharmacology, immunology, and pathophysiology; the availability of specific active drugs that cross the placenta; and therapeutic procedures. Progress in providing specific treatments for accurately diagnosed diseases has improved with the advent of real-time ultrasonography, amniocentesis, and cordocentesis (see [Tables 115.1](#) and [115.8](#)).

The incidence of sensitization of Rh-negative women by Rh-positive fetuses has been reduced by prophylactic administration of Rh(D) immunoglobulin to mothers early in pregnancy and after each delivery or abortion, thus reducing the frequency of hemolytic disease in their subsequent offspring. **Fetal erythroblastosis** (see [Chapter 124.2](#)) may be accurately detected by fetal Doppler assessment of the peak systolic velocity of the middle cerebral artery and treated with intrauterine transfusions of packed Rh-negative blood cells via
the intraperitoneal or, more often, intraumbilical vein approach.

**Pharmacologic** approaches to fetal immaturity mostly revolve around the administration of antenatal corticosteroids to the mother to promote fetal production of surfactant with a resultant decrease in the incidence of **respiratory distress syndrome** (see Chapter 122.3). Tocolytic agents have been demonstrated to prolong pregnancy to allow the administration of antenatal corticosteroids (48 hr); however, there is no proven benefit beyond this timeframe. Maternal administration of magnesium sulfate for fetal/neonatal neuroprotection is recommended in pregnancies deemed to be at risk of imminent delivery before 32 wk gestation in light of evidence demonstrating a reduction in frequency of cerebral palsy compared to those who did not receive this treatment.

Management of definitively diagnosed fetal genetic disease or congenital anomalies consists of multidisciplinary parental counseling. Rarely, high-dose **vitamin therapy** for a responsive inborn error of metabolism (e.g., biotin-dependent disorders) or fetal transfusion (with red blood cells or platelets) may be indicated. **Fetal surgery** is well-established treatment for certain conditions but remains a largely experimental approach to therapy for other conditions and is available only in a few, highly specialized perinatal centers (see Table 115.8 and Chapter 116). The nature of the defect and its consequences must be considered, as well as ethical implications for the fetus and the parents. **Termination of pregnancy** is also an option that should be discussed during the initial phases of counseling.

**Folic acid supplementation** decreases the incidence and recurrence of NTDs. Because the neural tube closes within the 1st 28 days of conception, periconceptional supplementation is needed for prevention. It is recommended that women without a prior history of a NTD ingest 400 µg/day of folic acid throughout their reproductive years. Women with a history of a prior pregnancy complicated by an NTD or a first-degree relative with an NTD should have preconceptional counseling and should ingest 4 mg/day of supplemental folic acid beginning at least 1 mo before conception. Fortification of cereal grain flour with folic acid is established policy in the United States and some other countries. The optimal concentration of folic acid in enriched grains is somewhat controversial. The incidence of NTD in the United States and other countries has decreased significantly since these public health initiatives were implemented. Use of some antiepileptic drugs (valproate, carbamazepine) during pregnancy is associated with an increased risk of NTD. Women taking these medications
should ingest 1-5 mg of folic acid daily in the preconception period.

8. Amniotic Bands

- Progressive constrictions causing irreversible neurologic or vascular damage
- Prevention of amniotic band syndrome leading to deformities and function loss

9. Abnormal Monochorionic Twinning: Twin-to-Twin Transfusion; Fetus Cardiacus, and Discordant Anomalies

- Intertwin transfusion leading to oligopolyhydramnios sequence, hemodynamic changes; preterm labor, and rupture of membranes; in utero damage to brain, heart, or other organs
- In utero fetal death may cause damage to co-twin
- Cardiac failure of pump twin and consequences of polyhydramnios
- Serious anomaly raising the question of termination of pregnancy
- Selective fetocide

- Arrest of intertwin transfusion; prevention/reversal of cardiac failure and/or neurologic damage, including at in utero death; prolongation of gestation
- Selective fetocide to arrest parasitic relationship, to prevent consequences of in utero fetal death, and to avoid termination of entire pregnancy

AV, Arteriovenous; CSF, cerebrospinal fluid.

**Fetal Therapy Ethics**

With the development of advanced fetal ultrasound (US), fetal MRI, and fetal echocardiography, the ability to accurately diagnose fetal disease has improved substantially over the past 3 decades. There have also been advances in maternal anesthesia and tocolysis, reduction in maternal morbidity, development of fetal surgery–specific equipment, improved clinical expertise of the fetal care team, and construction of state–of-the-art fetal treatment centers. Fetal surgery remains controversial, however, and every discussion of fetal surgery must include a careful consideration of the ethical conflicts inherent to these procedures.

Unlike most surgical procedures, fetal surgery must consider 2 patients simultaneously, balancing the potential risks and benefits to the fetus with those to the mother during the current and future pregnancies. The **International Fetal Medicine and Surgery Society** (IFMSS) established a consensus statement on fetal surgery, as follows:

1. A fetal surgery candidate should be a singleton with no other abnormalities observed on level II ultrasound, karyotype (by amniocentesis), α-fetoprotein (AFP) level or viral cultures.
2. The disease process must not be so severe that the fetus cannot be saved.
and also not so mild that the infant will do well with postnatal therapy.

3. The family must be fully counseled and understand the risks and benefits of fetal surgery, and they must agree to long-term follow-up to track efficacy of the fetal intervention.

4. A multidisciplinary team must concur that the disease process is fatal without intervention, that the family understands the risks and benefits, and that the fetal intervention is appropriate.

**Obstructive Uropathy**

Obstructive uropathy is most frequently caused by posterior urethral valves (PUV) but can be caused by a variety of other defects, including urethral atresia, persistent cloaca, caudal regression, and megacystis–microcolon–intestinal hypoperistalsis syndrome (see Chapters 555 and 556). Obstructive uropathy usually presents on fetal US with an enlarged bladder, bilateral hydronephrosis, and oligohydramnios. Mild forms of obstructive uropathy may lead to minimal short- or long-term clinical sequelae. However, the lack of fetal urine output and resulting oligohydramnios or anhydramnios in more severe forms can cause significant pulmonary hypoplasia, which is associated with death shortly after delivery in >80% of infants. Pulmonary survivors are still subject to high mortality and chronic morbidity resulting from renal dysplasia, renal failure, and the need for chronic renal replacement therapy.

The primary objective of fetal intervention in fetuses with obstructive uropathy is **restoration of amniotic fluid volume to prevent pulmonary hypoplasia**. Although prevention of ongoing renal injury is also desired, the efficacy of fetal intervention in achieving this goal is uncertain. Several studies have attempted to use fetal urine evaluation to predict renal outcome in these patients, but the reliability of these markers has been disappointing due to the influence of gestational age on many of these markers. Therefore, fetal intervention for obstructive uropathy is currently limited to fetuses in whom the obstruction is sufficient to cause oligohydramnios or anhydramnios.

For fetuses who still have adequate renal function and are capable of producing urine, treatment options include vesicoamniotic shunting, valve ablation via cystoscopy, and vesicostomy. **Vesicoamniotic shunting** is the most common and involves percutaneous, US-guided placement of a double-pigtailed shunt from the fetal bladder to the amniotic space, allowing decompression of the obstructed bladder and restoration of the amniotic fluid volume (Fig. 116.1).
Although simple in concept, bladder decompression may not always occur, and many catheters will become dislodged as the fetus develops; a fetus typically requires 3 catheter replacements before completion of pregnancy. Vesicoamniotic shunting may improve perinatal survival, but at the expense of poor long-term renal function.

**FIG. 116.1** Ultrasound image showing fetoscopic placement of a transurethral vesicoamniotic shunt in a patient with posterior urethral valves. (Courtesy of Dr. Foong Lim, Cincinnati Fetal Center at Cincinnati Children's Hospital Medical Center.)

**Fetal cystoscopy** is more technically challenging than vesicoamniotic shunt placement, more invasive, and requires more sedation, but this option holds some important advantages. Cystoscopy allows for direct visualization of the obstruction and does not require amnioinfusion. Moreover, when the obstruction is visualized and the diagnosis of PUV confirmed, the valves can be treated, restoring urine flow to the amniotic space and eliminating the need for repeated fetal interventions in most patients. Creation of a vesicostomy (direct opening from bladder through fetal abdominal wall) by open fetal surgery has improved perinatal survival (Fig. 116.2). However, the current dataset evaluating this approach is still limited, and direct comparisons to shunting suggest no significant difference between these interventions.
Nonobstructive Renal Disease

Nonobstructive fetal renal disease can result from renal hypoplasia/dysplasia and from genetic disease such as autosomal recessive polycystic kidney disease. Similar to obstructive uropathy, fetal therapy is focused on restoring amniotic fluid volume in patients with oligohydramnios or anhydramnios. However, restoration of amniotic fluid volume in nonobstructive renal disease requires external sources of amniotic fluid. Current treatment options include serial percutaneous amnioinfusion and infusion of fluid by amniopent. **Serial amnioinfusions** are less invasive as a single procedure, but most pregnancies will require weekly infusions to maintain adequate amniotic fluid volume. Amnioinfusion through an **amniopent** involves open surgical placement of a catheter into the amniotic space that is connected to an ex utero subcutaneous port. This allows repeated fluid infusion into the amniotic space. The amniopent is more challenging and invasive as an individual procedure but provides more reliable access to the amniotic space for the duration of the pregnancy. Small studies suggest both these procedures improve pulmonary outcomes and perinatal survival in infants with renal disease, but these infants will require dialysis and then renal transplant when the infant is large enough (2-3 yr of age).
Congenital Diaphragmatic Hernia

Congenital diaphragmatic hernia (CDH) is a defect in the fetal diaphragm causing herniation of the abdominal contents into the thorax and inhibition of fetal lung growth (see Chapter 122.10). CDH occurs in 1 in 3,000 births and can range from mild to severe. In mild cases of CDH, surgical repair of the diaphragm is typically performed in the 1st few days of life. Lungs in these infants are smaller than normal at birth, but as they grow, these patients can lead normal, active lives. In the severe cases of CDH infants experience severe pulmonary hypoplasia and pulmonary hypertension, requiring extracorporeal membrane oxygenation (ECMO) in the perinatal period. Mortality is high in severely affected infants, and survivors often have long-term respiratory, feeding, and neurodevelopmental problems.

Early attempts at fetal intervention for CDH used in utero surgical correction of the diaphragm defect in severe CDH infants. Survival rates were poor, with most infants dying during or shortly after the fetal surgery. Since significant complications during this procedure involved reduction of the incarcerated liver, a follow-up study compared postnatal repair to in utero repair that was limited to infants without liver herniation in the chest. The fetal repair group had more premature delivery (32 vs 38 wk gestation) without an improvement in survival (75% fetal repair vs 86% postnatal repair). Therefore, attempts at in utero repair of CDH have been abandoned.

Occlusion of the fetal trachea causes lung growth, and this approach was capable of dramatically improving lung growth in animal models of pulmonary hypoplasia. Several groups explored the use of fetal tracheal occlusion in CDH. The fetal surgical team in Philadelphia evaluated both open fetal tracheal ligation and endoscopic tracheal occlusion with an inflatable balloon. Open fetal tracheal ligation was quickly abandoned, with most patients dying from either complications associated with the procedure or shortly after delivery from respiratory failure caused by the lack of alveolar type II cell maturation and surfactant production in the hyperexpanded lungs. Endoscopic balloon tracheal occlusion was eventually evaluated in a larger trial. Survival was better than open fetal tracheal ligation but still not improved over control patients. Development of fetoscopic balloon tracheal occlusion in CDH led to the multicenter prospective randomized Tracheal Occlusion to Accelerate Lung Growth (TOTAL) study. In this trial the balloon was inserted at 27-30 wk and removed at 34 wk. This timing is based on the hypothesis that tracheal occlusion
will promote lung expansion while removal of the balloon before delivery will promote alveolar type II cell maturation. Initial data suggest that this approach is associated with a high incidence of preterm delivery but a significant increase in survival. The use of fetoscopic tracheal occlusion in CDH therapy is gaining popularity, but this approach in both severe and moderate CDH is still under investigation.

**Congenital Pulmonary Airway Malformation**

Congenital pulmonary airway malformation (CPAM), previously referred to as congenital cystic adenomatoid malformation (CCAM), is caused by abnormal branching and hamartomatous growth of the terminal respiratory structures that results in cystic and adenomatoid malformations (see Chapter 423). Although rare, these remain the most common congenital lung lesion. CPAMs usually arise between 5 and 22 wk of gestation and continue to increase in size until around the 26th wk of pregnancy. If large enough, CPAM can cause significant pulmonary hypoplasia and in severe cases, hydrops fetalis. The size of the CPAM is tracked by CPAM volume ratio (CVR), an index that compares the volume of the CPAM to the fetal head circumference. Most studies indicate >95% survival in CPAM patients with no hydrops and CVR <1.6, with a much lower survival and greater risk for hydrops in patients with a CVR >1.6. Without intervention, CPAM with hydrops is uniformly fatal.

Open fetal resection of CPAM was considered one of the first clearly beneficial fetal surgeries. A less invasive option in fetal patients with CPAM composed of a large, dominant cyst is the insertion of a thoracoamniotic shunt into the dominant cyst. This decreases CPAM size, allowing lung growth and reducing risk of hydrops. An alternative surgical approach involving resection of the CPAM at delivery while the infant remains on placental support via an ex utero intrapartum therapy (EXIT) procedure has also demonstrated improved survival in a select group of patients.

Patients (in utero) receiving corticosteroids experience improved survival compared with those receiving open fetal resection. Survival rates approach 100% in high-risk CPAM (CVR >1.6) treated with steroids before the onset of hydrops and 50% in patients who have developed hydrops. Therefore the current approach to fetal therapy for CPAM has been away from open fetal resection and
toward single or multiple courses of antenatal corticosteroids in fetuses with CVR >1.6.

**Myelomeningocele**

Before the introduction of fetal repair of myelomeningocele (MMC), fetal surgery was limited to diagnoses considered fatal for the fetus or infant without intervention. However, a growing body of data suggests that the neurologic outcome in MMC is directly related to progressive injury from ongoing damage to the exposed spinal cord during pregnancy (see Chapter 609.3). Controversy remained as to whether the maternal and fetal risks of fetal repair should be accepted when the goal was to reduce postnatal morbidity rather than to improve survival.

The observation in early studies that patients receiving open fetal MMC repair were less likely to require ventriculoperitoneal (VP) shunt prompted the prospective randomized trial of prenatal vs postnatal MMC management (MOMS) (Fig. 116.3). The study was closed to enrollment in 2010 after 183 patients were randomized and the data safety monitoring board determined a clear advantage for prenatal surgery. The MOMS trial demonstrated a significant reduction in the need for VP shunt in the fetal repair group (40% vs 82% in postnatal repair group). The fetal repair group had an improved composite score for mental development and motor function at 30 mo, but also an increased risk of preterm delivery and uterine dehiscence. The average gestational age at delivery in the fetal repair group was 34 wk, with 10% delivering at <30 wk, compared to 37 wk and no infants <30 wk in the postnatal repair group.
Open fetal repair of MMC has been an important advance but the risk of prematurity significantly decreases the benefit of this procedure. In theory, the less invasive fetoscopic MMC repair approach, which is being developed at a limited number of centers, should reduce maternal morbidity and prematurity rates associated with open fetal MMC repair (Video 116.1).

**Other Indications**

Antenatal intervention for cardiac defects, such as aortic stenosis, pulmonic stenosis, and hypoplastic left heart syndrome (HLHS), have been used to dilate, with balloon valvuloplasty, stenotic valves (aortic stenosis) to prevent further development of HLHS (creating biventricular physiology) (Fig. 116.4) (see Chapter 458.10).
stenosis. Notice that the left ventricle (arrowhead) is dilated. Dilation occurs before the development of hypoplasia, which can be seen (arrowhead) in another fetus (left panel). B, Schematic representation of percutaneous valvuloplasty, in this case of the left ventricular outlet tract. (A, From van Mieghem T, Baud D, Devlieger R, et al: Minimally invasive fetal therapy, Best Pract Res Clin Obstet Gynaecol 26:711–725, 2012; B, copyright © UZ Leuven, Leuven, Belgium.)

**Laser therapy** has been used to treat twin-twin transfusions syndrome (Chapter 117.1) and amniotic bands (Fig. 116.5).
FIG. 116.5  Amniotic band sequence in two different fetuses. A and B, Effects on the
extremities. Images of the limbs of a fetus with amniotic band sequence show multiple amniotic bands (short arrows, A and B), amputation of fingers and toes (long arrows, A and B), and a fixed deformity of the hand at the wrist (arrowhead, B). C and D, Effects on the thorax and abdomen of the same fetus as in A and B. Sagittal image (C) shows a thoracoabdominal wall defect (arrows) with a large amount of herniated abdominal and thoracic contents (black H) outside the body. White H, Head. D, Axial image of the fetal abdomen (A) confirms the presence of a large ventral abdominal hernia (H), in the setting of amniotic bands (arrow). E to G, Effects on craniofacial structures in a different fetus. E, Coronal image of face shows multiple amniotic bands (short arrows) and nonvisualization of the calvarium. This results in a craniofacial appearance that resembles anencephaly (long arrow). F, A large encephalocele (black arrow) is seen above the level of the orbits (long white arrow) in a different scan plane. An amniotic band (short white arrow) is also seen. G, Coronal image of anterior portion of face shows facial clefts (black arrows) due to amniotic bands. Short white arrow, Amniotic band; long white arrow, orbits. H, Band constricting the ankle, leading to deformational defects. I, Pseudosyndactyly, amputation and disruption of finger morphogenesis. (A-G, From Hertzberg BS, Middleton WD: Ultrasound: the requisites, ed 3, Philadelphia, 2016, Elsevier, Fig 19-22; H and I, From Jones KL, Smith DW, Hall BD, et al. A pattern of craniofacial and limb defects secondary to aberrant tissue bands. J Pediatr 84:90–95:1974.)

Fetal Centers

The value of fetal centers extends beyond fetal surgery. Often, families will present to a fetal center with a newly discovered diagnosis and little understanding of what the diagnosis means for their baby. Prenatal counseling by the fetal team can provide comfort to the family by helping them understand the diagnosis and treatment options and by developing a management plan that may include fetal surgery. Some plans may call for enhanced monitoring of the fetus and mother, followed by complex deliveries involving multidisciplinary delivery teams and specialized equipment, as required for EXIT to ECMO, EXIT to airway, EXIT to tumor resection, delivery to cardiac catheterization, and procedures on placental support. Other plans may focus on postnatal therapy. Not all severely affected fetuses have available therapies in utero or after birth. In these lethal situations, fetal care planning will provide support for the family and a plan for delivery room or nursery palliative care (Table 116.3) (see Chapter 7).

The term *high-risk infant* designates an infant at greater risk for neonatal morbidity and mortality; many factors can contribute to an infant being high risk (Table 117.1). High-risk infants are categorized into 4 main groups: the preterm infant, infants with special health care needs or dependence on technology, infants at risk because of family issues, and infants with anticipated early death.

### Inborn errors of metabolism

#### PRESENT PREGNANCY
- Vaginal bleeding (abruptio placentae, placenta previa)
- Sexually transmitted infections (colonization: herpes simplex, group B streptococcus, chlamydia, syphilis, hepatitis B, HIV)
- Multiple gestation
- Preeclampsia
- Premature rupture of membranes
- Short interpregnancy time
- Poly-/oligohydramnios
- Acute medical or surgical illness
- Inadequate prenatal care
- Familial or acquired hypercoagulable states
- Abnormal fetal ultrasonographic findings
- Treatment of infertility

#### LABOR AND DELIVERY
- Premature labor (<37 wk)
- Postdates pregnancy (≥42 wk)
- Fetal distress
- Immature lecithin/sphingomyelin ratio; absence of phosphatidylglycerol
- Breech presentation
- Meconium-stained fluid
- Nuchal cord
- Cesarean delivery
- Forceps delivery
- Apgar score <4 at 5 min

#### NEONATE
- Birthweight <2,500 g or >4,000 g
- Birth <37 wk or ≥42 wk of gestation
- Small or large for gestational age
- Respiratory distress, cyanosis
- Congenital malformation
- Pallor, plethora, petechiae

All high-risk infants require closer evaluation and/or treatment by experienced physicians and nurses. This often starts at delivery and continues through a neonatal intensive care unit (NICU) stay (see Chapter 121). Regionalized care for infants is based on the acuity of care that can be provided at hospitals with different levels of care and whether transport should be undertaken (see Chapter 118). It is important to note that additional care does not stop at time of NICU discharge, and that many high-risk infants also benefit from additional resources and follow-up after discharge from the hospital (see Chapter 117.5).

Approximately 15 million infants are born preterm (before 37 wk gestational age) each year worldwide, accounting for approximately 1 in every 10 babies born, and the overwhelming majority of high-risk infants. The World Health Organization (WHO) defines infants born before 28 wk gestational age as extremely preterm infants, infants born between 28 and $31\frac{1}{2}$ wk as very preterm, and infants born between 32 and $36\frac{1}{2}$ weeks as moderate to late preterm infants.
Risk of both morbidity and mortality increases with earlier gestational age. Gestational age, birthweight, and gender are all important factors that impact neonatal mortality (Fig. 117.1). The highest risk of neonatal and infant mortality occurs in infants with birthweight <1,000 g and/or with gestational age <28 wk. The lowest risk of neonatal mortality occurs in infants with birthweight of 3,000-4,000 g and a gestational age of 39-41 wk. As birthweight increases from 400 to 3,000 g and gestational age increases from 23 to 39 wk, a logarithmic decrease in neonatal mortality occurs. Once birthweight exceeds 4000 g and/or gestational age exceeds 42 wk, the incidence of neonatal morbidities and mortality increases.

**FIG. 117.1** Contour plot of predicted survival according to gestational age, birthweight, and gender. A, Female. B, Male. The contour lines join combinations of gestational age and birthweight of equal estimated probability of survival. Birthweight percentiles are shown for information. Data based on singleton infants born in the United Kingdom between January 2008 and December 2010 who survived to NICU admission. Monozygotic vs Dizygotic Twins

Identifying twins as monozygotic or dizygotic is useful in determining the relative influence of heredity and environment on human development and disease. The previous assumption that twins not of the same sex are dizygotic can no longer be held as true. Sex discordance, placentation, and determination of amnionicity and chorionicity are not reliable ways of determining zygosity. Detailed blood typing, gene analysis, or tissue (human leukocyte antigen) typing can be used for zygosity testing (an exception being blood typing in cases of chimeric twins, where one or both twins contain distinct cell lines from multiple zygotes). Physical and cognitive differences may still exist between monozygotic twins because of other factors. The in utero environment may have been different. Additionally, differences may exist in the mitochondrial genome, in posttranslational gene product modification, and in the epigenetic modification of nuclear genes in response to environmental factors.

Examination of the Placenta

If the placentas are separate, twins are dichorionic, but not necessarily dizygotic. One third of monozygotic twins are dichorionic and diamnionic. An apparently single placenta may be present with either monozygotic or dizygotic twins, but inspection of a dizygotic placenta usually reveals that each twin has a separate chorion that crosses the placenta between the attachments of the cords and 2 amnions. Separate or fused dichorionic placentas may be disproportionate in size. The fetus attached to the smaller placenta or the smaller portion of the placenta is usually smaller than its twin or is malformed. Monochorionic twins are usually diamnionic, and the placenta is usually a single mass.

Incidence

The incidence of spontaneous twinning is highest among blacks and East Indians, followed by northern European whites, and is lowest in the Asian races. Differences in the incidence of twins worldwide mainly involve dizygotic twins. The incidence of monozygotic twins (3-5 per 1,000) is unaffected by racial or familial factors. Until recently, monozygotic twinning rates remained stable across continents and cultures. In 2014 the U.S. final natality report recorded a twin rate of 33.9 per 1,000 live births, which was a new high for the nation.
Increases in monozygotic and dizygotic twinning have been associated with advanced maternal age (AMA) and the use of assisted reproductive technologies (ART). The rate of triplets and higher-order multiple births is 113.5 per 100,000 live births in the United States and continues to decline. The use of single-embryo transfer in ART has decreased the numbers of triplet births and higher-order multiples. However, a doubling of monozygotic twinning and an increase in atypical twinning have been reported. The incidence of dizygotic multifetal gestation is also increasing, attributed to treatment of infertility with ovarian stimulants (clomiphene, gonadotropins).

**Etiology**

Polyovular pregnancies are more frequent beyond the 2nd pregnancy, in older women, and in families with a history of dizygotic twins. They may result from simultaneous maturation of multiple ovarian follicles, but follicles containing 2 ova have also been described as a genetic trait leading to twin pregnancies. Twin-prone women have higher levels of gonadotropin. Polyovular pregnancies occur in many women treated for infertility.

The occurrence of monozygotic twins appears to be independent of heritable factors. The etiology of monozygotic twinning is unknown, but there are 2 prevailing theories. In the classic **fission theory**, twinning results from the splitting of a single conceptus, with the timing of splitting resulting in differing amnionicity and chorionicity (i.e., the earlier the fission occurs, the more likely the twins are to be diamniotic dichorionic) (Fig. 117.2). However, this theory fails to account for several forms of atypical twinning, including the occurrence of **diamniotic dichorionic monozygotic** twinning after single-embryo transfer in the late blastocyst state, phenotypically-discordant monozygotic twins, and asymmetrically attached conjoined twins. An alternate **fusion theory** of twinning has been proposed to account for this discrepancy, in which the inner cell masses of trophectoderm fuse after the initial 2-cell splitting stage (Fig. 117.3).
FIG. 117.2  Classical fission theory of twinning. *Dizygotic twins* result from 2 distinct fertilization events, with dichorionic diamniotic twins each developing to become a genetically distinct individual. *Monozygotic twins* result from postzygotic splitting of the product of a single fertilization event. Splitting on days 1-3 (up to the morula stage) results in dichorionic diamniotic twins, on days 3-8 (during which blastocyst hatching occurs) in monochorionic diamniotic twins, on days 8-13 in monochorionic monoamniotic twins. (Illustration copyright © LeventEfe, CMI. www.leventefe.com.au.)
**FIG. 117.3** Fusion theory of monozygotic twinning. Splitting occurs at the postzygotic 2-cell stage, with each cell forming a distinct individual. If twin blastocysts hatch from the zona pellucida together, dichorionic diamniotic twins will result. If the 2 trophectoderms fuse before hatching and the inner cells masses are separated within the shared trophectoderm, monochorionic diamniotic twins will result. If the inner cell masses are fused and separated later, monochorionic monoamniotic twins will result. (Illustration copyright © LeventEfe, CMI. www.leventefe.com.au.)

**Atypical Twinning**

**Conjoined twins** (1 in 50,000 pregnancies and 1 in 250,000 live births) are
obligate monozygotes. Theoretically, they result from later fission of a single zygote (10-14 days) or from fusion of 2 zygotes (as proposed for asymmetrically attached conjoined twins). The majority of conjoined twins are female. The prognosis for symmetrically conjoined twins depends on the possibility of surgical separation, which in turn depends on the extent to which vital organs are shared. The site of connections varies: thoracoomphalopagus (28% of conjoined twins), thoracopagus (18%), omphalopagus (10%), craniopagus (6%), and incomplete duplication (10%). The term parasitic twin has historically been used to describe the smaller and less completely developed member of a pair of conjoined twins; this parasitic twin has typically had embryonic demise but remains vascularized by the surviving independent twin (the autocyte). For asymmetrically attached conjoined twins in whom one twin is dependent on the cardiovascular system of the intact autocyte (exoparasitic twins, 1 in 1 million live births) survival of the autocyte depends on the feasibility of excising the exoparasitic twin. For endoparasitic twins (fetus in fetu, 1 in 500,000 live births) in whom one (or more) fetus exists as a benign mass in the autocyte, survival of the autocyte is unaffected.

Superfecundation, or fertilization of an ovum by an insemination that takes place after one ovum has already been fertilized, and superfetation, or fertilization and subsequent development of an embryo when a fetus is already present in the uterus, have been proposed as explanations for differences in size and appearance of certain twins at birth.

Complications

Problems of twin gestation include polyhydramnios, hyperemesis gravidarum, preeclampsia, premature rupture of membranes (PROM), vasa previa, velamentous insertion of the umbilical cord, abnormal presentation (breech), and premature labor. Monoamniotic twins have a high fatality rate because of obstruction of the circulation secondary to intertwining of the umbilical cords. Compared with the 1st-born twin, the 2nd twin is at increased risk for respiratory distress syndrome and asphyxia. Twins are at risk for intrauterine growth restriction, twin-twin transfusion syndrome, and congenital anomalies, which occur predominantly in monozygotic twins. Anomalies are a result of compression deformation of the uterus from crowding (hip dislocation), vascular communication with embolization (ileal atresia, porencephaly, cutis aplasia) or without embolization (acardiac twin), and unknown factors (conjoined twins,
anencephaly, meningomyelocele).

**Twin Syndromes (TRAP, TTTS)**

Placental vascular anastomoses occur with high frequency in monochorionic twins. In monochorionic placentas, the fetal vasculature is usually joined, sometimes in a very complex manner. They are usually balanced so that neither twin suffers. Artery-to-artery communications cross over placental veins, and when anastomoses are present, blood can readily be stroked from one fetal vascular bed to the other. Vein-to-vein communications are similarly recognized but are less common. A combination of artery-to-artery and vein-to-vein anastomoses is associated with the condition of acardiac fetus. This rare lethal anomaly (1 in 35,000) is secondary to the twin reversed arterial perfusion (TRAP) syndrome. In utero radiofrequency or laser ablation of the anastomosis or cord occlusion can be used to treat heart failure in the surviving twin. However, death of the autocyte is reported in up to 75% of cases. In rare cases, one umbilical cord may arise from the other after leaving the placenta, and the twin attached to the secondary cord usually is malformed or dies in utero.

In twin-twin transfusion syndrome (TTTS), an artery from one twin acutely or chronically delivers blood that is drained into the vein of the other. The latter develops polyhydramnios, plethoric and large for dates, and the former has oligohydramnios, anemic and small (Fig. 117.4). TTTS is more common in monozygotic twins and affects up to 30% of monochorionic twins. Maternal polyhydramnios in a twin pregnancy suggests TTTS. Anticipating this possibility by preparing to transfuse the donor twin or bleed the recipient twin may be lifesaving. Death of the donor twin in utero may result in generalized fibrin thrombi in the smaller arterioles of the recipient twin, possibly as the result of transfusion of thromboplastin-rich blood from the macerating donor fetus. Disseminated intravascular coagulation (DIC) may develop in the surviving twin. Table 117.2 lists the more frequent changes associated with a large shunt. Treatment of this highly lethal problem includes maternal digoxin, aggressive amnioreduction for polyhydramnios, selective twin termination, and more often, laser or fetoscopic ablation of anastomosis (Fig. 117.5).
**Fig. 117.4** Representation of first-trimester risk assessment for the development of discordant growth, twin-twin transfusion syndrome (TTTS), or intrauterine demise. Discordant amniotic fluid in the first trimester generally corresponded with deepest vertical pockets ≤3 cm in one sac and ≥6.5 cm in the other. Discordance in crown-rump length (CRL) was present if the difference was ≥12 mm. (From Lewi L, Gucciardo L, Van Mieghem T, et al: Monochorionic diamniotic twin pregnancies: natural history and risk stratification, *Fetal Diagn Ther* 27:121–133, 2010.)

---

**Diagnosis**

A prenatal diagnosis of pregnancy with twins is suggested by a uterine size that is greater than that expected for gestational age, auscultation of 2 fetal hearts, and elevated maternal serum α-fetoprotein (AFP) or human chorionic gonadotropin (hCG) levels. It is confirmed by ultrasonography. Physical examination of twins is necessary but not sufficient to determine zygosity of twins. In the event that congenital anomalies are present or there are transfusion or transplantation considerations, genetic testing of zygosity should be performed. While noninvasive prenatal testing (NIPT) is becoming more common, the results should be interpreted with caution in multiple-gestation pregnancies until more findings are better established.
Prognosis

Most twins are born prematurely, and maternal complications of pregnancy are more common than with single pregnancies. The risk for twins is most often associated with twin-twin transfusion, ART, and early-onset discordant growth. Because most twins are premature, their overall mortality is higher than that of single-birth infants. The perinatal mortality of twins is about 4 times that of singletons, with monochorionic twins being particularly at risk. Monoamnionic twins have an increased likelihood of cord entanglement, which may lead to asphyxia. Twins are at greater risk for congenital malformations, with up to 25% of monozygotic twins being affected. Theoretically, the 2nd twin is more subject to anoxia than the 1st because the placenta may separate after birth of the 1st twin and before birth of the 2nd. In addition, delivery of the 2nd twin may be difficult because it may be in an abnormal presentation (breech, entangled), uterine tone may be decreased, or the cervix may begin to close after the 1st twin’s birth.

Triplet or higher-order births are associated with an increased risk of death or neurodevelopmental impairment compared with extremely-low-birthweight (ELBW) singleton and twin infants after controlling for gestational age. The mortality for multiple gestations with ≥4 fetuses is excessively high for each fetus. Because of this poor prognosis, selective fetal reduction has been offered as a treatment option. Monozygotic twins have an increased risk of one twin dying in utero. The surviving twin has a greater risk for cerebral palsy and other neurodevelopmental sequelae.

Treatment

Prenatal diagnosis enables the obstetrician and pediatrician to anticipate the birth of infants who are at high risk because of twinning. The risk of multiple-gestation pregnancies using ART may be reduced by elective single-embryo transfers. In addition, elective delivery of twins at 37 wk (or earlier for monochorionic, monoamniotic twins) reduces the complication rate for the fetuses and the mother. Furthermore, in twin pregnancies between 32 and 39 wk of gestation, planned vaginal delivery is preferred if the 1st twin is in the cephalic presentation. Close observation and attendance by a pediatric team are indicated in the immediate neonatal period so that prompt treatment of asphyxia or fetal transfusion syndrome can be initiated. The decision to perform an
immediate blood transfusion in a severely anemic “donor twin” or a partial exchange transfusion of a “recipient twin” must be based on clinical judgment.

low birthweight
neutral thermal environment
very low birthweight

Traditionally, a delivery date is determined 280 days after the last menstrual period (LMP). However, only 4% of pregnant women actually deliver at 280 days, and only 70% deliver within 10 days of the estimated delivery date.

Infants born before 37 wk from the 1st day of the LMP are termed premature by WHO. Infants born before 28 wk gestation are extremely preterm, also referred to as extremely low gestational age newborns (ELGANs); whereas infants born between 28 and 31\% are very preterm. Moderate and late preterm infants (born between 32 and 36\% wk gestation) are discussed in Chapter 117.3.

In addition to classification by gestational age, classification is also based on birthweight. Extremely low birthweight (ELBW) is used to describe infants with a birthweight <1000 g, very low birthweight (VLBW) describes infants <1500 g, and low birthweight (LBW) describes infants <2500 g at birth. Birthweight in general is a proxy for gestational age, but in the cases of intrauterine growth restriction (IUGR) and small-for-gestational-age (SGA) infants, birthweight can sometimes be misleading for true gestational age (see Chapter 117.4).

Incidence
Preterm birth, or birth before 37 wk of gestation, is fairly common. Worldwide, approximately 15 million preterm births occur annually. In the United States, approximately 10% of all births are preterm. After a prolonged period of increasing rates of preterm birth, preterm births in the United States peaked at 10.44% in 2007. From 2007 until 2014, a slow but steady decline occurred in preterm births, to 9.57% in 2014. Preliminary data show that preterm births have slightly increased since 2014, with 9.84% of all U.S. births being preterm in 2016 and a disproportionate increase in late preterm births (Fig. 117.6). Of preterm births in 2016, the majority were late preterm infants, approximately 72% of preterm births, with the remaining 28% being extremely
or early preterm.

**Etiology**

Despite the frequency of preterm birth, it is often difficult to determine a specific cause. The etiology of preterm birth is multifactorial and involves complex interactions between fetal, placental, uterine, and maternal factors. In the setting of maternal or fetal conditions that prompt early delivery, as well as placental and uterine pathology, causes of preterm birth can sometimes be identified (Table 117.3).

**Table 117.3**

</tr>
</tbody>
</table>
However, most preterm births are *spontaneous* without an identifiable cause. Older maternal age, poorer maternal health, history of previous preterm delivery, short interpregnancy interval, and lower socioeconomic status (SES) have all been associated with preterm birth. Racial disparities also exist, which seem to persist when taking into account SES. Large population studies have also found associations between maternal genetics and preterm birth. Gestational duration and actual preterm birth have been noted with genetic variants in the maternal genome. Many of these genes have roles in regulation of the estrogen receptor, uterine development, maternal nutrition, or vascular reactivity. In addition, cell free RNA transcripts in maternal blood may also be of value in predicting preterm birth.

**Assessment of Gestational Age**

With insufficient prenatal care or discrepancies between birthweight and predicted gestational age at birth, it is often helpful to be able to assess infants at birth for an estimated gestational age. Examination and assessment is needed to distinguish SGA and IUGR infants from preterm infants. Compared with a premature infant of appropriate weight, an infant with IUGR has a reduced
Birthweight and may appear to have a disproportionately larger head relative to body size; infants in both groups lack subcutaneous fat. Neurologic maturity (nerve conduction velocity) in the absence of asphyxia correlates with gestational age despite reduced fetal weight. Physical signs may be useful in estimating gestational age at birth. The commonly used **Ballard scoring system** is accurate to within 2 wk of actual gestational age (Figs. 117.7 to 117.9).

FIG. 117.9 Maturity rating. The physical and neurologic scores are added to calculate gestational age. (From Ballard JL, Khoury JC, Wedig K, et al: New Ballard score, expanded to include extremely premature infants, J Pediatr 119:417–423, 1991.)
Nursery Care

At birth, the general measures needed to clear the airway, initiate breathing, care for the umbilical cord and eyes, and administer vitamin K are the same for premature infants as for those of normal weight and maturity (see Chapter 121). Additional considerations are the need for (1) thermal control and monitoring of the heart rate and respiration, (2) oxygen therapy, and (3) special attention to the details of fluid requirements and nutrition. Safeguards against infection can never be relaxed. Routine procedures that disturb these infants may result in hypoxia. The need for regular and active participation by the parents in the infant's care in the nursery and the question of prognosis for later growth and development require special consideration.

Thermal Control

Neonatal temperature regulation decreases the risk of morbidity and mortality in ELBW and VLBW infants. Neonates in general, and ELBW and VLBW infants to an even greater extent, are at increased risk of heat loss compared with older children due to an increased body surface/weight ratio, decreased epidermal and dermal skin thickness, minimal subcutaneous fat, and an immature nervous system.

Preterm infants should be kept in a neutral thermal environment. This environment is a set of thermal conditions, including air and radiating surface temperatures, relative humidity, and airflow, at which heat production (measured experimentally as oxygen consumption) is minimal and the infant's core temperature is within the normal range. The neutral thermal environment is a function of the size and postnatal age of an infant; larger, older infants require lower environmental temperatures than smaller, younger infants. Incubators or radiant warmers can be used to maintain body temperature. Body heat is conserved through provision of a warm environment and humidity. The optimal environmental temperature for minimal heat loss and oxygen consumption for an unclothed infant is one that maintains the infant's core temperature at 36.5-37.0°C (97.7-98.6°F). The smaller and more immature the infant, the higher is the environmental temperature required. Infant warmth can be maintained by heating the air to a desired temperature or by servo-control. Continuous monitoring of the infant's temperature is required to maintain optimal body temperature. Kangaroo care with direct skin-to-skin contact between infant and
parent, with a hat and blanket covering the infant, is to be encouraged, without untoward effects on thermoregulation.

Maintaining a relative humidity of 40–60% aids in stabilizing body temperature by reducing heat loss at lower environmental temperatures; by preventing drying and irritation of the lining of respiratory passages, especially during the administration of oxygen and after or during endotracheal intubation; and by thinning viscid secretions and reducing insensible water loss. An infant should be weaned and then removed from the incubator or radiant warmer only when the gradual change to the atmosphere of the nursery does not result in a significant change in the infant's temperature, color, activity, or vital signs.

**Oxygen Administration**

Administering oxygen to reduce the risk of injury from hypoxia and circulatory insufficiency (risk of cerebral palsy, death) must be balanced against the risk of hyperoxia to the eyes (retinopathy of prematurity, ROP) and oxygen injury to the lungs (bronchopulmonary dysplasia, BPD). For ELBW infants at birth, guidelines should be followed to determine need for oxygen during resuscitation to maintain goal O₂ saturation limits (see Chapter 121).

After the initial resuscitation period, ideal target O₂ saturation limits for ELBW infants should be within the range of 90–95% for most infants.

**Nutrition for the High-Risk Infant**

Extreme prematurity must be considered a nutritional emergency. In the absence of early parenteral and enteral nutritional support, deficits in protein and energy will quickly accrue, placing the infant at risk for poor growth and neurodevelopmental outcomes. The goals of early nutritional support for extremely premature infants include approximating the rate and composition of growth for a normal fetus at the same postmenstrual age. Achieving this goal requires an understanding of the intrauterine growth rate to be targeted as well as the unique nutrient requirements of premature infants. Strategies to prevent growth faltering include a combined approach of early parenteral and enteral nutrition, fortification of human milk, and the use of standardized feeding guidelines. In addition, careful monitoring of not only weight gain but also length and head circumference using appropriate intrauterine growth curves, as well as consultation with an experienced neonatal dietitian, is important to
achieve optimal growth outcomes.

**Early Parenteral Nutrition**

In the absence of intravenous amino acids, extremely premature infants lose 1-2% of body protein stores per day. IV amino acids and dextrose should be started immediately after birth. Many units use a *starter* or *stock* solution of amino acids and dextrose to accomplish this goal in infants weighing <1,500 g. A minimum of 2 g/kg of amino acids should be given in the 1st 24 hr after birth, with the goal of supplying at least 3.5 g/kg within 24-48 hr after birth. To meet total energy requirements, IV lipids will also be needed.

**Benefits of Human Milk**

Maternal milk is the preferred source of enteral nutrition for premature infants and is associated with decreased in-hospital morbidity, including lower rates of necrotizing enterocolitis (NEC), late-onset sepsis, BPD, and severe ROP. Maternal milk feeding is also associated with superior neurodevelopmental outcomes at 18 and 30 mo corrected age compared to infants fed premature formula. Donor human milk is increasingly being used when maternal milk is not available, but is typically lower in protein and energy content than preterm maternal milk and may result in suboptimal growth unless adequately fortified. Although donor human milk has been associated with a reduction in NEC, the impact of donor human milk on neurodevelopmental outcomes remains unclear.

**Enteral Nutrition**

Early enteral feedings are recommended in ELBW and VLBW infants, typically beginning between 6 and 48 hr with some period of trophic/minimal enteral feeding volume. Feedings are typically advanced slowly (15-30 mL/kg/day) with a target goal of delivering approximately 110-135 kcal/kg/day and 3.5-4.5 g protein/kg/day. To accomplish these goals, human milk must be fortified, or a premature formula can be given.

**Standardized Feeding Guidelines**

Standardized feeding guidelines should be developed incorporating evidence-based strategies for the provision of parenteral and enteral nutrition in ELBW and VLBW infants, including a plan to manage feeding intolerance. Regardless of the specific protocol, having a feeding guideline leads to improved outcomes.
(e.g., time to regain birthweight, time to reach full enteral nutrition), decreased rates of late-onset sepsis and NEC, improved growth at 36 wk postmenstrual age, and reduced length of hospital stay.

**Transitioning to Discharge Nutrition**

The earlier an infant is born before expected, the greater the likelihood that not all nutritional deficits will be resolved before hospital discharge. Regardless of weight gain during the initial hospital stay, there is strong evidence for improved bone mineralization with the use of higher concentrations of calcium and phosphorus after discharge. Fortified human milk or preterm formula with higher protein, minerals, and trace elements is often recommended after discharge. An individualized approach to postdischarge nutrition should be developed to transition from the NICU.

**Prevention of Infection**

Extremely preterm infants have an increased susceptibility to infection, and thus meticulous attention to infection control is required. Prevention strategies include strict compliance with handwashing and universal precautions, minimizing the risk of catheter contamination and duration, meticulous skin care, encouraging early appropriate advancement of enteral feeding, education and feedback to staff, and surveillance of nosocomial infection rates in the nursery. Although no one with an active infection should be permitted in the nursery, the risks of infection must be balanced against the disadvantages of limiting the infant's contact with the family. Early and frequent participation by parents in the nursery care of their infant does not increase the risk of infection when preventive precautions are maintained.

Preventing transmission of infection from infant to infant is difficult because often neither term nor premature newborn infants have clear clinical evidence of an infection early in its course. When epidemics occur within a nursery, cohort nursing and isolation rooms should be used. **Hand hygiene** is of upmost importance. Because premature infants have immature immune function, some will develop nosocomial infection even when all precautions are followed.

Routine **immunizations** should be given on the regular schedule based on chronological age at standard doses.
Immaturity of Drug Metabolism

Great care must be taken when prescribing and dosing medications for premature infants (Table 117.4). Renal clearance of almost all substances excreted in the urine is diminished in newborn infants, and to even a greater extent in premature infants. The glomerular filtration rate rises with increasing gestational age; therefore, drug dosing recommendations vary with age. For drugs primarily excreted by the kidneys, longer intervals between dosages are often needed with increasing degree of prematurity. Drugs that are detoxified in the liver or require chemical conjugation before renal excretion should also be given with caution and in doses smaller than usual.

Many drugs apparently safe for adults on the basis of toxicity studies may be harmful to newborns, especially premature infants. Oxygen and a number of drugs have proved toxic to premature infants in amounts not harmful to term infants. Thus, administering any drug, particularly in high doses, that has not undergone pharmacologic testing in premature infants should be undertaken carefully after risks have been weighed against benefits.

## Morbidity and Mortality

Rates of neonatal morbidity and mortality are high in extremely preterm infants, and risks increase with decreasing gestational age and lower birthweight (Table 117.5). Data on extremely preterm infants born between 2003 and 2007 found that 42% of VLBW infants developed BPD, 12% developed ROP requiring treatment, 11% NEC, 36% late-onset sepsis, 16% grade III or IV intraventricular hemorrhage (IVH), and 3% periventricular leukomalacia (PVL). Morality increased with lower gestational age, with a 94% mortality in infants born at 22 wk and 8% mortality at 28 wk. As a whole, the group of extremely preterm infants had a 28% mortality rate, with 37% surviving without a significant neonatal morbidity.

* Major neonatal morbidities.

Another study found that morbidity and mortality among VLBW infants decreased between 2000 and 2009. This study was limited to live-born infants with birthweight of 500-1500 g. For infants born in 2009, this study found a 12.4% mortality rate; 28% of infants developed BPD, 7% severe ROP, 5% NEC, 15% late-onset sepsis, 6% grade III or IV IVH, and 3% PVL; 51% survived without significant neonatal morbidity.

Outcomes may be slightly improving with time; survival among infants born 22-24 wk gestation increased from 30% in 2000–2003 to 36% in 2008–2011. The percentage surviving without neurodevelopmental impairment increased from 16% to 20% over this same period. However, extreme prematurity is still associated with significant risk of both mortality and major neonatal morbidities. For infants who survive to discharge, prematurity, as well as neonatal morbidities, put them at increased risk for developmental delays and impairment as they age (see Chapter 117.5).

### 117.3

**Moderate and Late Preterm Infants**

*Jennifer M. Brady, Brenda B. Poindexter*

#### Keywords

- late preterm
- moderate preterm

WHO defines **moderate to late preterm** birth as infants born between 32 and $36\frac{1}{2}$ wk postmenstrual age (PMA). The American College of Obstetricians and Gynecologists (ACOG) further defines **late preterm** infants as those born between 34 and $36\frac{1}{2}$ wk PMA. Therefore, most define **moderate preterm** infants as those born between 32 and $33\frac{1}{2}$ wk PMA.

### Moderate Preterm Infant

Moderate preterm infants are still at risk for most postnatal morbidities, although to a lesser extent than very preterm infants are at risk. These morbidities include
but are not limited to poor feeding, weight loss, respiratory distress syndrome, risk of NEC, and difficulty with thermoregulation. Moderate preterm infants with birthweight >1,500 g and a fairly unremarkable NICU course are thought to be at fairly minimal risk for IVH and do not routinely need a head ultrasound. Little research has examined moderate preterm infants as an isolated group; more often these infants are grouped with very preterm infants when assessing complications and outcomes. A cohort of approximately 7,000 infants born between 29 and 33 wk gestational age were found in a recent study to have a mean hospital stay of 33.3 days. Compared with term counterparts, these infants had an increased incidence of many morbidities, including BPD, early- and late-onset sepsis, NEC, and PVL.

**Late Preterm Infant**

Late preterm infants account for approximately 8–9% of all births and almost three fourths of all preterm births in the United States. Historically, late preterm infants were referred to as near-term infants, and the approach to their care was similar to that of term infants. It has been increasingly recognized that late preterm infants have significantly increased morbidity, as well as mortality, compared with their term counterparts. There is an increased incidence of congenital anomalies in preterm infants, but even when these infants are excluded, late preterm infants continue to have significantly more morbidities. Immediately after birth, late preterm infants have an increased risk of requiring resuscitation, as well as increased incidence of hypoglycemia, respiratory distress, apnea, feeding difficulties, and jaundice. They also have a higher rehospitalization rate compared to their term peers.

Antenatal corticosteroids were traditionally only recommended for pregnant women between 24 and 34 wk gestation at risk of preterm delivery within the next 7 days, to reduce the incidence of death and respiratory distress syndrome. A randomized controlled trial of women at 34–36 wk gestation at risk of preterm labor found a decreased rate of respiratory complications in the newborns whose mothers received antenatal corticosteroids. An increased rate of neonatal hypoglycemia was seen in the steroid group as well, but no other significant differences were found. Based on these findings, ACOG recommends a single course of antenatal corticosteroids for pregnant women between 34 and 36 wk gestation at risk for preterm birth within 7 days, who have not received a
previous course of antenatal corticosteroids.

Between 34 and $36\frac{1}{2}$ wk gestation is regarded as a critical period for growth and development. In the past, elective deliveries without medical indications often occurred as early as 35 wk. ACOG recommends elective delivery without medical indications only after 39 wk gestation in well-dated pregnancies. Some studies suggest a higher risk of lower school readiness at kindergarten and increased risk of academic difficulties in childhood when comparing late preterm infants with term peers.

**Bibliography**

**117.4**

**Term and Postterm Infants**
ACOG further divides term infants into subgroups: early term (37–38 wk), full term (39–40 wk), and late term (41–41½ wk). Many risk factors for term infants put them at higher risk for complications, such as meconium aspiration syndrome (see Chapter 122.8), hemolytic disease of the newborn (Chapter 124.2), infant of a diabetic mother (Chapter 127.1), and neonatal abstinence syndrome (Chapter 126.1). Both small for gestational age (SGA) and large for gestational age (LGA) are associated with increased morbidities.

Small for Gestational Age and IUGR

There is an important distinction between the terms small for gestational age (SGA) and intrauterine growth restriction (IUGR). SGA is based on physical evaluation of an infant at birth, usually by a pediatrician or neonatologist. If the infant's weight is <10th percentile, the infant is SGA. The diagnosis of SGA does not differentiate between normal biologic growth potential and a pathologic or growth-restricted state in utero. In contrast, IUGR is a prenatal diagnosis to describe a fetus who fails to reach in utero growth potential, often diagnosed by the obstetrician. Therefore, not all infants with IUGR are SGA, and similarly, not all infants who are SGA have IUGR.

Although it is important to understand the difference between SGA and IUGR, due to difficulty standardizing a classification of IUGR, many studies evaluate postnatal outcomes based on a diagnosis of either SGA or IUGR.
IUGR is associated with medical conditions that interfere with the circulation and efficiency of the placenta, with the development or growth of the fetus, or with the general health and nutrition of the mother (Table 117.6). Many factors are common to both prematurely born and LBW infants with IUGR. IUGR is associated with decreased insulin production or insulin-like growth factor (IGF) action at the receptor level. Infants with IGF-1 receptor defects, pancreatic hypoplasia, or transient neonatal diabetes have IUGR. Genetic mutations affecting the glucose-sensing mechanisms of the pancreatic islet cells result in decreased insulin release (loss of function of the glucose-sensing glucokinase gene) and give rise to IUGR.

IGF2 mutation (paternal)

IUGR may be a normal fetal response to nutritional or oxygen deprivation; therefore the issue is not the IUGR but rather the ongoing risk of fetal malnutrition or hypoxia. IUGR is often classified as *reduced growth* that is
symmetric (head circumference, length, and weight equally affected) or asymmetric (with relative sparing of head growth). Symmetric IUGR often has an earlier onset in the first trimester of pregnancy and is associated with diseases that seriously affect fetal cell number, such as conditions with chromosomal, genetic, malformation, teratogenic, infectious, or severe maternal hypertensive etiologies. It is important to assess gestational age carefully in infants suspected to have symmetric IUGR because incorrect overestimation of gestational age may lead to the diagnosis of symmetric IUGR. Asymmetric IUGR is often of late onset in the 2nd half of pregnancy, demonstrates preservation of Doppler waveform velocity to the carotid vessels, and is associated with poor maternal nutrition or with late onset or exacerbation of maternal vascular disease (preeclampsia, chronic hypertension).

Table 117.7 lists common problems of infants with IUGR. In addition, in both preterm and term infants, SGA has been shown to be associated with an increased risk of neurodevelopmental impairment.

↓, Decreased; ↑, increased.

Large-for-Gestational-Age Infants

Infants with birthweight >90th percentile for gestational age are called large for
gestational age (LGA). Neonatal mortality rates decrease with increasing birthweight until approximately 4,000 g, after which they increase. These oversized infants are usually born at term, but preterm infants with weights high for gestational age also have a significantly higher mortality than infants of the same size born at term; maternal diabetes and obesity are predisposing factors. Some infants are constitutionally large because of large parental size. LGA infants, regardless of their gestational age, have a higher incidence of birth injuries, such as cervical and brachial plexus injuries, phrenic nerve damage with paralysis of the diaphragm, fractured clavicles, cephalohematomas, subdural hematomas, and ecchymoses of the head and face. LGA infants are also at increased risk for hypoglycemia and polycythemia.

The incidence of congenital anomalies, particularly congenital heart disease, is also higher in LGA infants than in term infants of normal weight.

Postterm Infants

Postterm infants are those born after 42 completed wk of gestation, as calculated from the mother's LMP. Historically, approximately 12% of pregnancies resulted in delivery after 42 wk. However, with current evidence suggesting that both morbidity and mortality increase significantly after 42 wk gestation, obstetric interventions to induce labor often occur before 42 wk, resulting in a decreasing rate of postterm births. The cause of postterm birth or postmaturity is unknown. Postterm infants often have normal length and head circumference but may have decreased weight if there is placental insufficiency. Infants born postterm in association with presumed placental insufficiency may have various physical signs. Desquamation, long nails, abundant hair, pale skin, alert faces, and loose skin, especially around the thighs and buttocks, give them the appearance of having recently lost weight; meconium-stained nails, skin, vernix, umbilical cord, and placental membranes may also be noted. Common complications of postmaturity include perinatal depression, meconium aspiration syndrome, persistent pulmonary hypertension, hypoglycemia, hypocalcemia, and polycythemia.

Infants born at ≥42 wk gestational age experience approximately 3 times the mortality of infants born at term. Mortality has been greatly reduced through improved obstetric management. Data suggest that elective delivery during the 39th wk of gestation for both nulliparous and multiparous women is associated with decreased maternal and neonatal complications compared with those who
were expectantly managed.

Careful obstetric monitoring, including nonstress testing (NST), biophysical profile (BPP), or Doppler velocimetry, usually provides a rational basis for choosing 1 of 3 courses: nonintervention, induction of labor, or cesarean delivery. Induction of labor or cesarean birth may be indicated in older primigravidas >2-wk beyond term, particularly if evidence of fetal distress is present. Medical problems in the newborn are treated if they arise.

developmental delays
Discharge From the Hospital

Numerous criteria need to be met before a high-risk infant is ready for discharge from the hospital (Table 117.8). Before discharge, infants should be taking most or all nutrition by nipple, either bottle or breast. Some medically fragile infants may be discharged home while receiving gavage feedings after the parents have received appropriate training and education. Growth should be occurring at steady increments, with a goal weight gain of approximately 30 g/day. Temperature should be stable and normal in an open crib. Infants should have had no recent episodes of apnea or bradycardia requiring intervention for at least 5-7 days prior to discharge. Stable infants recovering from BPD may be discharged on a regimen of home oxygen given by nasal cannula as long as careful follow-up is arranged with home pulse oximetry monitoring and outpatient visits. All infants with birthweight <1,500 g or gestational age <30 wk at birth should undergo an eye examination to screen for ROP. If born preterm, hemoglobin or hematocrit should be determined to screen for possible anemia of prematurity. Every infant should have a hearing test before discharge. Routine vaccinations should be given based on chronological age before discharge. In addition, palivizumab (Synagis) should be given to eligible infants during respiratory syncytial virus (RSV) season immediately before discharge for prophylaxis against RSV, with continued monthly doses arranged as an outpatient as appropriate.

Ophthalmologic examination if <30 wk of gestation or <1,500 g at birth
Parental knowledge, skill, and confidence documented in:
  Administration of medications (diuretics, methylxanthines, aerosols, etc.)
  Use of oxygen, apnea monitors, oximeters
Nutritional support:
  Timing
  Volume
  Mixing concentrated formulas
Recognition of illness and deterioration
Basic cardiopulmonary resuscitation
Infant safety
Scheduling of referrals:
  Primary care provider
  Neonatal follow-up clinic
  Occupational therapy/physical therapy
  Imaging (head ultrasound)
Assessment of and solution to social risks

If all major medical problems have resolved and the home setting is adequate, premature infants may then be discharged when their weight approaches 1,800-2,000 g, they are >34-35 wk PMA, and all the above criteria are met. Parental education, close follow-up, and healthcare provider accessibility are all essential for early discharge protocols. Ideally, the primary caregivers for the infant have a chance to provide infant care in the hospital with nursing supervision and help before discharge home. All high-risk infants should follow-up with their primary care provider within a few days of discharge.

Postdischarge Follow-Up

Medical Follow-Up

Even after discharge from the hospital, high-risk infants need very close medical follow-up. They continued to be at increased risk for poor weight gain and failure to thrive. In the setting of viral illness, premature infants are at increased risk for significant respiratory distress. Infants who are sent home on oxygen
need very close medical follow-up with frequent visits and assessments, often with pulmonology. Table 117.9 lists common sequelae of prematurity.

Medically complex infants can go home with a multitude of subspecialty appointments to help manage existing morbidities secondary to prematurity. For example, cardiology for management of a patent ductus arteriosus or pulmonary hypertension, pulmonary for BPD, nephrology for hypertension, ophthalmology for ROP, neurosurgery for hydrocephalus, and neurology for history of seizures. The extensive follow-up requirements can be overwhelming and daunting for families. It is very important that these infants have a primary care provider who serves as their “medical home” to help coordinate and assimilate the care from all these providers for families.

**Developmental Follow-Up**

It is well known that premature infants are at greater risk for developmental delays than their term counterparts; the more preterm, the greater the risk of delay. In addition, certain postnatal morbidities (severe BPD, grade III or IV intraventricular hemorrhage, severe ROP) are associated with significantly increased risk of developmental delays. It is very important that preterm infants
are followed and assessed for developmental delay, so that if delays are detected, interventions can be instituted early.

It is recommended that developmental follow-up be available for infants born <32 wk PMA, or at a minimum <28 wk PMA and/or <1 kg birthweight. Developmental follow-up in the United States is most often provided in a neonatal follow-up program for the 1st 2-3 yr of life, and in some cases, until school age. Assessments focus on 5 main developmental domains: cognitive development, language development, fine and gross motor skills, social development, and emotional development. Although many assessments exist, the most widely used assessment in the United States is the Bayley Scales of Infant and Toddler Development, Third Edition.

It is important to note that for at least the 1st 2 yr of life, a child's corrected age should be used in determining if a delay exists. Corrected age is calculated by subtracting the weeks born premature from a child's chronological age. In doing so, a corrected age accounts for a child's prematurity. Some debate surrounds whether corrected age should continue to be used after age 2 yr.

If it is determined that a delay exists, a child should be referred for appropriate therapy to help minimize the delay as the child ages. Federal law under the Individuals with Disabilities Act requires states to provide early intervention services to children <3 yr old with developmental delay. States vary greatly in how delay is defined and what services are offered. Early intervention is associated with improved cognitive outcomes in infancy and preschool age, but not lasting into school age. Motor outcomes are improved in infancy for children who receive early intervention, but this has not been shown to be a lasting effect into preschool and school age.

Premature infants, especially those with a history of grade III or IV intraventricular hemorrhage or PVL seen on head imaging, are also at increased risk of motor impairments. Cerebral palsy is nonprogressive but permanent disorder of movement and posture caused by disturbance to the developing immature brain. Historically, cerebral palsy had not been diagnosed until 18-24 mo of age, but current tests such as the General Movements Assessment (GMA) and Hammersmith Infant Neurological Examination (HINE) are helping to identify children at high risk for cerebral palsy within the 1st few mo to yr of life. This enables these children to access early intervention services and therapy at an earlier age, as well as undergo more frequent surveillance as needed.

Children with a history of prematurity who do not show significant
developmental delays in the 1st few yr of life are still at risk of later developing learning disabilities, attention problems, and decreased school achievement. Continued screening by their primary care provider may be needed as these children age.

**Bibliography**

Regionalized Care of Newborns

The concept of regionalized care for neonates was first introduced in the 1976 March of Dimes Report Toward Improving the Outcome of Pregnancy. This report and future revisions stress the importance of providing regionalized care for infants in facilities with adequate personnel and equipment for an infant's severity of illness. Ideally, mothers deliver infants at a facility with the appropriate level of expertise and resources to care for the degree of prematurity and illness of the infant. Many studies have shown that very-low-birthweight (VLBW) infants, or infants <1,500 g at birth, have decreased morbidity and mortality when delivered at an appropriate level of care center (Level III hospitals). In a meta-analysis, neonatal or predischarge death occurred in 38% of VLBW infants receiving care at a non–Level III hospital and 23% of those receiving care at a Level III hospital. A main objective of Healthy People 2020 addresses this issue, with a goal of increasing the proportion of VLBW infants born at Level III hospitals or subspecialty perinatal centers to 83.7%. Where this is not possible, the infant should be transported to an appropriate level of care hospital after birth.

Levels of Neonatal Care

Although a formal national definition of levels of neonatal care does not exist, the American Academy of Pediatrics (AAP) and March of Dimes have standardized definitions for levels I, II, III, and IV. One must understand the
levels of care available before being able to arrange transport to an appropriate facility.

A **Level I** facility must be able to provide *basic neonatal care*. Appropriate equipment and staff must be available to perform neonatal resuscitation and care for healthy term and late preterm infants. In addition, Level I facilities must have the capacity to work to stabilize ill or preterm infants before transport to a higher level of care. A Level I nursery is the minimum requirement for a hospital providing inpatient maternity care. Providers at Level I facilities usually include pediatricians, family physicians, and nurse practitioners.

In addition to the care provided at a Level I facility, **Level II** nurseries must also be capable of providing care to moderately ill term infants with problems expected to resolve quickly. Level II centers also care for infants born ≥32 wk gestational age and >1,500 g at birth, and therefore must be comfortable with treating conditions common in this population, such as difficulty with oral feeds, apnea of prematurity, respiratory distress requiring continuous positive airway pressure (CPAP), and temperature regulation. These centers must also be capable of stabilizing infants born <32 wk gestation and <1,500 g until transfer to a higher-level facility is feasible, including the ability to intubate and provide mechanical ventilation for a brief duration if necessary. In addition to providers in Level I facilities, Level II facilities also typically have pediatric hospitalists, neonatologists, and neonatal nurse practitioners.

**Level III** neonatal intensive care units (NICUs) are equipped to care for the extremely preterm and critically ill neonates in addition to those infants cared for at Level I and II units. Level III units must have continuously available personnel and equipment to treat conditions commonly seen in this population, such as respiratory distress syndrome, pulmonary hypertension, and need for total parenteral nutrition. Resources should be available to obtain and interpret urgent imaging needed (e.g., CT, echocardiography). Pediatric subspecialists and pediatric surgeons should be available either on site or through prearranged consultative agreements.

In addition to the care available at Level III NICUs, **Level IV** NICUs are also capable of continuously available pediatric subspecialty consultation and pediatric surgical intervention. Many Level IV sites are located at regional children's hospitals and serve to provide outreach education.

*Transport of the Critically Ill Neonate*
In the event that a neonate requires a higher level of care after birth, transport must be arranged to a unit with the appropriate level of care available. Additional decisions that need to be made before transport include composition of the transport team, equipment required for transport, and mode of transportation.

The composition of the transport team varies depending on personnel available and the needs of the infant being transported. The transport team often comprises at least 2 individuals, whether 2 registered nurses (RN), an RN and a respiratory therapist, or an RN and a paramedic. In addition, occasionally a neonatologist, neonatology fellow, or neonatal nurse practitioner will accompany the transport team for critically ill neonates. A designated medical control physician is available and in communication with the transport team throughout the transport as needed.

Transport staff must be competent in the treatment of common neonatal conditions and complications, as well as neonatal procedures. Many Level IV facilities have specialized teams available for neonatal transport. A Cochrane review found no evidence to support or to refute improved infant morbidity or mortality when transport occurred with a specialized team. Depending on the volume of neonatal transports and composition of the team, staff may have limited exposure to neonatal transports and procedures. Simulation-based learning is recommended by the AAP Section on Transport Medicine (SOTM) as a method to help achieve and retain competency in rarely experienced procedures, as well as improve team interactions for transport teams.

The transport vehicle should be equipped with appropriate medicines, intravenous (IV) fluids, oxygen tanks, catheters, chest tubes, endotracheal tubes (ETTs), laryngoscopes, bag-valve-mask, and infant warming device. It should be well illuminated and have ample room for emergency procedures and monitoring equipment. Additional needs for the specific transport should be anticipated (e.g., nitric oxide).

Common modes of transport include ground transport by ambulance and air transport by helicopter or fixed-wing aircraft. The stability of the infant, travel distance, traffic, and weather must all be taken into account when deciding the most appropriate mode of transportation.

Steps should be taken to stabilize infants as able in a timely fashion prior to transport. Securing an airway, providing oxygen, assisting with infant ventilation, providing antimicrobial therapy, maintaining the circulation, providing a warmed environment, checking a glucose level, and placing IV or
arterial lines or chest tubes should be initiated, if indicated, before transport. Appropriate placement of lines and ETT should be evaluated before transport. **Risks** of transport and transportation **consent** should be reviewed and obtained from parents before transport. Although transport teams attempt to anticipate and prepare for possible complications that could occur during transport, there is an inherent risk of complications, including death, in the event of a decompensation during transport resulting from the limited resources and personnel available. Parents should be made aware of these risks. If the infant's condition allows, efforts should be made to allow parents to see their baby briefly before transport.

**Communication** with the transport team as well as the receiving facility is paramount throughout the transport process. Available prenatal history, information on the infant's resuscitation and hospital course, lab data, and radiographic images should be sent with the transport team to the receiving hospital to aid in future care.

**Reverse transport** of an infant back to a lower level of care should be considered when infants are stabilized after transport and no longer require the higher level care available at the receiving hospital. Transport back to the birth hospital aids in appropriate utilization of resources, decreases costs of care, and may further promote parent–infant bonding because of proximity to the mother's home.

**Bibliography**

Cheng ASM, Berry A, Jones LJ, Sivasangari S. Specialist teams for neonatal transport to neonatal intensive care units for

A variety of conditions that affect the newborn originate in utero, during birth, or in the immediate postnatal period. These disorders can be caused by prematurity, congenital malformations, disruption of chromosome structure, or acquired diseases and injuries. Recognizing disease in newborn infants requires knowledge of relevant pathophysiology and evaluation of nonspecific clinical signs and symptoms.

**Abnormal Movements**

**Neonatal seizures** usually suggest a central nervous system (CNS) disorder, such as hypoxic-ischemic encephalopathy (HIE), intracranial hemorrhage, stroke, cerebral anomaly, subdural effusion, or meningitis (see Chapter 611.7). In the neonate, seizures can also be secondary to hypocalcemia, hypoglycemia, benign familial seizures, or rarely, pyridoxine dependence, hyponatremia, hypernatremia, inborn errors of metabolism, or drug withdrawal.

Seizures in premature infants are often subtle and associated with abnormal eye movement (fluttering, tonic horizontal deviation, sustained eye opening with ocular fixation) or facial movement (chewing, tongue thrusting); the motor component is often that of tonic extension of the limbs, neck, and trunk. Autonomic phenomena include hypertension and tachycardia. Term infants may have focal or multifocal, clonic or myoclonic movements, but they may also have subtler manifestations of seizure activity. **Apnea** may be the 1st manifestation of seizure activity, particularly in a premature infant. Seizures may adversely affect the subsequent neurodevelopmental outcome and may even
predispose an infant to seizures outside the neonatal period. Electroencephalographic evidence of seizures can occur without clinical manifestations, particularly in preterm infants. If seizures are suspected, continuous amplitude integrated EEG (aEEG), or more accurately, long-term video EEG monitoring, will improve detection of both subtle and electrographic but clinically silent seizures. Many medications used to treat seizures have important side effects and limited efficacy, but current evidence suggests that the benefits of treating seizures outweigh the risks.

Seizures should be distinguished from the jitteriness, defined as recurrent tremors, that may be present in normal newborns, in infants of diabetic mothers, in those who experienced birth asphyxia or drug withdrawal, and in polycythemic neonates. An examiner may stop the tremors by holding the infant's extremity; jitteriness often depends on sensory stimuli and occurs when the infant is active, and it is not associated with abnormal eye movements. Tremors are often more rapid with a smaller amplitude than those of tonic-clonic seizures.

After severe birth asphyxia, infants may exhibit motor automatisms characterized by recurrent oral-buccal-lingual movements, rotary limb activities (rowing, pedaling, swimming), tonic posturing, or myoclonus. These motor activities are not usually accompanied by time-synchronized EEG discharges, may not signify cortical epileptic activity, respond poorly to anticonvulsant therapy, and are associated with a poor prognosis. Such automatisms may represent cortical depression that produces a brainstem release phenomenon or subcortical seizures.

Failure to move an extremity (pseudoparalysis) suggests fracture, dislocation, or nerve injury, often following a traumatic delivery. It is also seen in septic arthritis, osteomyelitis, and other infections that cause pain on movement of the affected part.

Altered Mental Status

Lethargy may be a manifestation of infection, asphyxia, hypoglycemia, hypercapnia, sedation from maternal analgesia or anesthesia, a cerebral defect, or, indeed, almost any severe disease, including an inborn error of metabolism. Shortly after birth, lethargy is most likely caused by maternal medications (opioids, magnesium, general anesthesia) or severe HIE. Lethargy appearing after the 2nd day should suggest infection or an inborn error of metabolism
manifesting with hyperammonemia, acidosis, or hypoglycemia. Lethargy with emesis suggests increased intracranial pressure or an inborn error of metabolism. **Irritability** may be a sign of discomfort accompanying intraabdominal conditions, meningeal irritation, drug withdrawal, infections, congenital glaucoma, trauma (birth, abuse), or any condition producing pain. It must be distinguished from normal crying behavior associated with hunger or benign environmental stimuli. **Hyperactivity**, especially in a premature infant, may be a sign of hypoxia, pneumothorax, emphysema, hypoglycemia, hypocalcemia, CNS damage, drug withdrawal, neonatal thyrotoxicosis, bronchospasm, esophageal reflux, or discomfort from a cold environment.

**Failure to feed** is an important sign of the sick newborn infants and should prompt a careful search for infection, a CNS (brain or spine) or peripheral nervous system disorder, inborn error of metabolism, intestinal obstruction, and other abnormal conditions.

**Apnea**

Periods of apnea, particularly in premature infants, can be attributed to many different underlying causes (see Chapter 122.2). When apnea recurs, or when the intervals are >20 sec or associated with cyanosis or bradycardia, an immediate diagnostic evaluation for the underlying cause is imperative.

**Congenital Anomalies**

Congenital anomalies are a major cause of stillbirths and in the United States and other developed countries are one of the main causes of neonatal mortality. In addition, congenital anomalies are a major cause of acute illness and long-term morbidity. Anomalies are discussed in general in Chapters 98 and 128 and specifically in the chapters on the various systems of the body. Early recognition of anomalies during fetal life is important to plan for delivery room management and subsequent neonatal care. Some malformations, including congenital heart disease, tracheoesophageal fistula, diaphragmatic hernia, choanal atresia, and intestinal obstruction, require immediate medical/surgical therapy for postnatal survival (Table 119.1). Parents are likely to feel anxious and guilty on learning of the existence of a congenital anomaly and require thoughtful, sensitive counseling.

Cyanosis

Central cyanosis generates a broad differential diagnosis encompassing respiratory, cardiac, CNS, infectious, hematologic, and metabolic etiologies (Table 119.2). Typically, 5 g/dL of deoxyhemoglobin must be present in the blood for central cyanosis to be clinically apparent. If respiratory insufficiency is caused by pulmonary conditions, respirations tend to be rapid with increased work of breathing. If caused by CNS depression, respirations tend to be irregular and weak and are often slow. Cyanosis unaccompanied by obvious signs of respiratory difficulty suggests cyanotic congenital heart disease or methemoglobinemia. Cyanosis resulting from congenital heart disease may, however, be difficult to distinguish clinically from cyanosis caused by respiratory disease. Episodes of cyanosis may also be the initial sign of hypoglycemia, bacteremia, meningitis, shock, or pulmonary hypertension.

Peripheral acrocyanosis is common in neonates and thought to represent peripheral venous congestion associated with immature control of peripheral vascular tone. It does not usually warrant concern unless poor perfusion is suspected.

Gastrointestinal Disturbances

Vomiting during the 1st day of life can suggest obstruction in the upper digestive tract, metabolic disease, or increased intracranial pressure and must be distinguished from benign reflux. Abdominal distention with emesis, usually a sign of intestinal obstruction or an intraabdominal mass, may also be seen in infants with enteritis, necrotizing enterocolitis (NEC), isolated intestinal perforation, ileus accompanying sepsis, respiratory distress, ascites, or hypokalemia. Imaging studies are indicated when obstruction is suspected; proximal intestinal obstruction often occurs with a normal physical examination, whereas distal obstruction will likely be accompanied by distention. Vomiting may also be a nonspecific symptom of an illness such as septicemia with associated abdominal distention and ileus. It is a common manifestation of overfeeding, inexperienced feeding technique, or normal reflux. Rarely, vomiting is caused by pyloric stenosis, milk allergy, duodenal ulcer, stress ulcer, an inborn error of metabolism (hyperammonemia, metabolic acidosis), or adrenal insufficiency. Vomitus containing dark blood is usually a sign of a serious illness; but the benign possibility of swallowed maternal blood associated with the delivery process should also be considered. Tests for maternal vs fetal hemoglobin can help discriminate between these possibilities. Bilious emesis strongly suggests obstruction below the ampulla of Vater and warrants urgent contrast-enhanced radiography.

Diarrhea may be a symptom of overfeeding (especially high–caloric density formula), acute gastroenteritis, congenital diarrhea syndromes, or malabsorption, or it may be a nonspecific symptom of infection. Diarrhea should be differentiated from the normal loose, seedy, yellow stool seen typically in breastfed infants. Diarrhea may occur in conditions accompanied by compromised circulation of part of the intestinal or genital tract, such as mesenteric thrombosis, NEC, strangulated hernia, intussusception, and torsion of the ovary or testis.

Hypotension
Hypotension in term infants implies hypovolemic shock (hemorrhage, dehydration), a systemic inflammatory response syndrome (bacterial sepsis, intrauterine infection, NEC), cardiac dysfunction (left heart obstructive lesions: hypoplastic left heart syndrome, myocarditis, asphyxia-induced myocardial stunning, anomalous coronary artery), pneumothorax, pneumopericardium, pericardial effusion, or metabolic disorders (hypoglycemia, adrenal insufficiency).

Hypotension is a common problem in sick preterm infants and may also be caused by any of the problems noted in a term infant. Some extremely low gestational age infants do not respond to fluids or inotropic agents but may improve with administration of intravenous hydrocortisone (Fig. 119.1). Sudden onset of hypotension in a very-low-birthweight (VLBW) infant suggests pneumothorax, intraventricular hemorrhage, or subcapsular hepatic hematoma. Strategies used to support blood pressure include volume expansion (normal saline or <5% albumin), vasopressors (dopamine, dobutamine, epinephrine, norepinephrine, vasopressin), or corticosteroids (hydrocortisone) (see Chapter 121).
Jaundice during the 1st 24 hr of life warrants diagnostic evaluation and should be considered pathologic until proved otherwise. Septicemia and intrauterine or perinatal infections, such as syphilis, cytomegalovirus, and toxoplasmosis, as well as neonatal hemochromatosis, should also be considered, especially in infants with an increase in direct bilirubin value. Immediate evaluation includes obtaining total and direct bilirubin, and confirmation as abnormally elevated indicates albumin level, infant blood type and Coombs status, complete blood cell count (CBC), and reticulocyte count. In the case of Coombs-positive hemolysis, strong consideration should be made to giving intravenous immune globulin (IVIG) if there is no response to intensive phototherapy.

Jaundice beyond the 1st 24 hr may be physiologic or may be caused by a wide range of conditions, including septicemia, hemolytic anemia, galactosemia,
hepatitis, congenital atresia of the bile ducts, inspissated bile syndrome after
erthroblastosis fetalis, syphilis, herpes simplex other congenital infections, or
other conditions (see Chapter 123.3).

**Pain**

Pain in neonates may be unrecognized and/or undertreated. The intensive care of
neonates may involve several painful procedures, including blood sampling
(heelstick, venous or arterial puncture), endotracheal intubation and suctioning,
mechanical ventilation, and insertion of chest tubes and intravascular catheters.

Pain in neonates results in obvious distress and acute physiologic stress
responses, which may have developmental implications for pain in later life.
Moreover, knowing that infants may experience pain contributes to parental
stress.

Pain and discomfort are potentially avoidable problems during the treatment
of sick infants. The most common causes of painful stimuli include circumcision
pain and that associated with phlebotomy for metabolic screening tests. **Oral
sucrose solutions** are well tolerated by most infants and have proven efficacy for
procedural pain. For NICU infants, the most frequently used drugs are
intermittent or continuous doses of opioids (morphine, fentanyl) and
benzodiazepines (midazolam, lorazepam). Although the long-term effects of
opioids and sedatives are not well established, the first concern should be the
treatment and/or prevention of acute pain. Continuous opiate infusions should be
used with caution. Some minor but painful procedures performed in well
neonates can be managed with oral sucrose solutions *(Table 119.3)*.

<tr>
<td><strong>Pain in the Neonate: General Considerations</strong></td>
</tr>
</tbody>
</table>

- Pain in newborns is often unrecognized and/or undertreated.
- If a procedure is painful in adults, it should be considered painful in newborns.
- Healthcare institutions should develop and implement patient care policies to assess, prevent, and manage pain in neonates.
- Pharmacologic agents with known pharmacokinetic and pharmacodynamic properties and demonstrated efficacy in neonates should be used. Agents known to compromise cardiorespiratory function should be administered only by persons experienced in neonatal airway management and in settings with the capacity for continuous monitoring.
- Educational programs to increase the skills of healthcare professionals in the assessment and management of stress and pain in neonates should be provided.
- Further research is needed to develop and validate neonatal pain assessment tools that are useful in the clinical
setting; to determine optimal behavioral and pharmacologic interventions; and to study long-term effects of pain and pain management.

119.1

Hyperthermia

Elizabeth Enlow, James M. Greenberg

Serious infection (pneumonia, bacteremia, meningitis, and viral infections, particularly herpes simplex or enteroviruses) may cause fever and must be considered, although such infections often occur without provoking a febrile response in newborn infants (see Chapters 201 and 202). Providers should consider evaluation for bacterial infection in infants <28 days old with a rectal temperature ≥38°C (100.5°F), including blood culture, urine culture, and lumbar puncture (LP), although stepwise approaches to identify low-risk patients and limiting LP to a subset of higher-risk infants are gaining favor. Fever immediately after birth may be caused by radiant warmers, maternal fever, or maternal epidural analgesia. Fever may also be caused by elevated environmental temperatures because of weather, overheated nurseries, incubators, or radiant warmers, or excessive clothing. It has also been attributed to dehydration, although dehydration fever is a diagnosis of exclusion in newborn infants.

### 119.2 Hypothermia and Cold Stress

*Elizabeth Enlow, James M. Greenberg*

Unexplained **hypothermia** may accompany infection or other serious disturbances of the circulation or CNS. A sudden servo-controlled increase in incubator ambient temperature to maintain body temperature is a sign of temperature instability and may be associated with sepsis or any of the conditions already mentioned.

**Cold stress** can lead to profound decompensation, including apnea, bradycardia, respiratory distress, hypoglycemia, and poor feeding. For this reason, it is paramount for the neonate to maintain normothermia in the delivery room and afterward, especially low-birthweight and premature infants. For VLBW infants, a combination of occlusive plastic wrap, radiant warmers, and thermal mattresses to maintain normothermia can be used to reduce cold stress.

**Bibliography**

### 119.3 Edema
Generalized edema in a neonate can be caused by hydrops fetalis secondary to several underlying causes (see Chapter 124.2), excessive fluid administration, respiratory disease, sepsis, NEC, and hepatic, renal, or cardiac dysfunction. An infant with suspected hydrops in utero should be delivered at a specialty perinatal center with capacity for neonatal intubation, thoracentesis, paracentesis, and pericardiocentesis in the delivery room.

**Bibliography**

**119.4**

**Hypocalcemia**

Hypocalcemia in a neonate can manifest as irritability, jitteriness, clonus, or seizures. Electrocardiography can show a prolonged QT interval. The cause may simply represent an exaggerated physiologic decrease in serum calcium levels.
within the 1st 24 hr of life or pathologic conditions such as genetic disorders (22q deletions), prematurity, growth restriction, perinatal hypoxia, hypomagnesemia, or maternal diabetes. Hypocalcemia is more common in term infants receiving formula than in those exclusively receiving breast milk. Most infants remain asymptomatic and can be managed conservatively with early nutrition and close monitoring, whereas symptomatic neonates should receive IV or oral calcium replacement.

Bibliography

119.5

Hypermagnesemia

Elizabeth Enlow, James M. Greenberg

Hypermagnesemia is most often caused by maternal administration of magnesium in the perinatal period for treatment of conditions such as preeclampsia and preterm labor, and as prophylaxis to mitigate brain injury associated with preterm birth. Infants are usually present with signs at birth and improve over the next 24-48 hr. Symptoms include respiratory depression, hypotonia, lethargy, and feeding intolerance. No treatment is indicated other than supportive measures.

Stevens B, Yamada J, Ohlsson A. Sucrose for analgesia in newborn infants undergoing painful procedures. Cochrane Database Syst Rev. 2010;(1) [CD001069].

Central nervous system (CNS) disorders are important causes of neonatal mortality and both short-term and long-term morbidity. The CNS can be injured as a result of asphyxia, hemorrhage, trauma, hypoglycemia, or direct cytotoxicity. The etiology of CNS injury is often multifactorial and includes perinatal complications, postnatal hemodynamic instability, and developmental abnormalities that may be genetic and/or environmental. Predisposing factors for brain injury include chronic and acute maternal illness resulting in uteroplacental dysfunction, intrauterine infection, macrosomia/dystocia, malpresentation, prematurity, and intrauterine growth restriction. Acute and often unavoidable emergencies during the delivery process may result in mechanical and hypoxic-ischemic brain injury.

120.1
The Cranium

Erythema, abrasions, ecchymoses, and subcutaneous fat necrosis of facial or scalp soft tissues may be noted after a normal delivery or after forceps or vacuum-assisted deliveries. The location depends on the area of contact with the pelvic bones or application of the forceps. Traumatic hemorrhage may involve
any layer of the scalp as well as intracranial contents (Fig. 120.1).

**FIG. 120.1** Sites of extracranial (and extradural) hemorrhages in the newborn. Schematic diagram of important tissue planes from skin to dura. (From Volpe JJ: Injuries of extracranial, cranial, intracranial, spinal cord, and peripheral nervous system structures. In Volpe’s neurology of the newborn, ed 6, Philadelphia, 2018, Elsevier, Fig 36-1.)

**Caput succedaneum** is a diffuse, sometimes ecchymotic, edematous swelling of the soft tissues of the scalp involving the area presenting during vertex delivery. It may extend across the midline and across suture lines. The edema disappears within the 1st few days of life. Molding of the head and overriding of the parietal bones are frequently associated with caput succedaneum and become more evident after the caput has receded; they disappear during the 1st few weeks of life. Rarely, a hemorrhagic caput may result in shock and require blood transfusion. Analogous swelling, discoloration, and distortion of the face are seen in face presentations. No specific treatment is needed, but if extensive
ecchymoses are present, hyperbilirubinemia may develop.  

**Cephalohematoma** is a subperiosteal hemorrhage and thus always limited to the *surface* of one cranial bone (Fig. 120.2). Cephalohematomas occur in 1–2% of live births. No discoloration of the overlying scalp occurs, and swelling is not usually visible for several hours after birth because subperiosteal bleeding is a slow process. The lesion becomes a firm, tense mass with a palpable rim localized over one area of the skull. Most cephalohematomas are resorbed within 2 wk to 3 mo, depending on their size. They may begin to calcify by the end of the 2nd wk. A few remain for years as bony protuberances and are detectable on radiographs as widening of the diploic space; cystlike defects may persist for months or years. An underlying skull fracture, usually linear and not depressed, may be associated with 10–25% of cases. A sensation of central depression suggesting but not indicative of an underlying fracture or bony defect is usually encountered on palpation of the organized rim of a cephalohematoma. Cephalohematomas require no treatment, although phototherapy may be necessary to treat hyperbilirubinemia. Infection of the hematoma is a very rare complication.
A subgaleal hemorrhage is a collection of blood beneath the aponeurosis that covers the scalp and serves as the insertion for the occipitofrontalis muscle (see Fig. 120.1). Bleeding can be very extensive into this large potential space and may even dissect into subcutaneous tissues of the neck. There is often an association with vacuum-assisted delivery. The mechanism of injury is most likely secondary to rupture of emissary veins connecting the dural sinuses within the skull and the superficial veins of the scalp. Subgaleal hemorrhages are sometimes associated with skull fractures, suture diastasis, and fragmentation of
the superior margin of the parietal bone. Extensive subgaleal bleeding is occasionally secondary to a hereditary coagulopathy (hemophilia). A subgaleal hemorrhage manifests as a fluctuant mass that straddles cranial sutures or fontanels that increases in size after birth. Some patients have a consumptive coagulopathy from massive blood loss. Patients should be monitored for hypotension, anemia, and hyperbilirubinemia. These lesions typically resolve over 2-3 wk.

**Fractures of the skull** may be caused by pressure from forceps or the maternal pelvis or by accidental falls after birth. *Linear fractures*, the most common, cause no symptoms and require no treatment. Linear fractures should be followed up to demonstrate healing and to detect the possible complication of a leptomeningeal cyst. *Depressed fractures* indent the calvaria similar to dents in a Ping-Pong ball. They are generally a complication of forceps delivery or fetal compression. Affected infants may be asymptomatic unless they have associated intracranial injury; it is advisable to elevate severe depressions to prevent cortical injury from sustained pressure. Although some may elevate spontaneously, some require treatment. Use of a breast pump or vacuum extractor may obviate the need for neurosurgical intervention. Suspected skull fractures should be evaluated with CT (3D reconstruction may be helpful) to confirm fracture and rule out associated intracranial injury.

**Subconjunctival** and **retinal hemorrhages** are frequent; petechiae of the skin of the head and neck are also common. All are probably secondary to a sudden increase in intrathoracic pressure during passage of the chest through the birth canal. Parents should be assured that these hemorrhages are temporary and the result of normal events of delivery. The lesions resolve rapidly within the 1st 2 wk of life.

# 120.2

**Traumatic, Epidural, Subdural, and Subarachnoid Hemorrhage**

*Stephanie L. Merhar, Cameron W. Thomas*
Traumatic epidural, subdural, or subarachnoid hemorrhage is especially likely when the fetal head is large in proportion to the size of the mother's pelvic outlet, with prolonged labor, in breech or precipitous deliveries, or as a result of mechanical assistance with delivery. Massive subdural hemorrhage, often associated with tears in the tentorium cerebelli or less frequently in the falx cerebri, is rare but is encountered more often in full-term than in premature infants. Patients with massive hemorrhage caused by tears of the tentorium or falx cerebri rapidly deteriorate and may die soon after birth. Most subdural and epidural hemorrhages resolve without intervention. Consultation with a neurosurgeon is recommended. Asymptomatic subdural hemorrhage may be noted within 48 hr of birth after vaginal or cesarean delivery. These are typically small hemorrhages, especially common in the posterior fossa, discovered incidentally in term infants imaged in the neonatal period and usually of no clinical significance. The diagnosis of large subdural hemorrhage may be delayed until the chronic subdural fluid volume expands and produces macrocephaly, frontal bossing, a bulging fontanel, anemia, and sometimes seizures. CT scan and MRI are useful imaging techniques to confirm these diagnoses. Symptomatic subdural hemorrhage in term infants can be treated by a neurosurgical evacuation of the subdural fluid collection by a needle placed through the lateral margin of the anterior fontanel. In addition to birth trauma, child abuse must be suspected in all infants with subdural effusion after the immediate neonatal period. Most asymptomatic subdural hemorrhages following labor should resolve by 4 wk of age.

Subarachnoid hemorrhage is often clinically silent in the neonate. Anastomoses between the penetrating leptomeningeal arteries or the bridging veins are the most likely source of the bleeding. Most affected infants have no clinical symptoms, but the subarachnoid hemorrhage may be detected because of an elevated number of red blood cells in a lumbar puncture sample. Some infants experience short, benign seizures, which tend to occur on the 2nd day of life. Rarely, an infant has a catastrophic hemorrhage and dies. There are usually no neurologic abnormalities during the acute episode or on follow-up. Significant neurologic findings should suggest an arteriovenous malformation, which can best be detected on CT or MRI.
Intracranial-Intraventricular Hemorrhage and Periventricular Leukomalacia

Stephanie L. Merhar, Cameron W. Thomas

Etiology

Intracranial hemorrhage in preterm infants usually develops spontaneously. Less frequently, it may be caused by trauma or asphyxia, and rarely, it occurs from a primary hemorrhagic disturbance or congenital cerebrovascular anomaly. Intracranial hemorrhage often involves the ventricles (intraventricular hemorrhage, IVH) of premature infants delivered spontaneously without apparent trauma. The IVH in premature infants is usually not present at birth but may develop during the 1st week of life. Primary hemorrhagic disturbances and vascular malformations are rare and usually give rise to subarachnoid or intracerebral hemorrhage. In utero hemorrhage associated with maternal idiopathic or, more often, fetal alloimmune thrombocytopenia may appear as severe cerebral hemorrhage or as a porencephalic cyst after resolution of a fetal cortical hemorrhage. Intracranial bleeding may be associated with disseminated intravascular coagulation, isoimmune thrombocytopenia, and neonatal vitamin K deficiency, especially in infants born to mothers receiving phenobarbital or phenytoin.

Epidemiology

The overall incidence of IVH has decreased over the past decades as a result of improved perinatal care, increased use of antenatal corticosteroids, surfactant to treat respiratory distress syndrome (RDS), and possibly prophylactic indomethacin. It continues to be an important cause of morbidity in preterm infants, as approximately 30% of premature infants <1,500 g have IVH. The risk
is inversely related to gestational age and birthweight; 7% of infants weighing 1,001-1,500 g have a severe IVH (grade III or IV), compared to 14% of infants weighing 751-1,000 g and 24% of infants ≤750 g. In 3% of infants <1,000 g, periventricular leukomalacia (PVL) develops.

Pathogenesis

The major neuropathologic lesions associated with very-low-birthweight (VLBW) infants are IVH and PVL. IVH in premature infants occurs in the gelatinous subependymal germinal matrix. This periventricular area is the site of origin for embryonal neurons and fetal glial cells, which migrate outwardly to the cortex. Immature blood vessels in this highly vascular region of the developing brain combined with poor tissue vascular support predispose premature infants to hemorrhage. The germinal matrix involutes as the infant approaches full-term gestation, and the tissue's vascular integrity improves; therefore IVH is much less common in the term infant. The cerebellum also contains a germinal matrix and is susceptible to hemorrhagic injury. Periventricular hemorrhagic infarction, previously known as grade IV intraventricular hemorrhage, often develops after a large IVH because of venous congestion. Predisposing factors for IVH include prematurity, RDS, hypoxia-ischemia, exaggerated fluctuations in cerebral blood flow (hypotensive injury, hypervolemia, hypertension), reperfusion injury of damaged vessels, reduced vascular integrity, increased venous pressure (pneumothorax, venous thrombus), or thrombocytopenia.

Understanding of the pathogenesis of PVL is evolving, and it appears to involve both intrauterine and postnatal events. A complex interaction exists between the development of the cerebral vasculature and the regulation of cerebral blood flow (both of which depend on gestational age), disturbances in the oligodendrocyte precursors required for myelination, and maternal/fetal infection and inflammation. Postnatal hypoxia or hypotension, necrotizing enterocolitis (NEC) with its resultant inflammation, and severe neonatal infection may all result in white matter injury. PVL is characterized by focal necrotic lesions in the periventricular white matter and/or more diffuse white matter damage. Destructive focal necrotic lesions resulting from massive cell death are less common in the modern era. Instead, diffuse injury leading to abnormal maturation of neurons and glia is more frequently seen. The risk for PVL increases in infants with severe IVH or ventriculomegaly. Infants with PVL
are at higher risk of cerebral palsy because of injury to the corticospinal tracts that descend through the periventricular white matter.

**Clinical Manifestations**

Most infants with IVH, including some with moderate to severe hemorrhages, have no initial clinical signs (silent IVH). Some premature infants in whom severe IVH develops may have acute deterioration on the 2nd or 3rd day of life (catastrophic presentation). Hypotension, apnea, pallor, stupor or coma, seizures, decreased muscle tone, metabolic acidosis, shock, and decreased hematocrit (or failure of hematocrit to increase after transfusion) may be the first clinical indications. A saltatory progression may evolve over several hours to days and manifest as intermittent or progressive alterations of levels of consciousness, abnormalities of tone and movement, respiratory signs, and eventually other features of the acute catastrophic IVH. Rarely, IVH may manifest at birth or even prenatally; 50% of cases are diagnosed within the 1st day of life, and up to 75% within the 1st 3 days. A small percentage of infants have late hemorrhage, between days 14 and 30. IVH as a primary event is rare after the 1st mo of life.

**PVL** is usually clinically asymptomatic until the neurologic sequelae of white matter damage become apparent in later infancy as spasticity and/or motor deficits. PVL may be present at birth but usually occurs later, when the echodense phase is seen on ultrasound (3-10 days of life), followed by the typical echolucent/cystic phase (14-20 days).

The severity of hemorrhage is defined by the location and degree of bleeding and ventricular dilation on cranial imaging. In a **grade I** hemorrhage, bleeding is isolated to the subependymal area. In **grade II** hemorrhage, there is bleeding within the ventricle without evidence of ventricular dilation. **Grade III** hemorrhage is IVH with ventricular dilation. In **grade IV** hemorrhage, there is intraventricular and parenchymal hemorrhage (Fig. 120.3 ). Another grading system describes 3 levels of increasing severity of IVH detected on ultrasound: In **grade I**, bleeding is confined to the germinal matrix–subependymal region or to <10% of the ventricle (approximately 35% of IVH cases); **grade II** is defined as intraventricular bleeding with 10–50% filling of the ventricle (40% of IVH cases); and in **grade III**, >50% of the ventricle is involved, with dilated ventricles (Fig. 120.3 ). **Ventriculomegaly** is defined as mild (0.5-1 cm dilation), moderate (1.0-1.5 cm dilation), or severe (>1.5 cm dilation).
**FIG. 120.3** Grading of the severity of germinal matrix–intraventricular hemorrhage (IVH): coronal (cor) and parasagittal (sag) ultrasound scans. A, Germinal matrix hemorrhage, grade I. B, IVH (filling <50% of ventricular area), grade II. C, IVH with ventricular dilatation, grade III. D, Large IVH with associated parenchymal echogenicity (hemorrhagic infarct), grade IV. (From Inder TE, Perlman JM, Volpe JJ: Preterm intraventricular hemorrhage/posthemorrhagic hydrocephalus. In Volpe's neurology of the newborn, ed 6, Philadelphia, 2018, Elsevier, Fig 24-2.)

**Diagnosis**

Intracranial hemorrhage is suspected on the basis of history, clinical manifestations, and knowledge of the birthweight-specific risks for IVH. Associated clinical signs of IVH are typically nonspecific or absent; therefore, it is recommended that premature infants <32 wk of gestation be evaluated with
routine real-time cranial ultrasonography (US) through the anterior fontanel to screen for IVH. Infants <1,000 g are at highest risk and should undergo cranial US within the 1st 3-7 days of age, when approximately 75% of lesions will be detectable. US is the preferred imaging technique for screening because it is noninvasive, portable, reproducible, and sensitive and specific for detection of IVH. All at-risk infants should undergo follow-up US at 36-40 wk postmenstrual age to evaluate adequately for PVL, as cystic changes related to perinatal injury may not be visible for up to 1 mo. In one study, 29% of low-birthweight (LBW) infants who later experienced cerebral palsy did not have radiographic evidence of PVL until after 28 days of age. US also detects the precystic and cystic symmetric lesions of PVL and the asymmetric intraparenchymal echogenic lesions of cortical hemorrhagic infarction (Fig. 120.4). Cranial US may be useful in monitoring delayed development of cortical atrophy, porencephaly, and the severity, progression, or regression of posthemorrhagic hydrocephalus.

![FIG. 120.4](image) Severe cystic periventricular leukomalacia. A, Parasagittal ultrasound image showing numerous large cysts superolateral to the lateral ventricle (arrow). B, Coronal T2-weighted MR image in which cysts are present superolateral to the lateral ventricles (arrow). (From Neil JJ, Volpe JJ: Encephalopathy of prematurity: clinical-neurological features, diagnosis, imaging, prognosis, therapy. In Volpe's neurology of the newborn, ed 6, Philadelphia, 2018, Elsevier, Fig 16-1.)

Approximately 3–5% of VLBW infants develop posthemorrhagic hydrocephalus (PHH). If the initial US findings are abnormal, additional interval US studies are indicated to monitor for the development of hydrocephalus and potential need for ventriculoperitoneal shunt insertion.

IVH represents only 1 facet of brain injury in the term or preterm infant. MRI is a more sensitive tool for evaluation of white matter abnormalities and
cerebellar injury and may be more predictive of adverse long-term outcome.

**Prognosis**

The degree of **IVH** and presence of **PVL** are strongly linked to survival and neurodevelopmental impairment (Tables 120.1 and 120.2). For infants with birthweight <1,000 g, the incidence of severe neurologic impairment (defined as Bayley Scales of Infant Development II mental developmental index <70, psychomotor development index <70, cerebral palsy, blindness, or deafness) after IVH is highest with grade IV hemorrhage and lower birthweight. PVL, cystic PVL, and progressive hydrocephalus requiring shunt insertion are each independently associated with a poorer prognosis (Table 120.3). Current data suggest that outcomes for infants with grade III/IV intraventricular hemorrhage may be improving, with rates of cerebral palsy and neurodevelopmental impairment closer to 30–40% at age 2 yr.

Most infants with IVH and acute ventricular distention do not have PHH. Only 10–15% of LBW neonates with IVH develop PHH, which may initially present without clinical signs (enlarging head circumference, lethargy, a bulging fontanel or widely split sutures, apnea, and bradycardia). In infants in whom symptomatic hydrocephalus develops, clinical signs may be delayed 2-4 wk despite progressive ventricular distention and compression and thinning of the cerebral cortex. Many infants with PHH have spontaneous regression; only 3–5% of VLBW infants with PHH ultimately require shunt insertion. Those infants
who require shunt insertion for PHH have lower cognitive and psychomotor performance at 18-22 mo.

**Prevention**

Improved perinatal care is imperative to minimize traumatic brain injury and decrease the risk of preterm delivery. The incidence of traumatic intracranial hemorrhage may be reduced by judicious management of cephalopelvic disproportion and operative (forceps, vacuum) delivery. Fetal or neonatal hemorrhage caused by maternal idiopathic thrombocytopenic purpura or alloimmune thrombocytopenia may be reduced by maternal treatment with corticosteroids, intravenous immune globulin (IVIG), fetal platelet transfusion, or cesarean birth. Meticulous care of the LBW infant's respiratory status and fluid-electrolyte management—avoidance of acidosis, hypocarbia, hypoxia, hypotension, wide fluctuations in neonatal blood pressure or $\text{PCO}_2$ (and secondarily fluctuation in cerebral perfusion pressure), and pneumothorax—are important factors that may affect the risk for development of IVH and PVL.

A single course of antenatal corticosteroids is recommended in pregnancies 24-37 wk of gestation that are at risk for preterm delivery. Antenatal steroids decrease the risk of death, grades III and IV intraventricular hemorrhage, and PVL in the neonate. The prophylactic administration of low-dose indomethacin (0.1 mg/kg/day for 3 days) to VLBW preterm infants reduces the incidence of severe IVH.

**Treatment**

Although no treatment is available for IVH that has occurred, it may be associated with other complications that require therapy. Seizures should be treated with anticonvulsant drugs. Anemia and coagulopathy require transfusion with packed red blood cells or fresh-frozen plasma. Shock and acidosis are treated with fluid resuscitation.

Insertion of a ventriculoperitoneal shunt is the preferred method to treat progressive and symptomatic PHH. Some infants require temporary cerebrospinal fluid diversion before a permanent shunt can be safely inserted. Diuretics and acetazolamide are not effective. Ventricular taps or reservoirs and externalized ventricular drains are potential temporizing interventions, although
there is an associated risk of infection and puncture porencephaly from injury to the surrounding parenchyma. A ventriculossubgaleal shunt inserted from the ventricle into a surgically created subgaleal pocket provides a closed system for constant ventricular decompression without these additional risk factors. Decompression is regulated by the pressure gradient between the ventricle and the subgaleal pocket.

Hypoxic-Ischemic Encephalopathy

Cameron W. Thomas, Stephanie L. Merhar

Hypoxemia, a decreased arterial concentration of oxygen, frequently results in hypoxia, or decreased oxygenation to cells or organs. Ischemia refers to blood flow to cells or organs that is inadequate to maintain physiologic function. Hypoxic-ischemic encephalopathy (HIE) is a leading cause of neonatal brain injury, morbidity, and mortality globally. In the developed world, incidence is estimated at 1-8 per 1,000 live births, and in the developing world, estimates are as high as 26 per 1,000.

Approximately 20–30% of infants with HIE (depending on the severity) die in the neonatal period, and 33–50% of survivors are left with permanent neurodevelopmental abnormalities (cerebral palsy, decreased IQ, learning/cognitive impairment). The greatest risk of adverse outcome is seen in
infants with severe fetal acidosis (pH <6.7) (90% death/impairment) and a base deficit >25 mmol/L (72% mortality). Multiorgan failure and insult can occur (Table 120.4).

**Etiology**

Most neonatal encephalopathy and seizure, in the absence of major congenital malformations or metabolic or genetic syndromes, appear to be caused by perinatal events. Brain MRI or autopsy findings in full-term neonates with encephalopathy demonstrate that 80% have acute injuries, <1% have prenatal injuries, and 3% have non–hypoxic-ischemic diagnoses. Fetal hypoxia may be caused by various disorders in the mother, including: (1) inadequate oxygenation of maternal blood from hypoventilation during anesthesia, cyanotic heart disease, respiratory failure, or carbon monoxide poisoning; (2) low maternal blood pressure from acute blood loss, spinal anesthesia, or compression of the vena cava and aorta by the gravid uterus; (3) inadequate relaxation of the uterus to permit placental filling as a result of uterine tetany caused by the administration of excessive oxytocin; (4) premature separation of the placenta; (5) impedance to the circulation of blood through the umbilical cord as a result of compression or knotting of the cord; and (6) placental insufficiency from maternal infections, exposures, diabetes, toxemia or postmaturity.

Placental insufficiency often remains undetected on clinical assessment. Intrauterine growth restriction may develop in chronically hypoxic fetuses.
without the traditional signs of fetal distress. Doppler umbilical waveform velocimetry (demonstrating increased fetal vascular resistance) and cordocentesis (demonstrating fetal hypoxia and lactic acidosis) identify a chronically hypoxic infant (see Chapter 115). Uterine contractions may further reduce umbilical oxygenation, depressing the fetal cardiovascular system and CNS and resulting in low Apgar scores and respiratory depression at birth.

After birth, hypoxia may be caused by (1) failure of oxygenation as a result of severe forms of cyanotic congenital heart disease or severe pulmonary disease; (2) severe anemia (severe hemorrhage, hemolytic disease); (3) shock severe enough to interfere with the transport of oxygen to vital organs from overwhelming sepsis, massive blood loss, and intracranial or adrenal hemorrhage; or (4) failure to breathe after birth because of in utero CNS injury or drug-induced suppression.

Pathophysiolozy and Pathology

The topography of cerebral injury typically correlates with areas of decreased cerebral blood flow and areas of relatively higher metabolic demand, although regional vulnerabilities are impacted by gestational age and severity of insult (Table 120.5). After an episode of hypoxia and ischemia, anaerobic metabolism occurs and generates increased amounts of lactate and inorganic phosphates. Excitatory and toxic amino acids, particularly glutamate, accumulate in the damaged tissue prompting overactivation of N-methyl-D-aspartate (NMDA), amino-3-hydroxy-5-methyl-4-isoxazole propionate (AMPA), and kainate receptors. This receptor overactivation increases cellular permeability to sodium and calcium ions. Because of inadequate intracellular energy, normal sodium and calcium homeostasis is lost, and intracellular accumulation of these ions results in cytotoxic edema and neuronal death. Intracellular calcium accumulation may also result in apoptotic cell death. Concurrent with the excitotoxic cascade, there is also increased production of damaging free radicals and nitric oxide in these tissues. The initial circulatory response of the fetus is increased shunting through the ductus venosus, ductus arteriosus, and foramen ovale, with transient maintenance of perfusion of the brain, heart, and adrenals in preference to the lungs, liver, kidneys, and intestine. Thus, serum laboratory evidence of injury to these organs may be present in more severe cases.

</table>

The pathology of hypoxia-ischemia outside the CNS depends on the affected organ and the severity of the injury. Early congestion, fluid leak from increased capillary permeability, and endothelial cell swelling may lead to signs of coagulation necrosis and cell death. Congestion and petechiae are seen in the pericardium, pleura, thymus, heart, adrenals, and meninges. Prolonged intrauterine hypoxia may result in inadequate perfusion of the periventricular white matter, resulting in PVL. Pulmonary arteriole smooth muscle hyperplasia may develop, which predisposes the infant to pulmonary hypertension (see Chapter 122.9). If fetal distress produces gasping, amniotic fluid contents (meconium, squames, lanugo) may be aspirated into the trachea or lungs with subsequent complications, including pulmonary hypertension and pneumothoraces.

**Clinical Manifestations**

Intrauterine growth restriction with increased vascular resistance may be an
indication of chronic fetal hypoxia before the peripartum period. During labor, the fetal heart rate slows and beat-to-beat variability declines. Continuous heart rate recording may reveal a variable or late deceleration pattern (see Chapter 115, Fig. 115.4). Particularly in infants near term, these signs should lead to the administration of high concentrations of oxygen to the mother and consideration of immediate delivery to avoid fetal death and CNS damage.

At delivery, the presence of meconium-stained amniotic fluid indicates that fetal distress may have occurred. At birth, affected infants may have neurologic impairment and may fail to breathe spontaneously. Pallor, cyanosis, apnea, a slow heart rate, and unresponsiveness to stimulation are also nonspecific initial signs of potential HIE. During the ensuing hours, infants may be hypotonic, may change from a hypotonic to a hypertonic state, or their tone may appear normal (Tables 120.6 and 120.7). Cerebral edema may develop during the next 24 hr and result in profound brainstem depression. During this time, seizure activity may occur; it may be severe and refractory to typical doses of anticonvulsants. Although most often a result of the HIE, seizures in asphyxiated newborns may also be caused by vascular events (hemorrhage, arterial ischemic stroke, or sinus venous thrombosis), metabolic derangements (hypocalcemia, hypoglycemia), CNS infection, and cerebral dysgenesis or genetic disorders (nonketotic hyperglycinemia, vitamin-dependent epilepsies, channelopathies). Conditions that result in neuromuscular weakness and poor respiratory effort may also result secondarily in neonatal hypoxic brain injury and seizure. Such conditions might include congenital myopathies, congenital myotonic dystrophy, or spinal muscular atrophy.

In addition to CNS dysfunction, systemic organ dysfunction is noted in up to 80% of affected neonates. Myocardial dysfunction and cardiogenic shock, persistent pulmonary hypertension, RDS, gastrointestinal perforation, and acute kidney and liver injury are associated with perinatal asphyxia secondary to inadequate perfusion (see Table 120.4).

The severity of neonatal encephalopathy depends on the duration and timing of injury. A clinical grading score first proposed by Sarnat continues to be a useful tool. Symptoms develop over days, making it important to perform serial neurologic examinations (see Tables 120.6 and 120.7). During the initial hours after an insult, infants have a depressed level of consciousness. Periodic breathing with apnea or bradycardia is present, but cranial nerve functions are often spared, with intact pupillary response and spontaneous eye movement. Seizures are common with extensive injury. Hypotonia is also common as an early manifestation of HIE, but it should be distinguished from other causes by history and serial examination.

**Diagnosis**

MRI is the most sensitive imaging modality for detecting hypoxic brain injury in
the neonate. Although such injury can be detected at various times and with varying pulse sequences, diffusion-weighted sequences obtained in the 1st 3-5 days following a presumed sentinel event are optimal for identifying acute injury. (Figs. 120.5 to 120.8 and Table 120.8). Where MRI is unavailable or prevented by clinical instability, CT scans may be helpful in ruling out focal hemorrhagic lesions or large arterial ischemic strokes. Loss of gray-white differentiation and injury to the basal ganglia in more severe HIE can be detected on CT by experienced readers, but CT often misses subtler forms of neonatal hypoxic brain injury. US has limited utility in evaluation of hypoxic injury in the term infant, but it too can be useful for excluding hemorrhagic lesions. Because of factors of size and clinical stability, US is the initial preferred (and sometimes only feasible) modality in evaluation of the preterm infant.

**FIG. 120.5** MR images of selective neuronal injury. The infant experienced intrapartum asphyxia and had seizures on the 1st postnatal day. MRI was performed on the 5th postnatal day. A, Axial, fluid-attenuated, inversion recovery image shows increased signal in the putamen bilaterally (arrows) but no definite abnormality in the cerebral cortex. B, By contrast, a diffusion-weighted image shows striking increased signal intensity (i.e., decreased diffusion) in the frontal cortex (in addition to a more pronounced basal ganglia abnormality). (From Volpe JJ, editor: Neurology of the newborn, ed 5, Philadelphia, 2008, Saunders/Elsevier, p 420.)
FIG. 120.6  MR images of basal ganglia/thalamic (BG/T) injury and signal intensity. Top row, Axial T1-weighted MR images showing A, mild BG/T lesions (arrow); B, moderate BG/T injury (arrows); and C, severe BG/T abnormalities (circled). Bottom row, Axial T1-weighted MR images showing A, normal signal intensity (SI) in the posterior limb of the internal capsule (PLIC) (arrow); B, equivocal, asymmetric, and slightly reduced SI in the PLIC (arrow); and C, abnormal, absent SI in the PLIC (arrow). (From Martinez-Biarge M, Diez-Sebastian J, Rutherford MA, Cowan FM. Outcomes after central grey matter injury in term perinatal hypoxic-ischaemic encephalopathy, Early Hum Dev 86:675–682, 2010.)
FIG. 120.7  MR image of a parasagittal cerebral injury. Coronal T1-weighted image, obtained on the 5th postnatal day in an asphyxiated term infant, shows striking triangular lesions in the parasagittal areas bilaterally; increased signal intensity is also apparent in the basal ganglia and thalamus bilaterally. (From Volpe JJ, editor: Neurology of the newborn, ed 5, Philadelphia, 2008, Saunders/Elsevier, p 421.)
FIG. 120.8 MR images of focal ischemic cerebral injury. MRI was performed on the 3rd postnatal day. A, Axial T2-weighted mage shows a lesion in the distribution of the main branch of the left middle cerebral artery. B, Diffusion-weighted image demonstrates the lesion more strikingly. (From Volpe JJ, editor: Neurology of the newborn, ed 5, Philadelphia, 2008, Saunders/Elsevier, p 422.)

Amplitude-integrated electroencephalography (aEEG) may help to determine which infants are at highest risk for developmental sequelae of neonatal brain injury (Tables 120.9 and 120.10). The aEEG background voltage
ranges, signal patterns, and rates of normalization, as assessed at various points in the 1st hours and days of life, can provide valuable prognostic information, with positive predictive value of 85% and negative predictive value of 91–96% for infants who will have adverse neurodevelopmental outcome. Unfortunately, even with recent improvements in technology, aEEG still has difficulty detecting seizures, particularly those that are brief or originate far from the electrodes. Sensitivity of aEEG for seizure detection, when used by a typical reader, is <50%. For this reason, conventional EEG montage with concurrent video of the patient are preferred for seizure monitoring.

* Associations with favorable or unfavorable outcome are generally ≥90%, but the clinical context must be considered.
Treatment

**Therapeutic hypothermia**, whether head cooling or systemic cooling (by servo-control to a core rectal or esophageal temperature of 33.5°C [92.3°F] within the 1st 6 hr after birth and maintained for 72 hr), has been shown in various trials to reduce mortality and major neurodevelopmental impairment at 18 mo of age. Infants treated with systemic hypothermia have a lower incidence of cortical neuronal injury on MRI, suggesting systemic hypothermia may result in more uniform cooling of the brain and deeper CNS structures than selective head cooling. The therapeutic effect of hypothermia likely results from decreased secondary neuronal injury achieved by reducing rates of apoptosis and production of mediators known to be neurotoxic, including extracellular glutamate, free radicals, nitric oxide, and lactate. There is also benefit in seizure reduction. The therapeutic benefit of hypothermia noted at 18-22 mo of age is maintained later in childhood. Once established, hypothermia may not alter the prognostic findings on MRI.

Numerous studies seeking ways to extend the benefits of therapeutic hypothermia have been attempted. Assessment of deeper or longer cooling failed to show benefit in short-term outcomes, although longer-term developmental outcomes of that trial are not yet published. Investigations into extending the therapeutic time window of hypothermia initiation beyond 6 hr or offering hypothermia to preterm infants are ongoing.

In addition to extending the benefit of therapeutic hypothermia, there is great interest in augmenting its benefit through other means. High-dose erythropoietin given as an adjunct to therapeutic hypothermia shows some promise in decreasing MRI indicators of brain injury and short-term motor outcomes. Further study as well as longitudinal follow-up of the study cohort is warranted to confirm these findings.

Complications of induced hypothermia include thrombocytopenia (usually without bleeding), reduced heart rate, and subcutaneous fat necrosis (sometimes with associated hypercalcemia) as well as the potential for overcooling and the cold injury syndrome. The latter is usually avoided with a servo-controlled cooling system. Therapeutic hypothermia may theoretically alter drug
metabolism, prolong the QT interval, and affect the interpretation of blood gases. In clinical practice, these concerns have not been observed.

For treating seizures associated with HIE, **phenobarbital**, the historical first-line drug for neonatal seizures, continues to be used in many instances. It is typically given by intravenous loading dose (20 mg/kg). Additional doses of 5-10 mg/kg (up to 40-50 mg/kg total) may be needed. Phenobarbital levels should be monitored 24 hr after the loading dose has been given and maintenance therapy (5 mg/kg/24 hr) begun. Therapeutic phenobarbital levels are 20-40 µg/mL. Animal models demonstrate decreased neurodevelopmental impact of hypoxic brain injury in animals that received a high-dose prophylactic injection of phenobarbital before onset of therapeutic hypothermia. Whether this benefit translates to humans is controversial.

For refractory seizures, there is a high degree of variability regarding choice of 2nd agent. Historically, phenytoin (20 mg/kg loading dose) or lorazepam (0.1 mg/kg) have been preferred, currently the use of **levetiracetam** is preferred (at times even as a first-line agent) as the most used second-line agent. Early reports of administration of levetiracetam in the neonate used low doses, but subsequent pharmacokinetic data suggest that due to the higher volume of distribution created by higher relative body water content in neonates, loading doses should be higher than in older children or adults. Suggested appropriate loading doses may be closer to 60 mg/kg. In addition to levetiracetam and phenytoin, other second- or third-line agents commonly used include midazolam, topiramate, and lidocaine. Pyridoxine should also be attempted, particularly in ongoing refractory seizures with highly abnormal EEG background.

Status epilepticus, multifocal seizures, and multiple anticonvulsant medications during therapeutic hypothermia are associated with a poor prognosis.

Additional therapy for infants with HIE includes supportive care directed at management of organ system dysfunction. Hyperthermia has been associated with impaired neurodevelopment and should be prevented, particularly in the interval between initial resuscitation and initiation of hypothermia. Careful attention to ventilatory status and adequate oxygenation, blood pressure, hemodynamic status, acid-base balance, and possible infection is important. Secondary hypoxia or hypotension from complications of HIE must be prevented. Aggressive treatment of seizures is critical and may necessitate continuous EEG monitoring. In addition, hyperoxia, hypocarbia, and hypoglycemia are associated with poor outcomes, so careful attention to
resuscitation, ventilation, and blood glucose homeostasis is essential.

**Prognosis**

The outcome of HIE, which correlates with the timing and severity of the insult, ranges from complete recovery to death. The prognosis varies depending on the severity of the insult and the treatment. Infants with initial cord or initial blood pH <6.7 have a 90% risk for death or severe neurodevelopmental impairment at 18 mo of age. In addition, infants with Apgar scores of 0-3 at 5 min, high base deficit (>20-25 mmol/L), decerebrate posture, severe basal ganglia/thalamic (BG/T) lesions (Fig. 120.9; see also Fig. 120.6), persistence of severe HIE by clinical examination at 72 hr, and lack of spontaneous activity are also at increased risk for death or impairment. These predictor variables can be combined to determine a score that helps with prognosis (see Table 120.6). Infants with the highest risk are likely to die or have severe disability despite aggressive treatment, including hypothermia. Those with intermediate scores are likely to benefit from treatment. In general, severe encephalopathy, characterized by flaccid coma, apnea, absence of oculocephalic reflexes, and refractory seizures, is associated with a poor prognosis (see Table 120.7). Apgar scores alone can also be associated with subsequent risk of neurodevelopmental impairment. At 10 min, each point decrease in Apgar score increases odds of death or disability by 45%. Death or disability occurs in 76–82% of infants with Apgar scores of 0-2 at 10 min. Absence of spontaneous respirations at 20 min of age and persistence of abnormal neurologic signs at 2 wk of age also predict death or severe cognitive and motor deficits.
The combined use of early conventional EEG or aEEG and MRI offers additional insight in predicting outcome in term infants with HIE (see Table 120.10). EEG or aEEG background characteristics such as pattern, voltage, reactivity, state change, and evolution after acute injury are important predictors of outcome. MRI markers include location of injury, identification of injury by certain pulse sequences, measurement of diffusivity and/or fractional anisotropy, and presence of abnormal metabolite ratios on MR spectroscopy, and all have shown correlation with outcome. There is also growing interest in quantitative measures (volumetric analysis, diffusion tensor imaging) of MRI as potential predictors of outcome. Severe BG/T lesions with abnormal signal in the posterior limb of the internal capsule is highly predictive of the poorest cognitive and motor prognosis (see Fig. 120.9). Normal MRI and EEG findings are associated with a good recovery.

Microcephaly and poor head growth during the 1st year of life also correlate with injury to the basal ganglia and white matter and adverse developmental outcome at 12 mo. All survivors of moderate to severe encephalopathy require comprehensive high-risk medical and developmental follow-up. Early identification of neurodevelopmental problems allows prompt referral for
developmental, rehabilitative, and neurologic early intervention services so that the best possible outcomes can be achieved.

**Brain death** after neonatal HIE is diagnosed from the clinical findings of coma unresponsive to pain, auditory, or visual stimulation; apnea with $P_{CO_2}$ rising from 40 to $>60$ mm Hg without ventilatory support; and absence of brainstem reflexes (pupillary, oculocephalic, oculovestibular, corneal, gag, sucking) (see Chapter 86). These findings must occur in the absence of hypothermia, hypotension, and elevations of depressant drugs (phenobarbital), which may take days to weeks to be metabolized and cleared completely from the blood. An absence of cerebral blood flow on radionuclide scans and of electrical activity on EEG (electrocerebral silence) is inconsistently observed in clinically brain-dead neonatal infants. Persistence of the clinical criteria for 24 hr in term infants predicts brain death in most asphyxiated newborns. There is no agreement on brain death criteria in preterm infants. Because of inconsistencies and difficulties in applying standard criteria, *no universal agreement has been reached regarding the definition of neonatal brain death*. Consideration of withdrawal of life support should include discussions with the family, the healthcare team, and, if there is disagreement, an ethics committee. The best interest of the infant involves judgments about the benefits and harm of continuing therapy or avoiding ongoing futile therapy.

**Spine and Spinal Cord**

*Cameron W. Thomas, Stephanie L. Merhar*

See also Chapter 729.

Injury to the spine/spinal cord during birth is rare but can be devastating. Strong traction exerted when the spine is hyperextended or when the direction of pull is lateral, or forceful longitudinal traction on the trunk while the head is still firmly engaged in the pelvis, especially when combined with flexion and torsion of the vertical axis, may produce fracture and separation of the vertebrae. Such injuries are most likely to occur when difficulty is encountered in delivering the shoulders in cephalic presentations and the head in breech presentations. The injury occurs most often at the level of the 4th cervical vertebra with cephalic presentations and the lower cervical–upper thoracic vertebrae with breech presentations. Transection of the cord may occur *with or without* vertebral fractures; hemorrhage and edema may produce neurologic signs that are indistinguishable from those of transection, except that they may not be permanent. Areflexia, loss of sensation, and complete paralysis of voluntary motion occur below the level of injury, although the persistence of a withdrawal reflex mediated through spinal centers distal to the area of injury is frequently misinterpreted as representing voluntary motion.

If the injury is severe, the infant, who from birth may be in poor condition because of respiratory depression, shock, or hypothermia, may deteriorate
rapidly to death within several hours before any neurologic signs are obvious. Alternatively, the course may be protracted, with symptoms and signs appearing at birth or later in the 1st wk; Horner syndrome, immobility, flaccidity, and associated brachial plexus injuries may not be recognized for several days. Constipation may also be present. Some infants survive for prolonged periods, their initial flaccidity, immobility, and areflexia being replaced after several weeks or months by rigid flexion of the extremities, increased muscle tone, and spasms. Apnea on day 1 and poor motor recovery by 3 mo are poor prognostic signs.

The differential diagnosis of neonatal spine/spinal cord injury includes amyotonia congenita and myelodysplasia associated with spina bifida occulta, spinal muscular atrophy (type 0), spinal vascular malformations (e.g., arteriovenous malformation causing hemorrhage or stroke), and congenital structural anomalies (syringomyelia, hemangioblastoma). US or MRI confirms the diagnosis. Treatment of the survivors is supportive, including home ventilation; patients often remain permanently disabled. When a fracture or dislocation is causing spinal compression, the prognosis is related to the time elapsed before the compression is relieved.

Bibliography

Brachial Palsy

Brachial plexus injury is a common problem, with an incidence of 0.6-4.6 per 1,000 live births. Injury to the brachial plexus may cause paralysis of the upper part of the arm with or without paralysis of the forearm or hand or, more often, paralysis of the entire arm. These injuries occur in macrosomic infants and when lateral traction is exerted on the head and neck during delivery of the shoulder in a vertex presentation, when the arms are extended over the head in a breech presentation, or when excessive traction is placed on the shoulders. Approximately 45% of brachial plexus injuries are associated with shoulder dystocia.

In **Erb-Duchenne paralysis** the injury is limited to the 5th and 6th cervical nerves. The infant loses the power to abduct the arm from the shoulder, rotate the arm externally, and supinate the forearm. The characteristic position consists of adduction and internal rotation of the arm with pronation of the forearm. Power to extend the forearm is retained, but the biceps reflex is absent; the Moro reflex is absent on the affected side (Fig. 120.10). The outer aspect of the arm may have some sensory impairment. Power in the forearm and hand grasps is preserved unless the lower part of the plexus is also injured; the presence of hand grasp is a favorable prognostic sign. When the injury includes the phrenic nerve, alteration in diaphragmatic excursion may be observed with US, fluoroscopy, or as asymmetric elevation of the diaphragm on chest radiograph.
Klumpke paralysis is a rare form of brachial palsy in which injury to the 7th and 8th cervical nerves and the 1st thoracic nerve produces a paralyzed hand and ipsilateral ptosis and miosis (Horner syndrome) if the sympathetic fibers of the 1st thoracic root are also injured. Mild cases may not be detected immediately after birth. Differentiation must be made from cerebral injury; from fracture, dislocation, or epiphyseal separation of the humerus; and from fracture of the clavicle. MRI demonstrates nerve root rupture or avulsion.

Most patients have full recovery. If the paralysis was a result of edema and hemorrhage around the nerve fibers, function should return within a few months; if it resulted from laceration, permanent damage may result. Involvement of the
deltoid is usually the most serious problem and may result in **shoulder drop** secondary to muscle atrophy. In general, paralysis of the upper part of the arm has a better prognosis than paralysis of the lower part.

Treatment consists of initial conservative management with monthly follow-up and a decision for surgical intervention by 3 mo if function has not improved. Partial immobilization and appropriate positioning are used to prevent the development of contractures. In upper arm paralysis, the arm should be abducted 90 degrees with external rotation at the shoulder, full supination of the forearm, and slight extension at the wrist with the palm turned toward the face. This position may be achieved with a brace or splint during the 1st 1-2 wk. Immobilization should be intermittent throughout the day while the infant is asleep and between feedings. In lower arm or hand paralysis, the wrist should be splinted in a neutral position and padding placed in the fist. When the entire arm is paralyzed, the same treatment principles should be followed. Gentle massage and range-of-motion exercises may be started by 7-10 days of age. Infants should be closely monitored with active and passive corrective exercises. If the paralysis persists without improvement for 3 mo, neuroplasty, neurolysis, end-to-end anastomosis, and nerve grafting offer hope for partial recovery.

The type of treatment and the prognosis depend on the mechanism of injury and the number of nerve roots involved. The mildest injury to a peripheral nerve (**neurapraxia**) is caused by edema and heals spontaneously within a few weeks. **Axonotmesis** is more severe and is a consequence of nerve fiber disruption with an intact myelin sheath; function usually returns in a few months. Total disruption of nerves (**neurotmesis**) or root avulsion is the most severe, especially if it involves C5-T1; microsurgical repair may be indicated. Fortunately, most (75%) injuries are at the root level C5-C6, involve neurapraxia and axonotmesis, and should heal spontaneously. Botulism toxin may be used to treat biceps-triceps co-contractions.

**Phrenic Nerve Paralysis**

Phrenic nerve injury (3rd, 4th, 5th cervical nerves) with diaphragmatic paralysis must be considered when cyanosis and irregular and labored respirations develop. Such injuries, usually unilateral, are associated with ipsilateral upper brachial plexus palsies in 75% of cases. Because breathing is thoracic in type, the abdomen does not bulge with inspiration. Breath sounds are diminished on the affected side. The thrust of the diaphragm, which may often be felt just under
the costal margin on the normal side, is absent on the affected side. The
diagnosis is established by US or fluoroscopic examination, which reveals
elevation of the diaphragm on the paralyzed side and seesaw movements of the 2
sides of the diaphragm during respiration. It may also be apparent on chest or
abdominal radiograph.

Infants with phrenic nerve injury should be placed on the involved side and
given oxygen if necessary. Some may benefit from pressure introduced by
continuous positive airway pressure (CPAP) to expand the paralyzed
hemidiaphragm. In extreme cases, mechanical ventilation cannot be avoided.
Initially, intravenous feedings may be needed; later, progressive gavage or oral
feeding may be started, depending on the infant's condition. Pulmonary
infections are a serious complication. If the infant fails to demonstrate
spontaneous recovery in 1-2 mo, surgical plication of the diaphragm may be
indicated.

Facial Nerve Palsy

Facial palsy is usually a peripheral paralysis that results from pressure over the
facial nerve in utero, during labor, or from forceps use during delivery. Rarely, it
may result from nuclear agenesis of the facial nerve.

Peripheral facial paralysis is flaccid and, when complete, involves the entire
side of the face, including the forehead. When the infant cries, movement occurs
only on the nonparalyzed side of the face, and the mouth is drawn to that side.
On the affected side the forehead is smooth, the eye cannot be closed, the
nasolabial fold is absent, and the corner of the mouth droops. Central facial
paralysis spares the forehead (e.g., forehead wrinkles will still be apparent on
the affected side) because the nucleus that innervates the upper face has
overlapping dual innervation by corticobulbar fibers originating in bilateral
cerebral hemispheres. The infant with central facial paralysis usually has other
manifestations of intracranial injury, most often 6th nerve palsy from the
proximity of the 6th and 7th cranial nerve nuclei in the brainstem. Prognosis
depends on whether the nerve was injured by pressure or the nerve fibers were
torn; improvement occurs within a few weeks in the former case. Care of the
exposed eye is essential. Neuroplasty may be indicated when the paralysis is
persistent. Facial palsy may be confused with absence of the depressor muscles
of the mouth, which is a benign problem or with variants of Möbius syndrome.

Other peripheral nerves are seldom injured in utero or at birth except when
they are involved in fractures or hemorrhage.

Bibliography

Most infants complete the transition to extrauterine life without difficulty; however, a small proportion require resuscitation after birth (Fig. 121.1). For a newborn infant, the need for resuscitation is often caused by a problem with respiration leading to inadequate ventilation. This is in contrast to an adult cardiac arrest, which is usually caused by inadequate circulation. The goals of neonatal resuscitation are to reestablish adequate spontaneous respirations, obtain adequate cardiac output, and prevent the morbidity and mortality associated with hypoxic-ischemic tissue (brain, heart, kidney) injury. High-risk situations should be anticipated from pregnancy history and labor. Improved perinatal care and prenatal diagnosis of fetal anomalies allow for appropriate maternal transports for high-risk deliveries. Infants who are born limp, cyanotic, apneic, or pulseless require immediate resuscitation before assignment of the 1 min Apgar score. Rapid and appropriate resuscitative efforts improve the likelihood of preventing brain damage and achieving a successful outcome.
Neonatal Resuscitation

See also Chapter 81.

Guidelines for the **Neonatal Resuscitation Program (NRP)** are based on recommendations from the International Liaison Committee on Resuscitation Consensus on Treatment Recommendations. These recommendations propose an *integrated* assessment/response approach for the initial evaluation of an infant, consisting of simultaneous assessment of infant general appearance and risk factors. The fundamental principles include evaluation of the airway and establishing effective respirations and adequate circulation. The guidelines also highlight the assessment and response to the neonatal heart rate.

Before the birth of a baby, sufficient preparation for the birth should occur. At least 1 individual capable of neonatal resuscitation should be present at the delivery, and if advanced resuscitation is anticipated, more individuals should be available to help. Necessary equipment should be available, which routinely includes: a warmer bed, blankets, infant hat, stethoscope, bulb suction, suction catheter with wall suction, bag-mask device, oxygen source with blender, pulse oximeter, laryngoscope with blade, and endotracheal tubes (ETTs). Based on the specific details of the pregnancy, further equipment that may be needed should be anticipated and readily available. The equipment should be checked to make
sure it is functioning appropriately. Team members should introduce themselves, define a team leader, assign roles for the resuscitation, and discuss what actions they will take during the resuscitation. For complex resuscitations, there may be 1 individual whose sole job is to keep track of time and record what interventions are taken, both to ensure the correct steps are performed in a timely manner and to review during debriefing later.

Immediately after birth, all term infants should be dried, warmed, and stimulated. If the infant does not need resuscitation, these steps can occur on the mother's abdomen while delayed cord clamping is taking place. Simultaneously, the infant's tone, respiratory effort, and heart rate should be assessed (Fig. 121.2).
Failure to initiate or sustain respiratory effort is fairly common at birth, with
5–10% of births requiring some intervention. Infants with primary apnea respond to stimulation by establishing normal breathing. Infants with secondary apnea require some ventilatory assistance in order to establish spontaneous respiratory effort. Secondary apnea usually originates in the central nervous system (CNS) as a result of asphyxia or peripherally because of neuromuscular disorders. The lungs in infants affected by conditions such as pulmonary hypoplasia and prematurity may be noncompliant, and initial efforts to begin respirations may be inadequate to initiate sufficient ventilation.

The steps in neonatal resuscitation follow the ABCs: A, anticipate and establish a patent airway by positioning the baby with the head slightly extended, sniffing position, and suctioning if secretions are blocking the airway; B, initiate breathing first by using tactile stimulation, followed by positive pressure ventilation (PPV) with a bag-mask device and ETT insertion should the baby remain apneic or PPV is not achieving effective ventilation; and C, maintain the circulation with chest compressions and medications, if needed. Fig. 121.2 outlines the steps to follow for immediate neonatal evaluation and resuscitation.

In term infants after stimulation, if no respirations are noted, or if the heart rate is <100 beats/min, PPV should be given through a tightly fitted and appropriately sized bag-mask device. PPV should be initiated at pressures of approximately 20 cm H₂O at a rate of 40-60 breaths/min initially with 21% fraction of inspired oxygen (FIO₂) for full-term infants.

At the same time PPV is initiated, a pulse oximeter should be placed on the right hand (pre ductal) and cardiac leads placed on the chest. In the past the recommended inspired gas for neonatal resuscitation had been 100% oxygen. However, resuscitation with room air in term infants is equally effective and may reduce the risk of hyperoxia, which is associated with decreased cerebral blood flow and generation of oxygen free radicals. Room air is the preferred initial gas for neonatal resuscitation in term infants. O₂ concentration administered should then be titrated as needed to obtain expected O₂ saturations in a term infant after birth, as defined by normal reference range by minute of life (see Fig. 121.2).

Successful and effective ventilation is signified by adequate chest rise, symmetric breath sounds, improved pink color, heart rate >100 beats/min, increasing O₂ saturation, spontaneous respirations, and improved tone. If after 30 sec of providing PPV there are no signs of effective ventilation, corrective steps should be performed to improve ventilation. The 6 ventilation corrective steps
can be remembered with the mnemonic MRSOPA: m ask readjustment, r eposition the head, s uction mouth and nose, o pen the mouth, p ressure increase, and a lternative airway).

In infants with severe respiratory depression who do not respond to PPV by bag-mask, after corrective steps have been taken, endotracheal intubation should be performed. For infants with an otherwise normal airway weighing <1,000 g, ETT size is usually 2.5 mm; for infants 1,000-2,000 g, 3 mm; and for infants >2,000 g, 3.5 mm. A general rule for depth of insertion from upper lip in centimeters is 6 plus infant's weight in kilograms. Poor response to ventilation may be a result of a loosely fitted mask, poor positioning of the ETT, esophageal intubation, airway obstruction, insufficient pressure, pleural effusions, pneumothorax, excessive air in the stomach leading to abdominal competition, asystole, hypovolemia, diaphragmatic hernia, or prolonged intrauterine asphyxia. Various devices to detect exhaled CO$_2$ and to confirm accurate ETT placement are available. A laryngeal mask airway may also be an effective tool to establish an airway, especially if PPV is ineffective and intubation attempts are unsuccessful.

The underlying cause for the vast majority of infants having a low heart rate is not a primary cardiac cause, but instead the result of ineffective ventilation. Therefore, if the heart rate remains <60 beats/min after 60 sec of PPV with corrective MRSOPA steps, the infant should be intubated (if not already done) to achieve effective ventilation. Once the infant is intubated, if the heart rate remains <60 beats/min, chest compressions should be initiated with continued ventilation, and $F_{I02}$ increased to 100%. Chest compressions should be initiated over the lower third of the sternum at a rate of 90/min. The ratio of compressions to ventilation is 3 : 1 (90 compressions:30 breaths). A provider, separate from the person providing ventilation, is needed to administer chest compressions. Two different techniques exist for performing chest compressions: the thumb technique and the 2-finger technique. For the thumb technique the tips of both thumbs are used to depress the sternum, with the fingers on each side encircling the chest; this is the preferred method to administer chest compressions, because it has been shown to achieve a higher blood pressure, increase coronary perfusion, and result in less fatigue. The 2-finger technique involves depressing the sternum with the tips of the middle finger and index finger while supporting the back with the palm of the other hand. In infants, regardless of whether an alternative airway has been secured, chest compressions are always coordinated with PPV. Chest compressions should continue uninterrupted for 45-60 sec.
before reassessing heart rate to determine next steps.

Medications are rarely required, but epinephrine should be administered when the heart rate is <60 beats/min after 60 sec of combined ventilation and chest compressions or during asystole. Persistent bradycardia in neonates is usually attributable to hypoxia resulting from respiratory arrest and often responds rapidly to effective ventilation alone. Persistent bradycardia despite what appears to be adequate resuscitation suggests inadequate ventilation or more severe cardiac compromise.

The umbilical vein can generally be readily cannulated and is the preferred method for administration of medications and volume expanders during neonatal resuscitation (Fig. 121.3). The ETT may be used for the administration of epinephrine if intravenous access is not yet available. Epinephrine (1 : 10,000 solution at 0.1-0.3 mL/kg intravenously or 0.5-1 mL/kg intratracheally) is given for asystole or for continued heart rate <60 beats/min after 60 sec of combined resuscitation. The dose may be repeated every 3-5 min. If adequate resuscitation continues for 10 min without a detectable heart rate, it is reasonable to stop resuscitative efforts.
Resuscitation of the Preterm Infant

Resuscitation of the preterm infant should follow the same steps as a term infant, with some special considerations. Whereas resuscitation of term infants should start with room air, resuscitation of most preterm infants can be initiated with slightly higher $\text{FiO}_2$, 21–30%. Pulse oximetry of the preductal (right) hand should be used to titrate $\text{O}_2$ concentrations for targeted saturations per the NRP algorithm (see Fig. 121.2).

Special attention should be paid to keeping the preterm infant warm in the delivery room. Quality improvement projects have initiated bundles to improve
admission temperatures of preterm infants to the neonatal intensive care unit (NICU) and have included such interventions as higher ambient temperatures in the delivery room, immediate placement of preterm infants into a plastic bag or under plastic wrap rather than drying, and exothermic mattress for resuscitation and transport of the preterm infant.

**Delayed cord clamping** for 1-3 min can be performed in both preterm and term infants but is especially recommended for preterm infants. Benefits to term infants include higher hemoglobin levels at birth with improved iron stores in the 1st several mo of life. Additional benefits for preterm infants include improved hemodynamic stability, decreased need for inotropic support, decreased need for transfusions, and decreased risk of necrotizing enterocolitis and intraventricular hemorrhage. The American College of Obstetricians and Gynecologists (ACOG) recommends at least 30-60 sec of delayed cord clamping after birth for vigorous term and preterm infants. It is unclear, however, whether delayed cord clamping should be continued when an infant requires resuscitation. Studies are investigating whether the onset of respirations before delayed cord clamping is beneficial for both hemodynamic stability and decreased neonatal mortality.

**Special Circumstances in the Delivery Room**

**Meconium**

Meconium staining of the amniotic fluid may be an indication of fetal stress. Previously, the presence of meconium-stained amniotic fluid in a *nonvigorous* infant required tracheal intubation to attempt to aspirate meconium below the cords; NRP recommendations (7th edition) no longer support this practice. If an infant is born through meconium-stained amniotic fluid, it does not matter whether they are vigorous or nonvigorous; the infant should receive the same initial steps of basic resuscitation and should be assessed as any other infant. Tracheal intubation may delay the initiation of effective PPV, which will help the baby to breathe and achieve effective gas exchange.

**Placental Abruption**

Placental abruption (abruptio placentae) at birth can lead to massive fetal blood
loss and a hypovolemic, anemic infant at delivery. Infants can present pale and apneic with poor tone, decreased perfusion, and bradycardia. In addition to performing routine neonatal resuscitation, when an infant is suspected to be symptomatic from a placental abruption, an emergency low-lying umbilical venous catheter (UVC) should be placed and emergent type O Rh-negative blood should be obtained. In acute blood loss, the blood should be administered as quickly as possible in 10 mL/kg aliquots in the delivery room. Adequate communication between obstetrics and pediatrics regarding suspected abruption is crucial to early recognition and treatment of the infant.

**Neonatal Encephalopathy**

Infants with neonatal encephalopathy are born with abnormal neurologic function, including level of consciousness, muscle tone, and reflexes. Although there are many possible etiologies, when symptoms are accompanied by a defined perinatal event such as cord prolapse or placental abruption, hypoxic-ischemic brain injury is the presumed cause. These infants are often born with impaired respiratory drive. In addition to routine neonatal resuscitation, term infants with concern for neonatal encephalopathy should be passively cooled in the delivery room by not turning on the warmer bed. After initial resuscitation and stabilization, a more thorough neurologic examination can be performed to assess if the infant meets formal criteria for moderate to severe encephalopathy in order to proceed with whole body cooling (see Chapter 120.4).

**Airway Obstruction**

Hypoplasia of the mandible with posterior displacement of the tongue may result in upper airway obstruction (Pierre Robin, Stickler, DiGeorge, and other syndromes; see Chapter 337). Symptoms may sometimes be temporarily relieved by pulling the tongue or mandible forward or placing the infant in the prone position. Other rare causes of upper airway obstruction at birth include laryngeal atresia or stenosis, teratomas, hygromas, and oral tumors. Critical fetal and then neonatal airway obstruction represents an emergency in the delivery room. High-risk perinatal care has led to the more frequent prenatal diagnosis of these disorders. When diagnosed prenatally, planning can identify the location of delivery and interventions available at delivery. The *ex utero intrapartum treatment (EXIT)* procedure allows time to secure the airway in an infant.
known prenatally to have critical airway obstruction, before the infant is separated from the placenta (Fig. 121.4 ). Uteroplacental gas exchange is maintained throughout the procedure.

![Fig. 121.4 EXIT procedure. Baby with teratoma and critical high airway obstruction syndrome. Trachea is displaced to the lateral neck. (Courtesy of Dr. Mark Wulkan, Pediatric Surgery, Emory University.]

**Respiratory Distress**

Both congenital abnormalities and iatrogenic causes secondary to required resuscitation can contribute to respiratory distress in the neonate. A scaphoid abdomen suggests a diaphragmatic hernia, as does asymmetry in contour or movement of the chest. An infant with a known diaphragmatic hernia should be immediately intubated in the delivery room and an orogastric tube placed to avoid gaseous distention of the bowel from crying or PPV. The infant should then be transferred to a tertiary referral center for surgical evaluation and treatment (see Chapter 122.1).

In infants with a prenatal diagnosis of hydrops, pleural effusions may be present at delivery, preventing adequate lung expansion and gas exchange. Similarly, infants requiring PPV in the delivery room are at risk for developing a pneumothorax. Infants with pulmonary hypoplasia or meconium-stained fluid are at increased risk of this complication. Clinically, infants with a pleural effusion or pneumothorax present with respiratory distress and hypoxia, with
diminished breath sounds on the affected side. Transillumination may be helpful to confirm the diagnosis. Emergency evacuation of a pneumothorax or pleural effusion without radiographic confirmation is indicated in an infant who is unresponsive to resuscitation efforts and has asymmetric breath sounds, bradycardia, and cyanosis. An angiocatheter attached to a stopcock and syringe should be used for evacuation. For a pneumothorax, an angiocatheter should be inserted perpendicular to the chest wall above the rib in the 2nd intercostal space in the midclavicular line and air evacuated. For a pleural effusion, with the infant in the supine position, the angiocatheter should be inserted in the 4th or 5th intercostal space in the anterior axillary line and directed posteriorly to evacuate the fluid (see Chapter 122).

**Abdominal Wall and Neural Tube Defects**

Appropriate management of patients with abdominal wall defects (omphalocele, gastroschisis) in the delivery room prevents excessive fluid loss and minimizes the risk for injury to the exposed viscera. *Gastroschisis* is the more common defect, and typically the intestines are not covered by a membrane. The exposed intestines should be gently placed in a sterile clear plastic bag after delivery. A membrane often covers an *omphalocele*, and care should be taken to prevent its rupture. A nasogastric tube should be placed and the infant transferred to a tertiary referral center for surgical consultation and evaluation for associated anomalies (see Chapter 125).

Similarly, infants born with neural tube defects such as a *myelomeningocele* need special care at delivery to protect the exposed neural tube tissue from trauma and infection; infants should be placed on their side or abdomen for resuscitation. The site of the neural tube defect should be covered with a moist sterile dressing to prevent drying and infection. The infant should then be transferred to a tertiary referral center for surgical evaluation and treatment.

**Injury During Delivery**

**Central Nervous System**

Both extracranial and intracranial birth injuries can be seen in infants after birth. *Extracranial* lesions include cephalohematoma, caput succedaneum, and subgaleal hemorrhage. *Intracranial* birth injuries include subdural hemorrhage,
subarachnoid hemorrhage, and epidural hematoma. The most common intracranial injury experienced at birth is subdural hemorrhage, with increasing incidence seen with instrument-assisted vaginal deliveries (see Chapters 120.1 and 120.2).

Fractures

The clavicle is the most frequently fractured bone during labor and delivery. It is particularly vulnerable to injury with difficult delivery of the shoulder in the setting of shoulder dystocia, as well as with extended arms in breech deliveries. In the treatment of shoulder dystocia, the obstetrician may intentionally fracture the clavicle so that delivery can proceed. Symptoms of a clavicular fracture include an infant not moving the arm freely on the affected side, palpable crepitus or bony irregularity, and asymmetric or absent Moro reflex on the affected side. The prognosis for this fracture is excellent. Often, no specific treatment is needed, although in some cases the arm and shoulder on the affected side are immobilized for comfort.

Fractures of the long bones are fairly rare. Injuries often present with absent spontaneous movement of the extremity. Associated nerve involvement may also occur. Treatment involves immobilization of the affected extremity with a splint and orthopedic follow-up.

Brachial Plexus Injuries

Brachial plexus injuries result from stretching and tearing of the brachial plexus (spinal roots C5-T1) at delivery. Although shoulder dystocia is associated with an increased risk of brachial plexus injury, it can also occur during a routine delivery (see Chapter 120.6).

Ongoing Care After Resuscitation

The “golden hour” after a baby's birth should emphasize effective neonatal resuscitation, postresuscitation care, prevention of hypothermia, immediate breastfeeding if able, prevention of hypoglycemia, and therapeutic hypothermia for cases of moderate to severe neonatal encephalopathy (birth asphyxia). After supportive measures have stabilized the infant's condition, a specific diagnosis should be established and appropriate continuing treatment instituted.
After initial resuscitation and stabilization, an infant with a significant metabolic acidosis may potentially require further treatment with sodium bicarbonate and/or 10 mL/kg of volume expander. If infection is suspected, appropriate antibiotics should be started as soon as possible. Severe neonatal encephalopathy may also depress myocardial function and cause cardiogenic shock despite the recovery of heart and respiratory rates. Fluids and dopamine or epinephrine as a continuous infusion should be started after initial resuscitation efforts, to improve cardiac output in an infant with poor peripheral perfusion, weak pulses, hypotension, tachycardia, or poor urine output. Regardless of the severity of neonatal encephalopathy or the response to resuscitation, asphyxiated infants should be monitored closely for signs of multiorgan hypoxic-ischemic tissue injury (see Chapter 120.4).

Bibliography

Respiratory disorders are the most frequent cause of admission for neonatal intensive care in both term and preterm infants. Signs and symptoms of respiratory distress include cyanosis, expiratory grunting, nasal flaring, retractions, tachypnea, decreased breath sounds with or without rales and/or rhonchi, and pallor. A wide variety of pathologic lesions may be responsible for respiratory disturbances, including pulmonary, airway, cardiovascular, central nervous system, infectious, and other disorders (Fig. 122.1).
It is occasionally difficult to distinguish respiratory from nonrespiratory etiologies on the basis of clinical signs alone. Signs of respiratory distress are an indication for a physical examination and diagnostic evaluation, including determination of ventilation by arterial blood gases and oxygenation by pulse oximetry, and assessment of lung fields with chest radiography. Timely and appropriate therapy is essential to improve outcome.

### 122.1

**Transition to Pulmonary Respiration**

_Shawn K. Ahlfeld_
Keywords

- fetal lung fluid
- functional residual capacity
- positive pressure ventilation
- surfactant
- periodic breathing

Successful establishment of adequate lung function at birth depends on airway patency, functional lung development, and maturity of respiratory control. *Fetal lung fluid* must be removed and replaced with gas. This process begins before birth as active sodium transport across the pulmonary epithelium drives liquid from the lung lumen into the interstitium with subsequent absorption into the vasculature. Increased levels of circulating catecholamines, vasopressin, prolactin, and glucocorticoids enhance lung fluid adsorption and trigger the change in lung epithelia from chloride secretion to sodium reabsorption. **Functional residual capacity (FRC)** must be established and maintained to develop a ventilation-perfusion relationship that will provide optimal exchange of oxygen and carbon dioxide between alveoli and blood.

The First Breath

Initiation of the first breath is caused by a decline in arterial oxygen tension (Pao\textsubscript{2}) and pH and a rise in arterial carbon dioxide partial tension (Paco\textsubscript{2}) as a result of interruption of the placental circulation, redistribution of cardiac output, decrease in body temperature, and various tactile and sensory inputs. The relative contributions of these stimuli to the onset of respiration are uncertain. Although spontaneously breathing infants do not need to generate an opening pressure to create airflow, infants requiring **positive pressure ventilation (PPV)** at birth need an opening pressure of 13-32 cm H\textsubscript{2}O and are more likely to establish FRC if they generate a spontaneous, negative pressure breath. Expiratory esophageal pressures associated with the 1st few spontaneous breaths in term newborns range from 45-90 cm H\textsubscript{2}O. This high pressure, caused by expiration against a partially closed glottis, may aid in the establishment of FRC but would be difficult to mimic safely with artificial ventilation. The higher
pressures needed to initiate respiration are required to overcome the opposing 
forces of surface tension (particularly in small airways) and the viscosity of 
liquid remaining in the airways, as well as to introduce about 50 mL/kg of air 
into the lungs, 20-30 mL/kg of which remains after the first breath to establish 
FRC. **Surfactant** lining the alveoli enhances the aeration of gas-free lungs by 
reducing surface tension, thereby lowering the pressure required to open alveoli. 
Air entry into the lungs displaces fluid, decreases hydrostatic pressure in the 
pulmonary vasculature, and increases pulmonary blood flow. The greater blood 
flow in turn increases the blood volume of the lung and the effective vascular 
surface area available for fluid uptake. The remaining fluid is removed by the 
pulmonary lymphatics, upper airway, mediastinum, and pleural space. Fluid 
removal may be impaired after cesarean birth or as a result of surfactant 
deficiency, endothelial cell damage, hypoalbuminemia, high pulmonary venous 
pressure, or neonatal sedation.

Compared with term infants, preterm infants have a very compliant chest wall 
and may be at a disadvantage in establishing FRC. Abnormalities in ventilation-
perfusion ratio are greater and persist for longer periods in preterm infants and 
may lead to hypoxemia and hypercarbia as a result of atelectasis, intrapulmonary 
shunting, hypoventilation, and gas trapping. The smallest immature infants have 
the most profound disturbances as a consequence of **respiratory distress 
syndrome (RDS)**. However, even in healthy term infants, oxygenation is 
impaired immediately after birth, and oxygen saturation (So$_2$) gradually 
increases and exceeds 90% only at about 5 min. In addition, because of the 
relatively high pulmonary arterial pressure present in the fetal lung, right-to-left 
shunting across the ductus arteriosus is common soon after birth. If pulse 
oximetry is performed soon after birth, the recommendation is to measure 
preductal So$_2$ in the right upper extremity.

**Breathing Patterns in Newborns**

During sleep in the 1st few mo after birth, normal full-term infants (and more 
frequently preterm infants) may have episodes when regular breathing is 
interrupted by short pauses. This **periodic breathing** pattern is characterized by 
brief episodes of respiratory pauses lasting 5-10 sec, followed by a burst of rapid 
respirations at a rate of 50-60 breaths/min for 10-15 sec. The brief interruptions 
in respiration are not associated with change in color or heart rate. Periodic
breathing is a normal characteristic of neonatal respiration and has no prognostic significance.

122.2

Apnea

Shawn K. Ahlfeld

Keywords

apnea
mixed apnea
central apnea
obstructive apnea
apnea of prematurity
nasal continuous positive airway pressure
heated humidified high-flow nasal cannula
methylxanthines
caffeine
gastroesophageal reflux
home monitoring
sudden infant death syndrome

Apnea is a prolonged cessation of respiration and must be distinguished from periodic breathing because apnea is often associated with serious illness. Although there is no universal agreement, apnea is usually defined as cessation of breathing for a period of ≥20 sec, or a period <20 sec that is associated with a change in tone, pallor, cyanosis, or bradycardia (<80-100 beats/min). Based on the absence of respiratory effort and/or airflow, apnea can be obstructive, central, or mixed. Obstructive apnea (pharyngeal instability, neck flexion) is characterized by absence of airflow but persistent chest wall motion. Pharyngeal
collapse may follow the negative airway pressures generated during inspiration, or it may result from incoordination of the tongue and other upper airway muscles involved in maintaining airway patency. Central apnea, which is caused by decreased central nervous system (CNS) stimuli to respiratory muscles, results in both airflow and chest wall motion being absent. Gestational age is the most important determinant of respiratory control, with the frequency of central apnea being inversely related to gestational age. The immaturity of the brainstem respiratory centers is manifest by an attenuated response to CO₂ and a paradoxical response to hypoxia that results in central apnea rather than hyperventilation. Mixed apnea is most often observed in apnea of prematurity (50–75% of cases), with obstructive apnea preceding central apnea. Short episodes of apnea are usually central, whereas prolonged ones are often mixed. Apnea depends on the sleep state; its frequency increases during active (rapid eye movement) sleep.

Although apnea is usually observed in preterm infants as a result of immature respiratory control or an associated illness, apnea in term infants is uncommon, often associated with serious pathology, and demands prompt diagnostic evaluation. Apnea accompanies many primary diseases that affect neonates (Table 122.1). These disorders produce apnea by direct depression of CNS control of respiration (hypoglycemia, meningitis, drugs, intracranial hemorrhage, seizures), disturbances in oxygen delivery (shock, sepsis, anemia), or ventilation defects (obstruction of the airway, pneumonia, muscle weakness). The term neonate with apnea should receive continuous cardiorespiratory monitoring while performing an assessment for bacterial or viral sepsis/meningitis, intracranial hemorrhage, seizures, and airway instability. Supportive care and close monitoring are essential while the underlying etiology is ascertained and appropriately treated.

**Apnea of Prematurity**

Apnea of prematurity results from immature respiratory control, most frequently occurs in infants <34 wk of gestational age (GA), and occurs in the absence of identifiable predisposing diseases. The incidence of idiopathic apnea of prematurity varies inversely with GA. Apnea of prematurity is almost universal in infants born at <28 wk GA, and the incidence rapidly decreases from 85% of infants <30 wk GA to 20% of infants <34 wk GA. The onset of apnea of prematurity can be during the initial days to weeks of age but is often delayed if there is RDS or other causes of respiratory distress. In premature infants without respiratory disease, apneic episodes can occur throughout the 1st 7 postnatal days with equal frequency.

Apnea in preterm infants is defined as cessation of breathing for ≥20 sec or for any duration if accompanied by cyanosis and bradycardia (<80-100 beats/min). The incidence of associated bradycardia increases with the length of the preceding apnea and correlates with the severity of hypoxia. Short apnea episodes (10 sec) are rarely associated with bradycardia, whereas longer episodes (>20 sec) have a higher incidence of bradycardia. **Bradycardia** follows the apnea by 1-2 sec in >95% of cases and is most often sinus, but on occasion it can be nodal. Vagal responses and rarely heart block are causes of bradycardia without apnea. Short, self-resolving oxygen desaturation episodes noted with continuous monitoring are normal in neonates, and treatment is not necessary.

Preterm infants born at <35 wk GA are at risk for apnea of prematurity and therefore should receive cardiorespiratory monitoring. Apnea that occurs in the absence of other clinical signs of illness in the 1st 2 wk in a preterm infant is likely apnea of prematurity, and therefore additional evaluation for other etiologies is often unwarranted. However, the onset of apnea in a previously well preterm neonate after the 2nd wk of life (or, as previously, in a term infant at any time) is a critical event that may be associated with serious underlying pathology. Prompt investigation for medication side effects, metabolic derangements, structural CNS anomalies, intracranial hemorrhage, seizures, or sepsis/meningitis is warranted.
Treatment

Gentle tactile stimulation or provision of flow and/or supplemental oxygen by nasal cannula is often adequate therapy for mild and intermittent episodes. Nasal continuous positive airway pressure (nCPAP, 3-5 cm H2O) and heated humidified high-flow nasal cannula (HHHFNC, 1-4 L/min) are appropriate therapies for mixed or obstructive apnea. The efficacy of both nCPAP and HHHFNC is related to their ability to splint the upper airway to prevent airway obstruction. Both are used widely, but nCPAP may be preferred in extremely preterm infants because of its proven efficacy and safety.

Recurrent or persistent apnea of prematurity is effectively treated with methylxanthines. Methylxanthines increase central respiratory drive by lowering the threshold of response to hypercapnia as well as enhancing contractility of the diaphragm and preventing diaphragmatic fatigue. Caffeine and theophylline are similarly effective methylxanthines, but caffeine is preferred because of its longer half-life and lower potential for side effects (less tachycardia and feeding intolerance). In preterm infants, caffeine reduces the incidence and severity of apnea of prematurity, facilitates successful extubation from mechanical ventilation, reduces the rate of bronchopulmonary dysplasia (BPD), and improves neurodevelopmental outcomes. Caffeine therapy can be safely administered orally (PO) or intravenously (IV) with an initial loading dose of 20 mg/kg of caffeine citrate followed 24 hr later by once-daily maintenance doses of 5 mg/kg (increased to 10 mg/kg daily as needed for persistent apnea). Because the therapeutic window is wide (therapeutic level: 8-20 µg/mL) and serious side effects associated with caffeine are rare, monitoring of serum drug concentrations are usually unnecessary. Monitoring is primarily through observation of vital signs (tachycardia) and clinical response. Higher doses of caffeine may be more effective without serious adverse events, but additional studies are needed to ensure safety. Retrospective cohort studies suggest that initiation of caffeine in the 1st 3 days of age in extremely preterm infants (<28 wk GA) may improve outcomes. However, it is reasonable to delay caffeine therapy until apnea occurs. Caffeine therapy is usually continued until an infant is free of clinically significant apnea or bradycardia for 5-7 days without positive pressure respiratory support, or at 34 wk postmenstrual age (PMA).

In an infant with significant anemia, transfusion of packed red blood cells (RBCs) increases blood O2-carrying capacity, improves tissue oxygenation, and is associated with a short-term reduction in apnea. However, a long-term benefit
in regard to apnea appears unlikely. **Gastroesophageal reflux (GER)** is common in neonates, but despite being associated with apnea anecdotally, data do not support a causal relationship between GER and apneic events. In preterm infants, medications that inhibit gastric acid production have potentially harmful side effects (increased incidence of sepsis, necrotizing enterocolitis, death) and may actually increase the incidence of apnea and bradycardia. Therefore the routine use of medications that inhibit gastric acid synthesis or promote gastrointestinal motility to reduce the frequency of apnea in preterm infants should be discouraged.

### Prognosis

In 92% of infants by 37 wk PMA and in 98% of infants by 40 wk PMA, apnea of prematurity resolves spontaneously. However, infants born well before 28 wk GA may experience apnea and bradycardic events until 44 wk PMA. Beyond 44 wk PMA, extreme events (apnea >30 sec and/or bradycardia <60 beats/min for >10 sec) are very rare. The period that an infant should be observed to ensure resolution of apnea and bradycardia is not defined and among institutions is highly variable. However, many experts would recommend that an infant demonstrate an event-free period of 5-7 days before discharge. Although the nature and severity of events should dictate the length of observation, sufficiently large retrospective cohort studies suggest that a 1-3 day (infants born at ≥30 wk GA), 9-10 day (27-28 wk GA), or 13-14 day (<26 wk GA) event-free period predicts resolution of apnea in up to 95% of infants successfully. Brief, isolated bradycardic episodes associated with oral feeding are common in preterm infants and are generally not considered significant during the event-free period. While not recommended routinely for preterm infants with apnea of prematurity, in rare cases an infant with persistent, prolonged apnea may be discharged with home cardiorespiratory monitoring. In the absence of significant events, home monitoring can be safely discontinued at 44 wk PMA. There is no evidence that home monitoring prevents death.

Despite its high frequency in preterm infants, the harm associated with apnea of prematurity is unknown. However, apnea of prematurity does not appear to alter an infant's prognosis unless it is severe, recurrent, and refractory to therapy. Prompt, effective therapy and careful monitoring are vital to avoid prolonged, severe hypoxia, which may increase the risk of death and neurodevelopmental impairment.
Apnea of Prematurity and Sudden Infant Death Syndrome

Although preterm infants are at higher risk for sudden infant death syndrome (SIDS), apnea of prematurity does not further increase that risk. The peak incidence of SIDS occurs earlier in infants born at 24-28 wk GA (47.1 wk PMA vs 53.5 wk PMA). The epidemiologic evidence that placing babies supine during sleep reduces the rate of SIDS deaths by >50% suggests that positioning, and not prematurity, primarily influences the incidence of SIDS. Supine positioning on a firm sleep surface separate from the parents’ bed, promotion of breastfeeding, and pacifier use during sleep reduce the incidence of SIDS. Avoidance of cigarette smoke exposure and no parental use of alcohol or illicit drugs during pregnancy and after birth are also important in the prevention of SIDS.

Incidence

Respiratory distress syndrome (RDS) occurs primarily in premature infants; its incidence is inversely related to gestational age and birthweight. It occurs in 60–80% of infants <28 wk GA, in 15–30% of those between 32 and 36 wk GA, and rarely in those >37 wk GA. The risk for development of RDS increases with maternal diabetes, multiple births, cesarean delivery, precipitous delivery, asphyxia, cold stress, and a maternal history of previously affected infants. The risk of RDS is reduced in pregnancies with chronic or pregnancy-associated hypertension, maternal heroin use, prolonged rupture of membranes, and antenatal corticosteroid prophylaxis.

Etiology and Pathophysiology

Surfactant deficiency (decreased production and secretion) is the primary cause of RDS. In the absence of pulmonary surfactant, significantly increased alveolar
surface tension leads to atelectasis, and the ability to attain an adequate FRC is impaired. As a consequence of progressive injury to epithelial and endothelial cells from atelectasis (atelectrauma), volutrauma, ischemic injury, and oxygen toxicity, effusion of proteinaceous material and cellular debris into the alveolar spaces (forming the classic hyaline membranes) further impairs oxygenation. Alveolar atelectasis, hyaline membrane formation, and interstitial edema make the lungs less compliant in RDS, so greater pressure is required to expand the alveoli and small airways. Additionally, compared with the mature infant, the highly compliant chest wall of the preterm infant offers less resistance to the natural tendency of the lungs to collapse. Thus, at end-expiration, the volume of the thorax and lungs tends to approach residual volume. Although surfactant is present in high concentrations in fetal lung homogenates by 20 wk of gestation, it does not reach the surface of the lungs until later. It appears in amniotic fluid between 28 and 32 wk. Mature levels of pulmonary surfactant are present usually after 35 wk of gestation.

The major constituents of surfactant are dipalmitoyl phosphatidylcholine (lecithin), phosphatidylglycerol, apoproteins (surfactant proteins SP-A, SP-B, SP-C, and SP-D), and cholesterol (Fig. 122.2). With advancing GA, increasing amounts of phospholipids are synthesized and stored in type II alveolar cells (Fig. 122.3). These surface-active agents are released into the alveoli, where they reduce surface tension and help maintain alveolar stability at end-expiration. Synthesis of surfactant depends in part on normal pH, temperature, and perfusion. Asphyxia, hypoxemia, and pulmonary ischemia, particularly in association with hypovolemia, hypotension, and cold stress, may suppress surfactant synthesis. The epithelial lining of the lungs may also be injured by high O₂ concentrations and mechanical ventilation, thereby further reducing secretion of surfactant.

**Atelectasis** results in perfused but not ventilated alveoli, causing hypoxia. Decreased lung compliance, small tidal volumes, increased physiologic dead space, and insufficient alveolar ventilation eventually result in hypercapnia. The combination of hypercapnia, hypoxia, and acidosis produces pulmonary arterial vasoconstriction with increased right-to-left shunting through the foramen ovale and ductus arteriosus and within the lung itself. Progressive injury to epithelial and endothelial cells and formation of hyaline membranes further impairs oxygenation, leading to a vicious cycle of diminished surfactant production, worsening atelectasis, lung injury, and severe hypoxia (Fig. 122.4).

**Clinical Manifestations**

Signs of RDS usually appear within minutes of birth, although they may not be
recognized for several hours in larger premature infants, until rapid, shallow respirations become more obvious. A later onset of tachypnea should suggest other conditions. Some patients require resuscitation at birth because of intrapartum asphyxia or initial severe respiratory distress (especially with birthweight <1,000 g). Characteristically, tachypnea, prominent (often audible) expiratory grunting, intercostal and subcostal retractions, nasal flaring, and cyanosis are noted. Breath sounds may be normal or diminished with a harsh tubular quality, and on deep inspiration, fine crackles may be heard. The natural course of untreated RDS is characterized by progressive worsening of cyanosis and dyspnea. If the condition is inadequately treated, blood pressure may fall; cyanosis and pallor increase, and grunting decreases or disappears, as the condition worsens. Apnea and irregular respirations are ominous signs requiring immediate intervention. Untreated patients may also have a mixed respiratory-metabolic acidosis, edema, ileus, and oliguria. Respiratory failure may occur in infants with rapid progression of the disease. In most cases the signs reach a peak within 3 days, after which improvement is gradual. Improvement is often heralded by spontaneous diuresis and improved blood gas values at lower inspired O\textsubscript{2} levels and/or lower ventilator support. Death can result from severe impairment of gas exchange, alveolar air leaks (pulmonary interstitial emphysema, pneumothorax), pulmonary hemorrhage, or intraventricular hemorrhage (IVH).

**Diagnosis**

The clinical course, chest x-ray findings, and blood gas values help establish the clinical diagnosis. On chest radiograph, the lungs may have a characteristic but not pathognomonic appearance that includes low lung volumes, a diffuse, fine reticular granularity of the parenchyma (ground-glass appearance), and air bronchograms (Fig. 122.5). The initial x-ray appearance is occasionally normal, with the typical pattern developing during the 1st day. Considerable variation in radiographic findings may be seen, especially in infants who have already received treatment with surfactant replacement and/or positive pressure respiratory support; this variation often results in poor correlation between radiographic findings and the clinical course. Blood gas findings are characterized initially by hypoxemia and later by progressive hypoxemia, hypercapnia, and variable metabolic acidosis.
In the differential diagnosis, early-onset sepsis may be indistinguishable from RDS. In neonates with pneumonia, the chest radiograph may be identical to that for RDS. Clinical factors such as maternal group B streptococcal colonization with inadequate intrapartum antibiotic prophylaxis, maternal fever (>38.6°C) or chorioamnionitis, or prolonged rupture of membranes (>12 hr) are associated with an increased risk of early-onset sepsis. Although complete blood counts are neither sensitive nor specific in the diagnosis of early-onset sepsis, the presence of marked neutropenia has been associated with increased risk. Cyanotic congenital heart disease (in particular, total anomalous pulmonary venous return) can also mimic RDS both clinically and radiographically. Echocardiography with color-flow imaging should be performed in infants who show no response to surfactant replacement, to rule out cyanotic congenital heart disease as well as ascertain patency of the ductus arteriosus and assess pulmonary vascular resistance (PVR). Persistent pulmonary hypertension, aspiration (meconium, amniotic fluid) syndromes, spontaneous pneumothorax, pleural effusions, and congenital anomalies (pulmonary congenital airway malformations, pulmonary
lymphangiectasia, diaphragmatic hernia, lobar emphysema) must be considered in patients with an atypical clinical course but can generally be differentiated from RDS through radiographic and other evaluations. Transient tachypnea may be distinguished by its shorter and milder clinical course and is characterized by low or no need for O₂ supplementation.

Although rare, genetic disorders may contribute to respiratory distress. Abnormalities in surfactant protein B and C genes as well as a gene responsible for transporting surfactant across membranes, ABC transporter 3 (ABCA3), are associated with severe and often lethal familial respiratory disease. **Congenital alveolar proteinosis** (congenital surfactant protein B deficiency) is a rare familial disease that manifests as severe and lethal RDS in predominantly term and near-term infants (see Chapter 434). In atypical cases of RDS, a lung profile (lecithin:sphingomyelin ratio and phosphatidylglycerol determination) performed on a tracheal aspirate can be helpful in establishing a diagnosis of surfactant deficiency. Other familial causes of neonatal respiratory distress (not RDS) include mucopolysaccharidosis, acinar dysplasia, pulmonary lymphangiectasia, and alveolocapillary dysplasia.

**Prevention**

Avoidance of unnecessary or poorly timed early (<39 wk GA) cesarean delivery or induction of labor, appropriate management of high-risk pregnancy and labor (including administration of antenatal corticosteroids), and prediction of pulmonary immaturity with possible in utero acceleration of maturation (see Chapter 119) are important preventive strategies. Antenatal and intrapartum fetal monitoring may decrease the risk of fetal asphyxia; asphyxia is associated with an increased incidence and severity of RDS.

Administration of antenatal corticosteroids to women before 37 wk gestation significantly reduces the incidence and mortality of RDS as well as overall neonatal mortality. Antenatal steroids also reduce (1) overall mortality, (2) admission to the neonatal intensive care unit (NICU) and need for/duration of ventilatory support, and (3) incidence of severe IVH, necrotizing enterocolitis (NEC), and neurodevelopmental impairment. Postnatal growth is not adversely affected. Antenatal corticosteroids do not increase the risk of maternal death, chorioamnionitis, or puerperal sepsis. Betamethasone and dexamethasone have both been used antenatally. Betamethasone may reduce neonatal death to a
greater extent than dexamethasone.

Although classically, antenatal corticosteroids were reserved for preterm birth before 34 wk gestation, the administration of betamethasone before late preterm birth (34+0 to 36+6 wk gestation) significantly reduces the need for respiratory support and the incidence of severe respiratory complications. Therefore the American College of Obstetricians and Gynecologists (ACOG) recommends that for all women between 24 and 36 wk gestation who present in preterm labor and are likely to deliver a fetus within 1 wk, antenatal corticosteroid administration should be considered.

**Treatment**

The basic defect requiring treatment in RDS is inadequate pulmonary O\textsubscript{2} -CO\textsubscript{2} exchange. Basic supportive care (thermoregulatory, circulatory, fluid, electrolyte, and respiratory) is essential while FRC is established and maintained. Careful and frequent monitoring of heart and respiratory rates, S\textsubscript{a}O\textsubscript{2}, P\textsubscript{a}O\textsubscript{2}, P\textsubscript{a}CO\textsubscript{2}, pH, electrolytes, glucose, hematocrit, blood pressure, and temperature are essential. Arterial catheterization is frequently necessary. Because most cases of RDS are self-limited, the goal of treatment is to minimize abnormal physiologic variations and superimposed iatrogenic problems. Treatment of infants with RDS is best carried out in the NICU.

Periodic monitoring of P\textsubscript{a}O\textsubscript{2}, P\textsubscript{a}CO\textsubscript{2}, and pH is an important part of the management and is used to provide supportive care; if assisted ventilation is being used, such monitoring is essential. Oxygenation (S\textsubscript{O}2) should be assessed by continuous pulse oximetry. Capillary blood samples are of limited value for determining PO\textsubscript{2} but may be useful for P\textsubscript{CO}2 and pH monitoring. Monitoring of blood gas parameters and mean arterial blood pressure through an umbilical or peripheral arterial catheter is useful in managing the shock-like state that may occur during the initial hours in premature infants who have been asphyxiated or have severe RDS (see Fig. 121.3). The position of a radiopaque umbilical catheter should be checked radiographically after insertion (see Fig. 122.5). The tip of an umbilical artery catheter should lie at L3-L5 just above the bifurcation of the aorta or at T6-T10. The placement and supervision should be carried out by skilled and experienced personnel. Catheters should be removed as soon as patients no longer have any indication for their continued use—usually when an infant is stable and the fraction of inspired oxygen (F\textsubscript{I}O\textsubscript{2}) is <40%.
Nasal Continuous Positive Airway Pressure

Warm, humidified oxygen should be provided at a concentration sufficient to keep $P_{aO_2}$ between 50 and 70 mm Hg (91–95% $S_{aO_2}$) to maintain normal tissue oxygenation while minimizing the risk of $O_2$ toxicity. If there is significant respiratory distress (severe retractions and expiratory grunting) or if $S_{aO_2}$ cannot be kept $>90\%$ at $F_{iO_2}$ of $\geq 40–70\%$, applying nCPAP at 5-10 cm H$_2$O is indicated and usually produces a rapid improvement in oxygenation. Nasal CPAP reduces collapse of surfactant-deficient alveoli and improves both FRC and ventilation-perfusion matching. *Early use of nCPAP for stabilization of at-risk preterm infants beginning early (in the delivery room) reduces the need for mechanical ventilation.*

Recognizing the benefits of surfactant replacement therapy, in addition to the potential protective effects of prophylactic nCPAP, some experts recommend intubation for prophylactic or early rescue surfactant replacement therapy, followed by extubation back to nCPAP immediately once the infant is stable (usually within minutes to <1 hr). The aforementioned method is commonly referred to as **intubate surfactant and extubate** (INSURE). A variation of the INSURE method has evolved known as MIST (**minimally invasive surfactant therapy**) or LISA (**less invasive surfactant administration**), in which a small feeding tube, rather than an endotracheal tube (ETT), is used to deliver intratracheal surfactant to a spontaneously breathing infant on nCPAP. The combination of early rescue surfactant by the INSURE, MIST, or LISA method with nCPAP has been associated with the reduced need for mechanical ventilation, and emerging evidence suggests modest benefits in terms of preventing BPD. The amount of nCPAP required usually decreases after approximately 72 hr of age, and most infants can be weaned from nCPAP shortly thereafter. *Assisted ventilation and surfactant are indicated for infants with RDS who cannot keep oxygen saturation >90\% while breathing 40–70\% oxygen and receiving nCPAP.*

In an effort to minimize ventilator-associated lung injury and prevent long-term pulmonary complications, the use of nCPAP as the initial respiratory support for extremely preterm infants is preferred. The decreased need for ventilator support with the use of nCPAP may allow lung inflation to be maintained while preventing lung injury. Early nCPAP is beneficial compared to intubation and prophylactic surfactant, because avoidance of mechanical ventilation is associated with a reduction in death and/or BPD. Infants at the
extremes of GA (<24 wk) and those that were not exposed to antenatal corticosteroids may still benefit from intubation and surfactant prophylaxis.

**Mechanical Ventilation**

Infants with respiratory failure or persistent apnea require assisted mechanical ventilation. Strict definitions for respiratory failure in extremely preterm infants with RDS are not agreed on universally, but reasonable measures of respiratory failure are (1) arterial blood pH < 7.20, (2) $\text{PaCO}_2 \geq 60$ mm Hg, (3) $\text{SaO}_2 < 90\%$ at O$_2$ concentration of 40–70% and nCPAP of 5-10 cm H$_2$O, and (4) persistent or severe apnea. The goal of mechanical ventilation is to improve oxygenation and ventilation without causing pulmonary injury or oxygen toxicity. Acceptable ranges of ABG values vary significantly among institutions but generally range from $\text{PaO}_2$ 50-70 mm Hg, $\text{PaCO}_2$ 45-65 mm Hg (and higher after the 1st few days when risk of IVH is less), and pH 7.20-7.35. During mechanical ventilation, oxygenation is improved by increasing either F$\text{IO}_2$ or the mean airway pressure. The mean airway pressure can be increased by raising the peak inspiratory pressure (PIP), inspiratory time, ventilator rate, or positive end-expiratory pressure (PEEP). Adjustment in pressure is usually most effective. However, excessive PEEP may impede venous return, thereby reducing cardiac output and O$_2$ delivery. Assisted ventilation for infants with RDS should always include appropriate PEEP (see Chapter 89.1). PEEP levels of 4-6 cm H$_2$O are usually safe and effective. CO$_2$ elimination is determined by the minute ventilation, which is a product of the tidal volume (dependent on the inspiratory time and PIP) and ventilator rate. Because of the homogeneous nature of the lung pathology associated with RDS, a high rate ($\geq 60$/min), low tidal volume (4-6 mL/kg) strategy is generally effective. Meta-analyses comparing high (>60 breaths/min) and low (usually 30-40 breaths/min) rates (and presumed low vs high tidal volumes, respectively) revealed that the high ventilatory rate strategy led to fewer air leaks and a trend for increased survival. With use of high ventilatory rates, sufficient expiratory time should be allowed to avoid air-trapping and inadvertent PEEP.

**Modes of Mechanical Ventilation**

*Synchronized intermittent mechanical ventilation* (SIMV) delivered by time-cycled, pressure-limited, continuous flow ventilators is a common method of
conventional ventilation for newborns. With pressure-limited SIMV, a set PIP is delivered in synchrony with the patient's own breaths for a specified rate per minute. For breaths above the set rate, pressure support breaths (8-10 cm H$_2$O above PEEP) are provided to help overcome the resistance associated with spontaneous breathing through the ETT. In *pressure-limited ventilation* the delivered tidal volume is directly proportional to the respiratory compliance. Rapid changes in compliance occur with surfactant replacement therapy, requiring careful attention to tidal volumes and appropriate adjustments in PIP. Advances in ventilator technology have allowed the delivery of very small (<10 mL) tidal volume breaths consistently. In *volume-targeted ventilation* a specific tidal volume is set, and the PIP required to deliver it varies inversely with the respiratory compliance. Other modes of volume-targeted ventilation calculate the lowest effective PIP to deliver the set tidal volume. Evidence suggests that volume-targeted ventilation results in fewer air leaks and may improve survival without BPD.

**High-frequency ventilation** (HFV) achieves desired alveolar ventilation by using smaller tidal volumes and higher rates (300-1,200 breaths/min or 5-20 Hz). HFV may improve elimination of CO$_2$ and improve oxygenation in patients who show no response to conventional ventilators, as well as those who have severe RDS, interstitial emphysema, recurrent pneumothoraces, or meconium aspiration pneumonia. **High-frequency oscillatory ventilation** (HFOV) and **high-frequency jet ventilation** (HFJV) are the most frequently used methods. HFOV may reduce BPD but the effect size is likely small. In severe respiratory failure unresponsive to conventional mechanical ventilation, HFOV strategies that promote lung recruitment, combined with surfactant therapy, may improve gas exchange. HFJV is particularly useful to facilitate resolution of air leaks. Elective use of either HFV method, in comparison with conventional ventilation, generally does not offer advantages when used as the initial ventilation strategy to treat infants with RDS.

**Permissive Hypercapnia and Avoidance of Hyperoxia**

**Permissive hypercapnia** is a strategy for management of patients receiving ventilatory support in whom priority is given to limiting ventilator-associated lung injury by tolerating relatively high levels of PaCO$_2$ (>60-70 mm Hg). Permissive hypercapnia can be implemented during nCPAP and mechanical ventilation but has not been shown to significantly impact outcomes. **Hyperoxia**
may also contribute to lung injury in preterm infants. However, a lower target range of oxygenation (85–89%) compared with a higher range (91–95%) increases mortality and does not alter rates of BPD, BPD/death, blindness, or neurodevelopmental impairment. Therefore the currently recommended range of oxygen saturation targets is 91–95%.

Discontinuation of Mechanical Ventilation

Strategies for weaning infants from ventilators vary widely and are influenced by lung mechanics as well as the availability of ventilatory modes. Extubation to nCPAP prevents postextubation atelectasis and reduces the need for reintubation. Synchronized nasal intermittent positive pressure ventilation (NIPPV) also decreases the need for reintubation in premature infants, but ventilators capable of synchronization with nasal ventilation are not widely available. HHHFNC (1-8 L/min) oxygen is typically used to support term and near-term infants following extubation. It is not clear whether nCPAP, NIPPV, or HHHFNC is more efficacious for promoting normal lung development and preventing BPD, but there is more evidence associated with nCPAP in extremely preterm infants. Preloading with methylxanthines enhances the success of extubation.

Surfactant Replacement Therapy

Surfactant deficiency is the primary pathophysiology of RDS. Immediate effects of surfactant replacement therapy include improved alveolar-arterial oxygen gradients, reduced ventilatory support, increased pulmonary compliance, and improved chest radiograph appearance. In the past, intratracheal surfactant replacement for symptomatic premature infants immediately after birth (prophylactic) or during the 1st few hr of life (early rescue) showed reduced air leak and mortality from RDS. However, substantial evidence supports the feasibility and efficacy of prophylactic nCPAP as the primary means of respiratory support for preterm infants with RDS. CPAP started at birth is as effective as prophylactic or early surfactant and is associated with a reduction in BPD. Prophylactic nCPAP is therefore the approach of choice for the delivery room management of a preterm neonate at risk for RDS.

In neonates with RDS who fail nCPAP and require intubation and mechanical ventilation, treatment with endotracheal surfactant should be initiated immediately to avoid lung injury. Repeated dosing is given every 6-12 hr for a total of 2-4 doses, depending on the preparation. Exogenous surfactant should be
given by a physician who is qualified in neonatal resuscitation and respiratory management. Additional required onsite staff support includes nurses and respiratory therapists experienced in the ventilatory management of preterm infants. Appropriate monitoring equipment (radiology, blood gas laboratory, pulse oximetry) must also be available. Complications of surfactant replacement therapy include transient hypoxia, hypercapnia, bradycardia and hypotension, blockage of ETT, and pulmonary hemorrhage.

A number of surfactant preparations are available, including synthetic surfactants and natural surfactants derived from animal sources. There do not appear to be significant, consistent benefits to one preparation over another. Infants requiring ventilator support after 1 wk of age may experience transient episodes of surfactant dysfunction temporally associated with episodes of infection and respiratory deterioration. Surfactant treatment may be beneficial in these infants.

**Other Pharmacologic Therapies**

There are no pharmacologic therapies superior or equal to the efficacy of maintaining FRC (through noninvasive respiratory support and mechanical ventilation when necessary) and providing surfactant replacement therapy in the treatment of RDS. Systemic corticosteroids (predominantly dexamethasone), although effective in improving respiratory mechanics and preventing BPD and death, are associated with increased risk of cerebral palsy and neurodevelopmental impairment when used indiscriminately. Thus, routine use of systemic corticosteroids for the prevention or treatment of BPD is not recommended by the Consensus Group of the American Academy of Pediatrics and the Canadian Pediatric Society. Early (1st 10 days of life), low-dose administration (1 mg/kg/day hydrocortisone twice daily for 7 days; 0.5 mg/kg/day for 3 days) may reduce the risk of BPD in neonates <28 wk GA. In general, administration of inhaled corticosteroids to ventilated preterm infants during the 1st 2 wk after birth has not proved to be consistently advantageous.

**Inhaled nitric oxide (iNO)** has been evaluated in preterm infants following the observation of its effectiveness in term and near-term infants with hypoxemic respiratory failure. Although iNO improves oxygenation in term and near-term infants with hypoxic respiratory failure or persistent pulmonary hypertension of the neonate, trials in preterm infants have not shown significant benefit. The most current data do not support the routine administration of iNO in preterm
infants with hypoxemic respiratory failure.

Hypotension and low flow in the superior vena cava have been associated with higher rates of CNS morbidity and mortality and should be treated with cautious administration of crystalloid (if volume depletion due to hemorrhage or excessive insensible fluid losses is suspected) and early use of vaspressors. Dopamine is more effective in raising blood pressure than dobutamine. Hypotension that is refractory to vasopressor therapy, especially in neonates <1,000 g, may be caused by transient adrenal insufficiency. Administration of intravenous hydrocortisone at 1-2 mg/kg/dose every 6-12 hr may improve blood pressure and allow weaning of vaspressors.

Because of the difficulty in distinguishing group B streptococcal or other bacterial infections from RDS, empirical antibiotic therapy may be indicated until the results of blood cultures are available. Penicillin or ampicillin with an aminoglycoside is suggested, although the choice of antibiotics should be based on the recent pattern of bacterial sensitivity in the hospital where the infant is being treated (see Chapter 129).

Complications

Early provision of intensive observation and care of high-risk newborn infants can significantly reduce the morbidity and mortality associated with RDS and other acute neonatal illnesses. Antenatal corticosteroids, postnatal surfactant use, and improved modes of ventilation have resulted in low mortality from RDS (approximately 10%). Mortality increases with decreasing gestational age. Optimal results depend on the availability of experienced and skilled personnel, care in specially designed and organized regional hospital units, proper equipment, and lack of complications such as severe asphyxia, intracranial hemorrhage, or irremediable congenital malformation.

The most serious complications of endotracheal intubation are pulmonary air leaks, asphyxia from obstruction or dislodgment of the tube, bradycardia during intubation or suctioning, and the subsequent development of subglottic stenosis. Other complications include bleeding from trauma during intubation, posterior pharyngeal pseudodiverticula, need for tracheostomy, ulceration of the nares caused by pressure from the tube, permanent narrowing of the nostril as a result of tissue damage and scarring from irritation or infection around the tube, erosion of the palate, avulsion of a vocal cord, laryngeal ulcer, papilloma of a vocal cord, and persistent hoarseness, stridor, or edema of the larynx.
Measures to reduce the incidence of these complications include skillful intubation, adequate securing of the tube, use of polyvinyl ETTs, use of the smallest tube that will provide effective ventilation in order to reduce local pressure necrosis and ischemia, avoidance of frequent changes and motion of the tube in situ, avoidance of too frequent or too vigorous suctioning, and prevention of infection through meticulous cleanliness and frequent sterilization of all apparatus attached to or passed through the tube. The personnel inserting and caring for the ETT should be experienced and skilled in such care.

**Extrapulmonary air leaks** (pneumothorax, pneumomediastinum, pulmonary interstitial emphysema) are observed in 3–9% of extremely preterm infants with RDS (see Chapter 122.12). PPV with excessive inspiratory pressures (and therefore excessive tidal volumes), either during resuscitation at delivery or in the initial hours of mechanical ventilation, is a common risk factor, but air leaks can also occur in infants breathing spontaneously. Although the risk of air leak was increased in infants receiving a higher level of nCPAP (up to 8 cm H$_2$O) in the CPAP or Intubation at Birth (COIN) trial, subsequent trials have not demonstrated a similar effect.

Risks associated with **umbilical arterial catheterization** include vascular embolization, thrombosis, spasm, and vascular perforation; ischemic or chemical necrosis of abdominal viscera; infection; accidental hemorrhage; hypertension; and impairment of circulation to a leg with subsequent gangrene. Aortography has demonstrated that clots form in or about the tips of 95% of catheters placed in an umbilical artery. Aortic ultrasonography can also be used to investigate for the presence of thrombosis. **Renovascular hypertension** may occur days to weeks after umbilical arterial catheterization in a small proportion of neonates. Transient blanching of the leg may occur during catheterization of the umbilical artery. It is usually caused by reflex arterial spasm, the incidence of which is lessened by using the smallest available catheter, particularly in very small infants. The catheter should be removed immediately; catheterization of the other artery may then be attempted. **Umbilical vein catheterization** is associated with many of the same risks as umbilical artery catheterization. Additional risks are cardiac perforation and pericardial tamponade; improperly placed catheters in the portal vein can lead to thrombosis. The risk of a serious clinical complication resulting from umbilical catheterization is probably 2–5%.

Incidence

Bronchopulmonary dysplasia (BPD, also known as chronic lung disease of prematurity) is a clinical pulmonary syndrome that develops in the majority of extremely preterm infants and is defined by a prolonged need for respiratory support and supplemental oxygen. Almost 60% of infants born at ≤28 wk gestation will develop BPD, and the incidence of BPD increases inversely with gestational age. For infants born at the extreme of viability (22-24 wk), essentially 100% will develop BPD, the majority of whom will have moderate to severe disease. As neonatal care has improved and use of antenatal corticosteroids has become the standard of care, survival of infants born at the extreme of viability has improved, and BPD is encountered with increased prevalence. In the United States, an additional 10,000-15,000 new cases occur annually. Despite decades of experience, the incidence of BPD remains largely unchanged.

Etiology and Pathophysiology

BPD develops following preterm birth and the necessary life-supporting
interventions (particularly mechanical ventilation and supplemental oxygen) that cause neonatal lung injury. As the limit of viability has been lowered by advances in neonatal care, the clinical syndrome associated with BPD has evolved. The clinical, radiographic, and lung histology of classic BPD described in 1967, before widespread use of antenatal corticosteroids and postnatal surfactant, was that of a disease of preterm infants who were more mature. During that era, infants born ≤30-32 wk gestation rarely survived. Infants who developed BPD demonstrated classic RDS initially, but the injurious mechanical ventilation and excessive supplemental oxygen required to support them resulted in a progressive, severe fibroproliferative lung disease. Improvements in respiratory care, as well as the introduction of surfactant and antenatal steroids, have allowed for gentle respiratory support strategies, and the need for excessive ventilator support and high percentages of inspired supplemental oxygen has decreased.

Despite a reduction in the fibroproliferative disease described previously, infants born in the modern era of neonatal care continued to require supplemental oxygen for prolonged periods. The new BPD is a disease primarily of infants with birthweight <1,000 g who were born at <28 wk gestation, some of whom have little or no lung disease at birth but over the 1st weeks of age experience progressive respiratory failure. Infants with the new BPD are born at a more immature stage of distal lung development, and lung histology demonstrates variable saccular wall fibrosis, minimal airway disease, abnormal pulmonary microvasculature development, and alveolar simplification. Although the etiology remains incompletely understood, the histopathology of BPD indicates interference with normal alveolar septation and microvascular maturation.

The pathogenesis of BPD is likely multifactorial, but pulmonary inflammation and lung injury are consistently observed. Alveolar collapse (atelectrauma) as a consequence of surfactant deficiency, together with ventilator-induced phasic overdistention of the lung (volutrauma), promotes lung inflammation and injury. Supplemental oxygen produces free radicals that cannot be metabolized by the immature antioxidant systems of very-low-birthweight (VLBW) neonates and further contributes to the injury. Pulmonary inflammation evidenced by infiltration of neutrophils and macrophages in alveolar fluid, as well as a host of proinflammatory cytokines, contributes to the progression of lung injury. Pre- and postnatal infection, excessive pulmonary blood flow via the patent ductus arteriosus (PDA), excessive administration of intravenous fluid, and pre- and
postnatal growth failure are also significantly associated with the development of BPD. While the mechanisms are unclear, all likely promote lung injury by necessitating increased or prolonged respiratory support or interfering with lung repair. Regardless, the result is an interference with normal development of the alveolar-capillary unit and interference with normal gas exchange.

Clinical Manifestations

Over the 1st several wk of age, infants developing BPD demonstrate persistent, often progressive respiratory distress and the need for respiratory support and supplemental oxygen. In extremely-low-birthweight (ELBW) infants at risk for BPD, the need for supplemental oxygen over the 1st 2 wk of age follows 1 of 3 distinct patterns. Infants that follow the natural course of RDS, and by the 3-4 days of age require minimal (FIO₂ <0.25) supplemental oxygen, have a low (<20%) risk of developing BPD. Infants who initially have a low O₂ requirement (FIO₂ <0.25) during the 1st wk, but then experience early pulmonary deterioration and increased O₂ requirement (FIO₂ >0.25) during the 2nd wk, have a modest risk (approximately 50%) of developing BPD. Infants that have an early, persistently high (FIO₂ >0.25) need for supplemental oxygen have a significantly high (70%) risk of developing BPD.

Respiratory distress, commonly characterized by tachypnea and retractions, persists or worsens and is associated with hypercapnia, hypoxia, and oxygen dependence. The chest radiograph evolves from that of RDS to relative hyperinflation and fine, diffuse interstitial opacities. Wandering atelectasis is common. In the most severe cases, usually associated with prolonged mechanical ventilation and chronically high supplemental oxygen needs, frank cystic changes and/or pneumatoceles are observed (Fig. 122.6). Infants with severe BPD often demonstrate airway obstruction. Excessive airway mucus and edema, airway instability caused by acquired tracheobronchomalacia, and bronchospasm are proposed etiologies. Acute airway obstruction is manifest clinically by abrupt hypoxemia and bradycardia and is often referred to as BPD spells. Acute, intermittent right-to-left intracardiac or intrapulmonary shunting caused by abrupt elevations in pulmonary artery pressure may also contribute. Spells are notoriously difficult to control, but occasionally will respond to bronchodilators and sedation acutely.
FIG. 122.6  Pulmonary changes in infants treated with prolonged, intermittent positive pressure breathing with air containing 80–100% oxygen in the immediate postnatal period for the clinical syndrome of hyaline membrane disease. A, A 5 day old infant with nearly complete opacification of the lungs. B, A 13 day old infant with “bubbly lungs” simulating the radiographic appearance of the Wilson-Mikity syndrome. C, A 7 mo old infant with irregular, dense strands in both lungs, hyperinflation, and cardiomegaly suggestive of chronic lung disease. D, Large right ventricle and a cobbly, irregular aerated lung of an infant who died at 11 mo of age. This infant also had a patent ductus arteriosus. (From Northway WH Jr, Rosan RC, Porter DY: Pulmonary disease following respiratory therapy of hyaline-membrane disease, N Engl J Med 276:357–368, 1967.)

A common, increasingly recognized complication of BPD is pulmonary hypertension. Prospective surveillance indicates that in approximately 15% of all infants born at <1,000 g and <28 wk GA, echocardiographic signs of pulmonary hypertension will develop. Prenatal growth restriction, prolonged duration of mechanical ventilation and supplemental oxygen, and increasing severity of BPD are all associated with an increased risk. Pulmonary hypertension has been reported in as many as 40% of infants with the most severe BPD and can progress to right-sided heart failure. Consistently, pulmonary hypertension complicating BPD has been associated with increased mortality.

**Diagnosis**

BPD is diagnosed when a preterm infant requires supplemental oxygen for the 1st 28 postnatal days, and it is further classified at 36 wk PMA according to the degree of O₂ supplementation (Table 122.1). Neonates receiving positive pressure support or ≥30% supplemental O₂ at 36 wk PMA or at discharge (whichever occurs first) are diagnosed as having severe BPD; those requiring 22–29% supplemental O₂ have moderate BPD; and those who previously required O₂ supplementation for at least 28 days but are currently breathing room air have mild BPD. Infants receiving <30% supplemental O₂ should undergo a stepwise 2% reduction in supplemental O₂ to room air while under continuous observation and with S GOD monitoring to determine whether they can be weaned off oxygen (physiologic definition of BPD). This test is highly
reliable and correlated with discharge home on oxygen, length of hospital stay, and hospital readmissions in the 1st yr of life. The risk of neurodevelopmental impairment and pulmonary morbidity and the severity of BPD are directly correlated.

**Table 122.2**  
**Definition of Bronchopulmonary Dysplasia (BPD): Diagnostic Criteria**

Treatment with >21% oxygen for at least 28 days **plus:** |
| Mild BPD | Breathing room air at 36 wk PMA or discharge home, whichever comes first | Breathing room air by 56 days postnatal age or discharge home, whichever comes first |
| Moderate BPD | Need † for <30% oxygen at 36 wk PMA or discharge home, whichever comes first | Need † for <30% oxygen at 56 days postnatal age or discharge home, whichever comes first |
| Severe BPD | Need † for ≥30% oxygen and/or positive pressure (PPV or NCPAP) at 36 wk PMA or discharge home, whichever comes first | Need † for ≥30% oxygen and/or positive pressure (PPV or NCPAP) at 56 days postnatal age or discharge home, whichever comes first |

* BPD usually develops in neonates being treated with oxygen and PPV for respiratory failure, most frequently respiratory distress syndrome (RDS). Persistence of the clinical features of respiratory disease (tachypnea, retractions, crackles) is considered common to the broad description of BPD and has not been included in the diagnostic criteria describing the severity of BPD. Infants treated with >21% oxygen and/or PPV for nonrespiratory disease (e.g., central apnea or diaphragmatic paralysis) do not have BPD unless parenchymal lung disease also develops and they have clinical features of respiratory distress. A day of treatment with >21% oxygen means that the infant received >21% oxygen for >12 hr on that day. Treatment with >21% oxygen and/or PPV at 36 wk PMA or at 56 days postnatal age or discharge should not reflect an “acute” event, but should rather reflect the infant’s usual daily therapy for several days preceding and after 36 wk PMA, 56 days postnatal age, or discharge.

† A physiologic test confirming that the oxygen requirement at the assessment time point remains to be defined. This assessment may include a pulse oximetry saturation range.

NCPAP, Nasal continuous positive airway pressure; PMA, postmenstrual age; PPV, positive pressure ventilation.

Despite its simplicity, the current severity-based definition of BPD has limitations. Because of incomplete or inaccurate data related to hospital transfer or early discharge, in a significant number of infants the diagnosis of BPD is
either not documented or misapplied. Additionally, those infants requiring \(O_2\) support at relatively high flow (>2 L/min) or very low (<0.25 L/min) are not well characterized. Calculation of *effective oxygen* may be helpful but is cumbersome and not well validated. Many clinical trials have simply relied on the need for supplemental \(O_2\) at 36 wk PMA to define BPD. While this definition can diagnose BPD in the highest percentage of infants, it cannot discriminate between infants with milder BPD from those with most severe forms of BPD. In general, any definition of BPD striving to identify infants who benefit from long-term follow up and therapy has been disappointing. Therefore an improved yet feasible definition of BPD is required that accurately evaluates the utility of investigational therapies, predicts long-term outcomes, and directs clinical care.

**Prevention**

In general, there remains a lack of effective interventions that prevent BPD. Avoidance of mechanical ventilation with the early use of nCPAP and early, selective surfactant replacement therapy with rapid extubation decrease the incidence of BPD modestly. The avoidance of mechanical ventilation achieved by the combination of early rescue surfactant by the INSURE, MIST, or LISA method with nCPAP has been associated with a modest reduction in BPD. Gentle ventilation strategies, including volume-targeted ventilation and HFOV, have also been associated with small, inconsistent reductions in BPD. Caffeine therapy for apnea of prematurity has also been associated with a decreased risk of BPD. Although the mechanisms are unknown, caffeine likely supports effective spontaneous respiration and decreases the likelihood that an infant will need invasive mechanical ventilation.

Animal models of BPD have consistently demonstrated that vitamin A supplementation promotes distal alveolar development. Previously, provision of intramuscular (IM) vitamin A (5,000 IU 3 times/wk for 4 wk) to VLBW infants was shown to reduce the risk of BPD (1 case prevented for every 14-15 infants treated). However, with the widespread use of early nCPAP, it is unclear if a significant benefit remains, and therefore the use of vitamin A has been inconsistent. Despite promising preclinical data in animal models, the use of prophylactic iNO does not consistently prevent BPD, and its routine use is not recommended.

**Systemic corticosteroids** (dexamethasone) given either early (<7 days of age
to ventilated infants at risk of BPD) or late (>7 days of age to infants with progressing lung disease) prevent both mortality and BPD significantly, but because of the increased risk of cerebral palsy (CP) and neurodevelopmental impairment, their routine use is not recommended. The risk of neurodevelopmental impairment related to systemic corticosteroid use may be offset by the risk associated with BPD. A systematic review suggested that systemic corticosteroid therapy, when directed to infants with a ≥65% risk of developing BPD, may actually reduce the risk of neurodevelopmental impairment and CP. Although predictive models that use clinical characteristics have been described with promising accuracy, randomized trials using them to guide corticosteroid therapy have not been performed. Systemic hydrocortisone given early to extremely preterm infants at risk for BPD, especially those exposed to chorioamnionitis, may prevent BPD without neurodevelopmental impairment. However, at this time there are insufficient data on safety to support its routine use. Inhaled corticosteroids administered to VLBW infants requiring mechanical ventilation at 7-14 days of age did not prevent BPD significantly. However, early, prolonged administration to mechanically ventilated extremely preterm infants until they no longer require oxygen or positive pressure support has been shown to reduce the risk of BPD, but with a concerning trend toward increased mortality. Experience with local delivery of corticosteroids by spiking surfactant with budesonide is emerging, and early data suggest that endotracheal administration of corticosteroids may reduce pulmonary inflammation and the risk of BPD and death. However, additional evidence is needed before widespread use is implemented. The routine use of antibiotics, inhaled bronchodilators, or diuretics has not been shown to prevent BPD.

**Treatment**

Treatment of evolving and established BPD is supportive, and evidence-based therapies are lacking. The basic tenets of therapy should include appropriate support of ventilation and aggressive nutritional support to optimize linear growth and encourage normal lung repair and development. Despite a lack of support from investigational studies in the current era of BPD, numerous medical interventions are employed. Available evidence suggests short-term benefits (improved pulmonary mechanics, modest reductions in respiratory support parameters) without an indication of impact on clinically relevant outcomes (survival, need for long-term respiratory support, recurrent
hospitalization). Currently, available evidence does not support the routine use of any pharmacologic agents in infants with evolving or established BPD. Treatment decisions must weigh the perceived benefit against the potential harm, since data on not only efficacy, but more importantly safety, remain inadequate.

**Diuretics and Fluid Restriction**

Infants with BPD often have excessive pulmonary interstitial fluid that compromises lung function and increases work of breathing. Diuretic therapy (usually with furosemide or chlorothiazide) has been associated with short-term, temporary improvements in pulmonary compliance and the ability to wean respiratory support. **Furosemide** (1 mg/kg/dose IV or 2 mg/kg/dose PO every 12-24 hr) has been demonstrated to decrease pulmonary interstitial emphysema and PVR, improve pulmonary function, and facilitate weaning from mechanical ventilation and oxygen. Adverse effects of long-term furosemide therapy are common and include hyponatremia, hypokalemia, alkalosis, azotemia, hypocalcemia, hypercalciuria, cholelithiasis, renal stones, nephrocalcinosis, and ototoxicity. Potassium chloride supplementation is often necessary. Thiazide diuretics (e.g., chlorothiazide, 5-10 mg/kg/dose every 12 hr) have been used as an alternative to avoid hypercalciuria, limit nephrocalcinosis, and preserve bone development. Although avoidance of excessive fluid administration in the 1st few wk of age is associated with a reduced risk of BPD, there is no evidence that fluid restriction (130-140 mL/kg/day) in established BPD has any impact. Whether using diuretics or fluid restriction, careful attention to maintaining appropriate electrolyte levels as well as providing adequate caloric intake (often >120-130 kcal/kg/day) is paramount to avoid negatively impacting nutrition.

**Bronchodilators**

Inhaled bronchodilators improve lung mechanics by decreasing airway resistance. **Albuterol** is a specific $\beta_2$-agonist used to treat bronchospasm in infants with BPD. Albuterol may improve lung compliance by decreasing airway resistance secondary to smooth muscle cell relaxation. Changes in pulmonary mechanics may last as long as 4-6 hr. Hypertension and tachycardia are common adverse effects. **Ipratropium bromide** is a muscarinic antagonist related to atropine, but the bronchodilator effect is more potent. Use of ipratropium bromide in BPD has been associated with improved pulmonary mechanics.
Compared to either agent used alone, combined use of albuterol and ipratropium bromide may be more effective. Few adverse effects have been noted. With current aerosol administration strategies, exactly how much medication is delivered to the airways and lungs of infants with BPD, especially if they are ventilator dependent, is unclear.

**Corticosteroids**

In addition to their use at an early age (<7 days) to prevent BPD, **systemic corticosteroids** have also been used to treat evolving and established BPD. In mechanically ventilated infants, systemic corticosteroids improve pulmonary mechanics, allow weaning of ventilator support and supplemental O₂, and facilitate extubation. When given at >7 days of age, long-term benefits include a reduced need for O₂ at 36 wk PMA, improved survival, and decreased need for home O₂. Short-term adverse effects include hyperglycemia, hypertension, and transient hypertrophic obstructive cardiomyopathy. Long-term adverse effects include osteopenia, severe retinopathy of prematurity (ROP), abnormal neurological examination, poor brain growth, neurodevelopmental impairment, and CP. Although meta-analyses suggest that the long-term detrimental effects on neurodevelopment might be mitigated by later postnatal use, open-label use of corticosteroids in control groups makes analysis of safety unreliable. A strategy that utilizes a low cumulative dose (0.89 mg/kg given over 10-day taper) in preterm infants who remain ventilator dependent after 7 days of age (and therefore have a high risk of developing BPD) facilitates weaning of ventilator and oxygen support and promotes successful extubation without an impact on long-term outcomes, including the incidence of BPD or neurodevelopmental impairment. However, randomized controlled trials (RCTs) with appropriate power to assess safety are lacking. The controversy concerning the appropriate use of systemic corticosteroids to prevent and/or treat BPD is ongoing, and until additional evidence is available, their use remains limited to infants with severe respiratory failure (ventilator dependent at >7-14 days of age with significant respiratory and oxygen support needs) at high risk for imminent death.

In an effort to avoid the detrimental effects of systemic corticosteroids, **inhaled corticosteroids** (budesonide, fluticasone, and beclomethasone) have been described as an alternative antiinflammatory therapy in evolving or established BPD. Small RCTs and case reports in infants with established
moderate-severe BPD have not shown a significant benefit for pulmonary mechanics or reduction in the need for ventilator or oxygen support.

**Pulmonary Vasodilators**

Many infants with evolving or established moderate and severe BPD demonstrate pulmonary vascular resistance caused by pulmonary microvascular maldevelopment and abnormal vasoreactivity. In infants with BPD with pulmonary hypertension, acute exposure to even modest levels of hypoxemia can cause pulmonary artery pressure (PAP) to increase abruptly. Maintaining infants with established BPD and pulmonary hypertension at higher $\text{So}_2$ targets (92–96%) can lower PAP effectively. For infants in whom appropriate $\text{O}_2$ supplementation and support of ventilation are ineffective, the use of low-dose **inhaled NO** may improve oxygenation anecdotally. Despite its frequent use, there is no evidence to support the use of iNO to improve lung function, cardiac function, or oxygenation in evolving BPD. Several case series have reported on the use of the phosphodiesterase-5 inhibitor **sildenafil** in treating pulmonary hypertension in established moderate to severe BPD. Despite its widespread use, no RCTs are evaluating the safety and efficacy of sildenafil in preterm infants with BPD. However, many experts would recommend a trial of low-dose sildenafil (1 mg/kg/dose every 8 hr) for infants with evidence of pulmonary hypertension and persistent respiratory instability despite appropriate oxygen and ventilator support.

**Chronic Respiratory Support**

Evidence is lacking to guide respiratory management in evolving and established BPD. Experience suggests that maintaining FRC with appropriate positive pressure support (with noninvasive support whenever possible) promotes optimal lung growth and development. Provision of nCPAP until respiratory status improves and oxygen dependence resolves, with subsequent transition directly to room air, may be beneficial but is not based on evidence. Continuation of caffeine therapy may facilitate spontaneous breathing and weaning from support. Established severe BPD with cystic, heterogeneous lung disease requires prolonged mechanical ventilation. A long inspiratory time is required to adequately ventilate diseased lung units, and appropriate expiratory time is required to allow exhalation. The use of a low rate (<20-30 breaths/min),
long inspiratory time (≥0.6 sec) strategy is usually required. To attain appropriate minute ventilation, larger tidal volumes (10-12 mL/kg) are necessary. Higher PEEP (often >6-8 cm) may be needed to attain adequate expansion and minimize gas-trapping caused by dynamic airway collapse. Gradual weaning of ventilator settings should be attempted as the infant grows and lung disease improves, but the incidence of death or tracheostomy placement for chronic ventilation may be as high as 20%. By 2-3 yr of age, the majority of infants who undergo tracheostomy for severe BPD are successfully liberated from mechanical ventilation.

**Prognosis**

Compared with extremely preterm infants without BPD, infants with BPD have higher rates of neurodevelopmental impairment, lung diffusion impairment, wheezing and airflow obstruction, rehospitalization, and mortality. The risk of these complications increases with BPD severity. Prolonged mechanical ventilation, IVH, pulmonary hypertension, cor pulmonale, and oxygen dependence beyond 1 yr of life are poor prognostic signs. Mortality in infants with BPD ranges from 10–25% and is highest in infants who remain ventilator dependent for >6 mo. Cardiorespiratory failure associated with cor pulmonale and acquired infection (respiratory syncytial virus) are common causes of death. Infants are at risk for severe RSV infections and must receive prophylactic therapy (see Chapter 287).

Pulmonary function slowly improves in most survivors because of ongoing lung repair and the natural period of lung growth and alveolarization. **Rehospitalization** for impaired pulmonary function is most common during the 1st 3 yr of life and is much more common in infants requiring respiratory support at discharge. The incidence of physician-diagnosed asthma, use of bronchodilators, and wheezing is elevated. Despite a gradual decrease in symptom frequency, persistence of respiratory symptoms and abnormal pulmonary function test results are measurable in children, adolescence, and young adults. Although not always clinically apparent, pulmonary function testing consistently reveals impaired exercise capacity, reduced pulmonary diffusing capacity, and persistent expiratory flow obstruction. High-resolution chest CT scanning or MRI studies in children and adults with a history of BPD reveal lung abnormalities that correlate directly with the degree of pulmonary function abnormality. The ultimate long-term pulmonary health of survivors of
BPD is unknown. As trajectories of developing lung function remain abnormal in survivors of BPD, concerns have been raised highlighting the potential for pulmonary emphysema, chronic obstructive pulmonary disease, and pulmonary vascular disease resulting in early debilitating lung dysfunction.

Other complications of BPD include growth failure, neurodevelopmental impairment, and parental stress, as well as sequelae of therapy, such as nephrolithiasis, osteopenia, and electrolyte imbalance. Airway problems such as vocal cord paralysis, subglottic stenosis, and tracheomalacia are common and may aggravate or cause pulmonary hypertension. Subglottic stenosis may require tracheotomy or an anterior cricoid split procedure to relieve upper airway obstruction. Cardiac complications of BPD include pulmonary hypertension, cor pulmonale, systemic hypertension, left ventricular hypertrophy, and development of aortopulmonary collateral vessels, which, if large, may cause heart failure.

Keywords

patent ductus arteriosus
PDA
indomethacin
ibuprofen
cyclooxygenase inhibitors
surgical ligation

Incidence and Pathophysiology

Some neonates with RDS may have clinically significant shunting through a patent ductus arteriosus (PDA). Although ductal closure occurs by 72 hr after birth in almost all term infants, at the same age in 65% of preterm infants born at <30 wk GA, the ductus remains patent. Risk factors for delayed closure of the PDA include hypoxia, acidosis, increased pulmonary pressure secondary to vasoconstriction, systemic hypotension, immaturity, and local release of prostaglandins (which dilate the ductus). Shunting through the PDA may initially be bidirectional or right to left. As respiratory distress syndrome (RDS) resolves, pulmonary vascular resistance (PVR) decreases, and left-to-right shunting may occur, leading to left ventricular (LV) volume overload and pulmonary edema.

Clinical Manifestations

Manifestations of PDA may include (1) a hyperdynamic precordium, bounding peripheral pulses, wide pulse pressure, and a machine-like continuous or systolic
murmur; (2) radiographic evidence of cardiomegaly and increased pulmonary vascular markings; (3) hepatomegaly; (4) increasing oxygen dependence; (5) carbon dioxide retention; and (6) renal failure. Infants with a hemodynamically significant PDA often require escalation of ventilator and oxygen support. The diagnosis is confirmed by echocardiographic visualization of a PDA with Doppler flow imaging that demonstrates left-to-right or bidirectional shunting.

## Treatment

Management of the PDA is controversial, and evidence to guide treatment is limited. Prophylactic closure before signs of a PDA, closure of the asymptomatic but clinically detected PDA, and closure of the symptomatic PDA are 3 management strategies. Interventions to encourage ductal closure include fluid restriction, cyclooxygenase (COX) inhibitors (indomethacin or ibuprofen), and surgical ligation. Short-term benefits of any therapy have to be balanced against adverse effects, such as transient renal dysfunction and fluid imbalances associated with indomethacin.

By the time of discharge in the majority of extremely preterm infants (>90%), the PDA will close spontaneously. Spontaneous ductal closure may be facilitated by general supportive measures, including early (<7 days of age) avoidance of excessive fluid administration and judicious use of diuretics to manage pulmonary edema. However, within the 1st week of age, in 30% of infants with birthweight <1,500 g and 70% of infants <1,000 g, the PDA persists. Although many preterm infants with persistent PDA will remain clinically stable while awaiting spontaneous closure, approximately 60% of infants <1,000 g will develop significant clinical instability (hypotension, renal failure, worsening respiratory failure secondary to pulmonary edema). Pharmacologic and surgical ductal closure may be indicated in the premature infant with a moderate to large, hemodynamically significant PDA when there is a delay in clinical improvement or deterioration.

## Pharmacologic Closure

Pharmacologic closure of the PDA has been described using COX inhibitors that inhibit prostaglandin production, with equivalent efficacy and safety profiles described for ibuprofen and indomethacin. The efficacy of pharmacological therapy is inversely proportional to the gestational and postnatal age, and closure
is more likely when medication is administered before 14-21 days of age. However, successful closure has been reported up to 8 wk of age. Whether indomethacin or ibuprofen is used, 20–40% of infants demonstrate treatment failure, and of those infants, 10–20% require eventual surgical ligation. Rates of recurrence following successful pharmacologic closure in general are low (<15%). Neither therapy significantly impacts the rate of NEC, BPD, or mortality.

**General contraindications** to both indomethacin and ibuprofen include thrombocytopenia (<50,000 platelets/mm$^3$), active hemorrhage (including severe IVH), NEC or isolated intestinal perforation, elevated plasma creatinine (>1.8 mg/dL), or oliguria (urine output <1 mL/kg/hr). Importantly, the concomitant use of hydrocortisone and indomethacin in extremely preterm infants must be avoided, because the combination is associated with a dramatic increase in spontaneous intestinal perforation. Despite that indomethacin reduces mesenteric blood flow, mounting experience suggests that low-volume trophic enteral feeding during administration is safe.

Prophylactic **indomethacin** given over the 1st 72 hr of age to preterm infants with birthweight <1,000 g reduces the incidence of severe IVH (grade III/IV), pulmonary hemorrhage, symptomatic PDA, and need for surgical PDA ligation. Although often implicated in spontaneous intestinal perforation and NEC, RCTs have failed to demonstrate that indomethacin increases their risk significantly. Short-term side effects include reductions in cerebral, mesenteric, and renal blood flow. Oliguria unresponsive to diuretic therapy is observed frequently. Dosing regimens for indomethacin vary considerably, but it usually is administered as a slow IV infusion (0.1-0.2 mg/kg/dose over 30 min) every 12-24 hr for 3 doses. A repeat course can be attempted if the duct fails to close or reopens, but additional (>2) courses do not appear to be efficacious. Longer courses (5-7 days) of indomethacin are not recommended because of to an increased risk of NEC in one trial.

**Ibuprofen** is as effective as indomethacin in closing a PDA, but ibuprofen is associated with reduced rates of oliguria and a small but significant reduction in the length of mechanical ventilation. Although higher doses may improve closure rates in the most immature infants, the typical IV or enteral dosing regimen for ibuprofen is 10 mg/kg for 1 dose, followed by 2 doses of 5 mg/kg every 24 hr. As with indomethacin, a repeat course may be considered, but additional courses of ibuprofen are not efficacious and not recommended. Risk of NEC is not increased with indomethacin, but ibuprofen reduces the relative risk of NEC comparatively. Unlike indomethacin, ibuprofen has not been shown
to reduce the risk of severe IVH. Compared to the IV route, enteral ibuprofen may be more efficacious. Whether ibuprofen used in combination with hydrocortisone results in increased risk of spontaneous intestinal perforation is unknown.

Preliminary studies suggest that acetaminophen may be an effective drug to close a PDA, with fewer side effects than existing agents.

**Surgical Ligation**

The infant whose symptomatic PDA fails to close with pharmacologic interventions or who has contraindications to COX inhibitors is a candidate for surgical closure. Although the long-term benefits are unclear, surgical ligation in infants born at <28 wk GA and <1,250 g is associated with improved survival. Surgical mortality is very low even in ELBW infants. However, postligation cardiac syndrome, a significant drop in blood pressure 6-12 hr after ductal ligation, is experienced by up to 50% of LBW infants. The hypotension has been attributed to increased systemic vascular resistance along with decreased pulmonary venous return, resulting in impaired preload and LV function. Fluid resuscitation, inotropic support (with dobutamine or milrinone), and hydrocortisone are usually effective. Other complications of surgery include hemorrhage, pneumothorax, chylothorax, Horner syndrome, and injury to the recurrent laryngeal nerve resulting in vocal cord dysfunction. Inadvertent ligation of the left pulmonary artery or the transverse aortic arch has rarely been reported. Increased rates of neurodevelopmental impairment have been reported following surgical ligation, although a causal relationship remains uncertain.

fetal lung fluid
albuterol
salbutamol

Transient tachypnea of the newborn (TTN) is a clinical syndrome of self-limited tachypnea associated with delayed clearance of fetal lung fluid. Although the actual incidence is likely underreported, it is estimated at 3-6 per 1,000 term infant births, making TTN the most common etiology of tachypnea in the newborn. Twin gestation, maternal asthma, late prematurity, precipitous delivery, gestational diabetes, and cesarean delivery without labor are common associated risk factors. Clearance of fetal lung fluid occurs through increased expression of epithelial sodium channels (ENaC) and sodium-potassium adenosine triphosphatase (Na\(^+\),K\(^+\)-ATPase) that drive active sodium (and thereby fluid) reabsorption. TTN is believed to result from ineffective expression or activity of ENaC and Na\(^+\),K\(^+\)-ATPase, which slows absorption of fetal lung fluid and results in decreased pulmonary compliance and impeded gas exchange.
TTN is characterized by the early onset of tachypnea (>60 breaths/min), sometimes with retractions or expiratory grunting and occasionally with cyanosis that is relieved by minimal O₂ supplementation (<40%). The chest generally sounds clear without crackles or wheeze, and the chest radiograph shows prominent perihilar pulmonary vascular markings, fluid in the intralobar fissures, and rarely small pleural effusions. Hypercapnia and acidosis are uncommon. Respiratory failure requiring positive pressure support (either with nCPAP or mechanical ventilation) also is uncommon, but when it occurs usually resolves rapidly (<12-24 hr). Most infants recover with supportive care alone, and over the first 24-72 hours the tachypnea and O₂ requirements slowly resolve. Distinguishing TTN from RDS and other respiratory disorders (e.g., pneumonia) may be difficult, and transient tachypnea is frequently a diagnosis of exclusion. The distinctive features of TTN are rapid recovery of the infant and the absence of radiographic findings for RDS (low lung volumes, diffuse reticulogranular pattern, air bronchograms) and other lung disorders.

**Treatment** for TTN is supportive. There is no evidence supporting the use of oral furosemide or nebulized racemic epinephrine in this disorder. Inhaled β₂-agonists such as albuterol (salbutamol) increase expression and activation of ENaC and Na⁺,K⁺-ATPase and facilitate fluid clearance. Emerging evidence suggests that when given early in the course of TTN, albuterol may improve oxygenation, shorten the duration of supplemental O₂ therapy, and expedite recovery.

Aspiration of Foreign Material (Fetal Aspiration Syndrome, Aspiration Pneumonia)

Shawn K. Ahlfeld

Keywords

- aspiration pneumonia
- tracheoesophageal fistula
- gastroesophageal reflux

With fetal distress, infants often initiate vigorous respiratory movements in utero because of interference with the supply of oxygen through the placenta. Under such circumstances, the infant may aspirate amniotic fluid containing vernix caseosa, epithelial cells, meconium, blood, or material from the birth canal, which may block the smallest airways and interfere with alveolar exchange of O₂ and CO₂. Pathogenic bacteria may accompany the aspirated material, and pneumonia may ensue, but even in noninfected cases, respiratory distress accompanied by radiographic evidence of aspiration is seen (Fig. 122.7).
Postnatal pulmonary aspiration may also occur in newborn infants as a result of prematurity, tracheoesophageal fistula, esophageal and duodenal obstruction, gastroesophageal reflux, improper feeding practices, and administration of depressant medicines. To avoid aspiration of gastric contents, the stomach should be aspirated using a soft catheter just before surgery or other major procedures that require anesthesia or conscious sedation. The treatment of aspiration pneumonia is symptomatic and may include respiratory support and systemic antibiotics. Gradual improvement generally occurs over 3-4 days.
Meconium Aspiration

Shawn K. Ahlfeld

Keywords

meconium aspiration syndrome
MAS
persistent pulmonary hypertension
pneumothorax

Meconium-stained amniotic fluid is found in 10–15% of births and usually occurs in term or postterm infants. Meconium aspiration syndrome (MAS) develops in 5% of such infants; 30% require mechanical ventilation, and 3–5% die. Usually, but not invariably, fetal distress and hypoxia occur before the passage of meconium into amniotic fluid. The infants are meconium stained and may be depressed and require resuscitation at birth. Fig. 122.8 shows the pathophysiology of the MAS. Infants with MAS are at increased risk of persistent pulmonary hypertension (see Chapter 122.9).
Clinical Manifestations

Either in utero or with the first breath, thick, particulate meconium is aspirated into the lungs. The resulting small airway obstruction may produce respiratory distress within the 1st hours, with tachypnea, retractions, grunting, and cyanosis observed in severely affected infants. Partial obstruction of some airways may lead to pneumomediastinum, pneumothorax, or both. Overdistention of the chest may be prominent. The condition usually improves within 72 hr, but when its course requires assisted ventilation, it may be severe with a high risk for mortality. Tachypnea may persist for many days or even several weeks. The typical chest radiograph is characterized by patchy infiltrates, coarse streaking of
both lung fields, increased anteroposterior diameter, and flattening of the diaphragm. A normal chest radiograph in an infant with severe hypoxemia and no cardiac malformation suggests the diagnosis of pulmonary hypertension.

**Prevention**

The risk of meconium aspiration may be decreased by rapid identification of fetal distress and initiation of prompt delivery in the presence of late fetal heart rate deceleration or poor beat-to-beat FHR variability. Despite initial enthusiasm for amnioinfusion, it does not reduce the risk of MAS, cesarean delivery, or other major indicators of maternal or neonatal morbidity. Intrapartum nasopharyngeal suctioning in infants with meconium-stained amniotic fluid does not reduce the risk for MAS. Routine intubation and aspiration of depressed infants (those with hypotonia, bradycardia, or decreased respiratory effort) born through meconium-stained fluid is not effective in reducing the MAS or other major adverse outcomes and is not recommended for neonatal resuscitation.

**Treatment**

Treatment of the MAS includes supportive care and standard management for respiratory distress. The beneficial effect of mean airway pressure on oxygenation must be weighed against the risk of pneumothorax. Administration of exogenous surfactant and/or iNO to infants with MAS and hypoxemic respiratory failure, or pulmonary hypertension requiring mechanical ventilation, decreases the need for extracorporeal membrane oxygenation (ECMO), which is required by the most severely affected infants who show no response to therapy. In infants with MAS who demonstrate no other signs of sepsis, there is no role for routine antibiotic therapy. Severe meconium aspiration may be complicated by persistent pulmonary hypertension. Patients with MAS refractory to conventional mechanical ventilation may benefit from HFV or ECMO (see Chapter 122.9).

**Prognosis**

The mortality rate of meconium-stained infants is considerably higher than that of nonstained infants. The decline in neonatal deaths caused by MAS in recent
decades is related to improvements in obstetric and neonatal care. Residual lung problems are rare but include symptomatic cough, wheezing, and persistent hyperinflation for up to 5-10 yr. The ultimate prognosis depends on the extent of CNS injury from asphyxia and the presence of associated problems such as pulmonary hypertension.

**Persistent Pulmonary Hypertension**
of the Newborn (Persistent Fetal Circulation)

Shawn K. Ahlfeld

Keywords

persistent pulmonary hypertension of the newborn
PPHN
persistent fetal circulation
extracorporeal membrane oxygenation
ECMO
inhaled nitric oxide
iNO
sildenafil
high-frequency oscillatory ventilation
HFOV
alveolocapillary dysplasia
ACD

Persistent pulmonary hypertension of the newborn (PPHN) occurs in term and postterm infants most often. Predisposing factors include birth asphyxia, MAS, early-onset sepsis, RDS, hypoglycemia, polycythemia, maternal use of nonsteroidal antiinflammatory drugs with in utero constriction of the ductus arteriosus, maternal late trimester use of selective serotonin reuptake inhibitors, and pulmonary hypoplasia caused by diaphragmatic hernia, amniotic fluid leak, oligohydramnios, or pleural effusions. PPHN is often idiopathic. Some patients with PPHN have low plasma arginine and NO metabolite concentrations and polymorphisms of the carbamoyl phosphate synthase gene, findings suggestive of a possible subtle defect in NO production. The incidence is 1 in 500-1,500 live births, with a wide variation among clinical centers. Regardless of etiology of PPHN, profound hypoxemia from right-to-left shunting and normal or
elevated $\text{Paco}_2$ are present (Fig. 122.9).

**FIG. 122.9**  Cardiopulmonary interactions in persistent pulmonary hypertension of the newborn (PPHN). FO, Foramen ovale; LV, left ventricular; PDA, patent ductus arteriosus; PVR, pulmonary vascular resistance; RV, right ventricular; SVR, systemic vascular resistance. (From Kinsella JP, Abman SH: Recent developments in the pathophysiology and treatment of persistent pulmonary hypertension of the newborn, *J Pediatr* 126:853–864, 1995.)

**Pathophysiology**

Persistence of the fetal circulatory pattern of right-to-left shunting through the PDA and foramen ovale after birth is a result of excessively high pulmonary vascular resistance (PVR). Fetal PVR is usually elevated relative to fetal systemic or postnatal pulmonary pressure. This fetal state normally permits shunting of oxygenated umbilical venous blood to the left atrium (and brain) through the foramen ovale, from which it bypasses the lungs through the ductus arteriosus and passes to the descending aorta. After birth, PVR normally declines rapidly as a consequence of vasodilation secondary to lung inflation, a rise in postnatal $\text{Pao}_2$, a reduction in $\text{Paco}_2$, increased pH, and release of vasoactive substances. Increased neonatal PVR may be (1) **maladaptive** from an acute
injury (not demonstrating normal vasodilation in response to increased O₂ and other changes after birth); (2) the result of increased pulmonary artery medial muscle thickness and extension of smooth muscle layers into the usually nonmuscular, more peripheral pulmonary arterioles in response to chronic fetal hypoxia; (3) a consequence of **pulmonary hypoplasia** (diaphragmatic hernia, Potter syndrome); or (4) **obstructive** as a result of polycythemia, total anomalous pulmonary venous return (TAPVR), or congenital diffuse development disorders of acinar lung development.

**Clinical Manifestations**

PPHN usually manifests in the delivery room or within the 1st 12 hr after birth. Idiopathic PPHN or PPHN related to polycythemia, hypoglycemia, hypothermia, or asphyxia may result in severe cyanosis and respiratory distress. In some cases, however, initial signs of respiratory distress may be minimal. Infants who have PPHN associated with meconium aspiration, group B streptococcal pneumonia, diaphragmatic hernia, or pulmonary hypoplasia usually exhibit cyanosis, grunting, flaring, retractions, tachycardia, and shock. Multiorgan involvement may be present (see Table 119.2). Myocardial ischemia, papillary muscle dysfunction with mitral and tricuspid regurgitation, and biventricular dysfunction produce cardiogenic shock with decreases in pulmonary blood flow, tissue perfusion, and O₂ delivery.

Hypoxemia is often labile and out of proportion to the findings on chest radiographs. In asphyxia-associated and idiopathic PPHN, chest x-ray findings are often normal, whereas in PPHN associated with pneumonia and diaphragmatic hernia, parenchymal opacification and bowel/liver in the chest, respectively, are seen.

**Diagnosis**

Independent of the prenatal history, PPHN should be suspected in all term infants who have cyanosis. Hypoxemia is universal and intermittently unresponsive to 100% O₂ given by oxygen hood. A transient improvement may occur in response to hyperoxic hyperventilation administered by positive pressure ventilation. A PaO₂ or Sao₂ gradient between a preductal (right radial artery) and a postductal (umbilical artery) site of blood sampling suggests right-
to-left shunting through the ductus arteriosus. Intracardiac shunting through the patent foramen ovale does not lead to a $P_aO_2$ or $S_aO_2$ gradient.

Real-time echocardiography combined with Doppler flow imaging is very helpful in evaluating PPHN. Systolic flattening of the interventricular septum as the right ventricular systolic pressure approaches the left ventricular systolic pressure can be used to estimate the degree of pulmonary hypertension. The peak velocity of the tricuspid valve regurgitation jet, when present, yields a quantitative estimate of the right ventricular systolic pressure. Likewise, the direction and velocity of a shunt across the PDA provides a quantitative comparison between the aortic and pulmonary artery pressures. In advanced cases, right-to-left or bidirectional shunting across a PDA and a patent foramen ovale can be observed.

The differential diagnosis of PPHN includes cyanotic heart disease (especially obstructed TAPVR), idiopathic pulmonary vein stenosis, congenital surfactant deficiency syndromes, pulmonary artery thrombosis, and congenital diffuse development disorders of acinar lung development (acinar dysplasia, congenital alveolar dysplasia, and alveolar capillary dysplasia with misalignment of the pulmonary veins).

**Alveolocapillary dysplasia (ACD)** is a rare, highly lethal autosomal recessive disorder of distal lung development characterized by immature lobular development and reduced capillary density. Infants with ACD present with idiopathic PPHN, demonstrating little or no parenchymal lung disease and profound hypoxemia. Over 60% of infants with ACD manifest hypoxemia and respiratory failure within 48 hr of birth, while some with milder disease present beyond 6 mo of age. The diagnosis is made on autopsy in 90% of cases, and the constellation of findings include thickened alveolar septa, increased muscularization of the pulmonary arterioles, a reduced number of capillaries, with the remaining capillaries demonstrating abnormal apposition to the air interface, and misalignment of the intrapulmonary veins. In up to 80% of cases, extrapulmonary malformations of the genitourinary, gastrointestinal, or cardiovascular system are present. Mutations in the transcription factor gene $FOXFI$ have been identified in up to 40% of cases, but the diagnosis continues to rest on clinical and histopathologic features. ACD is uniformly lethal and should be suspected in infants with idiopathic PPHN who fail to respond to maximal medical therapy, or when symptoms recur after successful weaning from ECMO. In a United Kingdom ECMO report, up to 14% of infants who failed ECMO ultimately were diagnosed with ACD. Regardless of the timing of presentation,
ACD is uniformly fatal, and lung transplantation remains the sole, experimental therapy.

**Treatment**

Therapy for PPHN is directed toward correcting any predisposing condition (e.g., hypoglycemia, polycythemia) and improving poor tissue oxygenation. The response to therapy is often unpredictable, transient, and complicated by the adverse effects of drugs or mechanical ventilation. Initial management includes O₂ administration and correction of acidosis, hypotension, and hypercapnia. Persistent hypoxemia should be managed with intubation and mechanical ventilation.

Infants with PPHN are usually managed without hyperventilation or alkalization. Gentle ventilation with normocarbia or permissive hypercarbia and avoidance of hypoxemia result in excellent outcomes and a low incidence of chronic lung disease and ECMO use.

Because of their instability and ability to fight the ventilator, newborns with PPHN usually require **sedation**. The use of paralytic agents is controversial and reserved for the newborn who cannot be treated with sedatives alone. Muscle relaxants may promote atelectasis of dependent lung regions and ventilation-perfusion mismatch and may be associated with an increased risk of death.

**Inotropic therapy** is frequently needed to support blood pressure and perfusion. Whereas dopamine is frequently used as a first-line agent, other agents, such as dobutamine, epinephrine, and milrinone, may be helpful when myocardial contractility is poor. Some of the sickest newborns with PPHN demonstrate hypotension refractory to vasopressor administration. This results from desensitization of the cardiovascular system to catecholamines by overwhelming illness and relative adrenal insufficiency. Hydrocortisone rapidly upregulates cardiovascular adrenergic receptor expression and serves as a hormone substitute in cases of adrenal insufficiency.

**Inhaled NO** is an endothelium-derived signaling molecule that relaxes vascular smooth muscle and can be delivered to the lung by inhalation. *Use of iNO reduces the need for ECMO support by approximately 40%.* The optimal starting dose is 20 ppm. Higher doses have not been shown to be more effective and are associated with side effects, including methemoglobinemia and increased levels of nitrogen dioxide, a pulmonary irritant. Most newborns
require iNO for <5 days. Although NO has been used as long-term therapy in children and adults with primary pulmonary hypertension, prolonged dependency is rare in neonates and suggests the presence of lung hypoplasia, congenital heart disease, or ACD. The maximal safe duration of iNO therapy is unknown. The infant can be weaned to 5 ppm after 6-24 hr of therapy. The dose can then be reduced slowly and discontinued when FiO₂ is <0.6 and the iNO dose is 1 ppm. Abrupt discontinuation should be avoided because it may cause rebound pulmonary hypertension. iNO should be used only at institutions that offer ECMO support or have the capability of transporting an infant on iNO therapy if a referral for ECMO is necessary. Some infants with PPHN do not respond adequately to iNO. Therapy with continuous inhaled or IV prostacyclin (prostaglandin I₂) has improved oxygenation and outcome in infants with PPHN. The safety and efficacy of sildenafil (type 5 phosphodiesterase inhibitor) in newborns with PPHN is under investigation; initial results are promising.

In 5–10% of patients with PPHN, the response to 100% O₂, mechanical ventilation, and drugs is poor, and many of these infants benefit from ECMO. In such patients, 2 parameters have been used to predict mortality: the alveolar-arterial oxygen gradient (P₂ₐ-aO₂), and the oxygenation index (OI), calculated as FiO₂ (as %) × MAP/PaO₂. A P₂ₐ-aO₂ >620 for 8-12 hr and OI >40 unresponsive to iNO predict a high mortality rate (>80%) and are indications for ECMO. In carefully selected, severely ill infants with hypoxemic respiratory failure caused by RDS, meconium aspiration pneumonia, congenital diaphragmatic hernia, PPHN, or sepsis, ECMO significantly improves survival.

**ECMO** is a form of cardiopulmonary bypass that augments systemic perfusion and provides gas exchange. Most experience has been with venoarterial bypass, which requires carotid artery ligation and the placement of large catheters in the right internal jugular vein and carotid artery. **Venovenous bypass** avoids carotid artery ligation and provides gas exchange, but it does not support cardiac output. Blood is initially pumped through the ECMO circuit at a rate that approximates 80% of the estimated cardiac output, 150-200 mL/kg/min. Venous return passes through a membrane oxygenator, is rewarmed, and returns to the aortic arch in venoarterial ECMO and to the right atrium in venovenous ECMO. Venous O₂ saturation values are used to monitor tissue O₂ delivery and subsequent extraction for infants undergoing venoarterial ECMO, whereas arterial O₂ saturation values are used to monitor oxygenation for infants receiving venovenous ECMO.
Because ECMO requires complete heparinization to prevent clotting in the circuit, its use is generally avoided in patients with existing intracranial hemorrhage or who are at high risk of developing IVH (weight <2 kg, gestational age <34 wk). In addition, infants being considered for ECMO should have reversible lung disease, no signs of systemic bleeding, and no severe asphyxia or lethal malformations, and they should have been ventilated for <10 days. Complications of ECMO include thromboembolism, air embolization, bleeding, stroke, seizures, atelectasis, cholestatic jaundice, thrombocytopenia, neutropenia, hemolysis, infectious complications of blood transfusions, edema formation, and systemic hypertension.

**Prognosis**

Survival in patients with PPHN varies with the underlying diagnosis. The long-term outcome for infants with PPHN is related to the associated hypoxic-ischemic encephalopathy and the ability to reduce PVR. The long-term prognosis for infants who have PPHN and who survive after treatment with hyperventilation is comparable to that for infants who have underlying illnesses of equivalent severity (e.g., birth asphyxia, hypoglycemia, polycythemia). The outcome for infants with PPHN who are treated with ECMO is also favorable; >80–90% survive, and 60–75% of survivors appear normal at 1-3.5 yr of age.

Diaphragmatic Hernia

Shawn K. Ahlfeld

Keywords

- congenital diaphragmatic hernia
- CDH
- hiatal hernia
- Bochdalek hernia
- Morgagni hernia
- paraesophageal hernia
- extracorporeal membrane oxygenation
- inhaled nitric oxide
- sildenafil
- high-frequency oscillatory ventilation
- in utero tracheal occlusion
- observed-to-expected total lung volume
- observed-to-expected lung-to-head ratio

A diaphragmatic hernia is defined as a communication between the abdominal and thoracic cavities with or without abdominal contents in the thorax (Fig. 122.10). The etiology is rarely traumatic and usually congenital. The symptoms and prognosis depend on the location of the defect and associated anomalies. The defect may be at the esophageal hiatus (hiatal hernia); paraesophageal, adjacent to the hiatus (paraesophageal hernia; Chapter 122.12); retrosternal (foramen of Morgagni hernia; Chapter 122.11); or at the posterolateral portion of the diaphragm (Bochdalek hernia). In congenital diaphragmatic hernia (CDH) the Bochdalek hernia accounts for up to 90% of the hernias seen, with 80–90% occurring on the left side. The Morgagni hernia accounts for 2–6% of CDH. The size of the defect is highly variable, ranging from a small hole to complete agenesis of this area of the diaphragm. These lesions may cause significant respiratory distress at birth, can be associated with other congenital
anomalies, and have significant mortality and long-term morbidity. The overall survival from the CDH Study Group is approximately 70%, but survival is >80% at many centers.

FIG. 122.10  A, A normal diaphragm separating the abdominal and thoracic cavity. B, Diaphragmatic hernia with a small lung and abdominal contents in the thoracic cavity.

**Congenital Diaphragmatic Hernia (Bochdalek)**

**Pathology and Etiology**

Although CDH is characterized by a structural diaphragmatic defect, a major limiting factor for survival is the associated **pulmonary hypoplasia**. Lung hypoplasia was initially thought to be solely caused by the compression of the lung from the herniated abdominal contents, which impaired lung growth. However, emerging evidence indicates that pulmonary hypoplasia, at least in some cases, may precede the development of the diaphragmatic defect.

Pulmonary hypoplasia is characterized by a reduction in pulmonary mass and the number of bronchial divisions, respiratory bronchioles, and alveoli. The pathology of pulmonary hypoplasia and CDH includes abnormal septa in the
terminal saccules, thickened alveoli, and thickened pulmonary arterioles. Biochemical abnormalities include relative surfactant deficiencies, increased glycogen in the alveoli, and decreased levels of phosphatidylcholine, total DNA, and total lung protein, all of which contribute to limited gas exchange.

**Epidemiology**

The incidence of CDH is between 1 in 2,000 and 1 in 5,000 live births, with females affected twice as often as males. Defects are more common on the left (85%) and are occasionally bilateral (<5%). Pulmonary hypoplasia and malrotation of the intestine are part of the lesion, not associated anomalies. Most cases of CDH are sporadic, but familial cases have been reported. Associated anomalies have been reported in up to 30% of cases, including CNS lesions, esophageal atresia, omphalocele, and cardiovascular lesions. CDH is recognized as part of several chromosomal syndromes: trisomies 21, 13, and 18 and Fryns, Brachmann–de Lange, Pallister-Killian, and Turner syndromes.

**Diagnosis and Clinical Presentation**

In >50% of cases, CDH can be diagnosed on prenatal ultrasonography (US) between 16 and 24 wk of gestation. High-speed fetal MRI can further define the lesion. US findings may include polyhydramnios, chest mass, mediastinal shift, gastric bubble or a liver in the thoracic cavity, and fetal hydrops. Certain imaging features may predict outcome; these include liver position in the chest, observed-to-expected total lung volume (TLV), and observed-to-expected lung-to-head ratio (LHR). Nonetheless, no definitive characteristic reliably predicts outcome. After delivery, a chest radiograph is needed to confirm the diagnosis (Fig. 122.11). In some infants with an echogenic chest mass, further imaging is required. The differential diagnosis may include other diaphragm disorders, such as eventration or a cystic lung lesion (pulmonary sequestration, cystic adenomatoid malformation).
Arriving at the diagnosis early in pregnancy allows for prenatal counseling, possible fetal interventions, and planning for postnatal care. A referral to a center providing high-risk obstetrics, pediatric surgery, and tertiary care neonatology is advised. Careful evaluation for other anomalies should include echocardiography and amniocentesis. To avoid unnecessary pregnancy termination and unrealistic expectations, an experienced multidisciplinary group must carefully counsel the parents of a child diagnosed with a diaphragmatic hernia.

Respiratory distress is a cardinal sign in babies with CDH. It may occur immediately after birth, or there may be a “honeymoon” period of up to 48 hr during which the baby is relatively stable. Early respiratory distress, within 6 hr after birth, is thought to be a poor prognostic sign. Respiratory distress is characterized clinically by tachypnea, grunting, use of accessory muscles, and cyanosis. Children with CDH may also have a scaphoid abdomen and increased chest wall diameter. Bowel sounds may also be heard in the chest with decreased breath sounds bilaterally. The point of maximal cardiac impulse may be displaced away from the side of the hernia if mediastinal shift has occurred. A chest radiograph and passage of a nasal gastric tube are usually sufficient to confirm the diagnosis.

A small group of infants with CDH present beyond the neonatal period. Patients with a delayed presentation may experience vomiting as a result of intestinal obstruction or mild respiratory symptoms. Occasionally, incarceration of the intestine proceeds to ischemia with sepsis and shock. Unrecognized
diaphragmatic hernia is a rare cause of sudden death in infants and toddlers. Group B streptococcal sepsis has been associated with delayed onset of symptoms and a CDH (often right side).

**Treatment**

**Initial Management**

Delivery at a tertiary center with experience in the management of CDH is required to provide early, appropriate respiratory support. In the delivery room, infants with respiratory distress should be rapidly stabilized with endotracheal intubation. *Prolonged mask ventilation in the delivery room, which enlarges the stomach and small bowel and thus makes oxygenation more difficult, must be avoided and a naso- or orogastric tube placed immediately for decompression.* Arterial (preductal and postductal) and central venous (umbilical) lines are mandated, as are a urinary catheter and nasogastric tube. A preductal arterial oxygen saturation (SpO₂) value ≥85% should be the minimum goal. Volutrauma is a significant problem. *Gentle ventilation with permissive hypercapnia* reduces lung injury, need for ECMO, and mortality. Factors that contribute to pulmonary hypertension (hypoxia, acidosis, hypothermia) should be avoided. Echocardiography is important to guide therapeutic decisions by measuring pulmonary and systemic pressures and defining the presence of cardiac dysfunction. Routine use of inotropes is indicated in the presence of left ventricular dysfunction. Babies with CDH may be surfactant deficient. Although surfactant is frequently used, no study has proved that it is beneficial in treatment of CDH, and it may precipitate decompensation. In infants with severe respiratory failure and hypoxemia, sedation and paralysis may be required.

**Ventilation Strategies**

Conventional mechanical ventilation, high-frequency oscillatory ventilation (HFOV), and ECMO are the 3 main strategies to support respiratory failure in the newborn with CDH. The goal is to maintain oxygenation and CO₂ elimination without inducing volutrauma. Conventional ventilation using a gentle, lung protective strategy (PIP <25, PEEP 3-5 cm H₂O) that allows for permissive hypercapnia (Paco₂ <65-70 mm Hg) is recommended. Permissive hypercapnia (as opposed to hyperventilation with high PIP) has reduced lung injury and improved survival. HFOV as a rescue therapy is indicated if a PIP
>25 is required to maintain appropriate ventilation or if hypoxemia persists.

Inhaled NO is a selective pulmonary vasodilator. Its use reduces ductal shunting and pulmonary pressures and results in improved oxygenation. Although iNO has been helpful in PPHN, randomized trials have not demonstrated improved survival or reduced need for ECMO when iNO is used in newborns with CDH. Nonetheless, iNO is used in patients with CDH as a bridge to ECMO.

**Extracorporeal Membrane Oxygenation**

The availability of ECMO and the utility of preoperative stabilization has improved survival of babies with CDH. ECMO is the therapeutic option for children in whom conventional ventilation or HFOV fails. ECMO is most often used before repair of the defect. Several objective criteria for ECMO have been developed. Birthweight and the 5 min Apgar score may be the best predictors of outcome in patients treated with ECMO. There is no strict lower weight limit for ECMO, but generally, vessels in infants <1,800-2,000 g are too small to cannulate.

The duration of ECMO for neonates with diaphragmatic hernia is longer (7-14 days) than for those with PPHN (persistent fetal circulation) or meconium aspiration and may last up to 2-4 wk. Timing of repair of the diaphragm while the infant receives ECMO is controversial; some experts prefer early repair to allow a greater duration of ECMO after the repair, whereas many defer repair until the infant has demonstrated the ability to tolerate weaning from ECMO. The recurrence of pulmonary hypertension is associated with high mortality and weaning from ECMO support should be cautious. If the patient cannot be weaned from ECMO after repair of CDH, options include discontinuing support and, in rare cases, lung transplantation.

**Novel Strategies for Infants With Congenital Diaphragmatic Hernia**

The most reliable prenatal predictors of outcome in children with CDH studied is fetal US. A prospective study of US at 24-26 wk compared fetal LHR with mortality. There were no survivors with LHR <1, but all babies with LHR >1.4 survived. A 2nd important consideration was the presence of liver in the thoracic cavity, which is a poor prognostic feature. Human studies have shown no benefit for in utero repair of CDH. In another single-center study, a late gestation (32-34
wk) fetal MRI-derived TLV >40 mL was associated with >90% survival and only 10% need for ECMO, while TLV <20 mL was associated with <35% survival and >85% need for ECMO.

Based on the observation that hydrostatic pressure exerted by fetal lung fluid plays a critical role in lung growth and maturity, a promising experimental therapy is in utero tracheal occlusion. Although initial studies in affected fetuses did not demonstrate success, emerging preliminary reports in those with severe CDH (LHR <1 and intrathoracic liver) suggest that fetoscopic tracheal occlusion is associated with significantly reduced mortality and need for ECMO (see Chapter 116).

**Surgical Repair**

The ideal time to repair the diaphragmatic defect is under debate. Most experts wait at least 48 hr after stabilization and resolution of the pulmonary hypertension. Good relative indicators of stability are the requirement for conventional ventilation only, a low peak inspiratory pressure, and $F_{I_O_2} <50$. If the newborn is receiving ECMO, an ability to be weaned from this support should be a consideration before surgical repair. In some centers the repair is done with the cannulas in place; in other centers the cannulas are removed. A subcostal approach is most frequently used (Fig. 122.12). This allows for good visualization of the defect, and if the abdominal cavity cannot accommodate the herniated contents, a polymeric silicone (Silastic) patch can be placed. Both laparoscopic and thoracoscopic repairs have been reported, but these should be reserved for only the most stable infants.
The defect size and amount of native diaphragm present are variable. Whenever possible, a primary repair using native tissue is performed. If the defect is too large, a porous polytetrafluoroethylene (Gore-Tex) patch is used. There is a higher recurrence rate of CDH in children with patches (the patch does not grow as the child grows) than in those with native tissue repairs. A loosely fitted patch may reduce the recurrence rates.

Following surgical repair, the infant must be carefully monitored for worsening pulmonary hypertension. In some patients, a postoperative course of ECMO is needed. Other recognized complications include bleeding, chylothorax, and bowel obstruction.

**Outcome and Long-Term Survival**

Overall survival of liveborn infants with CDH is 71%. Relative predictors of a
Poor prognosis include an associated major anomaly, symptoms before 24 hr of age, severe pulmonary hypoplasia, herniation to the contralateral lung, and the need for ECMO. The size of the defect appears to be the strongest predictor of morbidity.

Pulmonary problems continue to be a source of morbidity for long-term survivors of CDH. Children receiving CDH repair who were studied at 6-11 yr of age demonstrated significant decreases in forced expiratory flow at 50% of vital capacity and decreased peak expiratory flow. Both obstructive and restrictive patterns can occur. Those without severe pulmonary hypertension and barotrauma do the best. Those at highest risk include children who required ECMO and patch repair, but the data clearly show that CDH survivors who did not require ECMO also need frequent attention to pulmonary issues. At discharge, up to 20% of infants require oxygen, but only 1–2% require oxygen past 1 yr old. BPD is frequently documented radiographically but will improve as more alveoli develop and the child ages.

Gastroesophageal reflux disease (GERD) is reported in >50% of children with CDH. GERD is more common in children whose diaphragmatic defect involves the esophageal hiatus. Intestinal obstruction is reported in up to 20% of children and may result from a midgut volvulus, adhesions, or a recurrent hernia that became incarcerated. Recurrent diaphragmatic hernia is reported in 5–20% in most series. Children with patch repairs are at highest risk.

Children with CDH typically have delayed growth in the 1st 2 yr of life. Contributing factors include poor intake, GERD, and a caloric requirement that may be higher because of the energy required to breathe. Many children normalize and “catch up” in growth by the time they are 2 yr old.

Neurocognitive defects are common and may result from the disease or the interventions. The incidence of neurologic abnormalities is higher in infants who require ECMO (67% vs 24% of those who do not). The abnormalities are similar to those seen in neonates treated with ECMO for other diagnoses and include transient and permanent developmental delay, abnormal hearing or vision, and seizures. Serious hearing loss may occur in up to 28% of children who underwent ECMO. The majority of neurologic abnormalities are classified as mild to moderate.

Other long-term problems include pectus excavatum and scoliosis. Survivors of CDH repair, particularly those requiring ECMO support, have a variety of long-term abnormalities that appear to improve with time but require close monitoring and multidisciplinary support.

Foramen of Morgagni Hernia

Shawn K. Ahlfeld

Failure of the sternal and crural portions of the diaphragm to meet and fuse produces the foramen of Morgagni hernia. These defects are usually small, with a greater transverse than anteroposterior diameter, and are more often right sided (90%) but may be bilateral. The transverse colon, small intestine, or liver is usually contained in the hernial sac. Most children with these defects are asymptomatic and are diagnosed beyond the neonatal period, often by chest radiograph performed for evaluation of another condition. The anterolateral radiograph shows a structure behind the heart, and a lateral film localizes the mass to the retrosternal area. Chest CT or MRI confirms the diagnosis. When symptoms occur, they can include recurrent respiratory infections, cough, vomiting, or reflux; in rare cases, incarceration may occur. Repair is recommended for all patients, in view of the risk of bowel strangulation, and can be accomplished laparoscopically. Prosthetic material is rarely required.

Paraesophageal Hernia

Shawn K. Ahlfeld

Paraesophageal hernia is differentiated from the hiatal hernia in that the gastroesophageal junction is in the normal location. The herniation of the stomach alongside or adjacent to the gastroesophageal junction is prone to
incarceration with strangulation and perforation. A previous Nissen fundoplication and other diaphragmatic procedures are risk factors. This unusual diaphragmatic hernia should be repaired promptly after identification.

122.13

Eventration

Shawn K. Ahlfeld

Eventration of the diaphragm is an abnormal elevation consisting of a thinned diaphragmatic muscle that causes elevation of the entire hemidiaphragm or more often the anterior aspect of the hemidiaphragm. This elevation produces a paradoxical motion of the affected hemidiaphragm. Most eventrations are asymptomatic and do not require repair. A congenital form is the result of either incomplete development of the muscular portion or central tendon or abnormal development of the phrenic nerves. Congenital eventration may affect lung development, but it has not been associated with pulmonary hypoplasia. The differential diagnosis includes diaphragmatic paralysis, diaphragmatic hernia, traction injury, and iatrogenic injury after heart surgery. Eventration is also associated with pulmonary sequestration, congenital heart disease, spinal muscular atrophy with respiratory distress, and chromosomal trisomies. Most eventrations are asymptomatic and do not require repair. The indications for surgery include continued need for mechanical ventilation, recurrent infections, and failure to thrive. Large or symptomatic eventrations can be repaired by plication through an abdominal or thoracic approach that is minimally invasive.

Extrapulmonary Air Leaks: Pneumothorax, Pneumomediastinum, Pulmonary Interstitial Emphysema, Pneumopericardium

Shawn K. Ahlfeld

Keywords

pneumothorax
pneumomediastinum
pulmonary interstitial emphysema
pneumopericardium
pulmonary hypoplasia
tension pneumothorax

Asymptomatic pneumothorax, usually unilateral, is estimated to occur in 1–2% of all newborn infants; symptomatic pneumothorax and pneumomediastinum are less common (see Chapter 113). The incidence of pneumothorax is increased in infants with lung diseases such as meconium aspiration and RDS; in those who receive assisted ventilation, especially if high-frequency ventilation (HFV) support is necessary; and in infants with urinary tract anomalies or oligohydramnios.

**Etiology and Pathophysiology**

The most common cause of pneumothorax is overdistention resulting in alveolar rupture. Alveolar overdistention can occur with positive pressure ventilation during neonatal resuscitation, or it may occur in association with the “ball-valve” phenomenon that results from aspiration (classically meconium) and bronchial/bronchiolar obstruction. Although spontaneous rupture of an underlying pulmonary malformation (e.g., lobar emphysema, congenital lung cyst, pneumatocele) occurs, it is usually in an otherwise normal lung, and no etiology is identified.

Pneumothorax associated with pulmonary hypoplasia is common, tends to occur during the 1st few hr after birth, and is caused by reduced alveolar surface area and poorly compliant lungs. It is associated with disorders of decreased amniotic fluid volume (Potter syndrome, renal agenesis, renal dysplasia, chronic amniotic fluid leak), decreased fetal breathing movement (oligohydramnios, neuromuscular disease), pulmonary space-occupying lesions (diaphragmatic hernia, pleural effusion, chylothorax), and thoracic abnormalities (thoracic dystrophies).

Gas from a ruptured alveolus escapes into the interstitial spaces of the lung, where it tracks along small conducting airways and dissects along the peribronchial and perivascular connective tissue sheaths to the hilum of the lung (pulmonary interstitial emphysema). If the volume of escaped air is great enough, it may collect in the mediastinal space (pneumomediastinum) or rupture into the pleural space (pneumothorax), subcutaneous tissue
subcutaneous emphysema), peritoneal cavity (pneumoperitoneum), and/or pericardial sac (pneumopericardium). Rarely, increased mediastinal pressure may compress the pulmonary veins at the hilum and thereby interfere with pulmonary venous return to the heart and cardiac output. On occasion, air may embolize into the circulation (pulmonary air embolism) and cause cutaneous blanching, air in intravascular catheters, an air-filled heart and vessels on chest radiographs, and death.

**Tension pneumothorax** occurs if an accumulation of air within the pleural space is sufficient to elevate intrapleural pressure above atmospheric pressure. Unilateral tension pneumothorax results in impaired ventilation not only in the ipsilateral lung but also in the contralateral lung because of a shift in the mediastinum toward the contralateral side. Compression of the vena cava and torsion of the great vessels may interfere with venous return.

**Clinical Manifestations**

The physical findings of a clinically asymptomatic pneumothorax are hyperresonance and diminished ipsilateral breath sounds with or without tachypnea. Symptomatic pneumothorax is characterized by respiratory distress, which varies from merely high respiratory rate to severe dyspnea, tachypnea, and cyanosis. Irritability and restlessness or apnea may be the earliest signs. The onset is usually sudden but may be gradual; an infant may rapidly become critically ill. Physical exam findings include chest asymmetry with an increased anteroposterior diameter, hyperresonance, and diminished or absent breath sounds. The heart is displaced toward the contralateral side, resulting in displacement of the cardiac apex and point of maximal impulse. The diaphragm is displaced downward, as is the liver with right-sided pneumothorax, and may result in abdominal distention. Because pneumothorax may be bilateral in approximately 10% of patients, symmetry of findings does not rule it out. In tension pneumothorax, signs of shock are typical.

Pneumomediastinum can occur in patients with pneumothorax and is usually asymptomatic. The degree of respiratory distress depends on the amount of trapped gas; if great, bulging of the midthoracic area is observed, the neck veins are distended, and blood pressure is low. The last 2 findings are a result of tamponade of the systemic and pulmonary veins. Although often asymptomatic, subcutaneous emphysema in newborn infants is almost pathognomonic of pneumomediastinum.
**Pulmonary interstitial emphysema (PIE)** may precede the development of a pneumothorax or may occur independently and lead to increasing respiratory distress as a result of decreased compliance, hypercapnia, and hypoxemia. Hypoxemia is caused by an increased \( P_A - aO_2 \) and intrapulmonary shunting. Progressive enlargement of blebs of gas may result in cystic dilation and respiratory deterioration resembling pneumothorax. In severe cases, pulmonary interstitial emphysema precedes the development of BPD. Avoidance of high inspiratory or mean airway pressures may prevent the development of pulmonary interstitial emphysema. Treatment may include bronchoscopy in patients with evidence of mucous plugging, selective intubation and ventilation of the uninvolved bronchus, oxygen, general respiratory care, and HFV.

**Diagnosis**

Pneumothorax and other air leaks should be suspected in newborn infants who show signs of respiratory distress, are restless or irritable, or have a sudden change in condition. The diagnosis of pneumothorax is established by chest radiography, with the edge of the collapsed lung standing out in relief against the pneumothorax (Fig. 122.13). Pneumomediastinum is signified by hyperlucency around the heart border and between the sternum and the heart border (Fig. 122.14). Transillumination of the thorax is often helpful in the emergency diagnosis of pneumothorax; the affected side transmits excessive light. Associated renal anomalies are identified by US. Pulmonary hypoplasia is suggested by signs of uterine compression (extremity contractures), a small thorax on chest radiographs, severe hypoxia with hypercapnia, and signs of the primary disease (hypotonia, diaphragmatic hernia, Potter syndrome).

FIG. 122.14  Pneumomediastinum in newborn infant. The anteroposterior view (left) demonstrates compression of the lungs, and the lateral view (right) shows bulging of the sternum, each resulting from distention of the mediastinum by trapped air.

Pneumopericardium may be asymptomatic, requiring only general supportive treatment, but it usually manifests as sudden shock with tachycardia, muffled heart sounds, and poor pulses suggesting tamponade.
Pneumoperitoneum from air dissecting through the diaphragmatic apertures during mechanical ventilation may be confused with intestinal perforation. Abdominal paracentesis can be helpful in differentiating the 2 conditions. The presence of organisms on Gram stain of intestinal contents suggests the latter. Occasionally, pneumoperitoneum can result in an abdominal compartment syndrome requiring decompression.

Treatment

Without a continued air leak, asymptomatic and mildly symptomatic, small pneumothoraces require only close observation. Conservative management of a pneumothorax is effective even in selected infants requiring ventilatory support. Frequent small feedings may prevent gastric dilation and minimize crying, which can further compromise ventilation and worsen the pneumothorax. Breathing 100% oxygen in term infants may accelerate the resorption of free pleural air into blood by reducing the nitrogen tension in blood and producing a resultant nitrogen pressure gradient from the trapped gas in the blood; the clinical effectiveness is not proved, however, and the benefit must be weighed against the risks of O₂ toxicity. With severe respiratory or circulatory embarrassment, emergency decompression by needle thoracentesis using a soft, small catheter is indicated. Either immediately or after catheter aspiration, a chest tube should be inserted and attached to underwater seal drainage (see Fig. 122.13). If the air leak is ongoing, continuous suction (−5 to −20 cm H₂ O) may be needed to evacuate the pneumothorax completely. A pneumopericardium requires prompt evacuation of entrapped air. Severe localized PIE may respond to selective bronchial intubation. Surfactant therapy for RDS reduces the incidence of pneumothorax.

**Pulmonary Hemorrhage**

*Shawn K. Ahlfeld*

---

**Keywords**

- pulmonary hemorrhage
- surfactant
- excessive pulmonary blood flow
- indomethacin
- patent ductus arteriosus

Massive pulmonary hemorrhage is a relatively uncommon, but catastrophic complication with a high risk of morbidity and mortality. Some degree of pulmonary hemorrhage occurs in about 10% of extremely preterm infants. However, massive pulmonary hemorrhage is less common and can be fatal. Autopsy demonstrates massive pulmonary hemorrhage in 15% of neonates who die in the 1st 2 wk of life. The reported incidence at autopsy varies from 1-4 per 1,000 live births. Approximately 75% of affected patients weigh <2,500 g at birth. Prophylactic indomethacin in ELBW infants reduces the incidence of pulmonary hemorrhage.

Most infants with pulmonary hemorrhage have had symptoms of respiratory distress that are indistinguishable from those of RDS. The onset may occur at
birth or may be delayed several days. **Hemorrhagic pulmonary edema** is the source of blood in many cases and is associated with significant ductal shunting and high pulmonary blood flow or severe left-sided heart failure resulting from hypoxia. In severe cases, sudden cardiovascular collapse, poor lung compliance, profound cyanosis, and hypercapnia may be present. Radiographic findings are varied and nonspecific, ranging from minor streaking or patchy infiltrates to massive consolidation.

The risk of pulmonary hemorrhage is increased in association with acute pulmonary infection, severe asphyxia, RDS, assisted ventilation, PDA, congenital heart disease, erythroblastosis fetalis, hemorrhagic disease of the newborn, thrombocytopenia, inborn errors of ammonia metabolism, and cold injury. Pulmonary hemorrhage is the only severe complication in which the rate is *increased* with surfactant treatment. Pulmonary hemorrhage is seen with all surfactants; the incidence ranges from 1–5% of treated infants and is higher with natural surfactant. Bleeding is predominantly alveolar in approximately 65% of cases and interstitial in the rest. Bleeding into other organs is observed at autopsy of severely ill neonates, suggesting an additional bleeding diathesis, such as disseminated intravascular coagulation. Acute pulmonary hemorrhage may rarely occur in previously healthy full-term infants. The cause is unknown. Pulmonary hemorrhage may manifest as hemoptysis or blood in the nasopharynx or airway with no evidence of upper respiratory or gastrointestinal bleeding. Patients present with acute, severe respiratory failure requiring mechanical ventilation. Chest radiographs usually demonstrate bilateral alveolar infiltrates. The condition usually responds to intensive supportive treatment (see Chapter 436).

**Treatment** of pulmonary hemorrhage includes blood replacement, suctioning to clear the airway, intratracheal administration of epinephrine, and tamponade with increased mean airway pressure (often requiring HFV). Although surfactant treatment has been associated with the development of pulmonary hemorrhage, administration of exogenous surfactant after the bleeding has occurred can improve lung compliance, because the presence of intraalveolar blood and protein can inactivate surfactant.

Alfaleh K, Smyth JA, Roberts RS, et al. Prevention and 18-

Meconium consists of bile salts, bile acids, and debris shed from the intestinal mucosa in the intrauterine period. More than 90% of full-term newborn infants and 80% of very-low-birthweight (VLBW) infants pass meconium within the 1st 24 hr. The possibility of intestinal obstruction should be considered in any infant who does not pass meconium by 24-36 hr.
Meconium plugs syndrome refers to intestinal obstruction, usually in the distal colon, rectum, and anal canal, caused by meconium plugs (Fig. 123.1). Resulting from a disproportionately low amount of water in the intestinal lumen, meconium plugs are a rare cause of intrauterine intestinal obstruction and meconium peritonitis unrelated to cystic fibrosis (CF). Anorectal plugs may also cause mucosal ulceration from bowel wall erosion and subsequent intestinal perforation. Meconium plugs are associated with small left colon syndrome in infants of diabetic mothers, CF (40%), Hirschsprung disease (40%), maternal opiate use, magnesium sulfate therapy for preeclampsia, and tocolysis. Up to 30% of patients can have spontaneous resolution. Initial treatment may include administration of a glycerin suppository or rectal irrigation with isotonic saline. In up to 95% of patients, a Gastrografin enema (meglumine diatrizoate, a hyperosmolar, water-soluble, radiopaque solution containing 0.1% polysorbate 80 [Tween 80] and 37% organically bound iodine) will be both diagnostic and therapeutic, inducing passage of the plug, presumably because the high osmolarity (1,900 mOsm/L) of the solution draws fluid rapidly into the intestinal lumen and loosens the inspissated material. Such rapid loss of fluid into the bowel may result in acute fluid shifts with dehydration and shock, so it is advisable to dilute the contrast material with an equal amount of water and provide intravenous (IV) fluids, during and for several hours after the procedure, sufficient to maintain normal vital signs, urine output, and electrolytes. After removal of a meconium plug, the infant should be observed closely and consideration given to performing diagnostic testing to identify Hirschsprung disease (congenital aganglionic megacolon; see Chapter 358.4) and CF (see Chapter 432).
Meconium Ileus

Meconium ileus, or impaction of inspissated meconium in the distal small bowel, accounts for up to 30% of cases of neonatal intestinal obstruction. It is common in patients with CF in whom the lack of fetal pancreatic enzymes inhibits digestive mechanisms, and meconium becomes viscid and mucilaginous. Clinically, neonates present with intestinal obstruction with or without perforation. Abdominal distention is prominent, and vomiting, often bilious,
becomes persistent, although occasionally inspissated meconium stools may be passed shortly after birth. Meconium ileus can present as early as in utero, in which the fetus develops acute intestinal obstruction resulting in volvulus or perforation, peritoneal ascites, meconium peritonitis, and hydrops; if untreated, fetal loss may occur.

Meconium ileus is primarily associated with cystic fibrosis transmembrane regulator (CFTR) mutations F508del, G542X, W1282X, R553X, and G551D. Patients with two copies of the F508del mutation have a 25% chance of presenting with meconium ileus. F508del plus any other CF mutation confers 17% risk, and two other CF mutations confer a 12% risk of meconium ileus. In addition, non-CFTR genetic modifier genes influence meconium ileus. In families who already have at least one child with CF complicated by meconium ileus, there is a 39% risk for meconium ileus in subsequent children, which is more than the rates expected with autosomal recessive inheritance. In a twin study, 82% of monozygotic twins showed concordance for meconium ileus, whereas only 22% of dizygotic and 24% of two affected siblings showed concordance. Positive newborn screening for CF should prompt sweat testing when the infant weighs >2 kg and is at least 36 wk of corrected gestational age. Genetic testing confirms the diagnosis of CF (see Chapter 432).

The differential diagnosis involves other causes of intestinal obstruction, including intestinal pseudoobstruction, and other causes of pancreatic insufficiency (see Chapter 377). Prenatal diagnosis is readily achieved by ultrasound with identification of enlarged bowel loops or a mass with distention of the proximal small bowel. Clinically the diagnosis can be made with a history of CF in a sibling, by palpation of doughy or cordlike masses of intestines through the abdominal wall, and from the radiographic appearance. Plain radiographs reveal small bowel obstruction. Air-fluid levels may not be apparent because of the thickened meconium.

In contrast to the generally evenly distended intestinal loops above an atresia, the loops may vary in width and are not as evenly filled with gas. At points of heaviest meconium concentration, the infiltrated gas may create a bubbly, granular appearance (Figs. 123.2 and 123.3).
FIG. 123.3 Uncomplicated meconium ileus. A, Abdominal radiograph in 3 day old infant with abdominal distention and bilious aspirates shows dilation of multiple loops of bowel. No calcifications are seen on the radiograph to suggest complicated meconium ileus. Orogastric tube near the gastroesophageal junction was subsequently advanced. B, Contrast enema demonstrates a microcolon, with multiple meconium plugs, consistent with the diagnosis of meconium ileus. (From Hernanz-Schulman M: Congenital and neonatal disorders. In Coley BD, editor: Caffey's pediatric diagnostic imaging, ed 13, Philadelphia, 2019, Elsevier, Fig 102-36).

Treatment for simple meconium ileus is a high-osmolarity Gastrografin enema, as described for meconium plugs. If the procedure is unsuccessful or perforation of the bowel wall is suspected, a laparotomy is performed and the ileum opened at the point of largest diameter of the impaction. Approximately 50% of these infants have associated intestinal atresia, stenosis, or volvulus that requires surgery. The inspissated meconium is removed by gentle and patient irrigation with warm isotonic sodium chloride or N-acetylcysteine (Mucomyst) solution through a catheter passed between the impaction and the bowel wall. Some patients will require bowel resection with a temporary double-barrel enterostomy followed by serial irrigations and distal refeeding, or primary anastomosis at the initial operation. Most infants with meconium ileus survive the neonatal period. If meconium ileus is associated with CF, the long-term prognosis depends on the severity of the underlying disease (see Chapter 432).

Meconium Peritonitis

Perforation of the intestine may occur in utero or shortly after birth. Frequently, the intestinal perforation seals naturally with relatively little meconium leakage into the peritoneal cavity. Perforations occur most often as a complication of
meconium ileus in infants with CF but occasionally result from a meconium plug or in utero intestinal obstruction of another cause.

Cases at the most severe end of the spectrum may be diagnosed on prenatal ultrasound with fetal ascites, polyhydramnios, bowel dilation, intraabdominal calcifications, and hydrops fetalis (Fig. 123.4). At the other end are cases in which an intestinal perforation may seal spontaneously and patients remain asymptomatic, except when meconium becomes calcified and is later discovered on radiographs. Alternatively, the clinical picture may be dominated by signs of intestinal obstruction (as in meconium ileus) with abdominal distention, vomiting, and absence of stools or chemical peritonitis presenting with sepsis. Treatment consists primarily of elimination of the intestinal obstruction and drainage of the peritoneal cavity with a timely surgical intervention proved to result in high survival rate and favorable outcome even in complicated meconium peritonitis.

**FIG. 123.4** Complicated meconium ileus. A, Abdominal radiograph in 2 day old girl with abdominal distention and bilious aspirates shows absence of bowel gas in the right abdomen with a partly calcified mass displacing gas-filled dilated loops of bowel to the left. B, Ultrasound image demonstrates the subhepatic, partly calcified mass with internal debris and fluid-fluid level. C, Additional ultrasound image shows a portion of the cyst wall (arrows) and multiple, abnormal, hyperechoic loops of bowel. D, Abdominal radiograph in different 1 day old infant shows a calcified mass in right upper quadrant, shown at sonography to represent a loculated complex meconium collection. E, Radiograph a few hours later of the same infant shown in D shows a persistent perforation with gas entering into the right upper quadrant collection. (From Hernanz-Schulman M: Congenital and neonatal disorders. In Coley BD, editor: Caffey’s pediatric diagnostic imaging, ed 13, Philadelphia, 2019, Elsevier, Fig 102-37).

### 123.2

**Necrotizing Enterocolitis**

*Rebeccah L. Brown*
Necrotizing enterocolitis (NEC) is the most common life-threatening emergency of the gastrointestinal (GI) tract in the newborn period. The disease is characterized by various degrees of mucosal or transmural necrosis of the intestine. The cause of NEC remains unclear but is most likely multifactorial. The incidence of NEC is 5–10% among infants with birthweight <1500 g, with mortality rates of 20–30% and approaching 50% in infants who require surgery. Both incidence and case fatality rates increase with decreasing birthweight and gestational age.

**Pathology and Pathogenesis**

Many factors contribute to the development of the pathologic findings of NEC, including mucosal ischemia and subsequent necrosis, gas accumulation in the submucosa of the bowel wall (pneumatosis intestinalis), and progression of the necrosis to perforation, peritonitis, sepsis, and death. The distal part of the ileum and the proximal segment of colon are involved most frequently; in fatal cases, gangrene may extend from the stomach to the rectum (NEC totalis). The pathogenesis of NEC remains to be completely elucidated, but 3 major risk factors have been implicated: prematurity, bacterial colonization of the gut, and formula feeding. NEC develops primarily in premature infants with exposure to metabolic substrate in the context of immature intestinal immunity, microbial dysbiosis, and mucosal ischemia. An underlying genetic predisposition is being recognized with variants in genes regulating immunomodulation and inflammation (e.g., Toll-like receptor-4, IL-6), apoptosis and cellular repair (e.g., platelet-activating factor), and oxidant stress (e.g., vascular endothelial growth factor, arginine, nitric oxide). *The greatest risk factor for NEC is prematurity.*
NEC rarely occurs before the initiation of enteral feeding and is much less common in infants fed human milk. Aggressive enteral feeding may predispose to the development of NEC.

Although nearly 90% of all cases of NEC occur in preterm infants, the disease can occur in full-term neonates. NEC in term infants is often a secondary disease, seen more frequently in infants with history of birth asphyxia, Down syndrome, congenital heart disease, rotavirus infections, gastroschisis, and Hirschsprung disease.

**Clinical Manifestations**

Infants with NEC have a variety of signs and symptoms and may have an insidious or sudden catastrophic onset (Table 123.1). The onset of NEC is usually in the 2nd or 3rd week of life but can be as late as 3 mo in VLBW infants. Age of onset is inversely related to gestational age. The first signs of impending disease may be nonspecific, including lethargy and temperature instability, or related to GI pathology, such as abdominal distention, feeding intolerance, and bloody stools. Because of nonspecific signs, sepsis may be suspected before NEC. The spectrum of illness is broad, ranging from mild disease with only guaiac-positive stools to severe illness with bowel perforation, peritonitis, systemic inflammatory response syndrome, shock, and death. Laboratory derangements may include neutropenia, anemia, thrombocytopenia, coagulopathy, and metabolic acidosis. Hypotension and respiratory failure are common. Progression may be rapid, but it is unusual for the disease to progress from mild to severe after 72 hr.

**Diagnosis**

A very high index of suspicion in treating preterm at-risk infants is crucial. Plain abdominal radiographs are essential to make a diagnosis of NEC. The finding of **pneumatosis intestinalis** (air in the bowel wall) confirms the clinical suspicion of NEC and is diagnostic; 50–75% of patients have pneumatosis when treatment is started (Fig. 123.5). Portal venous gas is a sign of severe disease, and **pneumoperitoneum** indicates a perforation (Figs. 123.6 and 123.7). Ultrasound with Doppler flow assessment may be useful to evaluate for free fluid, abscess, and bowel wall thickness, peristalsis, and perfusion.
FIG. 123.5  Necrotizing enterocolitis (NEC). Kidney-ureter-bladder film demonstrates abdominal distention, hepatic portal venous gas (arrow), and a bubbly appearance of pneumatosis intestinalis (arrowhead; right lower quadrant). The latter 2 signs are thought to be pathognomonic for neonatal NEC.

FIG. 123.6  Intestinal perforation. Cross-table abdominal radiograph in patient with neonatal NEC demonstrates marked distention and massive pneumoperitoneum, as evidenced by the free air below the anterior abdominal wall.

FIG. 123.7  Necrotizing enterocolitis (NEC). Plain abdominal x-ray film of an infant with
The differential diagnosis of NEC includes specific infections (systemic or intestinal), GI obstruction, volvulus, and isolated intestinal perforation. **Idiopathic focal intestinal perforation** can occur spontaneously or after the early use of postnatal corticosteroids and indomethacin. Pneumoperitoneum develops in such patients, but they are usually less ill than those with NEC.

**Treatment**

Rapid initiation of therapy is required for infants with suspected as well as proven NEC. There is no definitive treatment for established NEC, so therapy is directed at providing supportive care and preventing further injury with cessation of feeding, nasogastric decompression, and administration of IV fluids. Careful attention to respiratory status, coagulation profile, and acid-base and electrolyte balances are important. Once blood has been drawn for culture, systemic antibiotics (with broad coverage based on the antibiotic sensitivity patterns of the gram-positive, gram-negative, and anaerobic organisms in the particular neonatal ICU) should be started immediately. If present, umbilical catheters should be removed, but good IV access needs to be maintained. Ventilation should be assisted in the presence of apnea or if abdominal distention is contributing to hypoxia and hypercapnia. Intravascular volume replacement with crystalloid or blood products, cardiovascular support with fluid boluses and/or inotropes, and correction of hematologic, metabolic, and electrolyte abnormalities are essential to stabilize the infant with NEC.

The patient's course should be monitored closely by means of frequent physical assessments; sequential anteroposterior and cross-table lateral or lateral decubitus abdominal radiographs to detect intestinal perforation; and serial determinations of hematologic, electrolyte, and acid-base status. Gown and glove isolation and grouping of infants at similar increased risks into cohorts separate from other infants should be instituted to contain an epidemic.

A surgeon should be consulted early in the course of treatment. The only absolute indication for surgery is evidence of perforation on abdominal radiograph (pneumoperitoneum) present in less than half of infants with perforation or necrosis at operative exploration. Progressive clinical deterioration despite maximum medical management, a single fixed bowel loop
on serial radiographs, and abdominal wall erythema are relative indications for exploratory laparotomy. Ideally, surgery should be performed after intestinal necrosis develops but before perforation and peritonitis occur. The optimal surgical approach, however, remains controversial. The options for surgical treatment include **primary peritoneal drainage (PPD)** or exploratory laparotomy with resection of the necrotic intestine and usually stoma creation. Two randomized clinical trials in the mid-2000s comparing these approaches failed to demonstrate significant differences in survival, nutritional outcomes, or length of stay. A Cochrane analysis combining the results of both trials concluded that there were no significant benefits or harms of PPD over exploratory laparotomy. A 3rd randomized clinical trial (Necrotizing Enterocolitis Surgery Trial, NCT01029353) compares the 2 surgical approaches, with the primary outcome being death or neurodevelopmental outcomes at 18-22 mo adjusted age. A large, multicenter cohort study of 8,935 patients demonstrated that laparotomy was the initial therapy in two thirds of VLBW infants with surgical NEC, even in those <1,000 g. Mortality was about 30% in both the laparotomy group and the PPD-converted-to-laparotomy group (46% of PPD group eventually required laparotomy). PPD was found to be an independent risk factor for death (50% mortality), likely from its preferential use in the more seriously ill, unstable patients; however, 27% of patients undergoing PPD survived without further surgery. *The surgical approach depends on surgeon preference and physiologic status of the patient.*

**Prognosis**

Medical management fails in approximately 20–40% of patients with pneumatosis intestinalis at diagnosis; of these, 20–50% die. Early postoperative complications include wound infection, dehiscence, and stomal problems (prolapse, necrosis). Later complications include **intestinal strictures**, which occur in approximately 10% of surgically or medically managed patients. After massive intestinal resection, complications from postoperative NEC include **short bowel syndrome** (malabsorption, growth failure, malnutrition), complications related to central venous catheters (sepsis, thrombosis), and cholestatic jaundice. Preterm infants with NEC who require surgical intervention are at increased risk for adverse growth and neurodevelopmental outcomes.
Prevention

The most effective preventive strategy for NEC is the use of human milk. It is well documented that newborns exclusively breastfed have a reduced risk of NEC. However, because human milk does not provide complete nutritional support, fortification is essential for preterm infants. Some studies have suggested that an “exclusive human milk diet” using human rather than bovine fortifiers may further reduce the risk of NEC. Despite concerns about increased risk of NEC with early and aggressive feeding regimens in VLBW infants, a safe protocol remains unknown. While extensive data and meta-analyses would support the use of probiotics to prevent NEC, there is no clear consensus on the safest, most effective formulation, timing of administration, or length of therapy. Other preventive strategies using prebiotics and synbiotics have also been studied, with variable outcomes. Inhibitors of gastric acid secretion (H₂ -receptor blockers, proton pump inhibitors) or prolonged empirical antibiotics in the early neonatal period have been associated with increased risk of NEC and should be avoided.

Because early detection and treatment may prevent late deleterious consequences of NEC, considerable research is focused on identification of biomarkers for early identification of NEC, including C-reactive protein (CRP), urinary intestinal fatty acid–binding protein (I-FABP), claudin-3 (a tight junction protein), fecal calprotectin, acylcarnitine, IL-6, IL-8, and the heart rate characteristics (HRC) index. Near-infrared spectroscopy (NIRS) may be a promising predictive diagnostic modality for NEC.

Jaundice and Hyperbilirubinemia in the Newborn
Hyperbilirubinemia is a common and, in most cases, benign problem in neonates. Jaundice is observed during the 1st wk after birth in approximately 60% of term infants and 80% of preterm infants. The yellow color usually results from the accumulation of unconjugated, nonpolar, lipid-soluble bilirubin pigment in the skin. This unconjugated bilirubin (designated indirect-acting by nature of the van den Bergh reaction) is an end product of heme-protein catabolism from a series of enzymatic reactions by heme-oxygenase and biliverdin reductase and nonenzymatic reducing agents in the reticuloendothelial cells. It may also be partly caused by deposition of pigment from conjugated bilirubin, the end product from indirect, unconjugated bilirubin that has undergone conjugation in the liver cell microsome by the enzyme uridine diphosphoglucuronic acid (UDP)–glucuronyl transferase to form the polar, water-soluble glucuronide of bilirubin (direct-reacting). Although bilirubin may have a physiologic role as an antioxidant, elevations of indirect, unconjugated bilirubin are potentially neurotoxic. Even though the conjugated form is not neurotoxic, direct hyperbilirubinemia indicates potentially serious hepatic disorders or a systemic illness.

Etiology

During the neonatal period, metabolism of bilirubin is in transition from the fetal
Stage, during which the placenta is the principal route of elimination of the lipid-soluble, unconjugated bilirubin, to the adult stage, during which the water-soluble conjugated form is excreted from hepatic cells into the biliary system and gastrointestinal tract. Unconjugated hyperbilirubinemia may be caused or increased by any factor that (a) increases the load of bilirubin to be metabolized by the liver (hemolytic anemias, polycythemia, bruising or internal hemorrhage, shortened red blood cell [RBC] life as a result of immaturity or transfusion of cells, increased enterohepatic circulation, infection); (b) damages or reduces the activity of the transferase enzyme or other related enzymes (genetic deficiency, hypoxia, infection, thyroid deficiency); (c) competes for or blocks the transferase enzyme (drugs and other substances requiring glucuronic acid conjugation); or (d) leads to an absence or decreased amounts of the enzyme or to reduction of bilirubin uptake by liver cells (genetic defect, prematurity). Gene polymorphisms in the hepatic uridine diphosphate glucuronosyltransferase isoenzyme 1A1 (UGT1A1) and the solute carrier organic anion transporter 1B1 (SLCO1B1), alone or in combination, influence the incidence of neonatal hyperbilirubinemia.

The toxic effects of elevated serum concentrations of unconjugated bilirubin are increased by factors that reduce the retention of bilirubin in the circulation (hypoproteinemia, displacement of bilirubin from its binding sites on albumin by competitive binding of drugs such as sulfisoxazole and moxalactam, acidosis, and increased free fatty acid concentration secondary to hypoglycemia, starvation, or hypothermia). Neurotoxic effects are directly related not only to the permeability of the blood-brain barrier and nerve cell membranes but also to neuronal susceptibility to injury, all of which are adversely influenced by asphyxia, prematurity, hyperosmolality, and infection. Early and frequent feeding decreases, whereas breastfeeding and dehydration increase, serum levels of bilirubin. Delay in passage of meconium, which contains 1 mg bilirubin/dL, may contribute to jaundice by enterohepatic recirculation after deconjugation by intestinal glucuronidase (Fig. 123.8). Drugs such as oxytocin (in the mother) and chemicals used in the nursery such as phenolic detergents may also produce unconjugated hyperbilirubinemia.
Clinical Manifestations

Jaundice usually appears during the early neonatal period, depending on etiology. Whereas jaundice from deposition of indirect bilirubin in the skin tends to appear bright yellow or orange, jaundice of the obstructive type (direct bilirubin) has a greenish or muddy yellow cast. Jaundice usually becomes apparent in a cephalocaudal progression, starting on the face and progressing to the abdomen and then the feet, as serum levels increase. Dermal pressure may reveal the anatomic progression of jaundice (face, approximately 5 mg/dL; mid-abdomen, 15 mg/dL; soles, 20 mg/dL), but clinical examination cannot reliably estimate serum levels. Noninvasive techniques for transcutaneous measurement of bilirubin that correlate with serum levels may be used to screen infants, but determination of serum bilirubin level is indicated in patients with elevated age-
specific transcutaneous bilirubin measurement, progressing jaundice, or risk for hemolysis or sepsis. Infants with severe hyperbilirubinemia may present with lethargy and poor feeding and, without treatment, can progress to acute bilirubin encephalopathy (kernicterus) (see Chapter 123.4).

## Differential Diagnosis

The distinction between *physiologic* and *pathologic* jaundice relates to the timing, rate of rise, and extent of hyperbilirubinemia, because some of the same causes of physiologic jaundice (e.g., large RBC mass, decreased capacity for bilirubin conjugation, increased enterohepatic circulation) can also result in pathologic jaundice. Evaluation should be determined on the basis of risk factors, clinical appearance, and severity of the hyperbilirubinemia (*Tables 123.2 to 123.4*). Jaundice that is present at birth or appears within the 1st 24 hr after birth should be considered *pathologic* and requires immediate attention. Potential diagnoses would include erythroblastosis fetalis, concealed hemorrhage, sepsis, or congenital infections, including syphilis, cytomegalovirus (CMV), rubella, and toxoplasmosis. Hemolysis is suggested by a rapid rise in serum bilirubin concentration (>0.5 mg/dL/hr), anemia, pallor, reticulocytosis, hepatosplenomegaly, and a positive family history. An unusually high proportion of direct-reacting bilirubin may characterize jaundice in infants who have received intrauterine transfusions for erythroblastosis fetalis. Jaundice that first appears on the 2nd or 3rd day is usually *physiologic* but may represent a more severe form. Familial nonhemolytic icterus (*Crigler-Najjar syndrome*) and early-onset breastfeeding jaundice are seen initially on the 2nd or 3rd day. Jaundice appearing after the 3rd day and within the 1st week suggests bacterial sepsis or urinary tract infection; it may also be caused by other infections, notably syphilis, toxoplasmosis, CMV, and enterovirus. Jaundice secondary to extensive ecchymosis or blood extravasation may occur during the 1st day or later, especially in premature infants. Polycythemia may also lead to early jaundice.

### Table 123.2

**Risk Factors for Development of Severe Hyperbilirubinemia***
MAJOR RISK FACTORS
Predischarge TSB or TcB level in the high-risk zone (see Fig. 123.10)
Jaundice observed in the 1st 24 hr
Blood group incompatibility with positive direct antiglobulin test, other known hemolytic disease (G6PD deficiency), elevated end-tidal CO concentration
Gestational age 35-36 wk
Previous sibling received phototherapy
Cephalohematoma or significant bruising
Exclusive breastfeeding, particularly if nursing is not going well and weight loss is excessive
East Asian race †

MINOR RISK FACTORS
Predischarge TSB or TcB level in the high intermediate-risk zone
Gestational age 37-38 wk
Jaundice observed before discharge
Previous sibling with jaundice
Macrosomic infant of a diabetic mother
Maternal age ≥25 yr
Male gender

DECREASED RISK ‡
TSB or TcB level in the low-risk zone (see Fig. 123.10)
Gestational age ≥41 wk
Exclusive bottle feeding
Black race
Discharge from hospital after 72 hr

* In infants ≥35 wk of gestation; factors in approximate order of importance.
† Race as defined by mother’s description.
‡ These factors are associated with decreased risk of significant jaundice, listed in order of decreasing importance.

G6PD, Glucose-6-phosphate dehydrogenase; TcB, transcutaneous bilirubin; TSB, total serum bilirubin.

There is a long differential diagnosis for jaundice first recognized after the 1st week of life, including breast milk jaundice, septicemia, congenital atresia or paucity of the bile ducts, hepatitis, galactosemia, hypothyroidism, CF, and congenital hemolytic anemia crises related to RBC morphology and enzyme deficiencies (Fig. 123.9). The differential diagnosis for persistent jaundice during the 1st mo of life includes hyperalimentation-associated cholestasis, hepatitis, cytomegalic inclusion disease, syphilis, toxoplasmosis, familial nonhemolytic icterus, congenital atresia of the bile ducts, galactosemia, and inspissated bile syndrome following hemolytic disease of the newborn. Rarely, physiologic jaundice may be prolonged for several weeks, as in infants with hypothyroidism or pyloric stenosis.
Regardless of gestation or time of appearance of jaundice, patients with significant hyperbilirubinemia and those with symptoms or signs require a complete diagnostic evaluation, which includes determination of direct and indirect bilirubin fractions, hemoglobin, reticulocyte count, blood type, Coombs test, and examination of a peripheral blood smear. Indirect hyperbilirubinemia, reticulocytosis, and a smear with evidence of RBC destruction suggest hemolysis (see Table 123.3). In the absence of blood group incompatibility, non-immunologically induced hemolysis should be considered. If the reticulocyte count, Coombs test result, and direct bilirubin value are normal, physiologic or pathologic indirect hyperbilirubinemia may be present (see Fig. 123.9). If direct hyperbilirubinemia is present, diagnostic possibilities include hepatitis, congenital bile duct disorders (biliary atresia, paucity of bile ducts,
Byler disease), cholestasis, inborn errors of metabolism, CF, congenital hemosiderosis, and sepsis.

**Physiologic Jaundice (Icterus Neonatorum)**

Under normal circumstances, the level of indirect bilirubin in umbilical cord serum is 1-3 mg/dL and rises at a rate of <5 mg/dL/24 hr; thus, jaundice becomes visible on the 2nd or 3rd day, usually peaking between the 2nd and 4th days at 5-6 mg/dL and decreasing to <2 mg/dL between the 5th and 7th days after birth. Jaundice associated with these changes is designated *physiologic* and is believed to be the result of increased bilirubin production from the breakdown of fetal RBCs combined with transient limitation in the conjugation of bilirubin by the immature neonatal liver.

Overall, 6–7% of full-term infants have indirect bilirubin levels >13 mg/dL, and <3% have levels >15 mg/dL. Risk factors for elevated indirect bilirubin include maternal age, race (Chinese, Japanese, Korean, Native American), maternal diabetes, prematurity, drugs (vitamin K₃, novobiocin), altitude, polycythemia, male sex, trisomy 21, cutaneous bruising, blood extravasation (cephalohematoma), oxytocin induction, breastfeeding, weight loss (dehydration or caloric deprivation), delayed bowel movement, and a family history of, or a sibling who had, physiologic jaundice (see Table 123.2). In infants without these variables, indirect bilirubin levels rarely rise >12 mg/dL, whereas infants with several risk factors are more likely to have higher bilirubin levels. A combination of breastfeeding, variant-glucuronosyltransferase activity (1A1), and alterations of the organic anion transporter-2 gene increases the risk of hyperbilirubinemia. Predicting which neonates are at risk for exaggerated physiologic jaundice can be based on *hour-specific* bilirubin levels in the 1st 24-72 hr of life (Fig. 123.10). Transcutaneous measurements of bilirubin are linearly correlated with serum levels and can be used for screening. Indirect bilirubin levels in full-term infants decline to adult levels (1 mg/dL) by 10-14 days of life. Persistent indirect hyperbilirubinemia beyond 2 wk suggests hemolysis, hereditary glucuronyl transferase deficiency, breast milk jaundice, hypothyroidism, or intestinal obstruction. Jaundice associated with pyloric stenosis may be the result of caloric deprivation, relative deficiency of hepatic UDP–glucuronyltransferase, or an increase in the enterohepatic circulation of
bilirubin from the ileus. In premature infants, the rise in serum bilirubin tends to be the same or somewhat slower but of longer duration than in term infants. Peak levels of 8-12 mg/dL are not usually reached until the 4th-7th day, and jaundice is infrequently observed after the 10th day, corresponding to the maturation of mechanisms for bilirubin metabolism and excretion.

![Image of a graph showing risk designation of term and near-term well newborns based on their hour-specific serum bilirubin values. The high-risk zone is subdivided by the 95th percentile track. The intermediate-risk zone is subdivided into upper and lower risk zones by the 75th percentile track. The low-risk zone has been electively and statistically defined by the 40th percentile track. (From Bhutani VK, Johnson L, Sivieri EM: Predictive ability of a predischarge hour-specific serum bilirubin for subsequent significant hyperbilirubinemia in healthy term and near-term newborns, Pediatrics 103:6–14, 1999.)](image)

The diagnosis of physiologic jaundice in term or preterm infants can be established only by excluding known causes of jaundice on the basis of the history, clinical findings, and laboratory data (see Table 123.4). In general, a search to determine the cause of jaundice should be made if (1) it appears in the 1st 24-36 hr after birth, (2) serum bilirubin is rising at a rate faster than 5 mg/dL/24 hr, (3) serum bilirubin is >12 mg/dL in a full-term infant (especially in the absence of risk factors) or 10-14 mg/dL in a preterm infant, (4) jaundice persists after 10-14 days after birth, or (5) direct bilirubin fraction is >2 mg/dL at any time. Other factors suggesting a pathologic cause of jaundice are family history of hemolytic disease, pallor, hepatomegaly, splenomegaly, failure of phototherapy to lower the bilirubin level, vomiting, lethargy, poor feeding,
excessive weight loss, apnea, bradycardia, abnormal vital signs (including hypothermia), light-colored stools, dark urine positive for bilirubin, bleeding disorder, and signs of kernicterus (see Chapter 123.4).

Pathologic Hyperbilirubinemia

Jaundice and its underlying hyperbilirubinemia are considered pathologic if the time of appearance, duration, or pattern varies significantly from that of physiologic jaundice, or if the course is compatible with physiologic jaundice but other reasons exist to suspect that the infant is at special risk for neurotoxicity. It may not be possible to determine the precise cause of an abnormal elevation of unconjugated bilirubin, but many infants with this finding have associated risk factors such as Asian race, prematurity, breastfeeding, and weight loss. Frequently, the terms exaggerated physiologic jaundice and hyperbilirubinemia of the newborn are used in infants whose primary problem is probably a deficiency or inactivity of bilirubin glucuronyl transferase (Gilbert syndrome) rather than an excessive load of bilirubin for excretion (see Table 123.2). The combination of glucose-6-phosphate dehydrogenase (G6PD) deficiency and a mutation of the promoter region of UDP-glucuronyl transferase-1 produces indirect hyperbilirubinemia in the absence of signs of hemolysis. Nonphysiologic hyperbilirubinemia may also be caused by mutations in the gene for bilirubin UDP–glucuronyl transferase.

The greatest risk associated with indirect hyperbilirubinemia is the development of bilirubin-induced neurologic dysfunction, which typically occurs with high indirect bilirubin levels (see Chapter 123.4). The development of kernicterus (bilirubin encephalopathy) depends on the level of indirect bilirubin, duration of exposure to bilirubin elevation, the cause of jaundice, and the infant's well-being. Neurologic injury including kernicterus may occur at lower bilirubin levels in preterm infants and in the presence of asphyxia, intraventricular hemorrhage, hemolysis, or drugs that displace bilirubin from albumin. The exact serum indirect bilirubin level that is harmful for VLBW infants is unclear.

Jaundice Associated With Breastfeeding

Significant elevation in unconjugated bilirubin (breast milk jaundice) develops in an estimated 2% of breastfed term infants after the 7th day, with maximal
concentrations as high as 10-30 mg/dL reached during the 2nd-3rd wk. If breastfeeding is continued, the bilirubin gradually decreases but may persist for 3-10 wk at lower levels. If nursing is discontinued, the serum bilirubin level falls rapidly, reaching normal range within a few days. With resumption of breastfeeding, bilirubin seldom returns to previously high levels. Phototherapy may be of benefit (see Chapter 123.4). Although uncommon, kernicterus can occur in patients with breast milk jaundice. The etiology of breast milk jaundice is not entirely clear, although β-glucuronidase resulting in deconjugation of bilirubin and increased enterohepatic circulation and other factors in breast milk that might interfere with bilirubin conjugation (e.g., pregnanediol, free fatty acids) have been implicated.

The late jaundice associated with breast milk should be distinguished from an early onset, accentuated unconjugated hyperbilirubinemia known as breastfeeding jaundice, which occurs in the 1st week after birth in breastfed infants, who normally have higher bilirubin levels than formula-fed infants (Fig. 123.11). Lower milk intake before breast milk production is established can result in dehydration, which hemoconcentrates bilirubin, while also causing fewer bowel movements, which in turn increases the enterohepatic circulation of bilirubin. Prophylactic supplements of glucose water to breastfed infants are associated with higher bilirubin levels, in part because of reduced intake of the higher–caloric density breast milk, and are not indicated. Frequent breastfeeding (>10 in 24 hr), rooming-in with night feeding, and ongoing lactation support may reduce the incidence of early breastfeeding jaundice. In addition, supplementation with formula or expressed breast milk is appropriate if the intake seems inadequate, weight loss is excessive, or the infant appears dehydrated.
FIG. 123.11  Distribution of maximal bilirubin levels during the 1st wk of life in breastfed and formula-fed white infants weighing >2,500 g. (From Maisels MJ, Gifford K: Normal serum bilirubin levels in the newborn and the effect of breast-feeding, Pediatrics 78:837–843, 1986.)

Neonatal Cholestasis

See Chapter 383.1.

Congenital Atresia of the Bile Ducts

See Chapter 383.1.

Jaundice persisting for >2 wk or associated with acholic stools and dark urine suggests biliary atresia. All infants with such findings require immediate diagnostic evaluation, including determination of direct bilirubin.

- hyperbilirubinemia
- kernicterus
Kernicterus, or bilirubin encephalopathy, is a neurologic syndrome resulting from the deposition of unconjugated (indirect) bilirubin in the basal ganglia and brainstem nuclei. The pathogenesis of kernicterus is multifactorial and involves an interaction between unconjugated bilirubin levels, albumin binding and unbound bilirubin levels, passage across the blood-brain barrier (BBB), and neuronal susceptibility to injury. Disruption of the BBB by disease, asphyxia, and other factors and maturational changes in BBB permeability affect risk.

The precise blood level above which indirect-reacting bilirubin or free bilirubin will be toxic for an individual infant is unpredictable. In a large series, however, kernicterus occurred only in infants with a bilirubin >20 mg/dL, 90% of whom were previously healthy, predominantly breastfed, term and near-term infants. The duration of exposure to high bilirubin levels needed to produce toxic effects are unknown; the more immature the infant, the greater the susceptibility to kernicterus. Chapter 123.3 discusses the factors that potentiate the movement of bilirubin across the BBB and into brain cells.

**Clinical Manifestations**

Signs and symptoms of kernicterus usually appear 2-5 days after birth in term infants and as late as the 7th day in preterm infants, but hyperbilirubinemia may lead to encephalopathy at any time during the neonatal period. The early signs may be subtle and indistinguishable from those of sepsis, asphyxia, hypoglycemia, intracranial hemorrhage, and other acute systemic illnesses in a neonate. Lethargy, poor feeding, and loss of the Moro reflex are common initial signs. Subsequently, the infant may appear gravely ill and prostrate, with diminished tendon reflexes and respiratory distress. Opisthotonos with a bulging fontanel, twitching of the face or limbs, and a shrill, high-pitched cry may follow. In advanced cases, convulsions and spasm occur, with affected infants stiffly extending their arms in an inward rotation with the fists clenched (Table 123.5). Rigidity is rare at this late stage.

</tbody>
</table>

Many infants who progress to these severe neurologic signs die; the survivors are usually seriously damaged but may appear to recover and for 2-3 mo show few abnormalities. Later in the 1st yr, opisthotonos, muscle rigidity, irregular movements, and convulsions tend to recur. In the 2nd yr the opisthotonos and seizures abate, but irregular, involuntary movements, muscle rigidity, or, in some infants, hypotonia increase steadily. By 3 yr of age, the complete neurologic syndrome is often apparent: bilateral choreoathetosis with involuntary muscle spasms, extrapyramidal signs, seizures, mental deficiency, dysarthric speech, high-frequency hearing loss, squinting, and defective upward eye movements. Pyramidal signs, hypotonia, and ataxia occur in a few infants. In mildly affected infants, the syndrome may be characterized only by mild to moderate neuromuscular incoordination, partial deafness, or “minimal brain dysfunction,” occurring singly or in combination; these problems may be unapparent until the child enters school (see Table 123.5).

Incidence and Prognosis

By pathologic criteria, kernicterus develops in 30% of infants (all gestational ages) with untreated hemolytic disease and bilirubin levels >25-30 mg/dL. The incidence at autopsy in hyperbilirubinemic preterm infants is 2–16% and is related to the risk factors discussed in Chapter 123.3. Reliable estimates of the frequency of the clinical syndrome are not available because of the wide spectrum of manifestations. Overt neurologic signs carry a grave prognosis; >75% of infants die, and 80% of affected survivors have bilateral choreoathetosis with involuntary muscle spasms. Developmental delay, deafness, and spastic quadriplegia are common.
**Prevention**

Although kernicterus has been thought to be a disease of the past, there are reports of neurotoxic effects of bilirubin in term and near-term infants who were discharged as healthy newborns. Effective prevention requires ongoing vigilance and a practical, system-based approach to distinguish infants with benign newborn jaundice from those whose course may be less predictable and potentially harmful. Experts recommend predischarge universal screening for hyperbilirubinemia and assessment of clinical risk factors for severe jaundice and bilirubin-induced neurologic dysfunction. Either total serum bilirubin or transcutaneous bilirubin measurement (interchangeably) is recommended for initial screening, although transcutaneous instruments may be less accurate at higher bilirubin levels (>15 mg/dL) or for infants with darker skin. If transcutaneous levels are documented as ≥15 mg/dL or rising rapidly, confirmation with a total serum bilirubin is recommended. Serum values should also be measured once infants begin phototherapy, because transcutaneous measurement may falsely underestimate total bilirubin in this setting.

Protocols using the hour-specific bilirubin nomogram (see **Fig. 123.10**), physical examination, and clinical risk factors have been successful in identifying patients at risk for hyperbilirubinemia and candidates for targeted management. Potentially preventable causes of kernicterus include (1) early discharge (<48 hr) with no early follow-up (within 48 hr of discharge); this problem is particularly important in near-term infants (35-37 wk of gestation); (2) failure to check the bilirubin level in an infant noted to be jaundiced in the 1st 24 hr; (3) failure to recognize the presence of risk factors for hyperbilirubinemia; (4) underestimation of the severity of jaundice by clinical (visual) assessment; (5) lack of concern regarding the presence of jaundice; (6) delay in measuring the serum bilirubin level despite marked jaundice or delay in initiating phototherapy in the presence of elevated bilirubin levels; and (7) failure to respond to parental concern regarding jaundice, poor feeding, or lethargy. **Fig. 123.12** provides an evidence-based management algorithm for infants. In addition, it is recommended to determine before discharge each infant's risk factors from established protocols (see **Table 123.2**).
The following approach is further recommended: (1) any infant who is jaundiced before 24 hr requires measurement of total and direct serum bilirubin levels and, if it is elevated, evaluation for possible hemolytic disease, and (2) follow-up should be provided within 2-3 days of discharge to all neonates discharged earlier than 48 hr after birth. Early follow-up is particularly important for infants <38 wk of gestation. The timing of follow-up depends on the age at discharge and the presence of risk factors. In some cases, follow-up within 24 hr is necessary. Postdischarge follow-up is essential for early recognition of problems related to hyperbilirubinemia and disease progression. Parental communication with regard to concerns about the infant’s skin color and behavioral activities should be addressed early and frequently, including education about potential risks and neurotoxicity. Ongoing lactation promotion, education, support, and follow-up services are essential throughout the neonatal period. Mothers should be advised to nurse their infants every 2-3 hr and to avoid routine supplementation with water or glucose water to ensure adequate hydration and caloric intake.
Treatment of Hyperbilirubinemia

Regardless of the cause, the goal of therapy is to prevent neurotoxicity related to indirect-reacting bilirubin while not causing undue harm. Phototherapy and, if it is unsuccessful, exchange transfusion remain the primary treatment modalities used to keep the maximal total serum bilirubin below pathologic levels (Table 123.6 and Figs. 123.13 and 123.14). The risk of injury to the central nervous system from bilirubin must be balanced against the potential risk of treatment. There is lack of consensus regarding the exact bilirubin level at which to initiate phototherapy. Because phototherapy may require 6-12 hr to have a measurable effect, it must be started at bilirubin levels below those indicated for exchange transfusion. When identified, underlying medical causes of elevated bilirubin and physiologic factors that contribute to neuronal susceptibility should be treated, with antibiotics for septicemia and correction of acidosis (Table 123.7).

* Complications include perinatal asphyxia, acidosis, hypoxia, hypothermia, hypoalbuminemia, meningitis, intraventricular hemorrhage, hemolysis, hypoglycemia, or signs of kernicterus. Phototherapy is usually started at 50–70% of the maximal indirect level. If values greatly exceed this level, if phototherapy is unsuccessful in reducing the maximal bilirubin level, or if signs of kernicterus are evident, exchange transfusion is indicated.
Guidelines for phototherapy in hospitalized infants of ≥35 wk of gestation.

Note: These guidelines are based on limited evidence, and the levels shown are approximations. The guidelines refer to the use of intensive phototherapy, which should be used when the total serum bilirubin (TSB) exceeds the line indicated for each category. Infants are designated as “higher risk” because of the potential negative effects of the conditions listed on albumin binding of bilirubin, the blood-brain barrier, and the susceptibility of the brain cells to damage by bilirubin. “Intensive phototherapy” implies irradiance in the blue-green spectrum (wavelengths approximately 430-490 nm) of at least 30 µW/cm²/nm (measured at the infant's skin directly below the center of the phototherapy unit) and delivered to as much of the infant's skin surface area as possible. Note that irradiance measured below the center of the light source is much greater than that measured at the periphery. Measurements should be made with a radiometer specified by the manufacturer of the phototherapy system. If TSB levels approach or exceed the exchange transfusion line (see Fig. 123.14), the sides of the bassinet, incubator, or warmer should be lined with aluminum foil or white material, to increase both the surface area of the infant exposed and the efficacy of phototherapy. The presence of hemolysis is strongly suggested if the TSB does not decrease or continues to rise in an infant who is receiving intensive phototherapy. Infants who receive phototherapy and have an elevated direct-reacting or conjugated bilirubin value (cholestatic jaundice) may inconsistently have the bronze baby syndrome. G6PD, Glucose-6-phosphate dehydrogenase. (From American Academy of Pediatrics Subcommittee on Hyperbilirubinemia: Management of hyperbilirubinemia in the newborn infant 35 or more weeks of gestation, Pediatrics 114:297–316, 2004.)
Guidelines for exchange transfusion in hospitalized infants of ≥35 wk of gestation. Note: These suggested levels represent a consensus of most of the committee but are based on limited evidence, and the levels shown are approximations. During birth hospitalization, exchange transfusion is recommended if the total serum bilirubin (TSB) rises to these levels despite intensive phototherapy. In a readmitted infant, if the TSB level is above the exchange level, TSB measurement should be repeated every 2-3 hr; exchange transfusion should be considered if the TSB remains above the levels indicated after intensive phototherapy for 6 hr. The following B:A (bilirubin:albumin) ratios can be used together with, but not instead of, the TSB level as an additional factor in determining the need for exchange transfusion. G6PD, Glucose-6-phosphate dehydrogenase. (From American Academy of Pediatrics Subcommittee on Hyperbilirubinemia: Management of hyperbilirubinemia in the newborn infant 35 or more weeks of gestation, Pediatrics 114:297–316, 2004.)

Glucose-6-phosphate dehydrogenase if suggested by ethnic or geographic origin or if poor response to phototherapy
Urine for reducing substances
If history and/or presentation suggest sepsis, perform blood culture, urine culture, and cerebrospinal fluid for protein, glucose, cell count, and culture.

**INTERVENTIONS**

If TSB ≥25 mg/dL (428 µmol/L) or ≥20 mg/dL (342 µmol/L) in a sick infant or infant <38 wk gestation, obtain a type and crossmatch, and request blood in case an exchange transfusion is necessary.

In infants with isoimmune hemolytic disease and TSB level rising in spite of intensive phototherapy or within 2-3 mg/dL (34-51 µmol/L) of exchange level (see Fig. 123.14), administer intravenous immune globulin 0.5-1 g/kg over 2 hr and repeat in 12 hr if necessary.

If infant's weight loss from birth is >12% or there is clinical or biochemical evidence of dehydration, recommend formula or expressed breast milk. If oral intake is in question, give intravenous fluids.

**FOR INFANTS RECEIVING INTENSIVE PHOTOTHERAPY:**

Breastfeed or bottle-feed (formula or expressed breast milk) every 2-3 hr.
If TSB ≥25 mg/dL (428 µmol/L), repeat TSB within 2-3 hr.
If TSB 20-25 mg/dL (342-428 µmol/L), repeat within 3-4 hr. If TSB <20 mg/dL (342 µmol/L), repeat in 4-6 hr. If TSB continues to fall, repeat in 8-12 hr.
If TSB is not decreasing or is moving closer to level for exchange transfusion, or if the TSB/albumin ratio exceeds levels shown in Fig. 123.14, consider exchange transfusion (see Fig. 123.14 for exchange transfusion recommendations).

When TSB is <13-14 mg/dL (239 µmol/L), discontinue phototherapy.
Depending on the cause of the hyperbilirubinemia, it is an option to measure TSB 24 hr after discharge to check for rebound.

TSB, Total serum bilirubin.

**Phototherapy**

Clinical jaundice and indirect hyperbilirubinemia are reduced by exposure to high-intensity light in the visible spectrum. Bilirubin absorbs light maximally in the blue range (420-470 nm). Broad-spectrum white, blue, and special narrow-spectrum (super) blue lights have been effective in reducing bilirubin levels. Bilirubin in the skin absorbs light energy, causing several photochemical reactions. One major product from phototherapy is a result of a reversible photoisomerization reaction converting the toxic native unconjugated 4Z,15Z-bilirubin into an unconjugated configurational isomer, 4Z,15E-bilirubin, which can then be excreted in bile without conjugation. The other major product from phototherapy is lumirubin, which is an irreversible structural isomer converted from native bilirubin that can be excreted by the kidneys in the unconjugated state.

The therapeutic effect of phototherapy depends on the light energy emitted in
the effective range of wavelengths, the distance between the lights and the infant, and the surface area of exposed skin, as well as the rate of hemolysis and in vivo metabolism and excretion of bilirubin. Available commercial phototherapy units vary considerably in spectral output and the intensity of radiance emitted; therefore the wattage can be accurately measured only at the patient's skin surface. Dark skin does not reduce the efficacy of phototherapy. Maximal intensive phototherapy should be used when indirect bilirubin levels approach those noted in Fig. 123.13 and Table 123.7. Such therapy includes using “special blue” fluorescent tubes, placing the lamps within 15-20 cm (6-8 inches) of the infant, and putting a fiberoptic phototherapy blanket under the infant's back to increase the exposed surface area.

The use of phototherapy has decreased the need for exchange transfusion in term and preterm infants with hemolytic and nonhemolytic jaundice. When indications for exchange transfusion are present, phototherapy should not be used as a substitute; however, phototherapy may reduce the need for repeated exchange transfusions in infants with hemolysis. Conventional phototherapy is applied continuously, and the infant is turned frequently for maximal skin surface area exposure. It should be discontinued as soon as the indirect bilirubin concentration has reduced to levels considered safe with respect to the infant's age and condition. Serum bilirubin levels and hematocrit should be monitored every 4-8 hr in infants with hemolytic disease and those with bilirubin levels near toxic range for the individual infant. Others, particularly older neonates, may be monitored less frequently. Serum bilirubin monitoring should continue for at least 24 hr after cessation of phototherapy in patients with hemolytic disease, because unexpected rises in bilirubin may occur, requiring further treatment. Skin color cannot be relied on for evaluating the effectiveness of phototherapy; the skin of babies exposed to light may appear to be almost without jaundice in the presence of marked hyperbilirubinemia. Although not necessary for all affected infants, intravenous fluid supplementation added to oral feedings may be beneficial in dehydrated patients or infants with bilirubin levels nearing those requiring exchange transfusion.

**Complications** associated with phototherapy include loose stools, erythematous macular rash, purpuric rash associated with transient porphyrinemia, overheating, dehydration (increased insensible water loss, diarrhea), hypothermia from exposure, and a benign condition called “bronze baby syndrome,” which occurs in the presence of direct hyperbilirubinemia. Phototherapy is contraindicated in the presence of porphyria. Before
phototherapy is initiated, the infant's eyes should be closed and adequately covered to prevent light exposure and corneal damage. Body temperature should be monitored, and the infant should be shielded from bulb breakage. Irradiance should be measured directly. In infants with hemolytic disease, care must be taken to monitor for the development of anemia, which may require transfusion. Anemia may develop despite lowering of bilirubin levels. Clinical experience suggests that long-term adverse biologic effects of phototherapy are absent, minimal, or unrecognized.

The term **bronze baby syndrome** refers to a dark, grayish brown skin discoloration sometimes noted in infants undergoing phototherapy. Almost all infants observed with this syndrome have had significant elevation of direct-reacting bilirubin and other evidence of obstructive liver disease. The discoloration may result from photo-induced modification of porphyrins, which are often present during cholestatic jaundice and may last for many months. Despite the bronze baby syndrome, phototherapy can continue if needed.

**Intravenous Immune Globulin**

The administration of intravenous immunoglobulin (IVIG) is an adjunctive treatment for hyperbilirubinemia caused by isoimmune hemolytic disease. Its use is recommended when serum bilirubin is approaching exchange levels despite maximal interventions, including phototherapy. IVIG (0.5-1.0 g/kg/dose; repeat in 12 hr) reduces the need for exchange transfusion in both ABO and Rh hemolytic disease, presumably by reducing hemolysis.

**Metalloporphyrins**

A possible adjunct therapy is the use of metalloporphyrins for hyperbilirubinemia. The metalloporphyrin Sn-mesoporphyrin (SnMP) offers promise as a drug candidate. The proposed mechanism of action is competitive enzymatic inhibition of the rate-limiting conversion of heme-protein to biliverdin (an intermediate metabolite in the production of unconjugated bilirubin) by heme-oxygenase. A single intramuscular dose on the 1st day of life may reduce the need for subsequent phototherapy. Such therapy may be beneficial when jaundice is anticipated, particularly in patients with ABO incompatibility or G6PD deficiency, or when blood products are objected to, as with Jehovah's Witness patients. Complications from metalloporphyrins include
transient erythema if the infant is receiving phototherapy. Administration of SnMP may reduce bilirubin levels and decrease both the need for phototherapy and the duration of hospital stay; however, it remains unclear whether treatment with metalloporphyrins for unconjugated hyperbilirubinemia will alter the risk of kernicterus or long-term neurodevelopment impairment. Data on efficacy, toxicity, and long-term benefit are still being evaluated.

**Exchange Transfusion**

Double-volume exchange transfusion is performed if intensive phototherapy has failed to reduce bilirubin levels to a safe range and the risk of kernicterus exceeds the procedural risk. Potential complications from exchange transfusion are not trivial and include metabolic acidosis, electrolyte abnormalities, hypoglycemia, hypocalcemia, thrombocytopenia, volume overload, arrhythmias, NEC, infection, graft-versus-host disease, and death. This widely accepted treatment is repeated if necessary to keep indirect bilirubin levels in a safe range (see Fig. 123.14 and Table 123.7).

Various factors may influence the decision to perform a double-volume exchange transfusion in an individual patient. The appearance of clinical signs suggesting kernicterus is an indication for exchange transfusion at any level of serum bilirubin. A healthy full-term infant with physiologic or breast milk jaundice may tolerate a concentration slightly higher than 25 mg/dL with no apparent ill effect, whereas kernicterus may develop in a sick premature infant at a significantly lower level. A level approaching that considered critical for the individual infant may be an indication for exchange transfusion during the 1st or 2nd day after birth, when a further rise is anticipated, but not typically after the 4th day in a term infant or after the 7th day in a preterm infant, because an imminent fall may be anticipated as the hepatic conjugating mechanism becomes more effective.

**Bibliography**

Ip S, Chung M, Trikalinos T, et al. *Screening for bilirubin*

Anemia is a common laboratory and clinical finding in the newborn period and carries a broad differential diagnosis. Anemia in the newborn may be acute or chronic, and its clinical manifestations range from an asymptomatic laboratory finding to life-threatening signs and symptoms. The diagnosis and interpretation of anemia in the newborn infant are therefore complex and require careful consideration of the gestational age and general health of the infant, details of the perinatal course and delivery, and information regarding the general health of the mother both during pregnancy and through delivery into the postpartum period.
Before interpreting hemoglobin and hematocrit values for infants, it is important to understand the pathophysiology of hemoglobin-oxygen binding and delivery, both before and after birth. Because of the hypoxic environment in utero and the lack of direct gas exchange with the ambient atmosphere, fetal hemoglobin (HbF) predominates throughout late gestation because of its increased affinity to bind and transport oxygen compared to the mother's adult hemoglobin. Despite the predominance of HbF, the in utero environment remains hypoxic, such that the normal hemoglobin concentration is relatively high at birth.

**Normal Hematocrit and Hemoglobin Concentrations in Newborn Infants**

The diagnostic approach to anemia in the newborn infant begins comparing laboratory results with reference ranges for both gestational age and postnatal age. Although significant variability exists in suggested reference ranges, data collected from more than 25,000 preterm and term infants through the 1st 28 days of life have provided robust data-driven reference ranges. These data, illustrated in Fig. 124.1, demonstrate a near-linear increase in hemoglobin and hematocrit between 22 and 40 wk of gestation. Notably, the mean corpuscular volume (MCV) in neonates is strikingly higher than toddlers and older children, with normal values ranging from about 100-115 fL at birth. An MCV <100 fL at birth should prompt consideration of underlying α-thalassemia trait or maternal iron deficiency.
FIG. 124.1 Reference range for hematocrit and hemoglobin concentration according to gestational age. A and B, Reference ranges (5th percentile, mean, and 95th percentile) are shown for blood hemoglobin (A) and hematocrit (B). Concentrations were obtained during the 1st 6 hr after birth, among patients 22-42 wk gestation. Values were
excluded if the diagnosis included abruption, placenta previa, or known fetal anemia, or if a blood transfusion was given before the first hemoglobin was measured. C, References ranges for mean corpuscular volume (MCV) in neonates on 1st day after birth. The lower line shows the 5th percentile values, the middle line shows the mean values, and the upper line shows the 95th percentile values. (From Christensen RD, Jopling HE, Jopling J, Wiedemeir SE: The CBC: reference ranges for neonates, Semin Perinatol 33(1):3–11, 2009.)

Over the first days and weeks of postnatal life, increased oxygen in the environment reduces the erythropoietic drive, and this normal developmental and physiologic process results in a slow decrease in hematocrit and hemoglobin concentration. Fig. 124.2 demonstrates the expected decrease in hematocrit and hemoglobin concentration according to postnatal age for both term/postterm (Fig. 124.2A and B) and preterm (29-34 wk gestation) infants. The lower dashed lines in Fig. 124.2 represent the 5th percentile, below which a diagnosis of neonatal anemia should be defined. Eventually, oxygen delivery becomes limiting enough to stimulate new active erythropoiesis, and the hemoglobin concentration begins to rise. This physiologic nadir usually occurs between 6 and 10 wk of life for term infants, with a typical low hemoglobin value of 9-11 g/dL, while preterm infants reach their nadir earlier, at 4-8 wk of age with a hemoglobin concentration of 7-9 g/dL.
Classification of Anemia and Diagnostic Evaluation

As with any diagnostic approach to anemia, low hemoglobin concentration in the newborn period can be classified into 3 broad categories: blood loss; erythrocyte destruction; or underproduction of erythrocytes. Table 124.1 summarizes the most common causes of neonatal anemia according to these categories.

Prior to laboratory testing, a complete medical history, including careful review of the pregnancy and perinatal course, and a careful physical examination are important because they often suggest a specific diagnosis more effectively than extensive laboratory testing. A simple and efficient laboratory workup is critical to the timely diagnosis and associated treatment of neonatal anemia. In addition to a complete blood count (CBC), additional laboratory tests on the infant include the reticulocyte count, direct antiglobulin test, serum bilirubin, infant and maternal blood ABO group, and Rh type. The mother should also be screened with an indirect (serum) antiglobulin test for erythrocyte alloantibodies, and the Kleihauer-Betke test can identify fetal erythrocytes in the maternal circulation (Fig. 124.3). Fig. 124.4 shows a proposed diagnostic approach to anemia in newborn infants. Hemolytic anemia is usually associated with difficult-to-treat hyperbilirubinemia (Fig. 124.5), whereas congenital aregenerative anemias (e.g., Diamond-Blackfan anemia) usually do not manifest jaundice but have other features (Table 124.2).

![Image](Fig. 124.3) Acid elution technique of Kleithauer (Kleihauer-Betke test). Fetal red blood cells stain with eosin and appear dark. **Review of the peripheral blood smear is an essential component** of the evaluation of neonatal anemia. The presence of reticulocytes and nucleated red blood cells (RBCs) indicate chronic anemia with compensatory active erythropoiesis, while distinct erythrocyte morphologies (e.g., elliptocytes, acanthocytes) suggest a congenital intrinsic hemolytic anemia. The presence of spherocytes (often **microspherocytes** ) is consistent with immune-mediated hemolysis but can also indicate **hereditary spherocytosis**; the direct antiglobulin test (DAT, formerly the direct Coombs test) is needed to distinguish these 2 important diagnoses (Fig. 124.6). Neonatal blood smears often include atypical erythrocyte morphology with macrocytosis, poikilocytosis, and anisocytosis that reflect normal fetal erythropoiesis, and an experienced hematologist or pathologist may be required to identify a pathologic feature ([Table 124.3](#)) (see Chapter 474).

**Red Blood Cell Loss**

Blood loss is the most common cause of neonatal anemia. Repeated or frequent phlebotomy for routine laboratory tests, especially from premature or acutely ill neonates, is one of the most common causes of anemia. Several reports have documented large volumes of blood removed for laboratory testing among children in neonatal intensive care units (NICUs), with weekly phlebotomy volumes ranging from 15–30% of the infant's total blood volume (11-22 mL/kg/wk). Most other causes of blood loss occur just before or during delivery, such as placental abruption, and fetal hemorrhage is more common in emergent or traumatic deliveries (see Table 124.1).

**Fetomaternal hemorrhage (FMH)** is caused by bleeding from the fetal into the maternal circulation, either before or during delivery. Such bleeding occurs to some extent in most pregnancies, although the volume lost is typically small.
Estimates suggest that more substantial FMH, defined as >30 mL of fetal blood, occurs in 3 per 1,000 births, with large (>80 mL) or massive (>150 mL) FMH occurring in 0.9 and 0.2 per 1,000 births, respectively. Blood loss during gestation can be slow and well compensated by the fetus in terms of both blood volume and oxygen delivery, but faster or larger bleeds will not be fully compensated. Therefore the presentation of FMH is variable, but decreased or absent fetal movement is the most common antenatal presentation and should be associated with a high degree of clinical suspicion. After delivery, infant pallor, hypotension, and poor perfusion will indicate severe anemia. To diagnose FMH, the classic Kleihauer-Betke test, which identifies fetal erythrocytes containing HbF resistant to acid elution, is technically the gold standard but is labor intensive, highly dependent on the skills of the technician, and often not available as a rapid or point-of-care test (see Fig. 124.3). Some advanced laboratories offer a more precise test using flow cytometry to quantify fetal cells in the maternal circulation.

**Red Blood Cell Destruction**

RBC destruction is an important cause of neonatal anemia and most frequently reflects elimination of erythrocytes by immune-mediated mechanisms, which result from RBC antigen incompatibilities between the infant and mother. **Hemolytic disease of the fetus and newborn (HDFN)** is a broad term used to describe any fetus or infant who develops alloimmune hemolysis caused by the presence of maternal antibodies against RBC antigens within the circulation of the child (see Chapter 124.2). HDFN caused by anti-RhD antibodies, occurring in RhD-positive infants born to RhD-negative mothers, is the most severe form because of the highly immunogenic nature of the RhD antigen. ABO incompatibility, most often a mismatch between group O mothers and their non–group O infants, affects approximately 15% of pregnancies but is usually less severe than Rh disease, with only 4% of incompatible pregnancies resulting in neonatal hemolytic disease. Unlike Rh disease, in which sensitization usually occurs in the first pregnancy and HDFN occurs in subsequent pregnancies, ABO incompatibility can occur during a woman's first pregnancy, since group O mothers have naturally occurring anti-A and anti-B antibodies. A positive DAT on the infant's blood and a positive indirect antiglobulin test (IAT; also known as the antibody screen) in the mother provide diagnostic evidence of HDFN.

In addition to immune-mediated mechanisms of erythrocyte destruction,
congenital RBC enzyme and membrane disorders also can result in hemolytic anemia and jaundice within the neonatal period. The erythrocyte membrane is a complex structure with numerous critical proteins and lipids that result in a durable, flexible, circulating biconcave disc shape. Genetic deficiencies or abnormalities in RBC membrane proteins (e.g., ankyrin, band 3, α-spectrin, β-spectrin, protein 4.2) result in instability of the RBC membrane, decreased cellular deformability, and shape changes; the abnormal erythrocytes undergo splenic entrapment and removal by macrophages. Hereditary spherocytosis (HS), an autosomal dominant condition characterized by spherical erythrocytes, is the most common RBC membrane disorder, affecting 1 in 2,500-5,000 individuals of European descent. Nearly half of infants born with HS will develop jaundice early in the newborn period.

Hereditary elliptocytosis (HE), another autosomal dominant inherited erythrocyte membranopathy, characterized by elliptical-shaped erythrocytes, is a less common and less severe RBC membrane disorder. In contrast, hereditary pyropoikilocytosis (HPP) is an autosomal recessive RBC membrane disorder resulting in striking morphologic shape changes (poikilocytosis) noted on the peripheral blood smear, some of which resemble thermally damaged erythrocytes. HPP is most common in infants of African descent and can be associated with severe anemia and hemolysis in the newborn period. There is substantial clinical and genetic overlap between HPP and HE, because infants with HPP often have a family history of HE and may develop a milder condition resembling HE later in childhood. Clinical suspicion for a RBC membranopathy begins with a positive family history of hemolytic anemia, especially in an infant who develops early jaundice in the 1st 24 hr of life. The diagnostic evaluation should include a negative DAT, indirect hyperbilirubinemia, and hallmark features noted on the peripheral blood smear. The degree of anemia is variable, and reticulocytosis may also be present.

Erythrocyte enzymopathies are another important, but less common, etiology of neonatal anemia. Circulating RBCs lack a nucleus, mitochondria, or other essential organelles and thus rely solely on critical metabolic pathways to allow for their function in the transport and delivery of oxygen. Several enzymes are especially important to RBC metabolism and may result in hemolytic anemia when deficient. Glucose-6-phosphate dehydrogenase (G6PD) deficiency is the most common of these RBC enzymopathies. G6PD deficiency is a common X-linked disorder affecting >400 million people worldwide. There are several classes of G6PD deficiency with varying degrees of clinical severity, but most
affected persons are asymptomatic. In the setting of oxidative stress (drugs, infection, certain foods), however, some persons with G6PD deficiency may develop acute hemolytic anemia. There is a several-fold increase in the incidence of neonatal jaundice in G6PD-deficient infants, with jaundice typically occurring on day 2-3 of life. Severe anemia with reticulocytosis is not common, but hyperbilirubinemia in the setting of G6PD deficiency can be severe and prolonged. Clinical testing measuring G6PD activity can be performed (<1–2% suggests G6PD deficiency), but the testing will not be accurate in the setting of acute hemolysis or an elevated reticulocyte count, because reticulocytes have higher enzyme activity. **Pyruvate kinase (PK) deficiency** is the 2nd most common RBC enzymopathy and may also be associated with neonatal jaundice and bizarre morphology featuring acanthocytes.

**Red Blood Cell Production**

RBC underproduction is also common in the neonate, particularly among preterm infants. Because of relative polycythemia and the physiologic right shift in the oxyhemoglobin dissociation curve, there is typically sufficient oxygen delivery to the tissues during the 1st weeks of postuterine life. The erythropoietic drive is thus limited, and active erythropoiesis does not commence until the 2nd mo of life. This physiologic underproduction of erythrocytes appears to be prolonged in preterm infants and results in a steeper physiologic nadir referred to as **anemia of prematurity**. Anemia of prematurity is exacerbated by acute illness, frequent phlebotomy, and other comorbidities observed in premature infants.

In addition to physiologic underproduction of erythrocytes, several acquired and congenital conditions may further suppress bone marrow production (see **Table 124.2**). Both bacterial and viral infections may result in suppression of erythropoiesis and contribute to neonatal anemia; infectious etiologies are numerous but TORCH infections and parvovirus B19 are the most common. **Tables 124.1 and 124.2** list congenital causes of neonatal anemia, including congenital leukemia, bone marrow failure syndromes (Fanconi anemia, Schwachman-Diamond syndrome), Diamond-Blackfan anemia), and variants in γ-globin, β-globin, or α-globin. Notably, common β-hemoglobinopathies such as sickle cell disease and thalassemia do not present in the neonatal period, as a result of the protective effect of high levels of HbF in the first few months of life.
Treatment Options for Neonatal Anemia

Packed Red Blood Cell Transfusions

Treatement of neonatal anemia by blood transfusion depends on the severity of symptoms, the hemoglobin concentration, and the presence of comorbidities (e.g., bronchopulmonary dysplasia, cyanotic congenital heart disease, respiratory distress syndrome) that interfere with oxygen delivery. The benefits of blood transfusion should be balanced against its risks, which include hemolytic and nonhemolytic reactions; exposure to blood product preservatives and toxins; volume overload; possible increased risk of retinopathy of prematurity and necrotizing enterocolitis; graft-versus-host reaction; and transfusion-acquired infections such as cytomegalovirus (CMV), HIV, parvovirus, and hepatitis B and C (see Chapter 501). The frequency of transfusion for neonates in the NICU is high, particularly among premature and very-low-birthweight (VLBW) infants.

Few studies have evaluated the efficacy or safety of specific hemoglobin/hematocrit thresholds, but a Cochrane review summarized the available evidence and proposed guidelines for transfusion of VLBW infants. The review identified 4 trials comparing restrictive (lower) to liberal (higher) hemoglobin thresholds. There were no statistically significant differences in death or serious morbidity, and the restrictive thresholds modestly reduced exposure to blood products. Evidence was inconclusive, however, regarding the effectiveness of either threshold in optimizing long-term neurocognitive outcomes. The proposed guideline for the transfusion of neonates was based primarily on postnatal age and the presence or absence of respiratory support (Table 124.4). In addition to these factors, transfusion should be considered for infants with acute blood loss (>20%) or significant hemolysis, as well as before surgery. With no similar evidence-based guidelines for term infants, transfusion should be based on hemodynamic stability, respiratory status, overall clinical condition, and laboratory values.

When the decision to transfuse has been made, the appropriate blood product should be selected and a safe volume of blood should be transfused at a safe rate. It is important to transfuse packed erythrocytes (PRBCs) to all neonates in the form of **leukocyte-reduced** or **CMV-seronegative** PRBCs, to reduce the risk of CMV transmission. **Irradiation** of PRBCs removes the risk of transfusion-associated graft-versus-host disease (GVHD) but does not eliminate the risk of CMV transmission. The volume of transfusion should achieve the intended therapeutic goal while limiting blood product exposure. Typical transfusion protocols choose a transfusion volume ranging from 10-20 mL/kg. There are no clear data to favor a specific amount, but lower volumes expose infants to risks unnecessarily while higher volumes may cause fluid overload. One logical goal is to target a specific goal hemoglobin (Hb) concentration. The following commonly used shorthand equation can provide a good estimate of required blood volume, which usually results in a transfusion volume within the 10-20 mL/kg range:

\[
\text{PRBC transfusion volume} = (\text{Desired Hb [g/dL]} - \text{Actual Hb}) \times \text{Weight (kg)} \times 3
\]

Transfusion of PRBCs is typically delivered at a rate of 3-5 mL/kg/hr, with a slower rate preferred for very small, acutely ill infants with a tenuous fluid status. Each transfusion should be completed within 4 hours.

**Erythropoietin**

Because of the low physiologic levels of erythropoietin in neonates, the role of recombinant human erythropoietin (rhEPO) has been investigated for the treatment of anemia in neonates, particularly VLBW infants. A Cochrane review documented that rhEPO is associated with a significant reduction in the number of blood transfusions per infant, but also a significantly increased risk of retinopathy of prematurity. There were no differences in mortality or other neonatal morbidities among infants who did or did not receive rhEPO. Because of these limited benefits and potential serious risks of early rhEPO therapy, there is currently no strong indication for the routine use of rhEPO in infants with anemia, although it should be considered in individual settings.

Hemolytic Disease of the Fetus and Newborn

Omar Niss, Russell E. Ware

Keywords

exchange transfusion
fetal anemia
hemolytic anemia
intrauterine transfusion
Rh alloimmunization

Hemolytic disease of the fetus and newborn (HDFN), also known as erythroblastosis fetalis, is caused by the transplacental passage of maternal antibodies directed against paternally derived red blood cell (RBC) antigens, which causes increased RBC destruction (hemolysis) in the infant. HDFN is an important cause of anemia and jaundice in newborn infants, and early recognition and diagnosis are crucial for proper management. Although more than 60 different RBC antigens are capable of eliciting a maternal antibody response, clinically significant disease is associated primarily with incompatibility of ABO blood groups and the RhD antigen. Less frequently, hemolytic disease may be caused by differences in other antigens of the Rh
system or by other RBC antigens such as \( C^w \), \( C^x \), \( D^u \), \( K (\text{Kell}) \), M, Duffy, S, P, MNS, Xg, Lutheran, Diego, and Kidd. Notably, anti-Lewis maternal antibodies rarely cause HDFN.

**Hemolytic Disease Caused by Rh Incompatibility**

The Rh antigenic determinants are genetically transmitted from each parent and determine the Rh blood type by directing the production of Rh proteins (C, c, D, E, and e) on the RBC surface. **RhD** is responsible for 90% of HDFN cases involving the Rh antigen system, but other Rh antigens (especially E and c) also can be etiologic.

**Pathogenesis**

Alloimmune hemolytic disease from RhD antigen incompatibility is approximately 3 times more common among whites than among blacks, because of differences in Rh allele frequency. Approximately 85% of Caucasians express RhD antigen (**Rh-positive**), whereas 99% of persons from Africa or Asia are Rh-positive. When Rh-positive blood is infused into an unsensitized Rh-negative woman, antibody formation against the mismatched Rh antigen is induced in the recipient. This can occur through transfusion, but the typical scenario is when small quantities (usually >1 mL) of Rh-positive fetal blood, inherited from an Rh-positive father, enter the maternal circulation during pregnancy, through spontaneous or induced abortion, or at delivery. Once sensitization has occurred, considerably smaller doses of antigen can stimulate an increase in antibody titer. Initially, a rise in immunoglobulin (Ig) M antibody occurs, which is later replaced by IgG antibody. Unlike IgM antibodies, IgG readily crosses the placenta to cause hemolytic manifestations.

HDFN requires Rh-antigen mismatch between the infant and the mother, with prior maternal exposure to RBCs expressing the cognate antigen. Hemolytic disease rarely occurs during a first pregnancy because transfusion of Rh-positive fetal blood into an Rh-negative mother usually occurs near the time of delivery, which is too late for the mother to become sensitized and transmit antibody to that infant before delivery. However, fetal-to-maternal transfusion is thought to occur in only 50% of pregnancies, so Rh incompatibility does not always lead to
Rh sensitization. Another important factor is the allele frequency of the RhD antigen because homozygous Rh-positive fathers must transmit the antigen to the fetus, whereas heterozygous fathers have only a 50% chance of having Rh-positive offspring. A smaller family size also reduces the risk of sensitization.

The outcome for Rh-incompatible fetuses varies greatly, depending on the characteristics of both the RBC antigen and the maternal antibodies. Not all maternal-fetal antigen incompatibility leads to alloimmunization and hemolysis. Factors that affect the outcome of antigen-positive fetuses include differential immunogenicity of blood group antigens (RhD antigen being the most immunogenic), a threshold effect of fetomaternal transfusions (a certain amount of the immunizing blood cell antigen is required to induce the maternal immune response), the type of antibody response (IgG antibodies are more efficiently transferred across the placenta to the fetus), and differences in the maternal immune response, presumably related to differences in the efficiency of antigen presentation by various major histocompatibility complex (MHC) loci.

Notably, when the mother and fetus are also ABO incompatible, the Rh-negative mother is partially protected against sensitization due to rapid removal of the fetal Rh-positive cells by maternal isohemagglutinins (preexisting IgM anti-A or anti-B antibodies that do not cross the placenta). Once a mother has been sensitized, all subsequent infants expressing that cognate antigen on RBCs are at risk for HDFN. The severity of Rh illness typically worsens with successive pregnancies because of repeated immune stimulation. The likelihood that Rh sensitization affects a mother's childbearing potential argues urgently for the prevention of sensitization. The injection of anti-Rh immune globulin (RhoGAM) into the Rh-negative mother, both during pregnancy and immediately after the delivery of each Rh-positive infant, reduces HDFN caused by RhD alloimmunization.

**Clinical Manifestations**

The severity of HDFN is variable, ranging from only laboratory evidence of mild hemolysis to severe anemia with compensatory hyperplasia of erythropoietic tissues, leading to massive enlargement of the liver and spleen. When hemolysis exceeds the compensatory capacity of the hematopoietic system, profound anemia occurs and results in pallor, signs of cardiac decompensation (cardiomegaly, respiratory distress), massive anasarca, and circulatory collapse. This clinical picture of excessive abnormal fluid in 2 or
more fetal compartments (skin, pleura, pericardium, placenta, peritoneum, amniotic fluid), termed **hydrops fetalis**, frequently results in death in utero or shortly after birth.

The severity of hydrops is related to the level of anemia and the degree of edema caused by a reduction in serum albumin (oncotic pressure), which is partly a result of hepatic congestion and hepatic dysfunction. Alternatively, heart failure may increase right-sided heart pressure, with the subsequent development of edema and ascites. Failure to initiate spontaneous effective ventilation because of pulmonary edema or bilateral pleural effusions results in birth asphyxia. After successful resuscitation, severe respiratory distress may develop. Petechiae, purpura, and thrombocytopenia may also be present in severe cases, as a result of decreased platelet production or the presence of concurrent disseminated intravascular coagulation (DIC). Fortunately, with the routine use of RhoGAM to prevent Rh sensitization, *hydrops caused by HDFN has become rare and is more frequently encountered in nonhemolytic conditions.*

Jaundice may be absent at birth because of effective placental clearance of lipid-soluble unconjugated bilirubin, but in severe cases, bilirubin pigments can stain the amniotic fluid, cord, and vernix caseosa. *Jaundice is generally evident in the initial 24 hr of life, which is always pathologic,* because the infant's bilirubin-conjugating and excretory systems are unable to cope with the load resulting from massive hemolysis. Indirect-reacting bilirubin accumulates postnatally and may rapidly reach extremely high levels and present a significant risk of bilirubin encephalopathy (kernicterus). The risk of development of kernicterus from HDFN is greater than from comparable nonhemolytic hyperbilirubinemia, although the risk in an individual patient may be affected by other complications such as hypoxia or acidosis. *Hypoglycemia* also occurs in infants with severe HDFN and may be related to hyperinsulinism and hypertrophy of the pancreatic islet cells in these infants.

Infants with signs of severe disease in utero (hydrops, severe fetal anemia) may benefit from **intrauterine transfusion**, given either directly into the peritoneum or through the umbilical cord. Such infants usually have very high (but extremely variable) cord levels of bilirubin, reflecting the severity of the hemolysis and its effects on hepatic function. Infants treated with transfusions in utero may also have a benign postnatal course if the anemia and hydrops resolve before birth. Ongoing hemolysis can be masked by the previous intrauterine transfusion.
Laboratory Data

Before treatment, the direct antiglobulin test (DAT), or Coombs test, is positive, and anemia is generally present. The cord blood hemoglobin content varies and is usually proportional to the severity of the disease. In cases of hydrops fetalis, the hemoglobin concentration may be as low as 3-4 g/dL. Alternatively, despite hemolysis, hemoglobin may be within the normal range because of compensatory bone marrow and extramedullary hematopoiesis. The initial reticulocyte count is increased, another abnormal finding at birth, and the peripheral blood smear typically shows polychromasia with a marked increase in nucleated RBCs. The white blood cell count is usually normal but may be elevated, and thrombocytopenia develops in severe cases. Cord bilirubin levels are generally between 3 and 5 mg/dL; the direct-reacting (conjugated) bilirubin content may also be elevated (from cholestasis), especially if there was a previous intrauterine transfusion. Indirect-reacting bilirubin content rises rapidly to high levels in the 1st 6-12 hr of life.

After intrauterine transfusions, cord blood may show a normal hemoglobin concentration, negative DAT result, predominantly Rh-negative adult RBCs, low/normal reticulocyte count, and relatively normal blood smear findings.

Diagnosis

Definitive diagnosis of HDFN requires demonstration of blood group incompatibility between mother and infant and corresponding maternal antibody bound to the infant's RBCs.

Antenatal Diagnosis

Without proof of immunoglobulin prophylaxis, any Rh-negative women with previous pregnancy or abortion, prior exposure to transfused blood, or receipt of an organ transplant should be considered at risk for Rh sensitization. During pregnancy, the expectant parents should have blood tested for potential incompatibility, particularly for ABO and Rh antigens. If RhD incompatible, the maternal titer of IgG antibodies to the RhD antigen should be measured early in pregnancy. Paternal blood can be tested to determine the fetal risk of inheriting the cognate antigen, typically either 50% or 100% depending on whether the father is heterozygous or homozygous for the antigen. However, paternal serologic testing alone is not fully accurate to predict the zygosity of RhD.
antigen, and molecular genotyping is recommended for both parents in this setting.

Fetal RBC genotyping provides an accurate prediction for the development of HDFN in sensitized mothers. Fetal Rh status is available by isolating fetal cells or fetal DNA (plasma) from the maternal circulation, which is replacing the more invasive and risky fetal amniocyte testing by amniocentesis and chorionic villus sampling methods. The presence of elevated antibody titers or rising titers increases the risk of the baby developing severe HDFN.

Although maternal antibody titers are often used to predict the risk of HDFN, there is a poor correlation between the anti-D titer level and the severity of the disease, especially in subsequent pregnancies. If an Rh-negative mother is found to have RhD antibody titers of ≥1 : 16 (15 IU/mL in Europe) at any time during a subsequent pregnancy, the severity of fetal anemia should be monitored by Doppler ultrasonography (US) of the middle cerebral artery (MCA) and then percutaneous umbilical blood sampling (PUBS) if indicated (Fig. 124.7). If the mother has a history of a previously affected infant or a stillbirth, an Rh-positive infant is usually equally or more severely affected than the previous infant, and the severity of disease in the fetus should be monitored starting at 16-24 wk of gestation.

![Middle cerebral artery (MCA) Doppler study of elevated peak systolic velocity (PSV). MCA-PSV can predict fetal anemia with sufficient accuracy to determine management, including the need for intrauterine transfusion or, in the mid- to late third trimester, early delivery. Fetal hemoglobin is typically measured at the start and end of intravascular transfusion to validate the prediction from MCA-PSV results. The reliability of MCA-PSV can decrease after intrauterine transfusion because of the altered rheostatic characteristics of transfused adult blood. This is now the method of choice for detecting fetal anemia. (From Liley HG, Gardener G, Lopriore E, Smits-Wintjens V: Immune hemolytic disease. In Orkin SH, Nathan DG, Ginsburg D, et al,]
Pregnancies at risk for HDFN should be managed by maternal-fetal specialists. Assessment of the fetus includes US and PUBS. Real-time US is used to detect signs of hydrops (skin or scalp edema, pleural or pericardial effusions, and ascites) and fetal heart rate monitoring. Early US signs of hydrops include organomegaly (liver, spleen, heart), the double–bowel wall sign (bowel edema), and placental thickening. Progression to polyhydramnios, ascites, pleural or pericardial effusions, and skin or scalp edema may then follow. Extramedullary hematopoiesis and hepatic congestion compress the intrahepatic vessels and produce venous stasis with portal hypertension, hepatocellular dysfunction, and decreased albumin synthesis. Hydrops is typically present when fetal hemoglobin level is $<5\, \text{g/dL}$. Hydrops is also frequently seen with a fetal hemoglobin level $<7\, \text{g/dL}$, and in some cases between 7 and 9 g/dL.

Doppler US assesses fetal distress by demonstrating increased vascular resistance in fetal arteries, especially in the infant MCA (see Fig. 124.7). In fetuses without hydrops, moderate to severe anemia can be detected noninvasively by demonstration of an increase in the peak velocity of systolic blood flow in the MCA. The velocity of blood flow correlates with the severity of the anemia and therefore can be used as a noninvasive surrogate marker that can be followed. In pregnancies with moderate-severe fetal anemia (demonstrated by high cerebral velocities) or US evidence of hemolysis (hepatosplenomegaly), early or late hydrops, or fetal distress, further and more direct assessment of fetal hemolysis should be performed.

Amniocentesis was the classic method for assessing fetal hemolysis, by measuring changes in optical density of the amniotic fluid with serial determination of bilirubin levels. However, amniocentesis is an invasive procedure with risks to both the fetus and the mother, including fetal death, bleeding, bradycardia, worsening of alloimmunization, premature rupture of membranes, preterm labor, and chorioamnionitis. Doppler measurement of the peak velocity of systolic blood flow in the MCA has essentially replaced invasive testing in the management of HDFN.

PUBS is the standard approach to the assessment of the fetus if Doppler and real-time US findings suggest that the fetus has moderate to severe anemia. PUBS is performed to determine fetal hemoglobin levels and to transfuse packed RBCs into fetuses with serious fetal anemia (hematocrit $<30\%$) who are immature and not suitable for delivery.
Postnatal Diagnosis

Immediately after the birth of an infant to an Rh-negative woman, or any infant with the appearance of hydrops, blood from the umbilical cord or the infant should be tested for ABO blood group, Rh type, hematocrit and hemoglobin, reticulocyte count, serum bilirubin, and the DAT. A positive DAT result indicates the presence of maternal antibody on the infant RBC, and the incompatible RBC antigen must be identified. The infant's cells can be investigated, but maternal serum should also be screened for RBC antibodies using commercially available panels. These tests not only help establish the diagnosis, but also enable selection of compatible blood for exchange transfusion of the infant, if necessary. The DAT is usually strongly positive in clinically affected infants and may remain so for weeks or even several months.

Treatment

The main goals of therapy for HDFN are (1) to prevent intrauterine or extraterine death from severe anemia and hypoxia, (2) to prevent neurodevelopmental damage in affected children, and (3) to avoid neurotoxicity from hyperbilirubinemia.

Treatment of the Unborn Fetus

Survival of severely affected fetuses has improved with the advent of fetal US to assess the need for in utero transfusion. Intravascular (umbilical vein) transfusion of packed erythrocytes (PRBCs) is the preferred treatment of choice for fetal anemia, although intrauterine transfusion into the fetal peritoneal cavity is also effective. Hydrops or fetal anemia (hematocrit <30%) is an indication for umbilical vein transfusion in infants with pulmonary immaturity.

Fetal transfusion is facilitated by maternal and hence fetal sedation. PRBCs are slowly infused after being cross-matched against the mother's serum. The erythrocytes should be selected from a donor who is group O, negative for the mismatched antigen (e.g., RhD-negative), and CMV-negative. The blood should also be leukocyte-reduced to reduce the risk of allergic and nonhemolytic reactions and irradiated to avoid transfusion-associated GVHD. Some centers use extended group matching (e.g., RhCE, Kell) to decrease the risk of additional maternal antibody formation. Transfusions should achieve a posttransfusion hematocrit of 45–55% and can be repeated every 3-5 wk.
Intrauterine transfusions ameliorate neurologic complications in many fetuses; however, those with severe hydrops are at risk for cerebral palsy, developmental delay, and deafness. The overall survival rate after intrauterine transfusions is 89%, and the complication rate is 1–3%. In contrast, the outcome after cordocentesis and intrauterine transfusions performed earlier, such as the second trimester, is poor. Complications include rupture of the membranes and preterm delivery, infection, fetal distress requiring emergency cesarean delivery, and perinatal death. Maternal plasma exchange and intravenous immune globulin (IVIG) have been used as adjunctive therapies in women with prior severe HDFN, but there is limited evidence to support their routine use. Indications for early delivery include pulmonary maturity, fetal distress, complications of PUBS, and 35-37 wk of gestation. Careful antenatal care, including intrauterine transfusions, has decreased the need for postdelivery exchange transfusion.

Treatment of the Liveborn Infant
The birth should be attended by a physician skilled in neonatal resuscitation. Fresh, leukoreduced, and irradiated group O and Rh-negative blood, which has been cross-matched against maternal serum, should be immediately available. If clinical signs of severe hemolytic anemia (pallor, hepatosplenomegaly, edema, petechiae, ascites) are evident at birth, immediate resuscitation and supportive therapy, temperature stabilization, and monitoring before proceeding with exchange transfusion may save severely affected infants. Such therapy should include a small transfusion of compatible PRBCs to correct anemia; volume expansion for hypotension, especially in those with hydrops; correction of acidosis with 1-2 mEq/kg of sodium bicarbonate; and assisted ventilation for respiratory failure. Infants with HDFN should be closely monitored with frequent hemoglobin and bilirubin testing to determine their need for phototherapy, simple transfusion, or exchange transfusion.

Exchange Transfusion
The decision to proceed with an immediate full or partial exchange transfusion should be based on the infant's clinical condition at birth, with a judgment specifically regarding the likelihood of the infant rapidly developing a dangerous degree of anemia or hyperbilirubinemia. Cord hemoglobin value of ≤10 g/dL or bilirubin concentration ≥5 mg/dL suggest severe hemolysis, but neither
consistently predicts the need for exchange transfusion. Some physicians consider previous kernicterus or severe HDFN in a sibling, reticulocyte counts >15%, and prematurity to be additional factors supporting a decision for early exchange transfusion (see Chapters 123.3 and 123.4).

The hemoglobin concentration and serum bilirubin level should be measured at 4-6 hr intervals initially, with extension to longer intervals as the rate of change diminishes. The decision to perform an exchange transfusion is often based on the likelihood that the bilirubin levels, which can be plotted against postnatal hours of life, will reach dangerous levels (see Fig. 123.14 and Table 123.7 in Chapter 123). Term infants with bilirubin levels ≥20 mg/dL have an increased risk of kernicterus. Simple transfusions of ABO-compatible, Rh-negative, leukoreduced, and irradiated RBCs may be necessary to correct anemia up to 6-8 wk of age, after which the infant's own erythropoiesis can be expected to overcome any lingering hemolysis. Weekly determinations of hemoglobin values should be performed until the physiologic nadir is passed and a spontaneous rise has been demonstrated.

Careful monitoring of the serum bilirubin level is essential until a decline has been documented in the absence of phototherapy (see Chapter 123.3). Even then, an occasional infant, particularly if premature, may experience a significant rebound in serum bilirubin as late as the 7th day of life. Attempts to predict dangerously high levels of bilirubin based on levels exceeding 6 mg/dL in the 1st 6 hr of life, or 10 mg/dL in the 2nd 6 hr of life, or on increasing rates exceeding 0.5-1.0 mg/dL/hr, are often quoted but not necessarily reliable.

**Procedure**

The actual exchange transfusion can be performed most easily through an umbilical vein catheter or through peripheral arterial (remove) and venous (return) lines. The exchange should be carried out over 45-60 min and involves serial removal of 15-20 mL aliquots of infant blood (term infant), alternating with infusion of an equivalent volume of donor blood. Smaller, 5-10 mL aliquots may be better tolerated by sick or premature infants. The goal should be an isovolemic exchange of approximately 2 blood volumes of the infant (2 × 100 mL/kg) to achieve 90% replacement of fetal RBCs and 50% removal of bilirubin.

Blood for exchange transfusion should be as fresh as possible. Standard anticoagulants and preservatives such as citrate-phosphate-dextrose-adenine solution can be used. Blood selection is similar to that of intrauterine
transfusions, typically leukoreduced and irradiated erythrocytes from a group O and Rh-negative donor. Although the blood should be negative for the mismatched Rh antigen, a complete crossmatch should be performed before transfusion. Packed erythrocytes should be reconstituted with fresh-frozen plasma to a hematocrit of about 40% before the procedure. Blood should be gradually warmed and maintained at a temperature between 35°C and 37°C throughout the exchange transfusion. It should be kept well mixed by gentle squeezing or agitation of the bag to avoid sedimentation. The infant's stomach should be emptied before transfusion to prevent aspiration, and body temperature should be maintained and vital signs monitored. A competent assistant should be present to help monitor, tally the volume of blood exchanged, and perform emergency procedures.

Infants with acidosis and hypoxia from respiratory distress, sepsis, or shock may be further compromised by the significant exposure to citrate, which provides both an acute acid load (pH 7.0-7.2) and calcium binding. The subsequent metabolism of citrate may later result in metabolic alkalosis. Fresh heparinized blood avoids this problem but is not readily available in most settings. During the exchange transfusion, blood pH and PaO₂ should be serially monitored to avoid acidosis and hypoxia. Symptomatic hypoglycemia may occur before, during, or after an exchange transfusion in moderately to severely affected infants. Additional acute complications, noted in 5–10% of infants, include transient bradycardia with or without calcium infusion, cyanosis, transient vasospasm, thrombosis, thrombocytopenia, apnea with bradycardia requiring resuscitation, and death. Infectious risks include CMV, HIV, and hepatitis. Necrotizing enterocolitis is a rare complication of exchange transfusion for HDFN.

There is a risk of death from an exchange transfusion, even when performed by an experienced physician team, estimated at 3 per 1,000 procedures. With the fortunate decline of this procedure because of phototherapy and prevention of sensitization, experience with such procedures and physician competence are diminishing, and exchange should be performed only at experienced neonatal referral centers.

After exchange transfusion, the bilirubin level must be measured at frequent intervals (every 4-8 hr) because the serum value may rebound 40–50% because of reequilibration and ongoing production. Repeated exchange transfusions are occasionally necessary, with the primary aim of keeping the indirect bilirubin fraction from exceeding dangerous levels indicated in Table 123.7 (see Chapter
for preterm infants and 20 mg/dL for term infants. Signs and symptoms suggestive of kernicterus are mandatory indications for exchange transfusion at any time.

**Intravenous Immune Globulin**

Because of its ability to interfere with immune-mediated clearance of antibody-sensitized RBCs, early administration of IVIG may be an effective therapeutic intervention for HDFN. IVIG can prevent immune hemolysis, lower peak serum bilirubin levels, shorten the duration of phototherapy, and reduce both length of hospitalization and need for exchange transfusion. However, IVIG does not effectively prevent anemia, which results from both immune-mediated RBC destruction and inadequate erythropoiesis. Consequently, simple transfusions are usually needed as an adjunct to IVIG therapy. An IVIG dose of 0.5-1 g/kg is typically used, but optimal dosing has not been established. Treated infants with blood groups A or B should be monitored for worsening hemolysis caused by anti-A or anti-B antibodies present in IVIG.

**Late Complications**

Infants with HDFN, including those who have had an intrauterine or postnatal exchange transfusion, must be observed carefully for the development of late anemia and cholestasis.

**Late anemia**, operationally defined as occurring after the 1st 4-6 wk of life, can result from either persistent hemolysis caused by circulating maternal alloantibodies or from effects on the bone marrow. **Late hyporegenerative anemia** in HDFN results from suppression of erythropoiesis, in part from the higher hemoglobin concentration provided through an intrauterine or exchange transfusion. Late hyporegenerative anemia can be distinguished from hemolytic anemia by a low or absent reticulocyte count and a normal bilirubin level. Infants should be monitored for symptoms and signs of anemia, including poor feeding, sleepiness, and poor growth. Hemoglobin and reticulocyte counts should be monitored weekly to determine the need for transfusion, until the marrow spontaneously recovers after several weeks to months. Neutropenia can also be observed during recovery from HDFN or in association with the late hyporegenerative anemia. In addition to transfusion, treatment with supplemental iron or erythropoietin may be helpful to accelerate marrow
recovery.

**Inspissated bile syndrome** refers to the rare occurrence of persistent icterus in association with significant elevations in both direct and indirect bilirubin levels in infants with hemolytic disease. The cause is unclear, but jaundice clears spontaneously within a few weeks or months with conservative management. **Portal vein thrombosis** and portal hypertension may occur in children who have been subjected to exchange transfusion as newborn infants. It is probably associated with prolonged, traumatic, or septic umbilical vein catheterization.

**Prevention of Rh Sensitization**

The risk of initial sensitization of Rh-negative mothers has been reduced to less than 0.1% by the routine administration of Rh-immunoglobulin (RhoGAM) to all mothers at risk for Rh alloimmunization. The Rh-immunoglobulin product is administered to Rh-negative mothers as an intramuscular injection of 300 µg (1 mL) of human anti-D globulin within 72 hr of delivery of an Rh-positive infant. Additional clinical indications for RhoGAM administration include ectopic pregnancy, abdominal trauma during pregnancy, amniocentesis, chorionic villus biopsy, or abortion. This quantity of antibody is sufficient to eliminate approximately 10 mL of potentially antigenic fetal Rh-positive cells within the maternal circulation. Larger fetal-to-maternal transfers of blood will require proportionately more human anti-D globulin. RhoGAM administration provided at 28-32 wk of gestation and again at birth is more effective than a single dose.

It is also critical to use appropriately matched blood for all transfusions to Rh-negative girls and young women of childbearing years, including the use of group O, Rh-negative blood during emergencies, as a primary measure to prevent Rh antigen exposure. This approach, coupled with the use of anti-D immunoglobulin during/after pregnancy, plus improved methods of detecting maternal sensitization and measuring the extent of fetal-to-maternal transfusion, have dramatically decreased the incidence and severity of HDFN in developed countries. In addition, the use of fewer obstetric procedures that increase the risk of fetal-to-maternal bleeding should further reduce the incidence of this disorder. However, because serologic testing does not always accurately predict RhD type, since there are now well-recognized weak and partial RhD antigens, the use of fetal RhD genotyping will better guide appropriate use of Rh-immunoglobulin therapy in Rh-negative women.
Hemolytic Disease Caused by Blood Group A and B Incompatibility

Although ABO incompatibility is the most common cause of HDFN, this form is usually much milder than Rh disease and rarely requires aggressive clinical management or therapeutic intervention. Approximately 20% of live births are at theoretical risk for immune-mediated hemolysis based on ABO mismatch, most often the mother being group O and the infant either group A or B. Less often, the mother will be group A and the infant group B, or vice versa.

However, clinical manifestations of hemolysis develop in only 1–10% of at-risk infants, primarily because naturally occurring maternal antibodies against ABO blood group antigens are almost exclusively IgM and therefore do not cross the placenta. Some group O mothers will produce IgG antibodies against blood group A or B antigens, and these can cross the placenta and cause immune-mediated hemolysis. For example, an A-O incompatibility can cause hemolysis even in a firstborn infant, if the mother (group O) produces some anti-A IgG antibodies. A 2nd factor that accounts for the lower-than-predicted incidence of severe ABO hemolytic disease is the relatively low antigen frequency and expression on the RBC of the fetus and newborn infant. With few strong binding sites available for the maternal antibodies to bind, there is less hemolysis.

Clinical Manifestations

Most cases of ABO incompatibility are mild, with jaundice the only clinical manifestation. The infant is not generally affected at birth but will develop jaundice in the 1st 24 hr, which is always abnormal. Pallor and hepatosplenomegaly are not present, and the development of hydrops fetalis or kernicterus is extremely rare.

Diagnosis

A presumptive diagnosis is based on the presence of serologic ABO incompatibility between the mother and infant, plus a weakly to moderately positive DAT result. Hyperbilirubinemia is often the main laboratory abnormality. In 10–20% of affected infants, the unconjugated serum bilirubin level may reach 20 mg/dL or more unless phototherapy is administered. Usually
the infant has mild anemia and reticulocytosis; the peripheral blood smear may show polychromasia, nucleated RBCs, and spherocytes. However, the persistence of hemolytic anemia or spherocytosis beyond 2 wk should suggest an alternative diagnosis, such as hereditary (congenital) spherocytosis (see Fig. 124.6).

**Treatment**

Phototherapy may be effective in lowering serum bilirubin levels (see Chapter 123.4). In severe cases, IVIG administration can be helpful by reducing the rate of hemolysis and the need for exchange transfusion. Exchange transfusions with group O and Rh-compatible blood type may be needed in some cases to correct dangerous degrees of anemia or hyperbilirubinemia. Indications for this procedure are similar to those previously described for hemolytic disease caused by Rh incompatibility. Some infants with ABO hemolytic disease may require transfusion of PRBC at several weeks of age because of hyporegenerative or slowly progressive anemia. Postdischarge monitoring of hemoglobin or hematocrit is essential in newborns with ABO hemolytic disease.

**Other Forms of Hemolytic Disease**

Blood group incompatibilities other than Rh or ABO account for <5% of HDFN. The pathogenesis of hemolytic disease in this setting is similar, because of other RBC antigens that are mismatched between mother and infant. The likelihood of encountering mismatches for minor antigen mismatches relates to their frequency in the population, their density on the RBC surface, their immunogenicity in the mother, and the index of suspicion. Minor RBC antigen mismatch (especially on Kell group) is emerging as a common cause of HDFN in the developed countries where anti-D immunoglobulin is routinely used. In all cases, the maternal serum should have RBC alloantibodies identified that react against the infant (and paternal) erythrocytes. In addition, the infant's DAT result is invariably positive, and elution techniques can identify the antigen specificity.

Common RBC antigens that can lead to clinically relevant incompatibility include those in the Kell, Duffy, and MNS blood groups. Notably, maternal anti-Lewis antibodies do not lead to HDFN because they are IgM and do not cross the placenta, and Lewis antigens are poorly expressed on fetal erythrocytes. Kell is a particularly dangerous incompatibility because the severity of the hemolytic
anemia is difficult to predict based on previous obstetric history, amniotic fluid bilirubin determinants, or maternal antibody titer. Kell-alloimmunized infants often have inappropriately low numbers of circulating reticulocytes caused by erythroid suppression, and even low maternal titers of anti-Kell antibodies may cause significant hypoproliferative anemia. Table 124.5 summarizes the clinical characteristics of hemolytic disease caused by Rh, ABO, and Kell antigen systems. There are no specific pharmacologic therapies available to prevent sensitization caused by any blood group other than RhD. As with cases of Rh and ABO incompatibility, exchange transfusion may be indicated for severe hyperbilirubinemia or severe anemia in infants with HDFN caused by minor antigen incompatibility.

Bibliography

Neonatal polycythemia is defined as a central hemoglobin or hematocrit (Hct) exceeding 2 standard deviations (SD) above the normal value for gestational and postnatal age. A full-term infant is therefore considered to have polycythemia when the hemoglobin concentration is ≥22 g/dL or Hct is ≥65%. Measuring the central hemoglobin using an automated blood counter is important because both peripheral (heelstick) and capillary tube microcentrifugation yield higher Hct values than central values, by up to 15%. Timing is also important; because of fluid shifts in the newborn period, Hct peaks during the 1st 2-3 hr of life. The frequency of neonatal polycythemia is also increased for births at higher altitudes (5% at high altitude vs 1–2% at sea level). Polycythemia predisposes to hyperviscosity (not clinically measurable), which may be the primary issue. When Hct is >65%, hyperviscosity may rapidly increase.

Etiologies of neonatal polycythemia are numerous but can be grouped into two broad categories based on passive RBC transfusion into the fetus and increased intrauterine erythropoiesis. Causes of passive fetal RBC transfusion include delayed clamping of the umbilical cord (most common cause in term infants), twin-twin transfusion for the recipient, and rarely, maternal-fetal transfusions. In contrast, neonatal polycythemia secondary to increased fetal erythropoiesis has many causes, including postmaturity (3%) vs term (1–2%) infants; small-for-gestational-age (8%) or large-for-gestational-age (3%) vs average-for-gestational-age (1–2%) infants; infants of diabetic mothers; infants with trisomy 13, 18, or 21; adrenogenital syndrome; neonatal Graves disease;
hypothyroidism; infants of hypertensive mothers or those taking propranolol; and Beckwith-Wiedemann syndrome. Although the pathogenesis of increased erythropoiesis is not always fully understood, infants of diabetic or hypertensive mothers and those with growth restriction may have been exposed to chronic fetal hypoxia, which stimulates erythropoietin production and increases RBC production.

Signs and symptoms of polycythemia can result from hyperviscosity (sluggish blood flow causing decreased tissue perfusion) or metabolic disturbances, or both. Most polycythemic infants are asymptomatic. Symptoms often appear in the 1st few hr of life but can be delayed by up to 2-3 days. Symptoms include irritability, lethargy, tachypnea, respiratory distress, cyanosis, feeding disturbances, hyperbilirubinemia, hypoglycemia, and thrombocytopenia. Severe complications include seizures, stroke, pulmonary hypertension, necrotizing enterocolitis (NEC), renal vein thrombosis, and renal failure. Because most infants are asymptomatic and these symptoms overlap with many neonatal conditions, other respiratory, cardiovascular, and neurologic diseases should be ruled out. Dehydration should also always be considered as a cause. Whether these symptoms are truly caused by, or just associated with, polycythemia is undetermined. Hyperviscosity in infancy may be accentuated because neonatal RBCs are large and have decreased deformability, which together predispose to stasis in the microcirculation.

The treatment of polycythemia varies among centers and is often based primarily on local expert opinion. A capillary Hct >65% should always be confirmed with a venous sample and dehydration should be treated. All polycythemic infants should be closely monitored for intake and output, and blood glucose and bilirubin levels should be closely followed. Asymptomatic infants whose central Hct is 60–70% can be monitored closely and hydrated with adequate enteral intake or administration of intravenous (IV) fluids. Treatment of symptomatic polycythemic newborns is not well defined. A partial exchange transfusion (with normal saline) can be used in infants with severe polycythemia and symptoms of hyperviscosity and should be considered if the Hct is ≥70–75% and symptoms worsen despite aggressive IV hydration. Partial exchange transfusion lowers Hct and viscosity acutely and improves acute symptoms but may not affect long-term outcome in polycythemic infants.

Polycythemic infants treated with partial exchange transfusion may be at increased risk of NEC, and their long-term prognosis is unclear. Reported adverse outcomes include speech deficits, abnormal fine motor control, reduced
IQ, school problems, and other neurologic abnormalities. The underlying etiology (chronic intrauterine hypoxia) is likely the determinant of these outcomes rather than polycythemia itself. Most asymptomatic infants develop normally.

**Hemorrhage in the Newborn Infant**

*Cristina Tarango, Russell E. Ware*

**Keywords**
Neonates have a unique hemostatic system that places them at high risk for hemorrhagic complications, especially in the presence of illness or other stress. Plasma levels of the vitamin K–dependent coagulation factors (II, VII, IX, X, protein C, protein S) and antithrombin are low at birth and do not reach adult ranges until approximately 6 mo of age. Thrombin generation and platelet function are also altered in normal newborns. Consequently, both congenital and acquired bleeding disorders that affect primary or secondary hemostasis can manifest in the newborn period. In general, hemorrhage in a healthy neonate suggests an inherited coagulation defect or immune-mediated thrombocytopenia, whereas bleeding symptoms in a sick neonate are more likely to reflect underproduction or consumption of coagulation factors and/or platelets. 

**Vitamin K Deficiency Bleeding**

Vitamin K deficiency bleeding, previously referred to as **hemorrhagic disease of the newborn**, results from transient but severe deficiencies in the vitamin K–dependent factors and is characterized by hemorrhage that is most frequently gastrointestinal, nasal, subgaleal, intracranial, or postcircumcision. Prodromal or warning signs (mild bleeding) may occur before serious intracranial hemorrhage. Laboratory testing reveals that both the prothrombin time (PT) and partial thromboplastin time are prolonged, and plasma levels of prothrombin (II) and factors VII, IX, and X are substantially decreased. The pathophysiology of this acquired hemorrhagic disorder results because vitamin K facilitates posttranscriptional carboxylation of factors II, VII, IX, and X, which is
necessary for its full coagulation effects. In the absence of carboxylation, such factors form PIVKA (proteins induced in vitamin K absence), which have greatly reduced function; these can be measured and represent a sensitive marker for vitamin K status. In contrast, factors V and VIII, fibrinogen, bleeding time, clot retraction, and platelet count and function are normal for maturity.

Classically, vitamin K deficiency bleeding occurs early in the newborn period, typically between day 2 and 7 of life, and most often in exclusively breastfeeding infants who did not receive vitamin K prophylaxis at birth. Severe vitamin K deficiency is also more common in premature infants. This pathogenesis occurs from a lack of free vitamin K from the mother, coupled with absence of bacterial intestinal flora normally responsible for the synthesis of vitamin K. Breast milk is a poor source of vitamin K, which explains why hemorrhagic complications are more frequent in exclusively breastfed than in mixed-fed or formula-fed infants. This classic form of hemorrhagic disease of the newborn, which is responsive to (and entirely prevented by) exogenous vitamin K therapy, should be distinguished from rare congenital deficiencies of clotting factors that are unresponsive to vitamin K, which can occur in otherwise well-appearing infants (see Chapter 503).

Early-onset vitamin K deficiency bleeding (after birth but in 1st 24 hr) occurs if the mother has been treated chronically with certain drugs (e.g., anticoagulant warfarin, anticonvulsant phenytoin or phenobarbital, cholesterol-lowering medication) that interfere with vitamin K absorption or function. These infants can have severe bleeding, which is usually corrected promptly by vitamin K administration, although some have a poor or delayed response. If a mother is known to be receiving such drugs late in gestation, an infant PT should be measured using cord blood, and the infant immediately given 1-2 mg of vitamin K intravenously. If PT is greatly prolonged and fails to improve, or in the presence of significant hemorrhage, 10-15 mL/kg of fresh-frozen plasma should be administered. In contrast, late-onset vitamin K deficiency bleeding (after 2 wk of life) is usually associated with conditions that feature malabsorption of the fat-soluble vitamin K, such as cystic fibrosis, neonatal hepatitis, or biliary atresia, and bleeding can be severe (Table 124.6).

### Etiology/risk

- Maternal drugs (phenobarbital, phenytoin, warfarin, rifampin, isoniazid) that interfere with vitamin K levels or absorption
- Vitamin K deficiency
- Exclusive breastfeeding
- Vitamin K deficiency
- Abetalipoprotein deficiency
- Idiopathic in Asian breastfed infants
- Warfarin ingestion
- Cholestasis: malabsorption of vitamin K (biliary atresia, cystic fibrosis, hepatitis)
- Inherited coagulopathy

### Prevention

- Avoidance of high-risk medications
- Possibly antenatal vitamin K to treatment of mother (20 mg) before birth and postnatal administration to infant soon after birth
- Prevented by parenteral vitamin K at birth
- Oral vitamin K regimens require repeated dosing.
- Warfarin ingestion
- Prevented by parenteral and high-dose oral vitamin K during periods of malabsorption or cholestasis

### Incidence

- Very rare
- ~2% if infant not given vitamin K soon after birth
- Dependent on primary disease

---

Table: EARLY-ONSET DISEASE

Intramuscular (IM) administration of 1 mg of vitamin K (typically *phytonadione*, or vitamin K₁, the only form of vitamin K available in the United States) soon after birth prevents the pathologic decrease in vitamin K–dependent factors in full-term infants. However, such vitamin K prophylaxis is not uniformly effective to prevent all hemorrhagic disease of the newborn, particularly in exclusively breastfed and premature infants. When an infant presents with hemorrhage, a slow IV infusion of 1-5 mg of vitamin K₁ is effective treatment and leads to improvement in coagulation defects and cessation of bleeding within a few hours. Serious bleeding, particularly in premature infants or those with liver disease, may require transfusion of fresh-frozen plasma or even whole blood. With prompt recognition and treatment, the mortality rate is low.

Decades of experience have demonstrated that the routine use of IM vitamin K for prophylaxis in the United States is safe, and specifically is not associated with an increased risk of childhood cancer or leukemia. Although multiple doses of oral vitamin K (1-2 mg at birth, again at discharge, and again at 3-4 wk of
life) has been suggested as an alternative, oral vitamin K is less effective in preventing late-onset vitamin K deficiency bleeding and thus cannot be recommended for routine therapy. The IM route of vitamin K prophylaxis remains the method of choice.

Other forms of neonatal bleeding may be clinically indistinguishable from hemorrhagic disease of the newborn due to vitamin K deficiency, but they are neither prevented nor successfully treated with vitamin K. For example, an identical clinical presentation may also result from any congenital defect in blood coagulation factors (see Chapters 503 and 504). Hematomas, melena, and postcircumcision and umbilical cord bleeding may be present; up to 70% cases of hemophilia (factor VIII or IX deficiency) are clinically apparent in the newborn period. Treatment of these congenital deficiencies of coagulation factors requires specific factor replacement or fresh-frozen plasma if factor concentrate is not available.

**Disseminated Intravascular Coagulopathy**

Disseminated intravascular coagulation (DIC) in newborn infants results from consumption of circulating coagulation factors and platelets and therefore can present with either bleeding or thrombosis and usually with evidence of end-organ damage and increased mortality. Affected infants are often premature; their clinical course is frequently characterized by asphyxia, hypoxia, acidosis, shock, hemangiomas, or infection. Since DIC is a secondary event, the most effective treatment is directed at correcting the primary clinical problem, such as infection, to interrupt consumption of clotting factors and allow time to replace them (see Chapter 510). Infants with DIC who have central nervous system hemorrhage, or other bleeding posing an immediate threat to life, should receive fresh-frozen plasma, vitamin K, and blood if needed. However, treatment should always be preceded by specific testing for coagulation studies, as well as measurement of the platelet count.

**Neonatal Thrombocytopenia**

See Chapter 511.

Nonimmune Hydrops

Cristina Tarango, Russell E. Ware

Keywords

hydrops fetalis
mirror syndrome
nonimmune hydrops

Because of the success in preventing Rh alloimmune fetal hemolysis, nonimmune and often nonhematologic hydrops fetalis is the most common cause of fetal hydrops. Hydrops is defined by ≥2 abnormal fetal fluid collections, such as ascites, pleural, pericardial, or cutaneous edema (>5 mm) (Fig. 124.8). In addition, there may be associated placental edema (>6 mm), polyhydramnios (50%), and the rare occurrence of the mirror syndrome, in which the mother becomes edematous.
The incidence of nonimmune hydrops is approximately 1 in 3,000 births, many of whom are premature. The etiologies are broad; cardiac (structural and SVT) and chromosome disorders are the most common identifiable etiologies (Table 124.7). The etiology is unknown in 10–20%. The mechanisms for the development of nonimmune hydrops are not well established (Fig. 124.9).

IPEX, Immune dysregulation polyendocrinopathy enteropathy, X-linked.

In utero treatment has been successful for fetal supraventricular tachycardia (SVT), twin-twin transfusion syndrome, nonimmune fetal anemias, and some surgically treatable fetal conditions. Postnatal therapy includes a team approach to the delivery room management that often requires immediate endotracheal tube intubation and packed RBC transfusion in the presence of anemias. In premature infants, endotracheal surfactant is indicated; drainage of large pleural or pericardial effusions may also be needed. Once the infant is stabilized, diagnostic testing will direct further therapy based on the etiology. For patients with no obvious etiology, lymphangiography, whole exome (or genome) sequencing, and microarray duplication/deletion studies are recommended to establish a diagnosis.

Mortality is approximately 50% and is highest in the most premature infants, those with aneuploidy, and those with fetal anasarca.

Bibliography

Steurer MA, Peyvandi S, Baer RJ, et al. Epidemiology of live
The Umbilical Cord

The umbilical cord typically consists of 2 umbilical arteries, the umbilical vein, and a gelatinous substance called Wharton's jelly, all contained within a sheath derived from the amnion and coiled into a helical shape. The muscular umbilical arteries carry deoxygenated blood from the fetus to the placenta and are contiguous with the fetal internal iliac arteries. The umbilical vein carries oxygenated blood from the placenta back to the fetus, where it flows into the inferior vena cava by way of the ductus venosus. The umbilical cord itself contains an estimated 20 mL/kg of blood, and current recommendations are to delay clamping of the cord at delivery for 30-60 sec, to facilitate placental transfusion. At term, a normal umbilical cord is approximately 55 cm long. Abnormally short cords are associated with conditions causing decreased fetal movement, including fetal hypotonia, oligohydramnios, and uterine constraint, and lead to increased risk for complications during labor and delivery for both mother and infant. Long cords (>70 cm) increase the risk for true knots, wrapping around the fetus, and/or prolapse. Straight uncoiled cords are associated with anomalies, fetal distress, and intrauterine fetal demise.

When the cord is cut after birth, portions of these structures remain in the base but gradually become obliterated. The blood vessels are functionally closed but anatomically patent for 10-20 days. The umbilical arteries become the lateral umbilical ligaments; the umbilical vein, the ligamentum teres; and the ductus venosus, the ligamentum venosum. The umbilical cord stump usually sloughs within 2 wk. Delayed separation of the cord, after more than 1 mo, has been associated with neutrophil chemotactic defects and overwhelming bacterial infection (see Chapter 153).
A single umbilical artery is present in approximately 5-10/1,000 births; the frequency is higher (35-70/1,000) in twin births. It is estimated that 30% of infants with a single umbilical artery have other (and often multiple) congenital structural abnormalities. The presence of multiple anomalies is suggestive of an abnormal karyotype, including trisomies. Infants with isolated single umbilical artery are not thought to be at increased risk of having a chromosomal anomaly, and no specific evaluation is indicated for these infants aside from a thorough physical examination.

The **omphalomesenteric duct (OMD)** is an embryonic connection between the developing midgut and the primitive yolk sac. It typically involutes at 8-9 wk gestation, but failure of this process can leave an abnormal connection between the umbilical cord and the gastrointestinal (GI) tract. The most common remnant of the OMD is a **Meckel diverticulum** (see Chapter 357), whereas abnormalities that would become symptomatic in the neonatal period include a **sinus** or **fistula** that would drain mucus or intestinal contents through the umbilicus. An umbilical **polyp** is one of the least common OMD remnants and represents exposed GI mucosa at the umbilical stump. The tissue of the polyp is bright red, firm, and has a mucoid secretion. Therapy for all OMD remnants is surgical excision of the anomaly.

A **persistent urachus** (urachal cyst, sinus, patent urachus, or diverticulum) is a result of failure of closure of the allantoic duct and may be associated with bladder outlet obstruction. Patency should be suspected if a clear, light-yellow, urine-like fluid is being discharged from the umbilicus. Symptoms include drainage, a mass or cyst, abdominal pain, local erythema, and infection. Urachal anomalies should be investigated by ultrasonography and a cystogram. Therapy for a persistent urachus is surgical excision of the anomaly and correction of any bladder outlet obstruction if present.

**Hemorrhage**

Hemorrhage from the umbilical cord may be the result of trauma, inadequate ligation of the cord, or failure of normal thrombus formation. It may also indicate hemorrhagic disease of the newborn or other coagulopathies (especially factor XIII deficiency), septicemia, or local infection. The infant should be observed frequently during the first few days of life so that if hemorrhage does occur, it will be detected promptly.
Granuloma

The umbilical cord stump usually dries and separates within 1-2 wk after birth. The raw surface becomes covered by a thin layer of skin; scar tissue forms, and the wound is usually healed within 12-15 days. The presence of saprophytic organisms delays separation of the cord and increases the possibility of invasion by pathogenic organisms. Mild infection or incomplete epithelialization may result in a moist, granulating area at the base of the cord with a slight mucoid or mucopurulent discharge. Good results are usually obtained by cleansing with alcohol several times daily.

Persistence of granulation tissue at the base of the umbilicus is common. The tissue is soft, 3-10 mm in size, vascular and granular, colored dull red or pink, and may have a seropurulent discharge. Granulation tissue is treated by cauterization with silver nitrate, repeated at intervals of several days until the base is dry.

Infections

The devitalized umbilical cord provides an ideal medium for bacterial growth and a potential portal of entry for microbes. The term omphalitis refers to infection of the umbilical cord stump, navel, or the surrounding abdominal wall. The presence of cellulitis is associated with a high incidence of bacteremia, and complicated omphalitis may spread to the peritoneum, the umbilical or portal vessels, or the liver. Necrotizing fasciitis (which is often polymicrobial) is associated with a high mortality rate. Treatment of omphalitis includes prompt antibiotic therapy with agents effective against Staphylococcus aureus and Escherichia coli, such as an antistaphylococcal penicillin or vancomycin in combination with an aminoglycoside. If abscess formation has occurred, surgical incision and drainage may be required.

In community and primary care settings in developing countries, topical application of chlorhexidine to the umbilical cord has been shown to reduce omphalitis and neonatal mortality. However, the ideal approach to postnatal cord care in hospital settings in developed countries is still debated. There is no convincing evidence that application of antiseptics (including triple dye, alcohol, or chlorhexidine) is superior to dry cord care in minimizing the risk of omphalitis for infants in these settings, although these treatments do reduce bacterial colonization. The American Academy of Pediatrics does not currently
recommend any particular method of cord care as superior in the prevention of infection.

**Umbilical Hernia**

Often associated with *diastasis recti*, an umbilical hernia is caused by incomplete closure or weakness of the muscular umbilical ring. Predisposing factors include black race and low birthweight. The hernia appears as a soft swelling covered by skin that protrudes during crying, coughing, or straining and can be reduced easily through the fibrous ring at the umbilicus. The hernia consists of omentum or portions of the small intestine. The size of the defect varies from <1 cm in diameter to as much as 5 cm (2 inches), but large defects are rare. Most umbilical hernias that appear before age 6 mo disappear spontaneously by 1 yr. Even large hernias (5-6 cm in all dimensions) have been known to disappear spontaneously by 5-6 yr. **Strangulation** of intestinal contents is extremely rare. Surgery is not advised unless the hernia persists to age 4-5 yr, causes symptoms, becomes strangulated, or becomes progressively larger after age 1-2 yr. Defects exceeding 2 cm are less likely to close spontaneously.

**Congenital Omphalocele**

An **omphalocele** is a herniation or protrusion of the abdominal contents into the base of the umbilical cord (Fig. 125.1). In contrast to the more common umbilical hernia, the sac is covered with peritoneum without overlying skin, and the insertion of the distal umbilical cord into the sac itself distinguishes this condition from other abdominal wall defects such as gastroschisis. The size of the sac that lies outside the abdominal cavity depends on its contents. **Herniation** of intestines into the cord occurs in approximately 1/5,000 births, and herniation of liver and intestines in 1/10,000 births. The abdominal cavity may be proportionately small because of the lack of space-occupying viscera. Treatment for an omphalocele consists of covering the sac with moist, sterile dressings, then initiating prompt surgical repair if the abdomen is able to accommodate the eviscerated organs. If the omphalocele is too large to allow immediate repair, continued dressings may temporize and encourage epithelialization of the sac. Occasionally, mesh or similar synthetic material may
be used to cover the viscera if the sac has ruptured or if excessive mobilization of the tissues would be necessary to cover the mass and its intact sac.

![Image](image_url)

**FIG. 125.1**  
A, Omphalocele with umbilical cord insertion into the sac and intestine visible. B, Omphalocele with sac containing liver. (Courtesy of Dr. Foong Lim, Cincinnati Fetal Center at Cincinnati Children's Hospital Medical Center.)

Many infants with omphalocele (50–70%) have associated malformations, and about 30% have chromosomal abnormalities. The likelihood of an abnormal karyotype is increased when the liver is *intracorporeal* (not within the sac). Omphalocele can be part of well-defined syndromes, including **Beckwith-Wiedemann syndrome**, characterized by omphalocele, macrosomia, and hypoglycemia. The survival rate for affected infants is largely determined by the
presence of associated malformations or chromosomal abnormalities. For patients with isolated omphalocele, the survival rate is >90%.

**Tumors**

Tumors of the umbilicus are rare and include angioma, enteroteratoma, dermoid cyst, myxosarcoma, and cysts of urachal or OMD remnants.

**Bibliography**

Neonatal abstinence syndrome (NAS) is the clinical diagnosis given to infants who experience withdrawal signs after in utero exposure to opioids. Withdrawal signs develop in 55–94% of opioid-exposed infants, 30–65% of whom need pharmacologic treatment for severe withdrawal. The incidence of NAS has been...
increasing yearly since 2004 and was 5 times more prevalent in 2013 than 2004. This increase in NAS is caused by increased use of prescription medication by pregnant women, an increase in medication-assisted treatment (MAT) for opioid addiction, an increase in illicit use of prescription medications, and increased use of heroin. In 2011, 1.1% of pregnant women in the United States abused pain relievers and heroin, and up to 12.9–28% of women were prescribed an opioid at some point during their pregnancy. Many factors affect the severity and duration of withdrawal, including tobacco use during pregnancy, breastfeeding after delivery, rooming-in and parental involvement, genetic makeup, and polysubstance use.

The clinical signs of NAS result from central nervous system (CNS) hyperexcitability and autonomic instability (Fig. 126.1). NAS signs can begin within 24 hr of birth after heroin exposure, within 48 hr after short-acting opioids, and 72-96 hr after exposure to long-acting opioids such as methadone and buprenorphine. Tremors, poor feeding, excessive crying, poor sleeping, and hyperirritability are the most prominent signs of NAS. Other signs include sneezing, yawning, hiccups, myoclonic jerks, skin breakdown and abrasions, vomiting, loose stools, nasal stuffiness, and seizures in the most severe cases.
Identifying which infants are at risk for NAS before discharge is important because of the late onset of signs. Universal maternal screening for drug use is recommended by the American College of Obstetricians and Gynecologists (ACOG), and maternal consent should be obtained if drug testing is indicated. Universal maternal drug testing has been shown to improve identification of infants at risk for NAS but is more expensive and may not be helpful in states with punitive legislation. Maternal testing is preferred over infant testing because results are available promptly, typically by the time the infant is delivered. Testing mothers on admission to the hospital can also exclude iatrogenic exposure. Infant urine, meconium and umbilical cord testing are also used to help identify infants at risk for withdrawal and identify more distant use...
by the mother. Timing of these results and special collection methods makes routine use of these tests more difficult. Detectability in the neonatal urine specimen is typically 2-3 days for methadone (up to 6 days for methadone metabolites) and buprenorphine and 1-2 days for heroin.

MAT has been shown to be useful for pregnant women with an opioid substance use disorder. Mothers receiving MAT have a decreased mortality, reduced illicit drug use, reduced seroconversion of HIV, and decreased criminal activity. The most common medications in MAT are methadone or buprenorphine. Methadone is a full \( \mu \)-opioid agonist with a half-life of 24-36 hr, given once daily in methadone clinics because of the potential for overdose. Buprenorphine is a partial \( \mu \)-opioid agonist with a half-life of 36-48 hr, prescribed monthly as home therapy because a ceiling effect protects against overdosages.

**Treatment**

The first line of treatment for all opioid-exposed infants is **nonpharmacologic support**, which includes swaddling, placing the infant in a dark and quiet environment (e.g., dimmed lights, muted televisions), holding and Kangaroo care, reducing stimulation, and breastfeeding. Illicit (if continued) drug use is a contraindication to breastfeeding infants with NAS. Maternal methadone or buprenorphine use and hepatitis C are not contraindications to breastfeeding. Standardization of nonpharmacologic care with increased emphasis on clinical assessment (i.e., is the infant feeding well, sleeping well, and easily consoled?) over formal scoring tools, which typically require disturbing the infant, was associated with significantly less opioid use among infants with in utero methadone exposure.

The decision for pharmacologic treatment has been traditionally based on the nursing scoring assessment tool. The most widely used tools are the Finnegan and Modified Finnegan (Fig. 126.1). Other scoring tools include the Lipsitz, Neonatal Narcotic Withdrawal Index, Neonatal Withdrawal Inventory, and MOTHER NAS Scale. The main objectives when initiating pharmacologic treatment are to improve signs and comfort of the infant and to prevent worsening withdrawal that could lead to seizures.

Pharmacologic treatment for NAS, when necessary, is typically morphine or methadone (Table 126.1). **Morphine** is a short-acting opioid given every 3-4 hr as a weight-based or symptom-based regimen. **Methadone** is long-acting opioid
that can be given twice a day after loading doses, and a pharmacokinetic weight-based weaning protocol is available. Sublingual buprenorphine has been proposed as an alternate treatment. Buprenorphine and some methadone formulations contain high ethanol levels, which may be deleterious to the infant. Following a stringent NAS protocol with guidelines on initiation and weaning has been shown to decrease both length of stay and number of opioid treatment days and may be as important as which primary opioid is used for first-line treatment.

**Adjuvant therapy** is initiated when the primary opioid is not effective in controlling the signs of NAS. The 2 most common medications used as adjuvant therapy are phenobarbital and clonidine. Infants with NAS may also expend additional energy. Therefore, the infant should be weighted regularly and strategies to increase caloric intake implemented if weight loss beyond that expected in the 1st week of life occurs.
The long-term prognosis for infants with NAS is multifactorial and not fully known. Close follow-up needs to be initiated to monitor growth and development, visual disturbances, and behavioral/learning problems.

**Phenobarbital and benzodiazepine withdrawal** may occur in infants of mothers addicted to these drugs, but signs are self-limiting and do not require pharmacologic treatment. Signs may be late onset and begin at a median age of 7 days (range: 2-14 days). Infants may have a brief acute stage consisting of irritability, constant crying, sleeplessness, hiccups, and mouthing movements, followed by a prolonged stage consisting of increased appetite, frequent spit-ups and gagging, irritability, sweating, and a disturbed sleep pattern, all of which may last for weeks.

**Cocaine and methamphetamine abuse** in pregnant women is less common than opioid abuse, and acute withdrawal in these infants is unusual. However, labor complications can be severe with both drugs and may include preterm labor, placental abruption, intrauterine growth restriction, and fetal asphyxia. Detection in neonatal urine is 6-8 hr for cocaine and 1-2 days for methamphetamine. Early on, exposed infants may have abnormal sleep patterns, poor feeding, tremors, and hypertonia. Long-term outcomes include impaired auditory information processing, developmental delay, and learning disabilities. At age 4 yr, children exposed prenatally to cocaine demonstrate cognitive impairments and are less likely to have an IQ above the normative mean.

Asti L, Magers JS, Keels E, et al. A quality improvement

Ko JY, Wolicki S, Barfield WD, et al. CDC grand rounds:

Approximately 18% of women have depression during pregnancy. When pharmacologic treatment is required, selective serotonin reuptake inhibitors (SSRIs; fluoxetine, paroxetine, sertraline, citalopram, fluvoxamine) are most frequently prescribed. Additionally, serotonin norepinephrine reuptake inhibitors (SNRIs; venlafaxine, duloxetine) and tricyclic antidepressants (TCAs) have been used to treat pregnant women with depression or anxiety disorders. About 3.5% of all pregnant women in the Western world use psychotropic medications during their pregnancy, and all these agents cross the placenta. Exposure to these medications in utero may lead to a higher risk of congenital malformations, poor neonatal adaptation syndrome (PNAS), and persistent pulmonary
hypertension (PPHN).

Studies are conflicted on the risk of major birth defects, specifically cardiac defects, and antidepressant use in pregnancy. Use of paroxetine and fluoxetine are thought to have the highest risk of birth defects. Some reported defects include anencephaly, atrial septal defect, right ventricular outflow tract obstruction, omphalocele, and gastroschisis. Although the relative risk may be increased, the occurrence of birth defects is low.

PNAS symptoms usually appear within the 1st 8 hr after birth and often persist for the 1st 2-6 days of life. If symptoms do not develop within 48 hr, the infant is not likely to experience PNAS. PNAS affects the neurologic, autonomic, respiratory, and gastrointestinal systems. Symptoms include a weak suck reflex, irritability, tremors, hypertonia and hypotonia, hyperthermia, weak or absent cry, sleep disturbances, hypoglycemia, respiratory problems, vomiting and diarrhea, and seizures. Most symptoms are mild, and severe symptoms are rare. No deaths have been reported. Many researchers believe that the etiology of PNAS results from both toxicity and withdrawal from the antidepressant medications, and the symptoms of both toxicity and withdrawal are similar. Symptoms related to toxicity often occur immediately after birth when medication levels in the infant are high, whereas symptoms related to withdrawal often occur 8-48 hr after birth when drug concentrations in the infants are low.

Most studies have reported incidence of PNAS with SSRI exposure to be approximately 30%. Exposure to SNRIs has a similar risk as SSRIs. Infants exposed to TCAs have a 20–50% risk of PNAS.

PPHN is often observed immediately after delivery, but symptoms can be variable in intensity, from mild respiratory insufficiency to severe respiratory failure. SSRI exposure later in pregnancy has been associated with a higher risk of PPHN.

Treatment consists of supportive measures, and most cases are mild, of short duration, and self-limiting. Small, frequent, on-demand feedings; swaddling; and skin-to-skin contact are beneficial to support infants through this process. Breastfeeding is protective against developing PNAS and should be encouraged because many antidepressant medications are safe with breastfeeding. Infants can be observed on the maternity ward with their mothers unless specific symptoms warrant further evaluation and treatment. Infants should be observed for a minimum of 48 hr to ensure they do not develop significant symptoms of PNAS. There have been no reported differences in IQ or development in infants with PNAS. Further research is needed to examine long-term effects of in utero
antidepressant exposure.

PAE

Epidemiology

Approximately 1 in 10 pregnant women report consuming alcohol within the past 30 days, and 1 in 33 report binge drinking. When pregnant women report binge drinking, they report an average of 4.6 binge-drinking episodes. Of nonpregnant women of childbearing age, approximately 50% report consuming alcohol within the last 30 days, with about 1 in 5 reporting binge drinking. Because almost 50% of pregnancies in the United States are unplanned, unintentional prenatal alcohol exposure (PAE) can occur before a woman knows she is pregnant.

Alcohol is a known teratogen that can cause irreversible CNS damage leading to CNS dysfunction that can range from relatively mild to severe. PAE affects all stages of brain development from neurogenesis to myelination, through mechanisms that include disrupted cell-cell interactions, altered gene expression, and oxidative stress leading to abnormalities such as reduced brain volume in the frontal lobe, striatum and caudate nucleus, thalamus, and cerebellum; thinning of the corpus callosum; and abnormal functioning of the amygdala.

Fetal alcohol spectrum disorders (FASDs) are the most common causes of preventable developmental delay and intellectual disability. Prevalence rates vary for several reasons. First, the method of ascertainment and the specific diagnostic definitions used can influence rates. Further, it is often difficult to obtain accurate information regarding PAE because mothers often deny the
extent of alcohol use due to fear of child protective services and removal of their child from the home, shame and guilt associated with alcohol use during pregnancy, and fear of judgment. Lastly, mothers are often not asked in enough detail during or after pregnancy about alcohol consumption during pregnancy to accurately assess the extent of PAE. The U.S. Centers for Disease Control and Prevention (CDC) Fetal Alcohol Syndrome (FAS) Surveillance Network used medical records in several states and identified 0.3 children with FAS per 1,000 children age 7-9 yr. This prevalence rate is much lower than that obtained by active case ascertainment studies in the United States and Western Europe, which have estimated prevalence rates of 2–5%. Another study reported similar rates, 24-48 cases per 1,000 children (2.4–4.8%) for all FASDs, and 6-9 cases per 1,000 (0.6–0.9%) for FAS specifically. Studies that have examined PAE by anonymous meconium testing demonstrate 4.26 times greater identification of alcohol use during pregnancy compared with maternal self-report. Rates of FASDs have been reported to be higher in children living in poverty, in American Indian populations, and in children living in foster care. They often go undetected in these children, and as many as 86.5% of foster and adopted youth with FASDs go undiagnosed or are diagnosed incorrectly within the FAS spectrum.

**Diagnostic Criteria**

Updated clinical guidelines for diagnosing FASDs in the United States were published in 2016, as were updated Canadian guidelines, which overlap U.S. guidelines but also have important distinctions. PAE can result in a child having 1 of the FASDs, a nondiagnostic umbrella term in the United States. Diagnoses are determined based on the presence or absence of (1) the characteristic facial features; (2) prenatal/postnatal growth deficiency; (3) deficient brain growth, abnormal morphogenesis, or abnormal neurophysiology; (4) neurobehavioral impairment; and (5) maternal alcohol consumption during pregnancy.

FASDs include fetal alcohol syndrome (FAS), partial fetal alcohol syndrome (pFAS), alcohol-related neurodevelopmental disorder (ARND), alcohol-related birth defect (ARBD), and neurobehavioral disorder associated with prenatal alcohol exposure (ND-PAE), a term introduced in the Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition (DSM-5). Table 126.2 describes specific diagnostic features of each of the FASDs. The diagnosis of FAS and pFAS are the only FASDs that can be diagnosed in the
absence of a confirmed maternal history of PAE. The key facial dysmorphologic features include short palpebral fissures, a thin vermilion border of the upper lip, and a smooth philtrum (Fig. 126.2). The differential diagnosis for FAS includes Williams syndrome, Dubowitz syndrome, fetal valproate syndrome, maternal phenylketonuria (PKU) effects, and other prenatal toxin exposures, and when there is unconfirmed PAE, a genetics evaluation may be warranted. ND-PAE is included in the DSM-5 as a “condition for further study” and is also provided as an example under “Other Specified Neurodevelopmental Disorder.” Although the diagnosis of ND-PAE overlaps with ARND, ND-PAE aims to describe the behavioral and mental health effects on an individual with PAE. Unlike ARND, a diagnosis of ND-PAE can be given in addition to FAS or pFAS. ND-PAE has organized the deficits seen into 3 areas: neurocognitive impairment, impaired self-regulation, and impairment in adaptive functioning. In the updated Canadian guidelines, “fetal alcohol spectrum disorder” is considered a diagnostic term with 2 categories: FASD with sentinel facial features and FASD without sentinel facial features. These guidelines have also eliminated growth restriction as a diagnostic criterion and have included an at-risk category for children with confirmed PAE who were too young to meet the criteria for neurodevelopmental deficits, or in whom assessment was incomplete, and for children with cardinal facial features without documentation or evidence of severe impairment in neurodevelopmental domains.

* Documented prenatal alcohol exposure:
  ≥6 drinks/wk for ≥2 wk during pregnancy.
  ≥3 drinks per occasion on ≥2 occasions during pregnancy.

Documentation of alcohol-related social or legal problems in proximity to (before or during) the index pregnancy (e.g., driving while intoxicated or history of treatment of an alcohol-related condition).

Documentation of intoxication during pregnancy by blood, breath, or urine alcohol content testing.

Increased prenatal risk associated with drinking during pregnancy as assessed by a validated screening tool.
A safe threshold or pattern of alcohol consumption has not been identified, and any PAE is believed to present a risk to a developing fetus. Significant alcohol exposure has been carefully defined in the updated guidelines, and information can be obtained from a variety of sources, including, in addition to the birth mother, family members, foster or adoptive parents, social service agencies who observed maternal alcohol consumption during pregnancy, or medical records that document PAE, alcohol treatment, or social, legal, or medical problems related to drinking during pregnancy. PAE in the first trimester leads to the classic facial dysmorphia associated with FAS and other structural defects. PAE can have other deleterious effects (e.g., spontaneous abortion, growth defect) on the fetus throughout the pregnancy. Several well-validated screens are used to identify alcohol use in pregnant and nonpregnant women of childbearing years, including the T-ACE (Tolerance, Annoyance, Cut Down, Eye-Opener), CAGE (Cut Back, Annoyed, Guilty, Eye-Opener), CRAFFT, Audit-C (Alcohol Use Disorders Identification Test), and TWEAK (Tolerance, Worried, Eye opener, Amnesia, Kut Down). There are no well-validated screens designed to ask about past consumption of alcohol. Pediatricians can ask the following 2 questions to determine the likelihood of significant PAE: “In the 3 months before you knew you were pregnant, how many times did you have 4 or more alcohol drinks in a day?” and “During your pregnancy, how many times did you have any alcohol?” If a positive response is given to either question, the clinician can follow up to determine the level of PAE by asking, (1) “During
your pregnancy, on average, how many days per week did you have any alcohol?” (2) “During your pregnancy, on a typical day when you had an alcoholic beverage, how many drinks did you have?” and (3) “During your pregnancy, what was the maximum number of drinks that you had in a day?”

**Clinical Features**

There is tremendous variability in the presentation of the neurobehavioral and neurocognitive features of children with FASD due to the timing and amount of PAE and unique characteristics of the birth mother and the child. Presentation can range from relatively mild developmental delays to severe intellectual disability, although approximately 75% of individuals with an FASD do not have intellectual disability. In infants, the symptoms can be nonspecific and may include irritability, poor feeding, sleep difficulties, a tendency to become easily overstimulated, or difficulty forming attachments with caregivers. Young children may demonstrate developmental delays, inattention, impulsivity, internalizing and externalizing problems, social impairments and difficulty with peers, and behavioral difficulties such as mood lability, frequent tantrums or aggression. The neurocognitive profile of children with an FASD that emerges in elementary or middle school includes challenges with processing speed, memory, visual-spatial reasoning, math, auditory comprehension, use of pragmatic language, and executive functioning skills. Learning strengths often include decoding, reading, and speech. In adolescents, difficulties with abstract reasoning, time and money management, and social and adaptive skills may become more pronounced.

The most common comorbid mental health condition seen in children with an FASD is attention-deficit/hyperactivity disorder (see Chapter 49), which occurs in >50% of children. Individuals with FASD may present with problems of self-regulation, impulse control, and adaptive functioning. Additional mental health disorders typically seen in children and adolescents with an FASD include oppositional defiant and conduct disorder, anxiety disorder, adjustment disorder, sleep disorder, mood disorders (e.g., depression, bipolar disorder), and disinhibited social engagement disorder. FASD may increase the severity or complexity of these conditions.

**Interventions and Treatment**
Given the heterogeneity of presenting problems associated with the FASDs, interventions need to be tailored to address each individual child or adolescent's profile of strengths and difficulties. Although the evidence base examining interventions for children and adolescents with an FASD is limited, with most studies having small sample sizes, there is emerging evidence for effective programs and treatments specifically designed for children with an FASD. Studies support that the most successful interventions begin early and continue across the life span, include a preventive focus, are intensive and individualized, address multiple domains of functioning, include parent education and training, and are coordinated across systems of care. Children with an FASD often need support and intervention in the areas of learning, executive functioning, adaptive skills, social skills and peer relations, and mental health. To enhance generalizability of skills and to ensure they are encoded into memory, children with an FASD require consistent and predictable interventions, simplified directions, repeated instructions, and reduced distractions. Many children are treated with psychotropic medications, with stimulants most frequently prescribed. Children with an FASD are often treated with a higher number of drugs and at higher doses, likely because of atypical or less favorable responses.

**Outcomes**

Children with an FASD are at higher risk for **victimization and bullying**, often due to poor social judgment. Children and adolescents who are not identified early and aggressively treated are significantly more likely to have secondary disabilities, including encounters with juvenile justice and incarceration, substance abuse problems, severe mental health problems, sexual promiscuity and other inappropriate sexual behaviors, high rates of school failure, dropout and under- or unemployment, and health problems. Children and adolescents with an FASD have a 95% lifetime likelihood of having a mental health diagnosis and are at higher risk for **suicide**. Although an FASD cannot be cured, the long-term negative effects of the brain damage caused by PAE can be reduced through aggressive, sustained intervention initiated early. The estimated lifetime cost of caring for a child with FAS is $1.4 million, with average medical expenditures 9 times higher than expenses for children without FAS. These numbers increase significantly when the costs of caring for all children with any FASD are included.
The Pediatrician's Role

Pediatricians play an important role in identifying children and adolescents with an FASD, by asking parents about PAE and counseling mothers to abstain from alcohol consumption if they are planning to have additional children. Pediatricians need to screen all mothers for PAE and reduce the stigma associated with asking. They need to consider an FASD in a child who presents with complex neurodevelopmental and neurobehavioral problems, structural abnormalities, growth deficits, and facial dysmorphology. It is important that pediatricians remember that despite the increased risk in certain groups, FASDs occur across all economic, racial, and ethnic groups. Pediatricians need to document findings related to PAE and establish a medical home for the child with an FASD that includes a network of professionals who can help and support the child and family. The American Academy of Pediatrics has developed an FASD toolkit (www.aap.org/fasd ) to assist primary care providers in identifying children with an FASD and managing their challenges in an effort to reduce the lifelong adverse consequences.

Bibliography

Cook JL, Green CR, Lilley CM, et al. Fetal alcohol spectrum

Endocrine emergencies in the newborn period are uncommon, but prompt identification and proper treatment are vital to reduce morbidity and mortality.

**Pituitary dwarfism (growth hormone deficiency)** is not usually apparent at birth, although male infants with **panhypopituitarism** may have neonatal hypoglycemia, hyperbilirubinemia, and micropenis. Conversely, **primordial dwarfism** manifests as in utero growth failure that continues postnatally, with length and weight suggestive of prematurity when born after a normal gestational period; otherwise, physical appearance is normal.

**Congenital hypothyroidism** is one of the most common preventable causes of developmental disability. Congenital screening followed by thyroid hormone replacement treatment started within 30 days after birth can normalize cognitive development in children with congenital hypothyroidism. Congenital hypothyroidism occurs in approximately 1/2,000 infants worldwide (see Chapter 581). Because most infants with congenital hypothyroidism are asymptomatic at birth, all states screen for it. Even though screening is standard in many countries, millions of infants born throughout the world are not screened for congenital hypothyroidism. Thyroid deficiency may also be apparent at birth in genetically determined cretinism and infants of mothers with hyperthyroidism during pregnancy treated with antithyroid medications (PTU). Infants with trisomy 21 have a higher incidence of congenital hypothyroidism and should be screened in the newborn period. Constipation, prolonged jaundice, goiter, lethargy, umbilical hernia, macroglossia, hypotonia with delayed reflexes, mottled skin, or cold extremities should suggest severe chronic hypothyroidism. **Levothyroxine** is the treatment of choice, with the goal of rapid normalization of thyroid-stimulating hormone (TSH, thyrotropin) and free thyroxine (T4) to achieve the best outcome. Thyroid hormone treatment is aimed to maintain total
thyroxine or free thyroxine in the upper half of the normal range during the 1st 3 yr after birth. Early diagnosis and treatment of congenital thyroid hormone deficiency improve intellectual outcome and are facilitated by screening of all newborn infants for this deficiency. Newborn screening, with early referral to a pediatric endocrinologist for abnormal results, has improved early diagnosis and treatment of congenital hypothyroidism and improved intellectual outcome.

**Transient hypothyroxinemia** of prematurity is most common in ill and very premature infants. These infants have low thyroxine levels but normal levels of serum thyrotopin and other tests of the pituitary-hypothalamic axis indicating that they are probably chemically euthyroid. Trials of thyroid hormone replacement have reported no difference in developmental outcomes or other morbidities. Current practice is to follow thyroxine until levels normalize.

**Transient hyperthyroidism** may occur at birth in infants of mothers with established or cured hyperthyroidism (e.g., Graves disease with positive TSH receptor–stimulating antibodies). See Chapter 584 for details on diagnosis and treatment.

**Transient hypoparathyroidism** may manifest as tetany or seizure of the newborn due to hypocalcemia and is associated with low levels of parathyroid hormone and hyperphosphatemia. Testing for DiGeorge syndrome should be considered. (see Chapter 589).

Subcutaneous fat necrosis can cause **hypercalcemia** and can occur after a traumatic birth. On examination, firm purple nodules can be appreciated on the trunk or extremities. An infant with hypercalcemia presents with irritability, vomiting, increased tone, poor weight gain, and constipation. Other causes of hypercalcemia in the newborn period are iatrogenic (excess calcium or vitamin D), maternal hypoparathyroidism, Williams syndrome, parathyroid hyperplasia, and idiopathic.

The adrenal glands are subject to numerous disturbances, which may become apparent and require lifesaving treatment during the neonatal period. Acute **adrenal hemorrhage** and adrenal failure are uncommon in the neonatal period. Risk factors include vaginal delivery, macrosomia, and fetal acidemia. The clinical presentation is often mild, with spontaneous regression. In neonates with bilateral adrenal hemorrhage, an evaluation of cortisol production is required (high-dose ACTH stimulation test), and, if insufficient, treatment with glucocorticoids and mineralocorticoids is indicated. Differentiation of unilateral adrenal hemorrhage from neuroblastoma is important. All patients should have sonographic and clinical follow-up to ensure resolution.
**Congenital adrenal hyperplasia (CAH)** is suggested by vomiting, diarrhea, dehydration, hyperkalemia, hyponatremia, shock, ambiguous genitalia, or clitoral enlargement. Some infants have ambiguous genitalia and hypertension. In an infant with ambiguous genitalia, both pelvic and adrenal ultrasound can be performed to aid in diagnosis. An adrenal ultrasound showing bilateral, enlarged, coiled or cerebriform pattern is specific for CAH. Diagnosis is confirmed with an elevated 17-hydroxyprogesterone level for gestational age. Because the condition is genetically determined, newborn siblings of patients with the salt-losing variety of adrenocortical hyperplasia should be closely observed for manifestations of adrenal insufficiency. Newborn screening and early diagnosis and therapy for this disorder may prevent severe salt wasting and adverse outcomes. Congenitally hypoplastic adrenal glands may also give rise to adrenal insufficiency during the 1st few wk of life (*DAX1* mutation).

**Disorders of sexual development** can present in the newborn period with ambiguous or atypical genitalia, including bilateral cryptorchidism, hypospadias, micropenis, hypoplastic scrotum, or clitoromegaly. More than 20 genes have been associated with disorders of sexual development. The initial management should involve a multidisciplinary team (endocrinology, urology, genetics, and neonatology) and open communication with the family. Sex assignment and naming of the infant should be delayed until appropriate testing is completed. For more about disorders of sexual development, see Chapter 606.

Female infants with webbing of the neck, lymphedema, hypoplasia of the nipples, cutis laxa, low hairline at the nape of the neck, low-set ears, high-arched palate, deformities of the nails, cubitus valgus, and other anomalies should be suspected of having Turner syndrome. Lymphedema of the hands or lower extremities can sometimes be the only indication. A karyotype can confirm diagnosis (see Chapter 604.1).

**Transient neonatal diabetes mellitus** (TNDM) is rare and typically presents on day 1 of life (see Chapter 607). It usually manifests as polyuria, dehydration, loss of weight, or acidosis in infants who are small for gestational age. The most common cause (70%) is a disruption of the imprinted locus at chromosome 6q24. A select group of patients with TNDM are at risk for recurrence of diabetes later in life.
Infants of Diabetic Mothers

Nicole M. Sheanon, Louis J. Muglia

Keywords

diabetic embryopathy
gestational diabetes
hyperglycemia
hyperinsulinemia
hyperinsulinism
hypoglycemia
IDMs
infants of diabetic mothers
pregestational diabetes

Diabetes (type 1, type 2, or gestational) in pregnancy increases the risk of complications and adverse outcomes in the mother and the baby. Complications related to diabetes are milder in gestational vs pregestational (preexisting type 1 or type 2) diabetes. Pregnancy outcomes are correlated with onset, duration, and severity of maternal hyperglycemia. Prepregnancy planning and tight glycemic control (hemoglobin A$_{1c}$ [HbA$_{1c}$] <6.5%) is crucial in pregestational diabetes in order to achieve the best outcomes for the mother and the baby. The risk of diabetic embryopathy (neural tube defects, cardiac defects, caudal regression syndrome) and spontaneous abortions is highest in those with pregestational diabetes who have poor control (HbA$_{1c}$ >7%) in the first trimester. The risk of congenital malformations in gestational diabetes is only slightly increased compared to the general population, since the duration of diabetes is less and hyperglycemia occurs later in gestation (typically >25 wk).

Mothers with pregestational and gestational diabetes have a high incidence of complications during the pregnancy. Polyhydramnios, preeclampsia, preterm labor (induced and spontaneous), and chronic hypertension occur more
frequently in mothers with diabetes. Accelerated fetal growth is also common, and 36–45% of infants of diabetic mothers (IDMs) are born large for gestational age (LGA). Restricted fetal growth is seen in mothers with pregestational diabetes and vascular disease, but it is less common. Fetal mortality rate is greater in both pregestational and gestational diabetic mothers than in nondiabetic mothers, but the rates have dropped precipitously over the years. Fetal loss throughout pregnancy is associated with poorly controlled maternal diabetes, especially diabetic ketoacidosis. The neonatal mortality rate of IDMs is >5 times that of infants of nondiabetic mothers and is higher at all gestational ages and in every birthweight for gestational age category. The rate is higher in women with pregestational diabetes, smoking, obesity, hypertension, and poor prenatal care.

Pathophysiology

The probable pathogenic sequence is that maternal hyperglycemia causes fetal hyperglycemia, and the fetal pancreatic response leads to fetal hyperinsulinemia, or hyperinsulinism. It is important to recognize that while maternal glucose crosses the placenta, maternal and exogenous insulin dose not. Fetal hyperinsulinemia and hyperglycemia then cause increased hepatic glucose uptake and glycogen synthesis, accelerated lipogenesis, and augmented protein synthesis (Fig. 127.1). Related pathologic findings are hypertrophy and hyperplasia of the pancreatic β cells, increased weight of the placenta and infant organs (except the brain), myocardial hypertrophy, increased amount of cytoplasm in liver cells, and extramedullary hematopoiesis. Hyperinsulinism and hyperglycemia produce fetal acidosis, which may result in an increased rate of stillbirth. Separation of the placenta at birth suddenly interrupts glucose infusion into the neonate without a proportional effect on hyperinsulinism, leading to hypoglycemia during the 1st few hr after birth. The risk of rebound hypoglycemia can be diminished by tight blood glucose control during labor and delivery.
Hyperinsulinemia has been documented in infants of mothers with pregestational and gestational diabetes. The infants of mothers with pregestational diabetes have significantly higher fasting plasma insulin levels than normal newborns, despite similar glucose levels, and respond to glucose with an abnormally prompt elevation in plasma insulin. After arginine administration, they also have an enhanced insulin response and increased disappearance rates of glucose compared with normal infants. In contrast, fasting glucose production and utilization rates are diminished in infants of mothers with gestational diabetes. Although hyperinsulinism is probably the main cause of hypoglycemia, the diminished epinephrine and glucagon responses that occur may be contributing factors. Infants of mothers with pregestational and
gestational diabetes are at risk for neonatal hypoglycemia in the 1st hours of life, with an increased risk in both large- and small-for-gestational-age infants. Aggressive screening and treatment is recommended as outlined later.

**Clinical Manifestations**

Infants of mothers with pregestational diabetes and those of mothers with gestational diabetes often bear a surprising resemblance to each other (Fig. 127.2). They tend to be large and plump as a result of increased body fat and enlarged viscera, with puffy, plethoric facies resembling that of patients who have been receiving corticosteroids. These infants may also be of normal birthweight if diabetes is well controlled; or low birthweight if they are delivered before term or if their mothers have associated diabetic vascular disease. Infants that are macrosomic or LGA are at high risk of birth trauma (brachial plexus injury) and birth asphyxia because of not only their large size but also their decreased ability to tolerate stress, especially if they have cardiomyopathy and other effects of fetal hyperinsulinemia (Table 127.1).
FIG. 127.2  Large, plump, plethoric infant of a mother with gestational diabetes. The baby was born at 38 wk of gestation but weighed 9 lb, 11 oz (4,408 g). Mild respiratory distress was the only symptom other than appearance.

Table 127.1

Morbidity in Infants of Diabetic Mothers

- Congenital anomalies
- Heart failure and septal hypertrophy of heart
- Surfactant deficiency, respiratory distress syndrome, transient tachypnea of the newborn, persistent pulmonary hypertension
- Hyperbilirubinemia
- Hypoglycemia, hypocalcemia, hypomagnesemia
- Macrosomia, nerve injury related to birth trauma
- Renal vein thrombosis
- Small left colon
- Unexplained intrauterine demise
- Polycythemia
- Visceromegaly
- Predisposition to later-life obesity, insulin resistance, and diabetes

**Hypoglycemia** develops in approximately 25–50% of infants of mothers with pregestational diabetes and 15–25% of infants of mothers with gestational diabetes, but only a small percentage of these infants become symptomatic. The probability that hypoglycemia will develop in such infants increases with higher cord or maternal fasting blood glucose levels. The nadir in an infant's blood glucose concentration is usually reached between 1 and 3 hr of age. Hypoglycemia can persist for 72 hr and in rare cases last up to 7 days. Frequent feedings can be used to treat the hypoglycemia, but some infants require intravenous (IV) dextrose.

The infants tend to be jittery, tremulous, and hyperexcitable during the 1st 3 days after birth, although hypotonia, lethargy, and poor sucking may also occur. Early appearance of these signs is more likely to be related to hypoglycemia but can also be caused by hypocalcemia and hypomagnesemia, which also occur in the 1st 24-72 hr of life due to delayed response of the parathyrome system. Perinatal asphyxia is associated with increased irritability and also increases the risk of hypoglycemia, hypomagnesemia, and hypocalcemia.

**Tachypnea** develops in many IDMs during the 1st 2 days after birth and may be a manifestation of hypoglycemia, hypothermia, polycythemia, cardiac failure,
transient tachypnea, or cerebral edema from birth trauma or asphyxia. IDMs have a higher incidence of respiratory distress syndrome (RDS) than do infants of nondiabetic mothers born at comparable gestational age. The greater incidence is possibly related to an antagonistic effect of insulin on stimulation of surfactant synthesis by cortisol, leading to a delay in lung maturation. Polycythemia often occurs with RDS as they are both a result of fetal hyperinsulinism.

**Cardiomegaly** is common (30%), and heart failure occurs in 5-10% of IDMs. Interventricular septal hypertrophy may occur and may manifest as transient idiopathic hypertrophic subaortic stenosis. This is thought to result from chronic hyperglycemia and chronic hyperinsulinism leading to glycogen loading in the heart. Inotropic agents worsen the obstruction and are contraindicated. β-Adrenergic blockers have been shown to relieve the obstruction, but ultimately the condition resolves spontaneously over time.

**Acute neurologic abnormalities** (lethargy, irritability, poor feeding) can be seen immediately after birth and the cause elucidated by the timing of symptoms, as previously discussed (hypoglycemia, hypocalcemia, hypomagnesemia, or birth asphyxia). The symptoms will resolve with treatment of the underlying cause but may persist for weeks if caused by birth asphyxia. Neurologic development and ossification centers tend to be immature and to correlate with brain size (which is not increased) and gestational age rather than total body weight in infants of mothers with gestational and pregestational diabetes. In addition, IDMs have an increased incidence of hyperbilirubinemia, polycythemia, iron deficiency, and renal vein thrombosis. Renal vein thrombosis should be suspected in the infant with a flank mass, hematuria, and thrombocytopenia.

There is a 4-fold increase in congenital anomalies in infants of mothers with pregestational diabetes, and the risk varies with HbA$_{1c}$ during the first trimester when organogenesis occurs. The recommended goal for periconceptual HbA$_{1c}$ is <6.5%. Although the risk of congenital malformations increases with increasing HbA$_{1c}$ levels, there may still be an increased risk in the therapeutic goal range. Congenital anomalies of the central nervous system and cardiovascular system are most common, including failure of neural tube closure (encephalocele, meningomyelocele, and anencephaly), transposition of great vessels, ventricular septal defect (VSD), atrial septal defect (ASD), hypoplastic left heart, aortic stenosis, and coarctation of the aorta. Other, less common anomalies include caudal regression syndrome, intestinal atresia, renal agenesis, hydronephrosis,
and cystic kidneys. **Small left colon syndrome** is a rare anomaly that develops in the second and third trimester because of rapid fluctuations in maternal and therefore fetal glucose, leading to impaired intestinal motility and subsequent intestinal growth. Prenatal ultrasound and a thorough newborn physical examination will identify most of these anomalies. High clinical suspicion and a good prenatal history will help identify needed screening for subtle anomalies.

**Treatment**

Preventive treatment of IDMs should be initiated before birth by means of preconception and frequent prenatal evaluations of all women with preexisting diabetes and pregnant women with gestational diabetes. This involves evaluation of fetal maturity, biophysical profile, Doppler velocimetry, and planning of the delivery of IDMs in hospitals where expert obstetric and pediatric care is continuously available. Preconception glucose control reduces the risk of anomalies and other adverse outcomes in women with pregestational diabetes, and glucose control during labor reduces the incidence of neonatal hypoglycemia. Women with type 1 diabetes who have tight glucose control during pregnancy (average daily glucose levels <95 mg/dL) deliver infants with birthweight and anthropomorphic features similar to those of infants of nondiabetic mothers. Treatment of gestational diabetes (diet, glucose monitoring, metformin, and insulin therapy as needed) decreases the rate of serious perinatal outcomes (death, shoulder dystocia, bone fracture, or nerve palsy). Women with gestational diabetes may also be treated successfully with **glyburide**, which may not cross the placenta. In these mothers, the incidence of macrosomia and neonatal hypoglycemia is similar to that in mothers with insulin-treated gestational diabetes. Women with diabetes can begin to express breast milk before the birth of the baby (≥36 wk gestational age); this will provide an immediate supply of milk to prevent hypoglycemia.

Regardless of size, IDMs should initially receive close observation and care (Fig. 127.3). Infants should initiate feedings within 1 hr after birth. A screening glucose test should be performed within 30 min of the first feed. Transient hypoglycemia is common during the 1st 1-3 hr after birth and may be part of normal adaptation to extrauterine life. The target plasma glucose concentration is ≥40 mg/dL before feeds in the 1st 48 hr of life. Clinicians need to assess the overall metabolic and physiologic status, considering these in the management of hypoglycemia. Treatment is indicated if the plasma glucose is <47 mg/dL.
Feeding is the initial treatment for *asymptomatic* hypoglycemia. Oral or gavage feeding with breast milk or formula can be given. An alternative is prophylactic use of *dextrose* gel, although early feedings may be equally effective. Recurrent hypoglycemia can be treated with repeat feedings or IV glucose as needed. Infants with *persistent* (and unresponsive to oral therapy) glucose levels <25 mg/dL during the 1st 4 hr after birth and <35 mg/dL at 4-24 hr after birth should be treated with IV glucose, especially if symptomatic. A small bolus of 200 mg/kg of dextrose (2 mL/kg of 10% dextrose) should be administered to infants with plasma glucose below these limits. The small bolus should be followed by a continuous IV glucose infusion to avoid hypoglycemia. If question arises about an infant's ability to tolerate oral feeding, a continuous peripheral IV infusion at a rate of 4-8 mg/kg/min should be given. Neurologic symptoms of hypoglycemia *must* be treated with IV glucose. Bolus injections of hypertonic (25%) glucose should be avoided because they may cause further hyperinsulinemia and potentially produce rebound hypoglycemia (see Chapter 111). For treatment of hypocalcemia and hypomagnesemia, see Chapters 119.4 and 119.5; for RDS treatment, see Chapter 122.3; and for treatment of polycythemia, see Chapter 124.3.
FIG. 127.3  Screening algorithm for asymptomatic hypoglycemia during first day of life among at-risk infants. Screening is indicated for late preterm infants, those who are small for gestational age/intrauterine growth restriction, and infants of obese or diabetic mothers. ¹ Continue monitoring blood glucose concentrations until 3 consecutive blood glucose concentrations have been ≥45–50 mg/dL. ² There is no consensus for a threshold definition for neonatal hypoglycemia in the first day of life. Nonetheless, if the blood glucose is less than 45–50 mg/dL AND symptoms compatible with hypoglycemia are present (see text), treatment must be initiated with an IV minibolus of 10% glucose at 200 mg/kg followed by a continuous IV infusion of glucose at a starting rate of 5–8 mg/kg/min. IV, Intravenous; EBM, expressed breast milk. (Modified from Newborn Services Clinical Guidelines for the Management of Hypoglycaemia http://www.adhb.govt.nz/newborn/Guidelines/Nutrition/HypoglycaemiaManagement.htm )
Prognosis

The subsequent incidence of diabetes mellitus in IDMs is higher than that in the general population because of genetic susceptibility in all types of diabetes. Infants of mothers with either pregestational diabetes or gestational diabetes are at risk for obesity and impaired glucose metabolism in later life as a result of intrauterine exposure to hyperglycemia. Disagreement persists about whether IDMs have a slightly increased risk of impaired intellectual development because of the many confounding factors (e.g., parental education, maternal age, neonatal complications). In general, the outcomes have improved over the last several decades due to increased awareness, screening, and improved prenatal care for pregnant women with diabetes.

Dysmorphology is the study of differences in human form and the mechanisms that cause them. It has been estimated that 1 in 40 newborns, or 2.5%, have a recognizable birth defect or pattern of malformations at birth; approximately half these newborns have a single, isolated malformation, whereas in the other half, multiple malformations are present. From 20–30% of infant deaths and 30–50% of deaths after the neonatal period are caused by congenital abnormalities (http://www.marchofdimes.com/peristats/). In 2001, birth defects accounted for 1 in 5 infant deaths in the United States, with a rate of 137.6 deaths per 100,000 live births, which was higher than other causes of mortality, such as preterm/low birthweight (109.5/100,000), sudden infant death syndrome (55.5/100,000), maternal complications of pregnancy (37.3/100,000), and respiratory distress syndrome (25.3/100,000).

Classification of Birth Defects

Birth defects can be subdivided into isolated (single) defects or multiple congenital anomalies (multiple defects) in one individual. An isolated primary defect can be classified, according to the nature of the presumed cause of the defect, as a malformation, dysplasia, deformation, or disruption (Table 128.1 and Fig. 128.1). Most birth defects are malformations. A malformation is a structural defect arising from a localized error in morphogenesis that results in the abnormal formation of a tissue or organ. Dysplasia refers to the abnormal organization of cells into tissues. Malformations and dysplasias can both affect intrinsic structure. In contrast, a deformation is an alteration in shape or structure of a structure or organ that has developed, or differentiated, normally. A disruption is a defect resulting from the destruction of a structure that had
formed normally before the insult.

</table>

Most inherited human disorders with altered morphogenesis display multiple malformations rather than isolated birth defects. When several malformations coexist in a single individual, they can be classified as a syndrome, sequence, or an association. A syndrome is defined as a pattern of multiple abnormalities that are related by pathophysiology, resulting from a single, defined etiology. Sequences consist of multiple malformations that are caused by a single event, although the sequence itself can have different etiologies. An association refers to a nonrandom grouping of malformations in which there is an unclear, or unknown, relationship among the malformations, such that they do not fit the criteria for a syndrome or sequence.

**Malformations and Dysplasias**

Human malformations and dysplasias can be caused by gene mutations, chromosome aberrations and copy number variants, environmental factors, or interactions between genetic and environmental factors (Table 128.2). Some malformations are caused by deleterious sequence variants in single genes, whereas other malformations arise because of deleterious sequence variants in multiple genes acting in combination (digenic or oligogenic inheritance). In 1996 it was thought that malformations were caused by monogenic defects in 7.5% of patients; chromosomal anomalies in 6%; multigenic defects in 20%; and known environmental factors, such as maternal diseases, infections, and teratogens, in 6–7% (Table 128.3). In the remaining 60–70% of patients, malformations were classified as caused by unknown etiologies. Currently, the percentages have increased for all categories of known causes of malformations, the result of improved cytogenetic and molecular genetic methods for detecting small chromosomal abnormalities and next-generation sequencing studies that can screen multiple genes simultaneously and identify novel genes and deleterious sequence variants.

**UNKNOWN ETIOLOGIES**
Neural tube defects, such as anencephaly and spina bifida
Cleft lip/palate
Pyloric stenosis

**SPORADIC SEQUENCE COMPLEXES**
VATER/VACTERL sequence (vertebral defects, anal atresia, cardiac defects, tracheoesophageal fistula with esophageal atresia, radial and renal anomalies)
Pierre Robin sequence

**NUTRITIONAL**
Neural tube defects due to low folic acid

Many developmental abnormalities that are caused by deleterious sequence variants (mutations) in a single gene display characteristic, mendelian patterns of inheritance (autosomal dominant, autosomal recessive, and X-linked inheritance). Genes that cause birth defects or multiple congenital anomaly syndromes are often transcription factors, part of evolutionarily conserved signal transduction pathways, or regulatory proteins required for key developmental events (Figs. 128.2 and 128.3). Examples include spondylocostal dysostosis syndromes, Smith-Lemli-Opitz syndrome, Rubinstein-Taybi syndrome, and X-linked lissencephaly (“smooth brain”) syndrome (see Table 128.2).
FIG. 128.2 Deleterious sequence variants in genes that function together in a developmental pathway typically have overlapping clinical manifestations. Several components of the sonic hedgehog (SHH) pathway have been identified, and their relationships elucidated (see text for further details). Mutations in several members of this pathway result in phenotypes with facial dysmorphism, as seen in holoprosencephaly, Smith-Lemli-Opitz syndrome, Gorlin syndrome, Greig cephalopolysyndactyly syndrome, Pallister-Hall syndrome, and Rubinstein-Taybi syndrome. CNS, Central nervous system.
Patients with spondylocostal dysostosis (SCD) display a characteristic pattern of vertebral segmentation defects associated with a number of other malformations, such as neural tube defects. The SCD syndromes are etiologically heterogeneous and are often caused by mutations in the gene coding for delta-like 3 (DLL3), a ligand of the Notch receptors. The Notch/delta pathway is conserved throughout evolution and regulates a number of developmental events. Smith-Lemli-Opitz syndrome (SLOS) results from mutations in the sterol delta-7-dehydrocholesterol reductase (DHCR7) gene, an enzyme critical for normal cholesterol biosynthesis. Patients with SLOS (see Fig. 128.2) display syndactyly (fusion of the fingers and toes), in particular affecting the 2nd and 3rd toes; postaxial polydactyly (extra digits); antverted (upturned) nose; ptosis; cryptorchidism; and holoprosencephaly (failure of separation of the 2 cerebral hemispheres). Many of the features in SLOS are shared with those arising from deleterious sequence variants in the SHH genes, and these mutations link cholesterol biosynthesis pathogenically to the sonic

FIG. 128.3  The RAS/MAPK signal transduction pathway. The MAPK signaling pathway of protein kinases is critically involved in cellular proliferation, differentiation, motility, apoptosis, and senescence. The RASopathies are medical genetic syndromes caused by mutations in genes that encode components or regulators of the Ras/MAPK pathway (indicated by dashed lines). These disorders include neurofibromatosis type 1 (NF1), Noonan syndrome (NS), Noonan syndrome with multiple lentigines (NSML), capillary malformation–arteriovenous malformation syndrome (CM-AVM), Costello syndrome (CS), cardiofaciocutaneous syndrome (CFC), and Legius syndrome. RAS/MAPK, RAS protein family/mitogen-activated protein kinase. (From Rauen KA: The RASopathies, Annu Rev Genom Hum Genet 14:355–369, 2013.)
hedgehog (SHH) pathway, because SHH is posttranslationally modified by cholesterol (see Chapter 97). **Rubinstein-Taybi syndrome** (see Fig. 128.2) typically results from heterozygous, loss-of-function deleterious sequence variants in a gene coding for a broadly acting transcriptional coactivator called *CREB-binding protein* (CBP) and from deleterious sequence variants in the *EP300* gene. The CBP coactivator regulates the transcription of a number of genes, which is why patients with deleterious sequence variants in *CBP* have a pleiotropic phenotype that includes developmental delays and intellectual disability, broad and angulated thumbs and halluces (1st toes), and congenital heart disease. One of the transcription factors that binds to CBP is *GLI3*, a member of the SHH pathway (see Fig. 128.2). **X-linked lissencephaly** is a severe neuronal migration defect that causes a smooth brain with reduction or absence of gyri and sulci in males and that gives rise to a variable pattern of intellectual disability and seizures in females. X-linked lissencephaly is caused by deleterious sequence variants in *DCX*. The DCX protein regulates the activity of dynein motors that contribute to movement of the cell nucleus during neuronal migration.

Malformation syndromes can also be caused by chromosomal aberrations or copy number variants and teratogens (see Tables 128.2 and 128.3). **Down syndrome** typically results from an extra copy of an entire chromosome 21 or, less frequently, an extra copy of the Down syndrome critical region on chromosome 21. Chromosome 21 is a small chromosome that contains an estimated 250 genes, and thus individuals with Down syndrome typically have an increased dosage of the numerous genes encoded by this chromosome that causes their physical differences (see Chapter 98.2).

** Neural tube defects** (NTDs) are an example of a birth defect that displays multifactorial inheritance in most cases. NTDs and a number of other congenital malformations, such as cleft lip and palate, can recur in families, but inheritance for the majority of affected individuals does not occur in a straightforward, mendelian inheritance pattern, and in this situation, multiple genes and environmental factors together likely contribute to the pathogenesis (see Table 128.2). Many of the genes involved in NTDs are unknown, so one cannot predict with certainty the mode of inheritance or a precise recurrence risk in the individual case. Empirical recurrence risks can be provided on the basis of population studies and the presence of single or multiple family members with the same malformation. However, one important gene/environment interaction has been identified for NTDs (see Chapter 609.1). **Folic acid deficiency** is
associated with NTDs and can result from a combination of dietary factors and increased utilization during pregnancy. A common variant in the gene for an enzyme in the folate recycling pathway, 5,10-methylene-tetrahydrofolate reductase (MTHFR), that makes this enzyme less stable, may also be important in folic acid status. Several teratogenic causes of birth defects have been described (see Tables 128.2 and 128.3). Ethanol causes a recognizable malformation syndrome that is variably called fetal alcohol syndrome (FAS), fetal alcohol spectrum disorder (FASD), or fetal alcohol effects (FAE) (see Chapter 126.3). Children who were exposed to ethanol during the pregnancy can display microcephaly, developmental delays, hyperactivity, and facial dysmorphic features. Ethanol, which is toxic to the developing central nervous system (CNS), causes cell death in developing neurons.

**Deformations**

Many deformations involve the musculoskeletal system (Fig. 128.4). Fetal movement is required for the proper development of the musculoskeletal system, and restriction of fetal movement can cause musculoskeletal deformations such as clubfoot (talipes). Two major intrinsic causes of deformations are primary neuromuscular disorders and oligohydramnios, or decreased amniotic fluid, which can be caused by fetal renal defects. The major extrinsic causes of deformation are those that result in fetal crowding and restriction of fetal movement. Examples of extrinsic causes include oligohydramnios resulting from chronic leakage of amniotic fluid and abnormal shape of the amniotic cavity. When a fetus is in the breech position (Fig. 128.5), the incidence of deformations is increased 10-fold. The shape of the amniotic cavity also has a profound effect on the shape of the fetus and is influenced by many factors, including uterine shape, volume of amniotic fluid, and the size and shape of the fetus (Fig. 128.6).
FIG. 128.4 Deformation abnormalities resulting from uterine compression. (From Kliegman RM, Jenson HB, Marcdeante KJ, et al, editors: Nelson essentials of pediatrics, ed 5, Philadelphia, 2005, Saunders.)
FIG. 128.5  Breech deformation sequence.

FIG. 128.6  A, Consequences of renal agenesis. B, Multiple deformational
defects. C, Defects in amnion nodosum; brown-yellow granules from vernix have been ribbed into defects of the amniotic surface. (From Jones KL, Jones MC, Del Campo M, editors: Smith's recognizable patterns of human malformation, ed 7, Philadelphia, 2013, Elsevier, p 821.)

It is important to determine whether deformations result from intrinsic or extrinsic causes. Most children with deformations from extrinsic causes are otherwise completely normal, and their prognosis is usually excellent. Correction typically occurs spontaneously. Deformations caused by intrinsic factors, such as multiple joint contractures resulting from CNS or peripheral nervous system defects, have a different prognosis and may be much more significant for the child (Fig. 128.7).

**FIG. 128.7** A, Diagram demonstrates the etiologically heterogeneous phenotype that results from fetal akinesia. B, Infant born with myotonic dystrophy to a mother with the same condition. He had multiple joint contractures with thin bones and respiratory insufficiency. C, Infant immobilized in a transverse lie after amnion rupture at 26 wk. D, Fetus with bilateral renal agenesis resulting in oligohydramnios. (From Graham JL. Smith's recognizable patterns of human malformation, ed 3, Philadelphia, 2007, Elsevier, Fig 47-2.)
Disruptions

Disruptions are caused by destruction of a previously normally formed organ or body part. At least 2 mechanisms are known to produce disruptions. One involves entanglement, followed by tearing apart or amputation, of a normally developed structure, usually a digit or limb, by strands of amnion floating within amniotic fluid (amniotic bands) (Fig. 128.8). The other mechanism involves interruption to the blood supply to a developing part, which can lead to infarction, necrosis, and resorption of structures distal to the insult. If interruption to the blood supply occurs early in gestation, the disruptive defect typically involves atresia, or absence of a body part. Genetic factors were previously considered to play a minor role in the pathogenesis of disruptions; most occur as sporadic events in otherwise healthy individuals. The prognosis for a disruptive defect is determined entirely by the extent and location of the tissue loss.

![Fig. 128.8 A, Amniotic band disruption sequence. B, Bands constricting the ankle leading to deformational defects and amputations. (From Jones KJ: Smith's recognizable patterns of human malformation, ed 6, Philadelphia, 2006, Saunders.]

Multiple Anomalies: Syndromes and Sequences

The pattern of multiple anomalies that occurs when a single primary defect in early development produces multiple abnormalities because of a cascade of
secondary and tertiary developmental anomalies is called a sequence (see Fig. 128.9). When evaluating a child with multiple congenital anomalies, the physician must differentiate between multiple anomalies that are caused by a single localized error in morphogenesis (a sequence) from syndromes with multiple malformations. In the former, recurrence risk counseling for the multiple anomalies depends entirely on the risk of recurrence for the single, localized malformation. Pierre-Robin sequence is a pattern of multiple anomalies produced by mandibular hypoplasia. Because the tongue is relatively large for the oral cavity, it drops back (glossoptosis), blocking closure of the posterior palatal shelves and causing a U-shaped cleft palate. There are numerous causes of mandibular hypoplasia, all of which can result in characteristic features of Pierre-Robin sequence.

![Diagram of Holoprosencephaly sequence]

**Molecular Mechanisms of Malformations**
**Inborn Errors of Development**

Genes that cause malformation syndromes (as well as genes whose expression is disrupted by environmental agents or teratogens) can be part of numerous cellular processes, including evolutionarily conserved signal transduction pathways, transcription factors, or regulatory proteins required for key developmental events. When malformations are considered as alterations resulting from disturbances to important developmental pathways, this provides a molecular framework for understanding the birth defects.

**Sonic Hedgehog Pathway As Model**

The SHH pathway is developmentally important during embryogenesis to induce controlled proliferation in a tissue-specific manner; disruption of specific steps in this pathway results in a variety of related developmental disorders and malformations (see Fig. 128.2). Activation of this pathway in the adult leads to abnormal proliferation and cancer. The SHH pathway transduces an external signal, in the form of a ligand, into changes in gene transcription by binding of the ligand to specific cellular receptors. SHH is a ligand expressed in the embryo in regions important for development of the brain, face, limbs, and the gut.

Deleterious sequence variants in SHH can cause holoprosencephaly (see Fig. 128.2), a variably severe, midline defect associated with clinical effects ranging from cyclopia to a single maxillary incisor with hypotelorism or close spacing of the ocular orbits. The SHH protein is processed by proteolytic cleavage to an active N-terminal form, which is then further modified by the addition of cholesterol. Defects in cholesterol biosynthesis, in particular the sterol, delta-7-dehydrocholesterol reductase gene, result in SLOS, which is also associated with holoprosencephaly. The modified and active form of SHH binds to its transmembrane receptor Patched (PTCH1). SHH binding to PTCH1 inhibits the activity of the transmembrane protein Smoothened (SMO). SMO act to suppress downstream targets of the SHH pathway, the GLI family of transcription factors, so inhibition of SMO by PTCH1 results in activation of GLI1, GLI2, and GLI3, resulting in alteration of transcription of GLI targets. PTCH1 and its orthologue, PTCH2, can act as tumor suppressors, and somatic, inactivating sequence variants can be associated with loss of tumor suppressor function, whereas activating mutations in SMO can also be oncogenic, particularly in basal cell carcinomas and medulloblastomas. Germline, inactivating mutations in PTCH1 result in Gorlin syndrome (see Fig. 128.4), an autosomal dominant disorder.
characterized by dysmorphic features (broad face, dental anomalies, rib defects, short metacarpals), basal cell nevi that can undergo malignant transformation, and an increased risk of cancers, including medulloblastomas and rhabdomyosarcomas. *GLI1* amplification has been found in several human tumors, including glioblastoma, osteosarcoma, rhabdomyosarcoma, and B cell lymphomas; mutations or alterations in *GLI3* have been found in Greig cephalopolysyndactyly syndrome (GCPS), Pallister-Hall syndrome (PHS), postaxial polydactyly type A (and A/B), and preaxial polydactyly type IV (see Fig. 128.2 ). GCPS consists of hypertelorism (wide-spaced eyes), syndactyly, preaxial polydactyly, and broad thumbs and halluces. PHS is an autosomal dominant disorder characterized by postaxial polydactyly, syndactyly, hypothalamic hamartomas, imperforate anus, and occasionally holoprosencephaly. *GLI3* binds to CBP, the protein that is haploinsufficient in Rubinstein-Taybi syndrome.

Disorders that are caused by mutations in genes that function together in a developmental pathway typically have overlapping clinical manifestations. In this case, the overlapping features result from the expression domains of SHH that are important for development of the brain, face, limbs, and gut. Brain defects are found in holoprosencephaly (Fig. 128.9 ), SLOS, and PHS. Facial abnormalities are found in holoprosencephaly, SLOS, Gorlin syndrome, GCPS, and PHS. Limb defects are found in SLOS, Gorlin syndrome, GCPS, PHS, and the polydactyly syndromes. Overexpression, or activating mutations, affecting the SHH pathway results in cancer, including basal cell carcinomas, medulloblastomas, glioblastomas, and rhabdomyosarcomas.

The SHH pathway interaction with the primary cilium is critical to transduce the SHH extracellular signal through to the nuclear machinery. A number of disorders, including Bardet-Biedl syndrome, oral-facial-digital (OFD) syndrome type I, and Joubert syndrome, are caused by mutations in genes that function in the primary cilium. These disorders, called ciliopathies , overlap clinically with some of the phenotypic features described previously, again demonstrating that perturbations of conserved developmental pathways can cause overlapping presentations (Table 128.4 ).

Cytogenetic Aberrations and Chromosomal Imbalance

Cytogenetic imbalances resulting from an additional copy of a whole human chromosome can result in characteristic and recognizable syndromes. An additional copy of chromosome 21 results in Down syndrome (see Chapter 98.2); loss of one of the X chromosomes results in Turner syndrome (see Chapter 98 for discussion of syndromes with whole chromosomal imbalances). With the advent of high-resolution cytogenetic techniques, such as fluorescence in situ
hybridization (FISH), array comparative genomic hybridization (array CGH), and single nucleotide polymorphism (SNP) arrays, it has become possible to identify submicroscopic chromosome deletions and duplications. A number of recurrent deletions and duplications have been identified that cause characteristic and recognizable syndromes, including Williams syndrome (deletion of chromosome 7q11.23), Miller-Dieker syndrome (deletion of chromosome 17p13.3), Smith-Magenis syndrome (deletion of chromosome 17p11.2), and 22q11 deletion syndrome (deletion of chromosome 22q11.2, also known as velocardiofacial/DiGeorge syndrome). Array CGH and SNP arrays have also made it possible to uncover rarer microdeletions and microduplications associated with birth defects, intellectual disability, and neuropsychiatric disorders. The sensitivity and specificity chromosome microarrays have made this the technique of choice for the initial evaluation of a child with multiple congenital anomalies and/or intellectual disability, although it is important to note that all individuals may carry numerous small microdeletions and microduplications as normal or familial variation. Therefore, it is important to compare copy number variants in these children with birth defects with their parents’ chromosome analyses and with databases of normal variants detected in individuals without such birth defects.

**Approach to the Dysmorphic Child**

One approach to the dysmorphic child is the pattern recognition approach, which compares the manifestations in the patient against a broad and memorized (or computerized) knowledge of human pleiotropic disorders. Although this approach can be appropriate for a small number of experienced dysmorphologists, a systematic genetic mechanism approach can also be effective for clinicians who are not dysmorphology experts. By gathering and analyzing the clinical data, the general pediatrician can diagnose the patient in a straightforward case or initiate a referral to an appropriate specialist.

**Medical History**

The history for a patient with birth defects includes a number of elements related to etiologic factors. The pedigree or family history is necessary to assess the inheritance pattern, or lack thereof, for the disorder. For disorders that have a simple mendelian inheritance pattern, its recognition can be critical for
narrowing the differential diagnosis, then prioritizing common genes with the appropriate inheritance pattern causing the patient's clinical features. A number of common birth defects have a complex or multifactorial genetic etiology, such as isolated cleft palate and spina bifida. The recognition of a close relative affected with a birth defect that is similar to that in the proband can be useful. Typically, a 3-generation pedigree is sufficient for this purpose (see Chapter 97).

The perinatal history is also an essential component of the history. It includes the pregnancy history of the mother (useful for recognition of recurrent miscarriages that may be indicative of a chromosomal disorder), factors that may relate to deformations or disruptions (oligohydramnios), and maternal exposures to teratogenic drugs or chemicals (isotretinoin and ethanol are potential causes of microcephaly).

Another component of the history that is often useful is the natural history of the phenotype. Malformation syndromes caused by chromosomal aberrations and single-gene disorders are frequently static, meaning that, although the patients can experience new complications over time, the phenotype is typically not progressive. In contrast, disorders that cause dysmorphic features because of metabolic perturbations (e.g., Hunter or Sanfilippo syndrome) can be mild or may not be apparent at birth, but they can progress relentlessly, causing deterioration of patient status over time.

**Physical Examination**

The physical examination is very important for the diagnosis of a dysmorphic syndrome. The essential element of the physical evaluation is an objective assessment of the patient's clinical findings. The clinician needs to perform an organized evaluation of the size and formation of various body structures. Familiarity with the nomenclature of dysmorphic signs is helpful (Table 128.5). The size and shape of the head is relevant; for example, many children with Down syndrome have mild microcephaly and brachycephaly (shortened anteroposterior dimension of skull). Eye position and shape are useful signs for many disorders. Reference standards are available with which physical measurements (e.g., interpupillary distance) can also be compared. It is also useful to categorize abnormalities as “major” or “minor” birth defects. Major defects either cause significant dysfunction (e.g., absence of a digit) or require surgical correction (e.g., polydactyly), and minor defects neither cause significant dysfunction nor require surgical correction (e.g, mild clinodactyly).
By cataloging physical parameters, the clinician may be able to recognize the diagnosis.

### Table 128.5

**Definitions of Common Clinical Signs of Dysmorphic Syndromes**

<table>
<thead>
<tr>
<th>SIGN</th>
<th>DEFINITION</th>
</tr>
</thead>
<tbody>
<tr>
<td>Brachycephaly</td>
<td>A condition in which head shape is shortened from front to back along the sagittal plane; typically the back of the skull (occiput) and face are flatter than normal.</td>
</tr>
<tr>
<td>Brachydactyly</td>
<td>Short digits.</td>
</tr>
<tr>
<td>Brushfield spots</td>
<td>Speckled white spots or rings about two thirds of the distance to the periphery of the iris of the eye.</td>
</tr>
<tr>
<td>Camptodactyly</td>
<td>Permanent flexion of 1 or more fingers that can be associated with missing interphalangeal crease.</td>
</tr>
<tr>
<td>Clinodactyly</td>
<td>A medial or lateral curving of the fingers or toes; usually refers to incurving of the 5th finger.</td>
</tr>
<tr>
<td>Hypoplastic or small nail</td>
<td>A small nail on a digit.</td>
</tr>
<tr>
<td>Low-set ears</td>
<td>This designation is made when the helix meets the cranium at a level below a horizontal plane that is an extension of a line through both inner canthi.</td>
</tr>
<tr>
<td>Melia</td>
<td>A suffix meaning “limb” (e.g., amelia—missing limb; brachymelia—short limb).</td>
</tr>
<tr>
<td>Ocular hypertelorism or wide-set eyes</td>
<td>Increased distance between the center of the pupils of the 2 eyes; also known as <em>increased interpupillary distance</em> (IPD).</td>
</tr>
<tr>
<td>Plagiocephaly</td>
<td>A condition in which head shape is asymmetric in the sagittal or coronal plane; can result from asymmetry in cranial suture closure, asymmetry of brain growth, or deformation of the skull.</td>
</tr>
<tr>
<td>Posterior hair whorl</td>
<td>A single hair whorl occurs to the right or left of midline and is within 2 cm anterior to the posterior fontanel in 95% of cases.</td>
</tr>
<tr>
<td>Postaxial polydactyly</td>
<td>Extra finger or toe present on the lateral side of the hand or foot.</td>
</tr>
<tr>
<td>Preaxial polydactyly</td>
<td>Extra finger or toe present on the medial side of the hand or foot.</td>
</tr>
<tr>
<td>Prominent lateral palatine ridges</td>
<td>Relative overgrowth of the lateral palatine ridges that can be caused by a deficit of tongue thrust into the hard palate.</td>
</tr>
<tr>
<td>Scaphocephaly</td>
<td>A condition in which the head is elongated from front to back in the sagittal plane; most normal skulls are scaphocephalic; also termed <em>dolichocephaly</em>.</td>
</tr>
<tr>
<td>Shawl scrotum</td>
<td>The scrotal skin joins around the superior aspect of the penis and represents a mild deficit in full migration of the labial-scrotal folds.</td>
</tr>
<tr>
<td>Short palpebral fissures</td>
<td>Decreased horizontal distance of the eyelid folds based on measurements from the inner canthus to the outer canthus,</td>
</tr>
<tr>
<td>Syndactyly</td>
<td>Incomplete separation of the fingers or toes. It most commonly occurs between the 3rd and 4th fingers and between the 2nd and 3rd toes.</td>
</tr>
<tr>
<td>Synophrys</td>
<td>Eyebrows that meet in the midline.</td>
</tr>
<tr>
<td>Telecanthus</td>
<td>Lateral displacement of the inner canthi. The inner canthal distance (ICD) is increased, but the interpupillary distance (IPD) is normal.</td>
</tr>
<tr>
<td>Widow’s peak</td>
<td>V-shaped midline, downward projection of the scalp hair in the frontal region. It represents an upper forehead intersection of the bilateral fields of periocular hair growth suppression. It usually occurs because the fields are widely spaced, as in ocular hypertelorism.</td>
</tr>
<tr>
<td>CRANIOFACIAL</td>
<td></td>
</tr>
<tr>
<td>------------------------------</td>
<td></td>
</tr>
<tr>
<td>Large anterior fontanel</td>
<td></td>
</tr>
<tr>
<td>Flat or low nasal bridge</td>

Hydrocele
Shawl scrotum
Hypospadias
Hyoplasia of labia majora

* Approximately 15% of newborns have 1 minor anomaly, 0.8% have 2 minor anomalies, and 0.5% have 3. If 2 minor anomalies are present, the probability of an underlying syndrome or a major anomaly (congenital heart disease, renal, central nervous system, limbic) is 5-fold that in the general population. If 3 minor anomalies are present, there is a 20–30% probability of a major anomaly.

**Imaging Studies**

Imaging studies can be critical in diagnosing an underlying genetic etiology. If short stature or disproportionate stature (e.g., long trunk and short limbs) is noted, a full skeletal survey with radiographs should be performed. The skeletal survey can detect anomalies in bone number or structure that can be used to narrow the differential diagnosis. When there are abnormal neurologic signs or symptoms, such as microcephaly or hypotonia, brain imaging can be indicated. Other studies, such as echocardiography and renal ultrasonography, can also be useful to identify additional major or minor malformations that may serve as diagnostic clues.
Diagnosis

The examining physician should gather data on the patient's pedigree and perinatal and pediatric (for older children) history and should have an appreciation for the natural history of the clinical findings. At this point, the physician has examined the child, identified atypical physical features, and obtained appropriate imaging studies.

The clinician should now attempt to organize the findings to elucidate potential developmental processes. An assessment based on specificity can be helpful for this process. If a child has multiple findings, such as a patent ductus arteriosus (PDA), mild growth restriction, mild microcephaly, and holoprosencephaly, micropenis, and ptosis, a selection of the rarer or pathognomonic findings may be prioritized. The PDA, ptosis, mild growth restriction, and mild microcephaly are considered to be largely nonspecific findings (present in many disorders or often present as isolated features that are not part of a syndrome), whereas holoprosencephaly and micropenis are present in fewer syndromes and are not considered part of normal variation. The clinician can therefore search for disorders that include both holoprosencephaly and micropenis. The search can be performed manually using the features index of a textbook such as Smith's Recognizable Patterns of Human Malformation or a computerized database such as Online Mendelian Inheritance in Man (OMIM). Searching for both holoprosencephaly and micropenis returns a list of diagnostic possibilities, and the physician can then return to the patient to examine for additional features of the leading possible candidate disorders. Appropriate genetic testing can then be undertaken to confirm the clinician's hypothesis and verify the diagnosis.

Laboratory Studies and Genetic Testing

The laboratory evaluation of the dysmorphic child can be critical to reach or confirm the correct diagnosis. Cytogenetic studies with Giemsa-banded (G-banded) chromosome analysis, or karyotyping, was the gold standard previously performed in the evaluation of a dysmorphic patient. Array CGH and SNP arrays enable copy number variant detection and, in the case of SNP arrays, evaluation of loss of heterozygosity. Chromosome deletion syndromes may also be identified with specific and sensitive FISH analysis (Table 128.7). These tests are the most sensitive methods for the detection of cytogenetic alterations.
Molecular testing for deleterious sequence variants that cause pleiotropic malformation syndromes is also available for many disorders as clinical or research testing. In most cases, however, such testing should not be performed indiscriminately, but instead should be ordered thoughtfully after the differential diagnosis has been considered. The introduction of next-generation sequencing has led to the identification of innumerable novel genes and revolutionized the testing that is now available for patients and families with intellectual disability, birth defects, or other suspected genetic diseases. A strong suspicion of a genetic diagnosis warrants consideration of testing to confirm the diagnosis, facilitate

patient treatment and anticipatory guidance, clarify recurrence risks, and enable carrier testing for relevant inheritance patterns. Single nucleotide variants, exons, or genes are tested by Sanger sequencing targeting single or multiple exons. However, for diagnoses that have substantial genetic heterogeneity (e.g., hearing loss), panel testing, in which multiple relevant genes can be interrogated for single nucleotide variants, gene deletions, and gene duplications, is more expeditious than Sanger sequencing. Panel tests also frequently have the advantage of providing high coverage for the genes on the panel, compared to coverage for the same genes obtained by exome sequencing. However, in situations with diagnostic uncertainty, such as the investigation of a child with intellectual disability and dysmorphic features, for which there is no clinically recognizable pattern, exome sequencing may be most useful as a broad testing approach. **Whole exome sequencing** (WES) examines approximately 200,000 exons, or the 1–2% of the DNA that comprises the coding regions of the genome. WES is typically performed with a trio approach, in which the patient and both biological parents are tested simultaneously, so that the inheritance pattern, or segregation, of deleterious sequence variants can be determined, thus simplifying analysis. Trio sequencing has resulted in higher diagnostic yields than proband-only sequencing and can approach 30–40% for indications such as intellectual disability. In contrast, **whole genome sequencing** (WGS) examines all the DNA content, including noncoding regions, and includes analysis for cytogenetic rearrangements in addition to copy number loss or gain. WES and WGS are applicable to a wide range of birth defects and genetic diseases and can discover causative variants in known or novel genes associated with a particular condition.

**Management and Counseling**

Management of the affected patient and genetic counseling are essential aspects of the approach to the dysmorphic patient. Children with Down syndrome have a high incidence of hypothyroidism, and children with achondroplasia have a high incidence of cervicomedullary junction abnormalities. One of the many benefits of an early and accurate diagnosis is that **anticipatory guidance and medical monitoring** of patients for syndrome-specific medical risks can prolong and improve their quality of life. When a diagnosis is made, the treating physicians can access published information on the natural history and management of the disorder through published papers, genetics reference texts, and databases.
The 2nd major benefit of an accurate diagnosis is that it provides data for appropriate recurrence risk estimates. Genetic disorders may have direct effects on only 1 member of the family, but the diagnosis of the condition can have implications for the entire family. One or both parents may be carriers; siblings may be carriers or may want to know their genetic status when they reach their reproductive years. Recurrence risk provision is an important component of genetic counseling and should be included in all evaluations for families affected with birth defects or other inherited disorders (see Chapter 94).

Infections in the newborn are often classified by their timing relative to birth and include congenital, perinatal, early-onset, and late-onset disease. These are clinically useful designations because the mechanisms of infection, etiologies, and outcomes are distinct at each stage. **Congenital infection** denotes infection acquired in utero. Such infections are generally caused by viral or other non-bacterial organisms and are often associated with injury to developing organs (see Chapter 131). **Perinatal infection** indicates acquisition around the time of delivery. Perinatally acquired organisms include both bacteria and viruses, some of which are the same as those causing congenital infection but often manifest with different features. **Early-onset infection** occurs in the 1st wk of life and is generally the consequence of infection caused by organisms acquired during the perinatal period. **Late-onset infection** occurs between 7 and 30 days of life and may include bacteria, viruses, or other organisms that are typically acquired in the postnatal period. **Hospital-acquired infections** typically occur beyond the 1st wk of life (see Chapter 130).

Neonates are uniquely prone to invasive disease because of their lack of fully responsive innate immunity (Fig. 129.1). Attenuated immune responses often result in minimal or nonspecific clinical manifestations, and effective treatment requires attention to subtle signs of infection. Compared to older infants, newborns are often treated empirically while awaiting results of laboratory investigations. Preterm infants are particularly susceptible to infection because of their decreased innate immune and barrier defenses and their prolonged stay in hospital settings.
FIG. 129.1 Ontogeny of skin, soluble, and cellular innate defense systems. Host-protective barrier functions include physical, chemical, and functional components of the skin and mucous membrane epithelia of the fetus, neonate (birth to 28 days of age), and infant (1 mo to 1 yr of age). Skin: while physical and chemical barriers are impaired in early life, especially in the preterm newborn, the vernix caseosa and skin epithelia of full-term newborns robustly express antimicrobial proteins and peptides (APPs).

Mucous membranes: in parallel with and induced by an increasingly complex microbiota, the newborn intestinal mucosal epithelium rapidly changes structurally, with an increase in the population of crypts and crypt-based Paneth cells, as well as functionally with increasing APP expression. Blood: the composition of neonatal blood is distinct, with relatively low concentrations of complement components and APPs and high concentrations of the immunosuppressive purine metabolite adenosine. Plasma also contains maternal antibodies that are transferred beginning midgestation and supplemented by postnatal factors derived from breast milk. Innate immunity is detectable from the end of the 1st mo of gestation, with changes driven largely by the increasing exposure to environmental microbes. Neonatal antigen-presenting cells such as blood monocytes express pattern recognition receptors (e.g., Toll-like receptors, TLRs) with distinct functional responses, including limited Th1-polarizing cytokine production, to most stimuli. Adaptive immunity develops from 4 wk of gestation onward, with changes driven by an evolving chimerism reflecting fetal (liver-derived, shaded cells) regulatory T (Treg)-cell–rich lymphocytes, and more adultlike (bone marrow derived, unshaded cells) lymphocytes with distinct, epigenetically encoded functional programs. Ig, Immunoglobulin; RBC, red blood cell. (Modified from Kollmann TR, Kampmann B, Mazmanian SK, et al: Protecting the newborn and young infant from infectious diseases: lessons from immune ontogeny. Immunity 2007;46:350–363.)
Incidence and Epidemiology

Despite advances in maternal and neonatal care, infections remain a frequent and important cause of neonatal and infant morbidity and mortality. Up to 10% of infants have infections in the 1st mo of life. Newborn infection is more common in areas with limited access to healthcare than in areas with well-established healthcare infrastructure. The overall incidence of neonatal sepsis ranges from 1 to 5 cases per 1,000 live births. Estimated incidence rates vary based on the case definition and the population studied. Globally, neonatal sepsis and other severe infections were responsible for an estimated 430,000 neonatal deaths in 2013, accounting for approximately 15% of all neonatal deaths.

A number of bacterial and nonbacterial agents may infect newborns in the intrapartum or postpartum period (Table 129.1). Although herpes simplex virus (HSV), human immunodeficiency virus (HIV), hepatitis B virus (HBV), hepatitis C virus (HCV), and tuberculosis (TB) can each result in transplacental infection, the most common mode of transmission for these agents is intrapartum, during labor and delivery with passage through an infected birth canal (HIV, HSV, HBV), or postpartum, from contact with an infected mother or caretaker (TB) or with infected breast milk (HIV) (Fig. 129.2 and Table 129.2). Any microorganism inhabiting the genitourinary or lower gastrointestinal tract may cause intrapartum and postpartum infection. The most common bacteria are group B streptococcus (GBS), Escherichia coli, and Klebsiella spp. Salmonella spp. are common causes of gram-negative sepsis in developing countries; less common causes of bacterial infection in the United States include Citrobacter, enterococci, gonococci, Listeria monocytogenes, Streptococcus pneumoniae, and Haemophilus influenzae. The more common viruses are cytomegalovirus (CMV), HSV, enteroviruses, and HIV (Table 129.2).

**FIG. 129.2** Relative importance of neonatal viral infections related to the timing of acquisition of infection. Viruses are listed in declining order of importance relative to prenatal, perinatal (intrapartum), and postnatal timing of typical infection. Some neonatal virus infections (e.g., cytomegalovirus) can be substantial causes of disease whether acquired during gestation or acquired postpartum, whereas others (e.g., respiratory syncytial virus) are typically acquired in the postnatal period. Microorganisms causing pneumonia acquired during labor and delivery include GBS, gram-negative enteric aerobes, *L. monocytogenes*, genital *Mycoplasma, Chlamydia trachomatis*, CMV, HSV, and *Candida* spp. (Table 129.3).
The most common bacterial causes of neonatal meningitis are GBS, *E. coli*, and *L. monocytogenes*. *S. pneumoniae*, other streptococci, nontypable *H. influenzae*, both coagulase-positive and coagulase-negative staphylococci, *Klebsiella, Enterobacter, Pseudomonas, Treponema pallidum*, and *Mycobacterium tuberculosis* infection involving the central nervous system (CNS) may also result in meningitis.

**Early- and Late-Onset Neonatal Infections**

The terms *early-onset infection* and *late-onset infection* refer to the different ages at onset of infection in the neonatal period. **Early-onset sepsis** is defined as the onset of symptoms before 7 days of age, although some experts limit the definition to infections occurring within the 1st 72 hr of life. **Late-onset sepsis** is generally defined as the onset of symptoms at ≥7 days of age. Similar to early-onset sepsis, there is variability in the definition, ranging from an onset at >72 hr of life to ≥7 days of age. Early-onset infections are acquired before or during delivery (vertical mother-to-child transmission). Late-onset infections develop after delivery from organisms acquired in the hospital or the community. The age...
at onset depends on the timing of exposure and virulence of the infecting organism. **Very-late-onset infections** (onset after age 1 mo) may also occur, particularly in very-low-birthweight (VLBW) preterm infants or term infants requiring prolonged neonatal intensive care.

The incidence of neonatal bacterial sepsis varies from 1-4 per 1,000 live births, with geographic variation and changes over time. Studies suggest that term male infants have a higher incidence of sepsis than term females. This sex difference is less clear in preterm low-birthweight (LBW) infants. Attack rates of neonatal sepsis increase significantly in LBW infants in the presence of maternal chorioamnionitis, congenital immune defects, mutations of genes involved in the innate immune system, asplenia, galactosemia (*E. coli*), and malformations leading to high inocula of bacteria (e.g., obstructive uropathy).

Data from the Eunice Kennedy Shriver National Institute of Child Health and Human Development (NICHD) Neonatal Research Network documented rates of early-onset sepsis among almost 400,000 live births at Network centers. The overall rate of early-onset sepsis was 0.98 cases per 1,000 live births, with rates inversely related to birthweight: 401-1,500 g, 10.96 per 1,000 births; 1,501-2,500 g, 1.38/1,000; and >2,500 g, 0.57/1,000 (Table 129.4).

* NICHD Neonatal Research Network/CDC Surveillance Study of Early-Onset Sepsis.

The incidence of meningitis is 0.2-0.4 per 1,000 live births in newborn infants and is higher in preterm infants. Bacterial meningitis may be associated with sepsis or may occur as a local meningeal infection. **Up to one third of VLBW infants with late-onset meningitis have negative blood culture results**. The discordance between results of blood and cerebrospinal fluid (CSF) cultures suggests that meningitis may be underdiagnosed among VLBW infants and emphasizes the need for culture of CSF in VLBW infants when late-onset sepsis.
is suspected and in all infants who have positive blood culture results. Most neonates with sepsis presenting in the 1st day of life have a positive blood culture; analysis of CSF is usually deferred until the unstable cardiorespiratory status (shock, respiratory failure) has stabilized.

**Pathogenesis**

**Early-Onset Infections**

In most cases, the fetus or neonate is not exposed to potentially pathogenic bacteria until the membranes rupture and the infant passes through the birth canal and/or enters the extrauterine environment. The human birth canal is colonized with aerobic and anaerobic organisms that may result in ascending amniotic infection and/or colonization of the neonate at birth. Vertical transmission of bacterial agents that infect the amniotic fluid and vaginal canal may occur in utero or, more often, during labor and delivery (Fig. 129.3).

**FIG. 129.3** Pathways of ascending or intrapartum infection.

**Chorioamnionitis** results from microbial invasion of amniotic fluid, often as a result of prolonged rupture of the chorioamniotic membrane. Amniotic infection may also occur with apparently intact membranes or with a relatively brief duration of membrane rupture. The term *chorioamnionitis* refers to the clinical syndrome of intrauterine infection, which includes maternal fever, with
or without local or systemic signs of chorioamnionitis (uterine tenderness, foul-smelling vaginal discharge/amniotic fluid, maternal leukocytosis, maternal and/or fetal tachycardia). Chorioamnionitis may also be asymptomatic, diagnosed only by amniotic fluid analysis or pathologic examination of the placenta. The rate of histologic chorioamnionitis is inversely related to gestational age at birth (Fig. 129.4) and directly related to duration of membrane rupture.

![Histologic chorioamnionitis in liveborn preterm babies by gestational age](image)

Chorioamnionitis was thought to result from infection of the amniotic fluid but is now better defined by the term **intrauterine inflammation or infection at birth (Triple I)**. This is defined by fetal tachycardia, maternal leukocytosis (>15,000 cells in the absence of corticosteroids), purulent fluid from the cervical os, biochemical or microbiologic amniotic fluid changes consistent with infection, and fever ($\geq 39.0^\circ C/102.2^\circ F$) (see Chapter 131.2).

Rupture of membranes for >24 hr was once considered prolonged because microscopic evidence of inflammation of the membranes is uniformly present when the duration of rupture exceeds 24 hr. At 18 hr of membrane rupture, however, the incidence of early-onset disease with group B streptococcus (GBS) increases significantly; 18 hr is the appropriate cutoff for increased risk of neonatal infection (see Chapter 211).
Bacterial colonization does not always result in disease. Factors influencing which colonized infant will experience disease are not well understood but include prematurity, underlying illness, invasive procedures, inoculum size, virulence of the infecting organism, genetic predisposition, the innate immune system, host response, and transplacental maternal antibodies (Fig. 129.5). Aspiration or ingestion of bacteria in amniotic fluid may lead to congenital pneumonia or systemic infection, with manifestations becoming apparent before delivery (fetal distress, tachycardia), at delivery (failure to breathe, respiratory distress, shock), or after a latent period of a few hours (respiratory distress, shock). Aspiration or ingestion of bacteria during the birth process may lead to infection after an interval of 1-2 days.

![Diagram: Factors influencing the balance between health and disease in neonates exposed to a potential pathogen. ROM, Rupture of membranes. (Adapted from Baker CJ: Group B streptococcal infections, Clin Perinatol 24:59–70, 1997.)](image)

Resuscitation at birth, particularly if it involves endotracheal intubation, insertion of an umbilical vessel catheter, or both, is associated with an increased risk of bacterial infection. Explanations include the presence of infection at the time of birth or acquisition of infection during the invasive procedures associated with resuscitation.
Late-Onset Infections

After birth, neonates are exposed to infectious agents in the neonatal intensive care unit (NICU), the nursery, or in the community (including family). Postnatal infections may be transmitted by direct contact with hospital personnel, the mother, or other family members; from breast milk (HIV, CMV); or from inanimate sources such as contaminated equipment. The most common source of postnatal infections in hospitalized newborns is *hand contamination* of healthcare personnel, underscoring the importance of handwashing.

Most cases of meningitis result from hematogenous dissemination. Less often, meningitis results from contiguous spread as a result of contamination of open neural tube defects, congenital sinus tracts, or penetrating wounds from fetal scalp sampling or internal fetal electrocardiographic monitors. Cerebral abscess formation, ventriculitis, septic infarcts, hydrocephalus, and subdural effusions are complications of meningitis that occur more often in newborn infants than in older children. Metabolic factors, including hypoxia, acidosis, hypothermia, and inherited metabolic disorders (e.g., galactosemia), are likely to contribute to risk for and severity of neonatal sepsis.

Infection in Premature Infants

The most important neonatal factor predisposing to infection is prematurity or LBW. Preterm LBW infants have a 3- to 10-fold higher incidence of infection than full-term normal-birthweight infants. Possible explanations include (1) maternal genital tract infection is considered to be an important cause of preterm labor, with an increased risk of vertical transmission to the newborn; (2) the frequency of intraamniotic infection is inversely related to gestational age (see Figs. 129.1 and 129.5); (3) premature infants have documented immune dysfunction; and (4) premature infants often require prolonged intravenous access, endotracheal intubation, or other invasive procedures that provide a portal of entry or impair barrier and clearance mechanisms, putting them at continued risk for hospital-acquired infections.

Clinical Manifestations

The maternal history provides important information about maternal exposures to infectious diseases, bacterial colonization, immunity (natural and acquired),
and obstetric risk factors (prematurity, prolonged ruptured membranes, maternal chorioamnionitis). Signs and symptoms in the neonate are often subtle and nonspecific. Temperature instability, tachypnea, lethargy, and poor feeding are common initial signs and should raise suspicion for systemic or focal infection (Table 129.5).

**Bacterial Sepsis**
Neonates with bacterial sepsis may have either nonspecific manifestations or focal signs of infection (Table 129.5), including temperature instability, hypotension, poor perfusion with pallor and mottled skin, metabolic acidosis, tachycardia or bradycardia, apnea, respiratory distress, grunting, cyanosis, irritability, lethargy, seizures, feeding intolerance, abdominal distention, jaundice, petechiae, purpura, and bleeding. Table 129.6 lists World Health Organization international criteria for bacterial sepsis. The initial manifestation may involve only limited symptomatology and only one system, such as apnea alone or tachypnea with retractions, or tachycardia, or the infant may present with an acute catastrophic manifestation with multiorgan dysfunction and shock. Infants should be reevaluated over time to determine whether the symptoms have progressed from mild to severe. Later complications of sepsis include respiratory failure, pulmonary hypertension, cardiac failure, shock, renal failure, liver dysfunction, cerebral edema or thrombosis, adrenal hemorrhage and/or insufficiency, bone marrow dysfunction (neutropenia, thrombocytopenia, anemia), and disseminated intravascular coagulopathy (DIC).

IMCI, Integrated Management of Childhood Illness; WHO, World Health Organization.

A variety of noninfectious conditions can occur together with neonatal infection or can make the diagnosis of infection more difficult. Respiratory distress syndrome (RDS) secondary to surfactant deficiency can coexist with bacterial pneumonia. Because bacterial sepsis can be rapidly progressive, the physician must be alert to the signs and symptoms of possible infection and must initiate diagnostic evaluation and empirical therapy in a timely manner. The
differential diagnosis of many of the signs and symptoms that suggest infection is extensive; noninfectious disorders must also be considered (Table 129.7).

**Systemic Inflammatory Response Syndrome**

The clinical manifestations of infection depend on the virulence of the infecting organism and the body's inflammatory response. The term *systemic inflammatory response syndrome* (SIRS) is most frequently used to describe this unique process of infection and the subsequent systemic response (see Chapters
In addition to infection, SIRS may result from trauma, hemorrhagic shock, other causes of ischemia, necrotizing enterocolitis, and pancreatitis.

Patients with SIRS have a spectrum of clinical symptoms that represent progressive stages of the pathologic process. In adults, SIRS is defined by the presence of 2 or more of the following: (1) fever or hypothermia, (2) tachycardia, (3) tachypnea, and (4) abnormal white blood cell (WBC) count or an increase in immature forms. In neonates and pediatric patients, SIRS manifests as temperature instability, respiratory dysfunction (altered gas exchange, hypoxemia, acute respiratory distress syndrome), cardiac dysfunction (tachycardia, delayed capillary refill, hypotension), and perfusion abnormalities (oliguria, metabolic acidosis) (Table 129.8). Increased vascular permeability results in capillary leak into peripheral tissues and the lungs, with resultant peripheral and pulmonary edema. DIC results in the more severely affected cases. The cascade of escalating tissue injury may lead to multisystem organ failure and death.

**Table 129.8**

**Definitions of Systemic Inflammatory Respiratory Response Syndrome (SIRS) and Sepsis in Pediatric Patients**

| SIRS: the systemic inflammatory response to a variety of clinical insults, manifested by 2 or more of the following conditions: |
| Temperature instability <35°C (95°F) or >38.5°C (101.3°F) |
| Respiratory dysfunction: |
| Tachypnea >2 SD above the mean for age |
| Hypoxemia (Pao₂ <70 mm Hg on room air) |
| Cardiac dysfunction: |
| Tachycardia >2 SD above the mean for age |
| Delayed capillary refill >3 sec |
| Hypotension >2 SD below the mean for age |
| Perfusion abnormalities: |
| Oliguria (urine output <0.5 mL/kg/hr) |
| Lactic acidosis (elevated plasma lactate and/or arterial pH <7.25) |
| Altered mental status |

| Sepsis: the systemic inflammatory response to an infectious process |

**Temperature Instability**
Fever or hypothermia may be the only initial manifestation of serious infection in newborns. However, only approximately 50% of infected newborn infants have a temperature >37.8°C (100°F) (axillary) (see Chapter 202). Fever in newborn infants does not always signify infection; it may be caused by increased ambient temperature, isolette or radiant warmer malfunction, dehydration, CNS disorders, hyperthyroidism, familial dysautonomia, or ectodermal dysplasia. A single temperature elevation is infrequently associated with infection; fever sustained over 1 hr is more likely to be caused by infection. Most febrile infected infants have additional signs compatible with infection, although a focus of infection is not always apparent. Acute febrile illnesses occurring later in the neonatal period may be caused by urinary tract infection, meningitis, pneumonia, osteomyelitis, or gastroenteritis, in addition to sepsis, thus underscoring the importance of a diagnostic evaluation that includes blood culture, urine culture, lumbar puncture (LP), and other studies as indicated. Many agents may cause these late infections, including HSV, enteroviruses, respiratory syncytial virus (RSV), and bacterial pathogens. In premature infants, hypothermia or temperature instability requiring increasing ambient (isolette, warmer) temperatures is more likely to accompany infection.

**Respiratory and Cardiovascular Symptoms**

Early signs and symptoms of pneumonia may be nonspecific, including poor feeding, lethargy, irritability, cyanosis, temperature instability, and the overall impression that the infant is not well. Respiratory symptoms of increasing severity are grunting, tachypnea, retractions, flaring of the alae nasi, cyanosis, apnea, and progressive respiratory failure. If the infant is premature, signs of progressive respiratory distress may be superimposed on RDS or bronchopulmonary dysplasia (BPD). For infants on mechanical ventilation, the need to increase ventilator support may indicate infection. Although a common finding in neonatal sepsis, tachycardia is nonspecific. Bradycardia may also occur. Poor perfusion and hypotension are more sensitive indicators of sepsis but tend to be late findings. In a prospective national surveillance study, 40% of neonates with sepsis required volume expansion, and 29% required vasopressor support.

Signs of pneumonia on physical examination, such as dullness to percussion, change in breath sounds, and the presence of rales or rhonchi, are very difficult to appreciate in a neonate. Radiographs of the chest may reveal new infiltrates or
an effusion, but if the neonate has underlying RDS or BPD, it is very difficult to determine whether the radiographic changes represent a new process or worsening of the underlying disease.

The progression of neonatal pneumonia can be variable. Fulminant infection is most frequently associated with pyogenic organisms such as GBS (see Chapter 211). Onset may occur during the 1st hours or days of life, with the infant often manifesting rapidly progressive circulatory collapse and respiratory failure. With early-onset pneumonia in premature infants, the clinical course and chest radiographs may be indistinguishable from those with severe RDS.

In contrast to the rapid progression of pneumonia caused by pyogenic organisms, an indolent course may be seen in nonbacterial infection. The onset can be preceded by upper respiratory tract symptoms or conjunctivitis. The infant may demonstrate a nonproductive cough, and the degree of respiratory compromise is variable. Fever is usually absent or low grade, and radiographic examination of the chest shows focal or diffuse interstitial pneumonitis or hyperinflation. Infection is generally caused by *C. trachomatis*, CMV, *Ureaplasma urealyticum*, or one of the respiratory viruses. Rhinovirus has been reported to cause severe respiratory compromise in infants, particularly those who are preterm. Although *Pneumocystis (carinii) jiroveci* was implicated in the past, its etiologic role is now in doubt, except in newborns infected with HIV.

**Conjunctivitis**

Conjunctival infection is relatively common and may be caused by a variety of organisms. The presentation includes periorbital swelling, conjunctival injection, and purulent conjunctival drainage. *C. trachomatis* and *Neisseria gonorrhoea* are common causes; other gram-positive and gram-negative organisms are occasionally involved. *Pseudomonas aeruginosa* is an important pathogen in hospitalized VLBW infants and may be a precursor to invasive disease. Viral infections (e.g., HSV, adenovirus) are occasionally seen. Recognition of HSV infection is important to prevent corneal injury and dissemination to systemic sites.

**Skin and Soft Tissue Infection**

Cutaneous manifestations of infection include omphalitis, cellulitis, mastitis, and subcutaneous abscesses. Pustules likely indicate the presence of staphylococcal
infection but must be distinguished from the vesicular rash of HSV infection. Staphylococcal pustulosis results in larger, pus-filled lesions 1 mm in diameter and often scattered around the umbilicus, whereas HSV infection often appears as tiny vesicles in crops, often on the scalp. **Ecthyma gangrenosum** indicates infection with *Pseudomonas* spp. and is rare except in VLBW infants. The presence of small, salmon-pink papules suggests *L. monocyctogenes* infection. Mucocutaneous lesions suggest *Candida* spp. (see Chapter 261.1). Petechiae and purpura may be the result of systemic viral or bacterial infection.

**Omphalitis**

Omphalitis is a neonatal infection resulting from unhygienic care of the umbilical cord, which continues to be a problem, particularly in developing countries. The umbilical stump is colonized by bacteria from the maternal genital tract and the environment (see Chapter 125). The necrotic tissue of the umbilical cord is an excellent medium for bacterial growth. Omphalitis may remain a localized infection or may spread to the abdominal wall, the peritoneum, the umbilical or portal vessels, and the liver. Abdominal wall cellulitis or **necrotizing fasciitis**, with associated sepsis and a high mortality rate, may develop in infants with omphalitis. Prompt diagnosis and treatment are necessary to avoid serious complications. *Staphylococcus aureus* and gram-negative organisms are common pathogens involved.

**Tetanus**

Neonatal tetanus remains a serious infection in resource-limited countries (see Chapter 238). It results from unclean delivery and unhygienic management of the umbilical cord in an infant born to a mother who has not been immunized against tetanus. The surveillance case definition of neonatal tetanus requires the ability of a newborn to suck at birth and for the 1st few days of life, followed by an inability to suck. Neonatal tetanus typically occurs in infants 5-7 days after birth (range: 3-24 days), difficulty swallowing, spasms, stiffness, seizures, and death. **Bronchopneumonia**, presumably resulting from aspiration, is a common complication and cause of death. Neonatal tetanus can be prevented by immunizing mothers before or during pregnancy and by ensuring a clean delivery, sterile cutting of the umbilical cord and proper cord care after birth.
Laboratory Findings

Maternal history and infant signs should guide diagnostic evaluation (Table 129.9). Additionally, signs of systemic infection in newborn infants may be unrevealing, so laboratory investigation plays a particularly important role in diagnosis. Cultures and cell counts are obtained from blood and urine. CSF should be sent for Gram stain, routine culture, cell count with differential, and protein/glucose concentrations. Surface swabs, blood, and CSF are often obtained for HSV testing. Except for culture and directed pathogen testing, no single laboratory test is completely reliable for diagnosis of invasive infection in the newborn. Complete blood count may demonstrate elevated or decreased WBC count, often with a shift toward more immature forms. Thrombocytopenia can be seen in systemic bacterial or viral infection. Hyponatremia, acidosis, and other electrolyte abnormalities can be seen. Hyperbilirubinemia is nonspecific but may be an indication of systemic infection. Elevated serum transaminases may be a clue to systemic HSV or enterovirus infection.

**LABORATORY STUDIES**

**Evidence of Infection**
Culture from a normally sterile site (blood, CSF, other)
Demonstration of a microorganism in tissue or fluid
Molecular detection (blood, urine, CSF) by specific PCR and/or 16S ribosomal DNA
Maternal or neonatal serology (syphilis, toxoplasmosis)

**Evidence of Inflammation**
Leukocytosis, increased immature/total neutrophil count ratio
Acute-phase reactants: C-reactive protein, erythrocyte sedimentation rate, procalcitonin
Cytokines: interleukin-6, interleukin-B, tumor necrosis factor
Pleocytosis in CSF or synovial or pleural fluid
Disseminated intravascular coagulation: fibrin degradation products, D-dimer

**Evidence of Multiorgan System Disease**
Metabolic acidosis: pH, $\text{PCO}_2$
Pulmonary function: $\text{PO}_2$, $\text{PCO}_2$
Renal function: blood urea nitrogen, creatinine
Hepatic injury/function: bilirubin, alanine transaminase, aspartate transaminase, ammonia, prothrombin time, partial thromboplastin time
Bone marrow function: neutropenia, anemia, thrombocytopenia

* Diseases that increase the risk of infection or may overlap with signs of sepsis.

CSF, Cerebrospinal fluid; PCR, polymerase chain reaction.

Various serum biomarkers have been investigated for their ability to identify infants with **serious bacterial infection** (SBI). An immature-to-total phagocyte count (I/T ratio) ($\geq 0.2$) has the best sensitivity of the neutrophil indices for predicting neonatal sepsis. After the newborn period, serum C-reactive protein (CRP) and procalcitonin have demonstrated reasonable sensitivity and specificity for SBI. CRP may be monitored in newborn infants to assess response to therapy. Their value in the initial diagnosis of sepsis in the newborn period has yet to be clarified, as does the value of these biomarkers in determining optimal length of empirical therapy in infants with negative cultures. Cytokines (both proinflammatory cytokines such as interleukin (IL)-6 and tumor necrosis factor-$\alpha$ and antiinflammatory cytokines such as IL-4 and IL-10), chemokines, and other biomarkers are increased in infected infants. Elevations of serum amyloid A and the cell surface antigen CD64 also have high sensitivity for identifying infants with sepsis. Chest radiography is generally not indicated in infants without signs of respiratory infection.

**Table 129.9** and **129.10** list clinical features and laboratory parameters that are useful in the diagnosis of neonatal infection or sepsis.

*Investigational* refers to an assay or parameter that is undergoing evaluation for clinical use and applicability.

CRP, C-reactive protein; CSF, cerebrospinal fluid; EOS, early-onset sepsis; GA, gestational age; LOS, late-onset sepsis; MHC II, major histocompatibility complex class II; NPV, negative predictive value; TNF, tumor necrosis factor; WBC, white blood cell count.

General Approach to Management

In the absence of specific signs of focal infection, therapy for presumed infection in the neonate is often empirical and initiated on the basis of fever or hypothermia, listlessness, irritability, or apneic episodes. Antibiotics are chosen to cover the organisms typically causing neonatal sepsis, including GBS, gram-negative organisms, *Listeria*, and *Enterococcus*. Since the latter 2 organisms are intrinsically resistant to cephalosporins, ampicillin is generally included in the empirical treatment of infants with presumed neonatal infection *(Table 129.11)*.

</tr>
</tbody>
</table>

**PREVENTION STRATEGIES**
An empirical regimen for suspected early-onset sepsis in a term or late preterm infant is ampicillin, 150 mg/kg/dose intravenously (IV) every 12 hr, and gentamicin, 4 mg/kg/dose IV every 24 hr. This has long been a standard regimen for early-onset sepsis and provides coverage for the most prevalent organisms, predominantly GBS and gram-negative ones. Ampicillin plus cefotaxime (if available) or cefepime may be substituted if the patient presents with infection after discharge from the nursery, or when infection with ampicillin-resistant E. coli is suspected. Ceftriaxone may be substituted if premature infants are ≥41 wk postconception age; it may be used in term infants if they are not receiving intravenous calcium or do not have hyperbilirubinemia. There is concern this regimen may be associated with higher rates of mortality in NICU patients compared to ampicillin and gentamicin. Alterations to the standard regimen may be appropriate in some circumstances, such as suspected infection with S. aureus, in which case vancomycin may be substituted for ampicillin, and in environments where infections from antibiotic-resistant bacteria are prevalent.

Herpes simplex virus infection may present without cutaneous signs, in the
absence of maternal history of infection, and in mothers receiving suppressive antiviral therapy. Therefore, management of the ill newborn requires a high index of suspicion for HSV infection. Surface swabs, blood, and CSF are obtained for HSV culture or PCR, and empirical acyclovir is often recommended while the results of these studies are pending (see Chapters 202 and 279).

Systemic infection caused by Candida spp. is a concern in hospitalized infants, particularly VLBW infants with central venous access catheters and prior antibiotic use. Empirical therapy for fungal infection is generally not recommended unless the patient fails to respond to broad-spectrum antibiotic therapy. Definitive therapy is based on identification and susceptibility of the offending organism. In almost all circumstances, the least broad antibiotic with activity against the organism is chosen. Duration of therapy depends on the organism and the site of infection. In neonates with culture-proven sepsis, the usual course of therapy is 10 days. Longer treatment courses may be warranted if a specific focus of infection is identified (e.g., meningitis, osteomyelitis, septic arthritis). Antimicrobial therapy should be altered based on the susceptibility profile of the pathogen isolated. In infants with a negative blood culture but a clinical status that remains concerning for a systemic infection, antibiotic therapy can be extended for as long as a total of 5 to 10 days. Sepsis is unlikely in these infants if they remain well and the blood culture is sterile at 48 hr. Empirical antibiotic therapy should be discontinued after 48 hr in these neonates.

**Prevention**

Intrapartum antibiotics are used to reduce vertical transmission of GBS (Table 129.12), as well as to lessen neonatal morbidity associated with preterm labor and preterm premature rupture of membranes (see Figs. 211.2 and 211.3 in Chapter 211). With introduction of selective intrapartum antibiotic prophylaxis to prevent perinatal transmission of GBS, rates of early-onset neonatal GBS infection in the United States declined from 1.7/1,000 live births to 0.25/1,000. Intrapartum chemoprophylaxis does not reduce the rates of late-onset GBS disease and has no effect on the rates of infection with non-GBS pathogens (see Chapter 211). Of concern is a possible increase in gram-negative infections (especially E. coli) in VLBW and possibly term infants despite a reduction in early GBS sepsis by intrapartum antibiotics.
**Table 129.12**

<td></td>
</tr>
<tr>
<td>Intrapartum NAAT ‡ positive for GBS</td>
<td></td>
</tr>
</tbody>
</table>

* Recommendations for the use of intrapartum antibiotics for prevention of early-onset GBS disease in the setting of threatened preterm delivery are presented in Chapter 211 .

† If amnionitis is suspected, broad-spectrum antibiotic therapy that includes an agent known to be active against GBS should replace GBS prophylaxis.

‡ If intrapartum NAAT is negative for GBS but any other intrapartum risk factor (delivery at <37 wk gestation, amniotic membrane rupture ≥18 hr, or temperature ≥38.0°C/100.4°F) is present, intrapartum antibiotic prophylaxis is indicated.

GBS, Group B streptococcus; NAAT, nucleic acid amplification test.

Aggressive management of suspected maternal chorioamnionitis with antibiotic therapy during labor, along with rapid delivery of the infant, reduces the risk of early-onset neonatal sepsis. Vertical transmission of GBS and early-onset GBS disease is significantly reduced by selective intrapartum chemoprophylaxis (see Fig. 211.4 ). A number of candidate GBS vaccines are currently being studied. Neonatal infection with *Chlamydia* can be prevented by identification and treatment of infected pregnant women (see Chapter 253 ). Mother-to-child transmission of HIV is significantly reduced by maternal antiretroviral therapy during pregnancy, labor, and delivery, by cesarean delivery before rupture of membranes, and by antiretroviral treatment of the infant after
birth (see Chapter 302).

Prevention of congenital and perinatal infections predominantly focuses on maternal health. The Centers for Disease Control and Prevention (CDC) recommends the following screening tests and treatment when indicated:

1. All pregnant women should be offered voluntary and confidential HIV testing at the first prenatal visit, as early in pregnancy as possible. HIV screening should be part of routine prenatal testing, unless the mother declines testing (opt-out screening). For women at high risk of infection during pregnancy (multiple sexual partners or STIs during pregnancy, intravenous drug use, HIV-infected partners), repeat testing in the third trimester is recommended. Rapid HIV screening is indicated for any women who presents in labor with an undocumented HIV status, unless she declines testing.

2. A serologic test for syphilis should be performed on all pregnant women at the first prenatal visit. Repeat screenings early in the third trimester and again at delivery are recommended for women in whom syphilis test results in the first trimester were positive and for those at high risk for infection during pregnancy. Infants should not be discharged from the hospital unless the syphilis status of the mother has been determined at least once during pregnancy and preferably again at delivery.

3. Serologic testing for hepatitis B surface antigen (HBsAg) should be performed at the first prenatal visit, even if the woman has been previously vaccinated or tested. Women who were not screened prenatally, those who are at high risk for infection (multiple sexual partners, intravenous drug use, HBsAg-positive sex partner) and those with clinical hepatitis should be retested at the time of delivery.

4. A maternal genital culture for *C. trachomatis* should be performed at the first prenatal visit. Young women (<25 yr) and those at increased risk for infection (new or multiple partners during pregnancy) should be retested during the third trimester.

5. A maternal culture for *Neisseria gonorrhoeae* should be performed at the first prenatal visit. Those at high risk for infection should be retested in the third trimester.

6. All pregnant women at high risk for hepatitis C infection (intravenous drug use, blood transfusion or organ transplantation before 1992) should be screened for hepatitis C antibodies at the first prenatal visit.
7. Evidence does not support routine testing for bacterial vaginosis in pregnancy. For asymptomatic women at high risk for preterm delivery, testing may be considered. Symptomatic women should be tested and treated.

8. The CDC recommends universal screening for rectovaginal GBS colonization of all pregnant women at 35-37 wk gestation, and a screening-based approach to selective intrapartum antibiotic prophylaxis against GBS (Table 129.12) (see Figs. 211.2 and 211.3). Fig. 211.4 shows the approach to the infant born after intrapartum prophylaxis (see Chapter 211).

Bibliography

Curfman AL, Glissmeyer EW, Ahmad FA, et al. Initial

Premature and very-low-birthweight (VLBW) infants often have prolonged hospitalizations and are particularly prone to healthcare-acquired infection (HAI) because of their inefficient innate immunity, deficient skin barriers, presence of indwelling catheters and other devices, and prolonged endotracheal intubation (Table 130.1). HAIs are associated with increased length of hospitalization, increased cost of care, and significant morbidity and mortality.

**Pneumonia**

- Two or more serial chest radiographs with new/progressive and persistent infiltrate, cavitation, consolidation, or pneumatoceles for patients with underlying pulmonary or cardiac disease (respiratory distress syndrome, bronchopulmonary dysplasia, pulmonary edema) or 1 chest radiograph with the aforementioned abnormalities for patients without underlying pulmonary or cardiac disease and

- Worsening gas exchange and

- At least 3 of the following; (1) temperature instability; (2) white blood cell count <4,000/µL or >15,000/µL with
10% or more bands, (3) new-onset purulent sputum, change in character of sputum, increased respiratory secretions, or increased suctioning requirements; (4) physical examination findings consistent with increased work of breathing or apnea, wheezing, rales, or rhonchi; (5) cough; (6) bradycardia (<100 beats/min), and (7) tachycardia (>170 beats/min).

**Ventilator-Associated Pneumonia (VAP)**
- Pneumonia (as defined above) and
- Patient on ventilator for >2 days and
- Ventilator in place on day of or day before VAP diagnosis

**URINARY TRACT INFECTION**

**Symptomatic Urinary Tract Infection (SUTI)**
- At least 1 of the following symptoms: (1) fever (temperature >38.0°C), (2) hypothermia (temperature <36.0°C), (3) apnea, (4) bradycardia, (5) lethargy, (6) vomiting, or (7) suprapubic tenderness and
- Urine culture with no more than 2 species identified, at least 1 of which is present at >10^5 CFU/mL.

**Asymptomatic Bacteremic Urinary Tract Infection (ABUTI)**
- Urine culture with no more than 2 species identified, at least 1 of which is present at >10^5 CFU/mL and
- Bacteria identified in blood (culture-based or nonculture-based microbiologic method) that matches at least one of the bacteria present at more than 10^5 CFU/mL in urine.

**Catheter–Associated Urinary Tract Infection:**
- Urinary tract infection (as defined above, either SUTI or ABUTI) and
- Indwelling urinary catheter for >2 days and
- Urinary catheter in place on day of or day before urinary tract infection diagnosis.

* Centers for Disease Control and Prevention/National Healthcare Safety Network.

CFU, Colony-forming units.

**Incidence**

The most common HAIs in the neonatal intensive care unit (NICU) are bloodstream infections, predominantly central line–associated bloodstream infections. Ventilator-associated pneumonia (VAP) is the next most common, followed by surgical site infection and catheter-associated urinary tract infection.

Approximately 11% of NICU patients develop nosocomial infection during their hospitalization; up to 25% of VLBW infants will have blood culture–proven sepsis during their hospitalization. Infection rates are highest among the most premature infants. Ventilator-associated pneumonia accounts for approximately 25% of HAIs.

**Epidemiology**

HAIs in the NICU are predominantly caused by gram-positive organisms. The
largest fraction of **bloodstream infections (BSIs)** in the NICU are caused by coagulase-negative staphylococci (*Table 130.2*). Other agents that often cause HAIs in the newborn include *Staphylococcus aureus*, enterococci, gram-negative bacilli (*Escherichia coli, Klebsiella pneumoniae, Enterobacter* spp., *Pseudomonas aeruginosa*), and *Candida*. Viruses contributing to HAIs in the neonate include rotavirus, enteroviruses, hepatitis A virus (HAV), adenoviruses, influenza, respiratory syncytial virus (RSV), rhinovirus, parainfluenza, and herpes simplex virus (HSV).

VLBW, Very-low-birthweight (≤1,500 g); NICHD NRN, National Institutes of Child Health and Human Development Neonatal Research Network.

Bacteria responsible for most cases of nosocomial **pneumonia** typically
include staphylococcal species, gram-negative enteric aerobes, and occasionally, *P. aeruginosa*. Fungi are responsible for an increasing number of systemic infections, usually acquired during prolonged hospitalization of preterm neonates. Respiratory viruses cause isolated cases and outbreaks of nosocomial pneumonia. These viruses, usually endemic during the winter months and acquired from infected hospital staff or visitors to the nursery, include RSV, parainfluenza virus, influenza viruses, and adenovirus.

**Pathogenesis**

Colonization of the skin, oropharynx, or gastrointestinal (GI) tract is an important precursor to infection in hospitalized infants. Premature infants may first be exposed to pathogenic organisms from a parent or more frequently from the hospital environment. Hospitalized infants are more likely to be colonized with *Staphylococcus aureus*, pathogenic gram-negative bacteria, and *Candida* than are infants in the community setting. Antibiotic exposure, indwelling devices, and frequent contact with contaminated medical equipment or healthcare providers all likely contribute to high rates of pathogen colonization. Following colonization, organisms may gain access to the bloodstream directly through damaged skin or central venous catheters. Recent evidence suggests the intestine is an important reservoir for invasive organisms, which may transit directly from the gut to the bloodstream. Oropharyngeal colonization with subsequent aspiration into the lower respiratory tract is thought to be the major route of infection in infants with ventilator-associated pneumonia.

Gestational age and birthweight are the most important risk factors for HAI. Prolonged use of central venous or umbilical catheters, exposure to broad-spectrum antibiotics, parenteral nutrition, and high nurse-to-patient ratios are other documented risk factors. These factors may alter the patient's endogenous microbial community, placing the infant at risk for colonization with pathogenic organisms.

**Types of Infection**

**Central Line–Associated Bloodstream Infection**
Central venous catheters have become an essential component of the care of critically ill newborns. Presence of a percutaneous or umbilical catheter introduces risk for infection and thrombosis. Central line–associated bloodstream infection (CLABSI) is the most common HAI in NICUs, imposing significant burden on the affected infant and on healthcare systems. Each episode has an attributable mortality of 4–20%. Infants with CLABSI subsequently have increased requirement for NICU stay, mechanical ventilation, and increased rates of bronchopulmonary dysplasia and necrotizing enterocolitis. The median estimated additional cost per CLABSI episode is $42,609, and hospitalization is prolonged for a median of 24 days.

Coagulase-negative staphylococci (CoNS) are the most common cause of CLABSI, accounting for approximately half of cases. CoNS are much more likely to cause clinically evident sepsis in VLBW infants than in term infants of comparable postnatal age, despite the organism's low pathogenic potential. Isolation of the organism from blood culture may represent contamination from the infant's or healthcare worker's skin, and blood cultures should be obtained from both peripheral and central venous sites. If both yield CoNS, the likelihood of true infection is high, whereas a single positive is considered questionable. In practice, often a single culture is obtained, and antibiotics are initiated before availability of a 2nd culture. In this circumstance, clinical judgment is often used to assess the need for targeted therapy. *S. aureus*, *Enterococcus* spp., and gram-negative rods account for most of the remaining CLABSIs during the 1st mo of hospitalization. Thereafter, *Candida* spp. become more prevalent, caused at least in part by their enrichment after broad-spectrum antibiotic exposure.

CLABSIs are generally thought to result from contamination of the central venous catheter, predominantly at the connecting hub or the skin entry site. An association has been shown between density of hub colonization and risk for CLABSI. Prevention of CLABSI is aimed at reducing contamination of these sites. BSI may also result from direct transit from the GI tract or other cutaneous or mucosal surfaces, analogous to recently defined mucosal barrier injury–associated BSIs. The contribution of mucosal sites to direct invasive infection remains to be clarified but has implications for infection prevention.

**Healthcare-Associated Pneumonia**

Ventilator-associated pneumonia (VAP) is overall the 2nd most common HAI in neonatal units, although reported VAP rates vary widely (0.2-1.6 per 1,000
ventilator days). There is also variability in diagnosis of VAP, which consists of clinical, radiographic, and laboratory criteria, some of which are subjective or may be seen in noninfectious circumstances. The National Healthcare Safety Network and Centers for Disease Control and Prevention (CDC) definition of VAP requires at least 48 hr of mechanical ventilation accompanied by new and persistent radiographic infiltrates after the initiation of mechanical ventilation. In addition to these criteria, infants <1 yr old must exhibit worsening gas exchange and at least 3 of the following: (1) temperature instability with no other recognized cause; (2) leukopenia (white blood cell count <4,000/mm$^3$); (3) change in the character of sputum of increased respiratory secretions or suctioning requirements; (4) apnea, tachypnea, nasal flaring, or grunting; (5) wheezing, rales, rhonchi, or cough; or (6) bradycardia (<100 beats/min) or tachycardia (>170 beats/min). In practice, the diagnosis is often made on the basis of increased need for supplemental oxygen or new infiltrates on chest radiograph; either of which may be caused by factors other than infection. Further complicating the diagnosis of VAP, secretions aspirated from the airways of mechanically ventilated children often yield multiple organisms in culture, whether or not they have signs of infection. The most commonly reported organisms associated with VAP are gram-negative rods (including Pseudomonas), S. aureus, and Enterococcus. The source of infecting organisms is generally thought to be the infant’s oropharynx, although contaminated respiratory equipment and tracheal suction catheters are occasionally implicated.

**Skin and Soft Tissue Infection**

Cutaneous infections are relatively common among hospitalized premature infants. Simple abrasions of frail skin, frequent vascular access, and surgical procedures predispose the skin to infection. *Staphylococcus aureus* is the most frequently isolated organism. Methicillin-susceptible *S. aureus* (MSSA) predominates despite increases in methicillin-resistant *S. aureus* (MRSA) infection rates during the last 2 decades. Gram-negative organisms and *Candida* spp. may occasionally be seen, particularly after intraabdominal surgery.

**Invasive Fungal Infection**

Up to 3% of VLBW and 20% of extremely-low-birthweight (ELBW) infants will develop invasive fungal infection, with a cumulative incidence of 1–4% of all
NICU admissions (see Chapter 261.1). Colonization, a requisite for subsequent infection is common after the 1st wk of hospitalization and is seen in >60% of infants at 1 mo in the NICU. *Candida albicans* accounts for most cases of colonization and infection, although *C. parapsilosis* and *C. glabrata* are prevalent in some NICUs. As with other BSIs, invasive candidiasis is often central venous catheter associated. In addition to gestational age and birthweight, risk factors include exposure to ≥2 antibiotics, receipt of H₂ blockers, parenteral nutrition (especially use of lipid emulsifiers), lack of enteral feeding, and GI surgery. Invasive candidiasis is associated with greater morbidity and mortality than invasive bacterial infection, with mortality rates >20% and long term developmental abnormalities seen in >50% of surviving infants.

**Viral Infection**

Nosocomially acquired viral infections receive less attention than invasive bacterial or fungal infections but can account for significant morbidity. Approximately 10% of reported episodes in NICUs are caused by viruses. The most common viral agent is rotavirus, followed by RSV, enterovirus, HAV, adenovirus, and influenza. Consistent with the viral etiology, GI illness is the most frequently reported virus-associated condition. In most cases of viral infection in the NICU, the source cannot be identified, making it difficult to focus preventive efforts. Response to viral outbreaks in the NICU can include enhanced patient surveillance, patient cohorting, and occasionally, closure of the affected patient care area.

**Prevention**

**Hand Hygiene**

Hand hygiene is the single most important intervention proven to prevent nosocomial infections, whereas lack of hand hygiene is one of the strongest correlates of HAI. Colonization with pathogenic organisms is known to increase with longer time spent performing patient interactions. The CDC and the World Health Organization have published guidelines on timing and choice of sanitizing agent during patient care (Table 130.3). Alcohol-based hand sanitizers are at least as effective as chlorhexidine-containing soaps in decreasing bacterial burden but have poor activity against certain important pathogens, including
*Clostridium difficile*, HAV, rotavirus, enterovirus, and adenovirus. Time constraints and workload are considered important barriers to adequate hand care, and recent evidence suggests that shortening the application time of alcohol-based sanitizers to 15 sec may improve frequency of use without impacting antimicrobial efficacy. Observational studies suggest that monitoring with personal or group-level feedback is among the most effective means to improve hand hygiene compliance.

Central Line–Associated Bloodstream Infection

Hand hygiene is the most important intervention to prevent CLABSI in the NICU. “Care bundles” have been studied in numerous neonatal populations and found to reduce catheter-related infection. Insertion bundles include a combination of barrier precaution, hand hygiene standards, skin disinfection, dedicated teams and equipment, catheter site evaluation, checklists, and empowerment to stop the procedure. Maintenance bundles include recommendations for aseptic technique when accessing the line, dressing change protocols, and prompt removal when the line is no longer required (Table 130.4).

| Table 130.4 |
| Interventions to Prevent Catheter-Related Infections |

- Perform effective hand hygiene before and after any interaction with the catheter.
- Use sterile gowns, gloves, drapes, cap, and mask during catheter insertion.
- Disinfect skin with appropriate agent (chlorhexidine is most often used in United States; other disinfectants may be as effective).
- Use a transparent, semipermeable dressing to cover catheter site.
- Change the dressing when soiled or loose.
- Scrub access point with alcoholic chlorhexidine for at least 15 sec.
- Use aseptic nontouch technique to access the catheter.
- Change administration sets no more frequently than 96 hr unless required by the infused product.
- Avoid use of systemic prophylactic antibiotics for catheter insertion.
- Evaluate daily, and remove central venous catheter when no longer required.
- Ensure all healthcare professionals who interact with the patient are educated on central line management.

Ventilator-Associated Pneumonia

VAP prevention bundles have been applied to adult patients but are not readily adapted to premature infants. Thus far, few studies have demonstrated efficacy of infection control measures in preventing VAP in NICUs. A number of measures are believed to be helpful, including caregiver education, hand hygiene, donning of gloves when in contact with secretions, minimizing days of ventilation to the extent possible, suctioning the oropharynx, and removing condensate from the ventilator circuit.

**Early Feeding and Human Milk**

Several studies have demonstrated benefit to feeding infants maternal milk. Enteral feeding of human milk within 2-3 days of life is associated with decreased rates of necrotizing enterocolitis and nosocomial infection. Human milk contains a number of factors thought to contribute to beneficial effects, including secretory antibody, lactoferrin, phagocytes, and oligosaccharides that shape the neonatal microbial community. Interestingly, the benefits of human milk are not as evident when the milk comes from a donor other than the infant's mother, suggesting important compositional differences in maternal milk.

**Antifungal Prophylaxis**

Prophylactic administration of fluconazole during the 1st 6 wk of life reduces fungal colonization and invasive fungal infection in ELBW infants (<1000 g). In addition to the individual benefit afforded by prophylaxis for VLBW neonates, fluconazole prophylaxis may have a community impact by decreasing the overall fungal burden of a NICU. Results from more than 14 trials at multiple institutions with 3,100 neonates suggests that fluconazole prophylaxis decreases colonization of the urine, GI tract, and integument, without promoting the development of resistance and without adverse effects. Based on an annual U.S. preterm birth cohort of approximately 30,000 VLBW infants, fluconazole prophylaxis could prevent an estimated 2,000-3,000 cases of invasive candidiasis, 200-300 deaths, and the adverse neurodevelopmental outcomes of invasive candidiasis in 400-500 infants per year. Differing baseline rates of fungal infections, practices related to central venous catheter removal, severity of illness, and administration practices for broad-spectra antimicrobials make universal recommendations regarding prophylaxis challenging. A meta-analysis using patient-level data found that fluconazole prophylaxis was effective at
preventing colonization and invasive *Candida* infection and was not associated with adverse drug reactions or increased rates of fluconazole resistance. Neonatal practices that may reduce the risks of invasive candidiasis include limited use of broad-spectrum antimicrobials, use of an aminoglycoside instead of a cephalosporin for empirical therapy when meningitis or antimicrobial resistance is not suspected, limitation of postnatal corticosteroid use in VLBW infants, early enteral feeding, and establishment of the neonatal gut microbiome with human milk feeding.

**Nasal Decolonization**

*Staphylococcus aureus* is the 2nd most common cause of HAI in neonatal units. MSSA generally causes more invasive infections than MRSA, but most prevention efforts have been focused on MRSA. Several studies have documented MRSA transmission within the NICU and have identified nasal colonization as an important risk factor for subsequent invasive infection. Various measures have been implemented in attempt to decrease transmission and invasive infection, including contact precautions, cohorting and isolation, and nasal decolonization with mupirocin. Contact precautions have been associated with decreased rates of MRSA infection in NICU patients. Studies in other patient populations (predominantly adults undergoing peritoneal dialysis) found increased rates of gram-negative infection in those receiving mupirocin treatment. However, a recent multicenter study of mupirocin use in the NICU found a 64% decrease in gram-positive infections, with no change in gram-negative infection rates, among 384 treated infants.

**Bibliography**

Pierce R, Bryant K, Elward A, et al. Bacterial infections in

Infections are a frequent and important cause of neonatal morbidity and mortality. **Congenital** or intrauterine infections (i.e., those transmitted across the placenta) and **perinatal** infections (i.e., those transmitted from the mother to the fetus or newborn infant during the birth process) represent 2 major routes of neonatal infection.

### 131.1 Congenital Infections

As many as 2% of fetuses are infected in utero; disease can be acquired prenatally from a wide variety of etiologic agents, including bacteria, viruses, fungi, and protozoa. Clinical manifestations can range from asymptomatic or subclinical to life-threatening disease. History and physical examination findings provide insight into the best approach for this immunologically immature population. (See Fig. 129.2 and Table 129.2 in Chapter 129.)

**General Approach**

Infectious as well as noninfectious processes, such as underlying congenital
heart disease, genetic disorders, and inborn errors of metabolism, should be considered in the differential diagnosis of congenital and perinatal infections. Because maternal infection is a prerequisite for infection in the fetus, a thorough history is essential to assess the mother for her symptoms, travel, diet, medication use, occupational exposures, and any sexually transmitted infections (STIs) during pregnancy. Clinical manifestations are varied and overlap for many of the pathogens causing intrauterine infection. Laboratory testing and/or radiologic imaging is often required to confirm the diagnosis. Treatment depends on the specific pathogen and can range from symptomatic management with close follow-up for long-term sequelae to targeted antimicrobial therapy.

**Pathogenesis**

The route and timing of infection can provide helpful clues as to the potential infectious etiology ([Fig. 131.1](#) and [Table 131.1](#)). First-trimester infection may alter embryogenesis and result in malformations of the heart and eyes, as seen in congenital rubella syndrome. Third-trimester infection (e.g., congenital toxoplasmosis) can result in active infection with signs of hepatomegaly, splenomegaly, and generalized lymphadenopathy at birth. Infections that occur late in gestation (e.g., congenital syphilis) may lead to a delay in clinical manifestations until weeks to years after birth.

Clinical Manifestations

The clinical manifestations of intrauterine infections can range from asymptomatic to severe multiorgan system complications. For some agents (e.g.,
CMV, *T. pallidum*), ongoing injury after birth leads to late sequelae. The specific clinical signs in the newborn period are usually not sufficient to make a definitive diagnosis but are useful to guide more specific laboratory testing. Symptomatic congenital infections often affect the central nervous system (CNS; brain and eyes) and the reticuloendothelial system (RES; bone marrow, liver, and spleen). Table 131.2 presents the clinical manifestations of some specific congenital infections. Congenital Zika virus infection has features that are rarely seen with other congenital infections (Table 131.3). No hematologic or hepatic laboratory abnormalities have been documented in infants with congenital Zika virus infection. Table 131.4 provides late sequelae of some congenital infections.

### Diagnosis

**During Pregnancy**

The presence of IUGR or a physical abnormality on a prenatal fetal ultrasound raises concern for a congenital infection. The well-known acronym TORCH — *Toxoplasma gondii*, *O* ther (*Treponema pallidum*, human parvovirus B19, HIV, Zika virus, others), *R* ubella, *C* ytomegalovirus, and *H* erpes simplex virus (HSV)—is a useful mnemonic. However, the routine ordering of TORCH serology panels is *not* recommended because the presence of a TORCH agent IgG antibody in the mother indicates past infection but does not establish if the infection occurred during pregnancy. Maternal IgM titers to *specific* pathogens are only moderately sensitive, and a negative result cannot be used to exclude infection.

In certain cases, a fetal blood sample with cordocentesis can be obtained and tested for total and pathogen-specific IgM assays, polymerase chain reaction
assays (PCRs), or cultures. A total IgM concentration is a helpful screening test because a normal fetal IgM is <5 mg/dL, so any elevation in total IgM may indicate an underlying infection. A positive pathogen-specific IgM test is strongly suggestive of infection, but a negative test does not rule out the organism as the cause of the fetopathy. Amniotic fluid can also be obtained and sent for PCR or culture. The presence of CMV, *T. gondii*, or human parvovirus B19 in amniotic fluid indicates the fetus likely is infected but cannot establish the severity of disease. Although HSV is included in the TORCH acronym, it is rarely isolated from amniotic fluid and is rarely transmitted across the placenta from mother to fetus. Fetal blood can be collected to test for human parvovirus B19 IgM and PCR.

**Newborn Infant**

When a congenital infection is suspected because clinical signs are present, a complete blood count with differential and platelet count along with measurements of transaminases and total/direct bilirubin are routinely performed. Additional evaluations may include a dilated funduscopic examination, auditory brainstem response (ABR) for those failing the newborn hearing screen, and CNS imaging. If available, pathologic examination of the placenta may be informative. Infectious diseases consultation is valuable in guiding the evaluation.

Neonatal antibody titers for specific pathogens are often difficult to interpret because IgG is acquired from the mother by transplacental passage, and a positive result may reflect the mother's past infection and not infection of the newborn. Neonatal IgM antibody titers to specific pathogens have high specificity and only moderate sensitivity; a negative result cannot be used to exclude infection. Paired maternal and fetal-neonatal IgG antibody titers showing higher or rising infant IgG antibodies can diagnose some congenital infections (e.g., syphilis). Total cord blood IgM and IgA are not actively transported across the placenta to the fetus and are not specific for intrauterine infection.

Although viral culture has long been considered the standard for CMV and other viral infections, PCR is sensitive, specific, and now widely accepted. The Palo Alto Medical Foundation Toxoplasma Serology Laboratory (PAMF-TSL; Palo Alto, CA: [www.pamf.org/serology/](http://www.pamf.org/serology/); telephone: (650) 853-4828; e-mail: toxolab@pamf.org) offers specialized tests and physician experts to aid in the
diagnosis of congenital toxoplasmosis. If there is concern for congenital Zika virus infection, healthcare providers should refer to the Centers for Disease Control and Prevention (CDC) Guidance for US Laboratories Testing for Zika Virus Infection (www.cdc.gov/zika/laboratorie/lab-guidance.html) to assist in collecting and sending appropriate laboratory tests from the mother, newborn infant, placenta, and umbilical cord. Currently, testing for Zika virus with real-time reverse-transcription PCR (rRT-PCR) and IgM enzyme-linked immunosorbent assay (ELISA) from neonatal urine and serum specimens is recommended. However, the most reliable method of testing has not been established. In endemic areas, this workup should be done within 2 days of delivery because it is difficult to distinguish congenital from postnatal infection if testing is done later.

**Specific Infectious Agents**

Important congenital infections include more than the TORCH agents. The following is a list of pathogens that may be transmitted across the placenta and the respective chapters where they are discussed in more detail, including treatment.

**Bacteria**

*Listeria monocytogenes* (Chapter 215)  
Syphilis (*Treponema pallidum*) (Chapter 245)

**Viruses**

Cytomegalovirus (Chapter 282)  
Hepatitis B (Chapter 385)  
Hepatitis C (Chapter 385)  
Herpes simplex virus (Chapter 279)  
Human immunodeficiency virus (Chapter 302)  
Human parvovirus B19 (Chapter 278)  
Lymphocytic choriomeningitis virus (Chapter 298)  
Rubella (Chapter 274)
Perinatal infections are defined as those that are transmitted from the mother to the fetus or newborn infant during the birth process. Despite recommended universal screening of pregnant women for *Chlamydia trachomatis* and gonorrhea, transmission to the newborn still occurs. In addition to these STIs, other bacteria, viruses, and *Candida* spp. may cause perinatal infections. Similar to congenital infections, their presentation can range from asymptomatic to a sepsis-like syndrome.

**General Approach**

The general approach is similar to that for congenital infections and includes a detailed maternal history and a careful examination of the newborn (see Chapter 129). Many clinical syndromes overlap, and therefore laboratory testing is usually required to establish a specific microbiologic etiology and guide management decisions.

**Pathogenesis**
The human birth canal is colonized with aerobic and anaerobic bacteria. **Ascending amniotic infection** may occur with either apparently intact membranes or relatively brief duration of membrane rupture. Infectious agents can also be acquired as the newborn infant passes through the vaginal canal. This acquisition may result in either colonization or disease. Factors influencing which colonized infants will experience disease are not well understood but include prematurity, underlying illness, invasive procedures, inoculum size, virulence of the infecting organism, genetic predisposition, the innate immune system, host response, and transplacental maternal antibodies.

**Chorioamnionitis** has been historically used to refer to microbial invasion of the amniotic fluid, often as a result of prolonged rupture of the chorioamniotic membrane for >18 hr. The term *chorioamnionitis* is confusing because it does not convey the spectrum of inflammatory or infectious diseases, it leaves out other intrauterine components that can be involved (e.g., decidua), and it results in significant variability in clinical practice, with the potential for a significant number of well newborns being exposed to antimicrobial agents. The term **intrauterine inflammation or infection at birth**, abbreviated as **Triple I**, has become more accepted because of the heterogeneous nature of conditions that can affect the mother and neonate (**Table 131.5**). Regardless of the definition used, prematurity (<37 wk) is associated with a greater risk of early-onset sepsis, especially with group B streptococcus.

Adapted from Higgins RD, Saade G; Chorioamnionitis Workshop participants: Evaluation and management of women and newborns with a maternal diagnosis of chorioamnionitis: summary of
Aspiration or ingestion of bacteria in amniotic fluid may lead to congenital pneumonia or systemic infection, with manifestations becoming apparent before delivery (fetal distress, tachycardia), at delivery (failure to breathe, respiratory distress, shock), or after a latent period of a few hours (respiratory distress, shock). Aspiration or ingestion of bacteria during the birth process may lead to infection after an interval of 1-2 days.

Clinical Manifestations

Most perinatal infections present clinically during the 1st mo of life. Initial signs and symptoms may be either nonspecific or focal (see Chapter 129 ). Additional information on specific infectious agents and their management are reviewed in the chapters indicated below.

Specific Infectious Agents

Bacteria

*Chlamydia trachomatis* (Chapter 253 )
*Escherichia coli* (Chapter 227 )
Genital mycoplasmas (Chapter 251 )
Group B streptococci (Chapter 211 )
*Neisseria gonorrhoeae* (Chapter 219 )
Syphilis (*Treponema pallidum*) (Chapter 245 )

Viruses

Cytomegalovirus (Chapter 282 )
Enteroviruses (Chapter 277 )
Hepatitis B (Chapter 385 )
Herpes simplex virus (Chapter 279 )
Human immunodeficiency virus (Chapter 302 )
Fungi

*Candida* spp. *(Chapter 261)*

**Diagnosis**

The maternal history provides important information about maternal exposures to infectious diseases, bacterial colonization, immunity (natural and acquired), and obstetric risk factors (prematurity, prolonged ruptured membranes, chorioamnionitis). STIs acquired by a pregnant woman, including syphilis, *N. gonorrhoeae*, and *C. trachomatis*, have the potential for perinatal transmission.

Neonates with perinatal infections often present with nonspecific symptoms and signs; therefore the general diagnostic evaluation for the ill neonate as discussed in Chapter 202 should be followed. Table 131.6 provides a summary of laboratory tests that are useful to diagnose specific perinatal infections.

Chapter 147 Chronic Overlapping Pain Conditions
During the preteen, teenage, and young adult years, young people undergo not only dramatic changes in physical appearance, but also rapid changes in physiologic, psychological, and social functioning. Hormonally driven physiologic changes and ongoing neurologic development occur in the setting of social structures that foster the transition from childhood to adulthood. This period of development comprises adolescence, which is divided into 3 phases—early, middle, and late adolescence—each marked by a characteristic set of biologic, cognitive, and psychosocial milestones (Table 132.1). Although individual variations in the timing and pace of development undoubtedly exist, these changes follow a fairly predictable pattern of occurrence. Gender and culture profoundly affect the developmental course, as do physical, social, and environmental influences. Given the interaction of these domains, a biopsychosocial perspective is best suited to approach the healthcare of the adolescent.

Physical Development

**Puberty** is the biologic transition from childhood to adulthood. Pubertal changes include the appearance of the secondary sexual characteristics, increase in height, change in body composition, and development of reproductive capacity. Adrenal production of androgen, mainly dehydroepiandrosterone sulfate (DHEAS), may occur as early as 6 yr of age, with development of underarm odor and faint genital hair (adrenarche). Maturation of the gonadotropin-releasing hormone (GnRH) pulse generator is among the earliest neuroendocrine changes associated with the onset of puberty. Under the influence of GnRH, the pituitary gland secretes luteinizing hormone (LH) and follicle-stimulating hormone (FSH); initially this occurs in a pulsatile fashion primarily during sleep, but this diurnal variation diminishes throughout puberty. LH and FSH stimulate corresponding increases in gonadal androgens and estrogens. The triggers for these changes are incompletely understood but may be mediated in part by the hormone leptin, high concentrations of which are associated with increased body fat and earlier onset of puberty. Both genetic and environmental (epigenetic) contributions to the regulation of pubertal timing are likely.

Sexual Development

The progression of the development of the secondary sex characteristics may be described using the sexual maturity rating (SMR) scale (ranging from 1, preadolescence, to 5, sexual maturity), or Tanner stages. Figs. 132.1 and 132.2 depict the physical findings of breast and pubic hair maturation at each SMR (Tables 132.2 and 132.3). Although the ages at which individual pubertal changes occur may vary, the timing and sequence of these changes relative to one another is predictable (Figs. 132.3 and 132.4). The wide range of normal progress through sexual maturation is affected by genetics, the psychosocial environment, nutrition, and overall health status. Environmental exposures may play a role as well.

**FIG. 132.3** Sequence of pubertal events in males. Although the age of
onset of puberty is variable, the sequence of events relative to one another is predictable. SMR, Sexual maturity rating.

In males the first visible sign of puberty and the hallmark of SMR 2 is testicular enlargement, beginning as early as 9.5 yr, followed by the development of pubic hair. This is followed by penile growth during SMR 3. Peak growth occurs when testis volumes reach approximately 9-10 cm³ during SMR 4. Under the influence of LH and testosterone, the seminiferous tubules, epididymis, seminal vesicles, and prostate enlarge. Sperm may be found in the urine by SMR 3; nocturnal emissions may be noted at this time as well. Some degree of breast tissue growth, typically bilateral, occurs in 40–65% of males during SMR 2-4 as a presumed consequence of a relative excess of estrogenic stimulation. This usually resolves with ongoing maturation.

In females, typically the first visible sign of puberty and the hallmark of
SMR 2 is the appearance of breast buds (thelarche), between 7 and 12 yr of age. A significant minority of females develops pubic hair (pubarche) prior to thelarche. Less visible changes include enlargement of the ovaries, uterus, labia, and clitoris and thickening of the endometrium and vaginal mucosa. A clear vaginal discharge may be present before menarche (physiologic leukorrhea). Menses typically begins within 3 yr of thelarche, during SMR 3-4 (average age 12.5 yr; normal range 9-15 yr) (see Fig. 132.4). The timing of menarche is determined largely by genetics; contributing factors likely include adiposity, chronic illness, nutritional status, and the physical and psychosocial environment. Early menstrual cycles often are anovulatory and thus somewhat irregular, but typically occur every 21-45 days and include 3-7 days of bleeding, even during the 1st year following menarche.

The onset of puberty and menarche appear to be occurring at earlier ages than previously reported in the United States. Several studies from 1948–1981 identified the average age for the onset of breast development as ranging from 10.6-11.2 yr of age. Multiple reports since 1997 suggest a significantly earlier average age of onset, ranging from 8.9-9.5 yr in black females to 10.0-10.4 yr in white females. Almost 25% of black females and 10% of white females initiate breast development by 7 yr of age. Early breast development may be associated with a slower tempo of puberty (i.e., longer time to menarche). There also appears to be a trend toward decreasing ages for the onset of pubic hair development and menarche. Data from the National Health and Nutrition Examination Survey (NHANES), a nationally representative, longitudinal survey in the United States, show a decline in the average age of menarche of 4.9 mo between the 1960s and 2002. Changes in the timing of menarche within ethnic groups, however, were significantly smaller. The larger change seen in the population as a whole may be partially explained by changes in the ethnic makeup of the sample. The reasons for the larger decrease in age for breast development have been postulated to include the epidemic of childhood obesity as well as exposure to estrogen-like environmental toxins (endocrine disruptors), but further research in this area is needed.

Although fewer data are available on changes in the timing of puberty in males, they appear to be experiencing a similar trend. Although the method of assessing the onset of puberty (i.e., inspection vs. palpation of the testes) varies between studies, it appears that the average age for the onset of genital and pubic hair development may have decreased by 1-2 yr over the past several decades in many industrialized countries. Evidence for an association of obesity with the
timing of puberty in males has been inconsistent.

**Somatic Growth**

Linear growth acceleration begins in early adolescence for both genders, with 15–20% of adult height accrued during puberty. Females attain a peak height velocity (PHV) of 8-9 cm/yr at SMR 2-3, approximately 6 mo before menarche. Males typically begin their growth acceleration at a later SMR stage, achieve a PHV of 9-10 cm/yr later in the course of puberty (SMR 3-4), and continue their linear growth for approximately 2-3 yr after females have stopped growing (Fig. 132.5). The growth spurt begins distally, with enlargement of the hands and feet, followed by the arms and legs, and finally the trunk and chest. This growth pattern imparts a characteristic “awkward” appearance to some early adolescents. Body composition changes as well, after attainment of PHV. Males undergo an increase in lean body mass (“strength spurt”), whereas females develop a higher proportion of body fat. Scoliosis, if present, may progress with rapid axial skeleton growth (see Chapter 699.1). From 50–65% of total body calcium is laid down during puberty. Bone growth precedes increases in bone mineralization and bone density, which may increase the adolescent's risk of fracture during times of rapid growth. Since skeletal growth precedes muscle growth, sprains and strains may be more common during this time as well.

![FIG. 132.5](image-url) Height velocity curves for American males (solid line) and females (dashed line) who have their peak height velocity at the average age (i.e., average growth tempo). (From Tanner JM, Davies PSW: Clinical longitudinal standards for height and height velocity for North American
Cardiovascular changes in middle adolescence include increased heart size, higher blood pressure, and increases in blood volume and hematocrit, particularly in males. Coupled with an increase in lung vital capacity, these changes lead to greater aerobic capacity. Androgenic stimulation of sebaceous and apocrine glands may result in acne and body odor. Rapid enlargement of the larynx, pharynx, and lungs leads to changes in vocal quality in males, typically preceded by vocal instability (voice cracking). Elongation of the optic globe may result in the development of myopia (see Chapter 638). Dental changes include jaw growth, loss of the final deciduous teeth, and eruption of the permanent cuspids, premolars, and finally, molars (see Chapter 333). Orthodontic appliances may be needed, secondary to growth exacerbations of bite disturbances. Physiologic changes in sleep patterns and increased sleep requirements occur, causing many adolescents to delay sleep onset at night, with subsequent difficulty awakening for early school start times in the morning (see Chapter 31).

**Neurologic, Cognitive, and Moral Development**

As children progress through adolescence, they develop and refine their ability to use formal operational thought processes. Abstract, symbolic, and hypothetical thinking replaces the need to manipulate concrete objects. Middle and late adolescents develop the ability to consider multiple options and to assess the long-term consequences of their actions. The capacity for verbal expression is enhanced. Since adolescents' decision-making and subsequent behaviors are the primary determinants of their mortality and morbidity, understanding these cognitive processes is of critical importance.

Both structural and functional brain development continue throughout adolescence. Cortical gray matter volume peaks in preadolescence, then decreases because of selective “pruning” of rarely used synaptic connections. Cerebral white matter volume increases until mid-to-late adolescence, reflecting increasing myelination and subsequent facilitation of integrated brain activity and more efficient transmission of information between different regions of the brain, enhancing the “signal-to-noise” ratio. Although the frontal lobes and
prefrontal cortex, regions of the brain associated with executive function, have been considered to be among the last regions to mature, other cortical regions show similarly prolonged trajectories of maturation. Without question, adolescents are capable of the complex cognitive processes attributed to frontal lobe function. *Cognitive control*, however, continues to improve into adulthood, with progressive maturation and *integration* of component processes such as working memory, inhibition and impulse control, performance monitoring, and motivational circuitry.

The behavioral correlates of adolescent neurodevelopment remain speculative but are increasingly supported by a rapidly expanding body of research. Adolescents appear to demonstrate a unique sensitivity to the effects of dopamine on reward-relevant subcortical structures such as the ventral striatum, with some studies demonstrating increased activation in this region when receiving rewards, relative to children or adults. Other studies show reduced responsiveness to aversive stimuli in adolescents. This altered responsiveness to risk vs reward may underlie the increased risk taking and novelty seeking seen in adolescents. Early maturation and distinct patterns of neural reactivity in the amygdala and other limbic structures may explain the strong role that social and emotional stimuli play in adolescents, overwhelming the frontal executive function systems that facilitate the interpretation and regulation of those social and emotional experiences. This may explain why adolescents are more likely to make poor decisions in highly emotionally charged situations, relative to mature adults. These “hot cognition” processes may result in the adolescent making a different decision in the context of a strong affective experience than he or she would in a less emotional state (“cool cognition”). These 2 types of cognitive processes may not develop at the same rate; the adolescent may be able to use higher brain structures and functions more effectively when in states of lower emotional arousal.

**Early** adolescents often continue to employ the concrete operational cognitive processes of childhood. Although formal operational cognition is developing, it may be applied inconsistently across different domains. A young adolescent may be able to use abstract thought when completing schoolwork, but not when working through a personal dilemma. Early adolescence also is characterized by egocentricity—the belief of some adolescents that they are the center of everyone's attention. Despite being largely imagined, this perception of always being “on stage” can be stressful for adolescents, who may feel that others are constantly judging or evaluating them. Early adolescents express a greater need
for privacy than they did in childhood and begin to appreciate the privacy of their own thoughts. With ongoing cognitive development, middle adolescents are more able to consider the needs and feelings of other people. Their creativity and intellectual abilities are enhanced. Because of their increased capacity for abstract thought in combination with a persistent perception of uniqueness, middle adolescents may feel a sense of immortality and immunity to the consequences of risky behaviors. Late adolescents are more future oriented and able to delay gratification. They can think more independently, consider others' views, and compromise. They have a stronger sense of self and more stable interests. Under times of stress, adolescents may temporarily revert back to the cognitive processes and coping strategies used at younger ages.

Moral development generally accompanies cognitive development. Preadolescents, concrete and individualistic, follow rules in order to please authority figures and avoid punishment. As they move into early adolescence, they develop a stronger sense of right and wrong but are likely to perceive these as absolute and unquestionable. Middle and late adolescents may establish a sense of morality driven by their desire to be seen as a good person, to behave in a manner according to their perceived place in society, or by their sense of obligation to care for others. Moral decision-making, however, still may be highly subject to emotional context. Late adolescents may develop a rational conscience and an independent system of values, although these often are largely consistent with parental values. While going through this complex developmental process, religious or political organizations that promote simple answers to complex social or moral questions may hold great appeal to the adolescent.

Psychosocial Development

In contrast to cognitive development, psychosocial development correlates more strongly with pubertal status and physical maturation than with chronologic age. Whereas cognitive development is more biologically determined, psychosocial development is subject to greater environmental and cultural influences. Indeed, cultural variation can be dramatic. Some late adolescents move immediately from high school into marriage, childbearing, working, and financial independence; others remain dependent on the parents while pursuing their own education for several more years, in a period sometimes referred to as emerging adulthood. Psychosocial development also may be nonlinear, with different
domains of growth progressing along different timelines. An overriding theme of psychosocial development is the concept of identity formation and consolidation as the adolescent moves away from the nurturing protection of the family, develops an increased affiliation with the peer group(s), and ultimately defines himself or herself as an individual.

**Separation from the parents** is a hallmark of adolescent development. Early adolescents start to seek out more privacy at home, spending less time with the parents. They begin to reject parental advice and involvement in their decision-making as they explore the boundaries of their dependence on, and independence from, their parents. With evolving cognitive skills, an adolescent can conceive of an ideal parent and contrast this ideal with his or her own parents. Adolescents may seek out alternative adult role models, such as teachers, coaches, or parents of friends. Parent–child conflict often peaks during middle adolescence, with disagreements over privileges, independence, and other limits set by the parents. Adolescents may appear intermittently to seek and reject parental acceptance. It is theorized that perhaps the adolescent needs to conceive of the parents as “wrong” in order to ameliorate the pain of separating from them. Throughout this time, however, the parents remain a critical source of nurturing and support for the adolescent and continue to exert significant influence over the adolescent's decision-making. Paradoxically, frequent arguments and conflict may coexist with strong emotional bonds and closeness. The late adolescent may reestablish a more “adult–adult” type of relationship with the parents, once again seeking out and considering parental advice and guidance as they enter adulthood.

Increasing importance of the **peer group** also may buffer the emotional trauma of separating from the parents. Early adolescents tend to socialize largely with same-sex peers, both in their individual friendships and larger groups. Females' peer groups tend to be more relationship oriented, whereas males' peer groups are more likely to be centered around a particular interest or activity. In both cases, group cohesion and a sense of belonging become important. Peers become increasingly important in middle adolescence, during which time the adolescent may experiment with being a part of different groups and “try on” different identities. These groups may include both sexes. Peer groups may arise from organized activities, such as sports or clubs, or may simply be friendship based. Gang membership is another form of peer acceptance. **Conformity** with the peers in manners of dress, speech, and behavior is a normal part of this process, and should not necessarily be viewed negatively. Similarly, **peer**
pressure may exist, but its influence over the adolescent's decision-making may be positive, negative, or negligible. Acceptance and successful navigation of peer groups during adolescence may give the individual more confidence to move into and out of various social, academic, and professional groups in the future. Late adolescents are less vulnerable to peer group influence, having moved closer to establishing their own stable identity. Their cognitive skills allow them to choose selectively among different peer groups, endorsing and adopting individual values and behaviors that best reflect who they are becoming.

Early adolescents have increased sexual awareness and interest, which may manifest as sexual talk and gossip, and often is focused on sexual anatomy. Masturbation and other sexual exploration, sometimes with same-sex peers, are common. The prevalence of other forms of sexual behavior varies by culture; in general, these behaviors are less common in early adolescents. Romantic relationships, if they exist at all, lack emotional depth. Sexual curiosity, experimentation, and activity become more common among middle adolescents. Same-sex attraction is common; sexual orientation may become clear to some adolescents, but still may be evolving in others during this time. Dating behaviors may be seen, but this is culture dependent and may not be a popular construct for all adolescents. Individual relationships often continue to emphasize sexual attraction over emotional intimacy; the latter may not be seen until late adolescence. At that time, relationships increasingly involve love and commitment and demonstrate greater stability.

Body image may affect (and be affected by) adolescents' psychosocial development as well. Early and middle adolescence are usually the ages at which poor or distorted body image and eating disorders develop. Early adolescents undergo rapid physical changes and may experience uncertainty about whether all these anatomic and physiologic changes are progressing normally. Reassurance from adults, including their healthcare providers, may be comforting. As puberty comes to an end and these changes slow, the middle adolescent's preoccupation may shift to whether the adolescent is attractive to others. A strong emphasis on physical appearance during this time is normal. Although this focus on physical appearance may continue into adulthood, late adolescence generally is characterized by a shifting balance toward introspection, with somewhat less emphasis placed on external characteristics.

The timing of pubertal changes also can affect psychosocial development and well-being. The progression of pubertal changes in males is generally
associated with a positive self-image. Females may initially perceive these changes in their physical appearance more negatively. This appears to be especially true for early-maturing females, some of whom experience greater decreases in self-esteem, engage in more disruptive behaviors, and have more conflict with their parents than do on-time or late-maturing females. Perhaps because they are more comfortable associating with older peers, early-maturing females are vulnerable to making poor decisions when exposed to high-risk situations, still lacking the cognitive skills to effectively navigate these situations. Early-maturing males tend to have greater self-confidence, social, and academic success, while later-maturing males are at risk for more internalizing behaviors and diminished self-esteem. Many other factors influence how adolescents experience puberty, and supportive peers and adults can have a positive impact on psychosocial development. With successful navigation of these domains, emerging adults move into the world with a strong sense of personal identity and their place in society. They are able to work toward a vocation and financial independence and to manage the responsibilities of adulthood.

**Implications for Providers, Parents, and Policymakers**

Providers can help parents approach their child's adolescent years by reframing some of the “challenges” of adolescence as normal developmental milestones that should be anticipated and accepted. Puberty and emerging sexuality should be approached as positive and health-affirming life changes, rather than focusing discussions only on the negative reproductive risks and outcomes. Even good-natured teasing about bodily changes can be detrimental to the adolescent's self-image. Early-maturing females and late-maturing males should be supported, recognizing their potential increased risk for psychosocial challenges. Emerging positive coping strategies should be promoted in all youth, particularly those with chronic illness or other challenges. Providers need to determine the young adolescent's cognitive development and capacity for abstract thought and tailor their communication and counseling style accordingly. Physical examinations should be performed in private with the parent outside the exam room (provided the adolescent is comfortable with this), which also affords the adolescent and provider an opportunity to discuss confidential issues. Reassurance of normal
development should be provided.

As adolescents develop more independence and parent–child conflict peaks, providers should remind parents that this is typical, and that arguing does not mean the adolescent does not value the parents' input and perspectives. Although some may rebel initially, most adolescents ultimately adopt a value system very similar to that of their parents. Even if discussions feel ineffective to parents, they should continue to demonstrate and model these values to their child. Similarly, rather than categorically dismissing their child's “negative” interests, such as playing a violent video game, parents should be encouraged to use these opportunities to model critical thinking about the impact of such an activity. Potentially negative peer groups may be approached the same way, while fostering the development of positive peer networks. Authoritative parenting, in which clear and appropriate negotiated limits are set in the context of a caring and mutually respectful parent–child relationship, is most strongly associated with positive psychosocial development. Parental connectedness and close supervision or monitoring of the youth's activities and peer group can be protective against early onset of sexual activity and involvement in other risk-taking behaviors and can foster positive youth development. Parents should also assume an active role in their adolescent's transition to adulthood to ensure that their child receives appropriate preventive health services.

Parents and providers may each work with adolescents to foster good decision-making. In addition to providing adolescents with accurate and complete health information, the adolescent's cognitive ability to use this information in various contexts must be considered. Adolescents may find themselves needing to make important decisions in highly charged situations where they may be unable to manage their emotions and use their higher cognitive functions to examine the consequences of their decision. For example, a couple in a sexual situation with high emotional arousal may make the decision to proceed with unprotected intercourse. By anticipating this situation ahead of time, under conditions of lower emotional arousal, and making a plan to deal with this, they may make a different decision (e.g., stick with their prior decision never to have sex without protection), when the time comes. Parents and healthcare providers are in a position to encourage and foster this anticipation and planning under conditions of “cool cognition.”

Providers may need to help parents distinguish normal adolescent development and risk-taking behaviors from possible signs of a more serious mental health or conduct problem. Bids for autonomy, such as avoiding family
activities, demanding privacy, and increasing argumentativeness, are normal; extreme **withdrawal** or **antagonism** may be dysfunctional, signaling a mental health or substance use concern. Bewilderment and dysphoria at the start of middle school are normal; continued failure to adapt several months later suggests a more serious problem. Although some degree of risk taking is normal, progressive escalation of risk-taking behaviors is problematic. In general, when the adolescent's behaviors cause significant dysfunction in the domains of home life, academics, or peer relationships, they should be addressed by the parents and healthcare provider, and referral to a mental health provider may be considered. In most cases, parents can be reassured that although adolescence can pose unique challenges, their adolescent, like most adolescents, will come through it to become a successful and happy adult.

At national and international levels, adolescents are at risk for environmental, health, behavioral, and societal challenges. Table 132.4 provides suggestions to address these issues.

CHAPTER 133

Gender and Sexual Identity

Walter O. Bockting

Terms and Definitions

Sex and Sexual Identity

Sex is multifaceted, with at least 9 components: chromosomal sex, gonadal sex, fetal hormonal sex (prenatal hormones produced by the gonads), internal morphologic sex (internal genitalia), external morphologic sex (external genitalia), hypothalamic sex (sex of the brain), sex of assignment and rearing, pubertal hormonal sex, and gender identity and role. Sexual identity is a self-perceived identification distilled from any or all aspects of sexuality and has at least 4 components: sex assigned at birth, gender identity, gender expression, and sexual orientation.

Sex Assigned at Birth

A newborn is assigned a sex before (typically through ultrasound) or at birth based on the external genitalia (natal sex). In case of a disorder of sex development (intersex), these genitalia may appear ambiguous, and additional components of sex (e.g., chromosomal, gonadal, hormonal sex) are assessed. In consultation with specialists, parents assign the child a sex that they believe is most likely to be consistent with gender identity, which cannot be assessed until later in life (see Chapter 606).

Gender Terms

Gender identity refers to a person's basic sense of being a boy/man, girl/woman, or other gender (e.g., transgender, genderqueer, nonbinary, gender
fluid). **Gender role** refers to one's role in society, typically the male or female role. Gender identity needs to be distinguished from **gender expression**, which refers to characteristics in personality, appearance, and behavior that are, in a given culture and time, considered masculine or feminine. Gender role is about one's presentation as a boy/man or girl/woman, whereas gender expression is about the masculine and/or feminine characteristics one exhibits in a given gender role. Both boys/men, girls/women, and transgender, genderqueer, or nonbinary persons can be masculine and/or feminine to varying degrees; gender identity and gender expression are not necessarily congruent. A child or adolescent might be **gender nonconforming**, that is, a predominantly feminine boy or a predominantly masculine girl.

**Sexual Orientation and Behavior**

**Sexual orientation** refers to attractions, behaviors, fantasies, and emotional attachments toward men, women, or both. **Sexual behavior** refers to any sensual activity to pleasure oneself or another person sexually.

**Transgender**

**Transgender** people are a diverse group of individuals whose gender identity differs from their sex assigned at birth. They include **transsexuals** (usually referred to as transgender) (who typically live in the other gender role and seek hormonal and/or surgical interventions to modify primary or secondary sex characteristics); **cross-dressers** (who wear clothing and adopt behaviors associated with the other sex for emotional or sexual gratification and may spend part of the time in the other gender role); **drag queens** and **kings** (female and male impersonators); and individuals identifying as **genderqueer** (differently gendered), **nonbinary** (neither male nor female, both, or in-between), or **gender fluid** (not fixed but changing). Transgender individuals may be attracted to men, women, or other transgender persons.

**Factors That Influence Sexual Identity Development**

During prenatal sexual development, a gene located on the **Y chromosome** (*XRY*
induces the development of testes. The hormones produced by the testes direct sexual differentiation in the male direction resulting in the development of male internal and external genitalia. In the absence of this gene in XX chromosomal females, ovaries develop and sexual differentiation proceeds in the female direction, resulting in female internal and external genitalia. These hormones may also play a role in sexual differentiation of the brain. In disorders of sex development, chromosomal and prenatal hormonal sex varies from this typical developmental pattern and may result in ambiguous genitalia at birth.

Gender identity develops early in life and is typically fixed by 2-3 yr of age. Children first learn to identify their own and others’ sex (gender labeling), then learn that gender is most often stable over time (gender constancy), and finally learn that gender is typically permanent (gender consistency). What determines gender identity remains largely unknown, but it is thought to be an interaction of biologic, environmental, and sociocultural factors.

Some evidence shows the impact of biologic and environmental factors on gender expression, whereas their impact on gender identity remains less clear. Animal research shows the influence of prenatal hormones on sexual differentiation of the brain. In humans, prenatal exposure to unusually high levels of androgens in girls with congenital adrenal hyperplasia is associated with more masculine gender expression, transgender identity, and same-sex sexual orientation, but cannot account for all the variance found (see Chapter 594). Research on environmental factors has focused on the influence of sex-typed socialization. Gender-based stereotypes develop early in life. Until later in adolescence, boys and girls are typically socially segregated by gender, reinforcing sex-typed characteristics such as boys’ focus on “rough-and-tumble play” and asserting dominance, and girls focus on verbal communication and creating relationships. Parents, other adults, teachers, peers, and the media serve as gender-socializing role models and agents by treating boys and girls differently.

For information on the development of sexual orientation, see Chapter 134.

Nonconformity in Gender Expression Among Children and Adolescents

Prevalence
Nonconformity in gender expression needs to be distinguished from a transgender identity. The former operates on the level of personality, appearance, and behavior (masculinity, femininity), whereas the latter is about self-perceived, core gender identity. Nonconformity in gender expression is more common among girls (7%) than boys (5%), but boys are referred more often than girls for concerns regarding gender identity and expression. This is likely a result of parents, teachers, and peers being less tolerant of gender nonconformity in boys than in girls.

Nonconformity in gender expression as part of exploring one's gender identity and role is part of normal sexual development. Gender nonconformity in childhood may or may not persist into adolescence. Marked gender nonconformity in adolescence often persists into adulthood. Only a minority of gender-nonconforming children develop an adult transgender identity; most develop a gay or lesbian identity, and some, a heterosexual identity.

**Etiology of Gender-Nonconforming Behavior**

Prenatal hormones play a role in the development of nonconformity in gender expression, but cannot completely account for all the variance. A heritable component of gender-nonconforming behavior likely exists, but twin studies indicate that genetic factors also do not account for all of the variance. Family-of-origin factors hypothesized to play a role in the development of gender nonconformity lack empirical support. Maternal psychopathology and emotional absence of the father are the only possible factors associated with gender nonconformity, yet it is unclear whether these factors are cause or effect.

**Stigma, Stigma Management, and Advocacy**

Gender nonconforming children are subject to ostracism and bullying (see Chapter 14.1) from peers, which may negatively impact their psychosocial adjustment and lead to social isolation, loneliness, low self-esteem, depression, suicide, and behavioral problems. To assist children and families, individual stigma management strategies, as well as interventions to change the environment, can be offered. Stigma management might involve consultation with a health professional to provide support and education, normalizing gender-nonconforming behavior and encouraging the child and family to build on the child's strengths and interests to foster self-esteem. It might also involve making
choices about certain preferences (e.g., a boy who likes to wear feminine attire) to limit these to times and environments that are more accepting. *Most health professionals agree that too much focus on curtailing gender-nonconforming behavior leads to increased shame and undermines the child's self-esteem.*

The health professional and family can also assist the child or adolescent to find others with similar interests (within and beyond the gender-related interests) to strengthen positive peer support. Equally important are interventions in school and society to raise awareness and promote accepting and positive attitudes, take a stand against bullying and abuse, and implement antibullying policies and initiatives. *Gay, lesbian, bisexual, transgender, and straight alliance groups are helpful in providing a haven for gender-nonconforming youth, as well as recognizing them as part of diversity to be respected and embraced within the school system.* Healthcare system level approaches are outlined in Table 133.1.

Culturally competent care is provided to LGBTQ youth of color, and services are available for patients who are not native English speaking. Services are provided free-of-charge for uninsured LGBTQ youth. |

### Transgender and Gender-Nonconforming Identities Among Children and Adolescents

#### Prevalence

Approximately 1% of parents of 4-11 yr old boys report that their son wished to be of the other sex, with 3.5% for 4-11 yr old girls. Only a minority of children's gender identity concerns persist into adolescence (20% in one study of boys). Persistence of gender identity concerns from adolescence into adulthood is higher; the majority identify as transgender in adulthood and may pursue gender-affirming medical interventions (i.e., hormone therapy, surgery). The prevalence of transgender adults in the United States is estimated at 1 : 200.

#### Etiology of Transgender or Gender-Nonconforming Identities

The etiology of transgender and gender-nonconforming identities remains unknown. Environmental and biologic factors are hypothesized to play a role in the development of a transgender or gender-nonconforming identity. Gender-
nonconforming children seem to have more trouble than other children with basic cognitive concepts concerning their gender. They may experience emotional distance from their father. Whether these factors are cause or effect remains unclear.

Prenatal and perinatal hormones may influence sexual differentiation of the brain. Some girls with congenital adrenal hyperplasia develop a male gender identity, but most do not. The size of the sex-dimorphic central part of the bed nucleus of the stria terminalis in the hypothalamus of transgender women is smaller than in males and within the range of nontransgender women; the opposite is true for transgender men. This structure is regulated by hormones in animals, but in humans no evidence yet exists of a direct relationship between prenatal and perinatal hormones and the sexually dimorphic nature of this nucleus. In addition, differences have been shown between transgender men and women and nontransgender controls in white matter microstructure of the brain.

Clinical Presentation

Children and adolescents with a gender-nonconforming identity may experience 2 sources of stress: internal distress inherent to the incongruence between sex assigned at birth and gender identity (gender dysphoria) or distress associated with social stigma. The 1st source of distress is reflected in discomfort with the developing primary and secondary sex characteristics and the gender role assigned at birth. The 2nd source of distress relates to feeling different, not fitting in, peer ostracism, and social isolation, and may result in shame, low self-esteem, anxiety, or depression.

Boys with a gender-nonconforming identity may at an early age identify as a girl, expect to grow up female, or express the wish to do so. They may experience distress about being a boy and/or having a male body, prefer to urinate in a sitting position, and express a specific dislike of their male genitals and even want to cut off their genitals. They may dress up in girls' clothes as part of playing dress up or in private. Girls may identify as a boy and expect or wish to grow up male. They may experience distress about being a girl and/or having a female body, pretend to have a penis, or expect to grow one. Girls may express a dislike of feminine clothing and hairstyles. In early childhood, children may spontaneously express these concerns, but depending on the response of the social environment, these feelings may go underground and may be kept more private. The distress may intensify by the onset of puberty; the physical changes
of puberty are described by many transgender adolescents and adults as “traumatic.” Boys and girls may also identify outside of the gender binary (e.g., as boygirl, girlboy, genderqueer, gender fluid) and describe their identity as neither male nor female, both male and female, in-between, or some other alternative gender different from their sex assigned at birth. Adopting a nonbinary identity may be part of identity exploration or constitute a gender identification that persists over time.

Gender-nonconforming children and transgender adolescents may struggle with a number of general behavior problems. Both boys and girls predominantly internalize (anxious and depressed) rather than externalize behavioral difficulties. Boys are more prone to anxiety, have more negative emotions and a higher stress response, and are rated lower in self-worth, social competence, and psychological well-being. Gender-nonconforming children have more peer relationship difficulties than controls. Both femininity in boys and masculinity in girls are socially stigmatized, although the former seems to carry a higher level of stigma. Boys have been shown to be teased more than girls; teasing for boys increases with age. Poor peer relations is the strongest predictor of behavior problems in both boys and girls.

Transgender adolescents may struggle with a number of adjustment problems as a result of social stigma and lack of access to gender-affirming healthcare. Transgender youth, especially those of ethnic/racial minority groups, are vulnerable to verbal and physical abuse, academic difficulties, school dropout, illicit hormone and silicone use, substance use, difficulty finding employment, homelessness, sex work, forced sex, incarceration, HIV/sexually transmitted infections (STIs), and suicide. Parental support can buffer against psychological distress, but many parents react negatively to their child's gender nonconformity, although mothers tend to be more supportive than fathers.

The Diagnosis of Gender Dysphoria: Criteria and Critique

Gender dysphoria (or gender incongruence) is classified as a mental disorder in the Diagnostic and Statistical Manual of Mental Disorders (DSM) and International Classification of Diseases (ICD), which, particularly for children, is controversial (Table 133.2 ). Critics have argued that the distress children experience is mainly the result of social stigma rather than being inherent to gender nonconformity and thus should not be considered a mental disorder.
Critics have also expressed concern about children with normal variation in gender role being labeled with a mental disorder perpetuating social stigma, yet there is a tendency of clinicians to underdiagnose rather than overdiagnose children whose gender nonconformity goes beyond behavior and who report gender dysphoria. These children may benefit from the diagnosis to receive early treatment in the form of support, education, advocacy, and, in case of clinically significant distress, changes in gender role, puberty suppression, and/or feminizing or masculinizing hormone therapy in adolescence.

Table 133.2

Summary of DSM-5 Diagnostic Criteria for Gender Dysphoria

<table>
<thead>
<tr>
<th>GENDER DYSPHORIA IN CHILDREN (302.6) (F64.2)</th>
</tr>
</thead>
<tbody>

B. The condition is associated with clinically significant distress or impairment in social, school, or other important areas of functioning.

**SPECIFY IF WITH A DISORDER OF SEX DEVELOPMENT (E.G., CONGENITAL ADRENAL HYPERPLASIA OR ANDROGEN INSENSITIVITY SYNDROME)**

**GENDER DYSPHORIA IN ADOLESCENTS OR ADULTS**

A. A marked incongruence between one's experienced/expressed gender and assigned gender, of at least 6 mo duration, as manifested by at least 2 of the following:

1. A marked incongruence between one's experienced/expressed gender and primary and/or secondary sex characteristics (or in young adolescents, the anticipated secondary sex characteristics).
2. A strong desire to be rid of one's primary and/or secondary sex characteristics because of a marked incongruence with one's experienced/expressed gender (or in young adolescents, a desire to prevent the development of the anticipated secondary sex characteristics).
3. A strong desire for the primary and/or secondary sex characteristics of the other gender.
4. A strong desire to be of the other gender (or some alternative gender different from one's assigned gender).
5. A strong desire to be treated as the other gender (or some alternative gender different from one's assigned gender).
6. A strong conviction that one has the typical feelings and reactions of the other gender (or some alternative gender different from one's assigned gender).

B. The condition is associated with clinically significant distress or impairment in social, occupational, or other important areas of functioning.

**SPECIFY IF WITH A DISORDER OF SEX DEVELOPMENT (E.G., CONGENITAL ADRENAL HYPERPLASIA OR ANDROGEN INSENSITIVITY SYNDROME)**

**SPECIFY IF POSTTRANSITION:** The individual has transitioned to full-
time living in the desired gender (with or without legalization of gender change) and has undergone (or is preparing to have) at least one cross-sex medical procedure or treatment regimen, namely, regular cross-sex hormone treatment or gender reassignment surgery confirming the desired gender (e.g., penectomy, vaginoplasty in a natal male; mastectomy or phalloplasty in a natal female).

**Transgender Identity Development**

A stages model of coming out might be helpful to understand the experience and potential challenges transgender youth might face. In the pre-coming out stage, the child or adolescent is aware that their gender identity is different from that of most boys and girls. In addition to a gender identity that varies from sex assigned at birth, some of these children are also nonconforming in gender expression while others are not. Those who are also nonconforming in gender expression cannot hide their transgender identity, are noticed for who they are, and may face teasing, ridicule, abuse, and rejection. They must learn to cope with these challenges at an early age and usually proceed quickly to the next stage of coming out. Children who are not visibly nonconforming in gender expression are able to avoid stigma and rejection by hiding their transgender feelings. They often experience a split between their gender identity cherished in private and expressed in fantasy and a false self presented outwardly to fit in and meet gendered expectations. These children and adolescents often proceed to coming out later in adolescence or adulthood.

Coming out involves acknowledging one's transgender identity to self and others (parents, other caregivers, trusted health providers, peers). An open and accepting attitude is essential; rejection can perpetuate stigma and its negative emotional consequences. By accessing transgender community resources, including peer support (either online or offline), transgender youth can then proceed to the exploration stage. This is a time of learning as much as possible about being transgender, getting to know similar others, and experimenting with various options for gender expression. Changes in gender role are carefully considered, as are medical interventions to delay puberty and/or feminize or
masculinize the body to alleviate dysphoria. Successful resolution of this stage is a sense of pride in being transgender and comfort with gender role and expression.

Once gender dysphoria has been alleviated, youth can proceed with other human development tasks, including dating and relationships in the intimacy stage. As a result of social stigma and rejection, transgender youth may struggle with feeling unlovable. Sexual development has often been compromised by gender and genital dysphoria. Now that greater comfort has been achieved with gender identity and gender expression, dating and sexual intimacy have a greater chance of succeeding. Finally, in the integration stage, transgender is no longer the most important signifier of identity, but one of several important parts of overall identity.

**Interventions and Treatment**

Health providers can assist gender-nonconforming children, transgender adolescents, and their families by directing them to resources and by helping them to make informed decisions about changes in gender role and the available medical interventions to reduce intense and persistent gender dysphoria. To alleviate socially induced distress, interventions focus on stigma management and stigma reduction. It might be in the child's best interest to set reasonable limits on gender expression contributing to teasing and ridicule. The main goal of these interventions is not to change the child's gender-nonconforming behavior but to assist families, schools, and the wider community to create a supportive environment where the child can thrive and safely explore his or her gender identity and expression. Decisions to change gender roles, particularly in school, are not to be taken lightly and are best carefully anticipated and planned in consultation with parents, child, teachers, school counselor, and other providers involved in the adolescent's care. Medical interventions are available as early as Tanner Stage 2. Such treatment is guided by the Standards of Care set forth by the World Professional Association for Transgender Health (WPATH). Although some controversy still exists about the appropriateness of early medical intervention, follow-up studies of adolescents treated in accordance with these guidelines show its effectiveness in alleviating intense and persistent gender dysphoria.

Pubertal suppression with gonadotrophin-releasing hormone analogues (usually begun in early puberty) that delay puberty are helpful before gender-
affirmation hormone therapies. Certain features of puberty are difficult to reverse (e.g., male facies, Adam’s apple), so pubertal suppression avoids these physical features. Pubertal suppression may also reduce gender dysphoria. Gender-affirming hormones can then be initiated; testosterone for masculinizing and estrogen plus an adrogen inhibitor for feminization. Gender-affirming surgery (most commonly “top” surgery) to create a male-typical chest is usually delayed until adulthood.

Pediatricians who encounter transgender youth in their practice should be careful not to make assumptions about gender and sexual identity, but rather ask youth how they would describe themselves. This includes asking if they like being a boy or girl, have ever questioned this, wished they were born the other sex, or define their gender identity in a nonbinary or otherwise different way; and if they have a preferred nickname or pronoun (he/him, she/her, or they/them; if not sure, avoid pronouns). It also includes asking how they feel about their maturing body and sex characteristics, and what they would change about that if they could. Extra caution should be exercised during physical and genital exams because transgender youth may be particularly uncomfortable with their anatomy. When considering contraceptive options for female-to-male transgender youth, alternatives to feminizing agents should be explored. For gender-affirming medical interventions, transgender youth should be referred to specialists in the treatment of gender dysphoria (see www.wpath.org). For other health concerns, ensure referral to transgender or lesbian, gay, bisexual, transgender (LGBT)-friendly providers, especially in the case of gender-segregated treatment facilities. Gender Spectrum (www.genderspectrum.org), Advocates for Youth (www.advocatesforyouth.org), and Parents, Families and Friends of Lesbians and Gays (www.pflag.org) offer excellent support resources for transgender youth and their families.

Bibliography

Coleman E, Bockting W, Botzer M, et al. Standards of care for

Understanding a child's or adolescent's sexual and emotional development is an essential part of any comprehensive pediatric evaluation. For youth who are or might be gay, lesbian, or bisexual (GLB), such understanding is particularly important. GLB youth as a group have the same health and developmental needs as all youth, and their sexual orientation is part of the spectrum of human sexuality. However, they encounter distinct developmental challenges and can have additional physical and mental health needs related to their orientation and others’ reaction to it. Their sexual orientation is often different from that expected by family, peers, and society (although expectations have been changing in many contexts), and they must cope with peer rejection, bullying, or family nonacceptance more frequently than most youth. Although the majority of GLB adolescents grow up physically and mentally healthy, they are at increased risk for certain health problems as a result of these stresses and the epidemiology of health threats such as HIV and other sexually transmitted infections (STIs). Pediatric clinicians are key in monitoring for such issues, supporting healthy development, and intervening when necessary to prevent or treat the problems for which GLB youth are at increased risk.

**Sexual orientation** refers to an individual's attraction to others based on sex or gender. It encompasses emotional and erotic desires, physiologic arousal, sexual behavior, sexual identity, and social role. As sexuality develops, youth can be oriented entirely toward a particular sex or gender, or more than one, to various degrees on a continuum. **Homosexuality** involves orientation toward people of one's same sex or gender, and **bisexuality** involves orientation toward males and females. **Gay** is a common term for homosexual males and females; **lesbian** refers to homosexual females. Some do not fit these categories and use
other terms to describe themselves. Those unsure of their orientation are curious or questioning. The term young men who have sex with men (YMSM) is sometimes used in the research literature to denote male youth who engage in sexual activity with other males, regardless of how they identify themselves.

**Prevalence of Homosexuality and Bisexuality in Youth**

Some junior high and high school students self-identify as gay, lesbian, or bisexual. Some who do not identify as GLB report same-sex attraction, fantasies, or behavior. Some are unsure of their sexual orientation. Certainty about sexual orientation tends to increase through adolescence with sexual experience, although one can be aware of one's orientation without having had sexual partners. Those who fear nonacceptance may try to suppress or deny their orientation. Consequently, various aspects of orientation—attraction, behavior, and identity—may not be consistent in an individual and may change during development. Not all youth with homosexual attraction or experience identify as “gay,” consistent in part with reluctance about having or revealing a gay identity and underscoring the differences among attraction, behavior, and identity. A report providing national estimates of the number of high school students with GLB identity in 2015 found that across 25 states and 19 large urban school districts, a median of 2.7% said they were gay/lesbian, 6.4% said they were bisexual, and 4.0% reported being unsure of their sexual orientation.

**Development of Sexual Orientation in Childhood and Adolescence**

Sexual orientation development appears to begin prenatally and continue through childhood and adolescence and into adulthood. Both gender role behavior in childhood and sexual orientation in puberty and adolescence are partly influenced by prenatal genetic and neuroendocrine factors. Sociocultural and psychological factors also influence sexual development. A gay or lesbian sexual orientation is sometimes preceded developmentally in childhood by nonconforming gender expression, or variation from population averages in expression of gender-related behavior such as activities, interests, styles, and
other attributes recognized as masculine or feminine, such as toy preferences and preference for playmates of a particular gender. Although childhood gender nonconformity is not experienced by all gay or lesbian people—and not all children with nonconforming gender role behavior grow up to be gay or lesbian—nonconformity is not uncommon (particularly among males) and leads many gay or lesbian people to feel different from peers in childhood, even before sexual desire or identity emerges. Depending on the setting, gender-nonconforming children may experience ostracism, bullying, or family nonacceptance. These reactions to gender nonconformity can lead to later difficulty with gender-related self-esteem and long-term mental health problems.

Less frequently, gay or lesbian sexual orientation in adolescence is preceded by childhood gender variant identity, a phenomenon in which the gender identity of an individual at any age differs from phenotypic sex and assigned sex at birth (see Chapter 135).

**Stigma, Risk, and Resilience**

Homosexuality has been documented across cultures and historical periods. However, its meaning and acceptance vary greatly with social context. Although gay people are now generally more visible and accepted than previously, youth are often exposed to antihomosexual attitudes. For many GLB youth, revealing their sexual orientation (“coming out”) to family, peers, healthcare providers, and others is a significant step. Specific racial/ethnic, religious, and other demographic groups may experience distinct developmental stressors. For example, black youth report feeling less comfortable than white peers with a gay identity and less comfortable disclosing it.

Some GLB youth experience difficulty coping with stigma. A longitudinal study that investigated bullying and victimization among youth from 5th through 10th grade found that the girls and boys that identified as GLB in 10th grade were more likely than their peers to report that they had been bullied and victimized across grades. GLB youth may be perceived by others as different before they themselves have any GLB attraction or experience, or identify as GLB. Even when not overtly threatened, GLB youth frequently encounter negative attitudes that force them to hide at a time when acceptance holds great developmental significance. Family nonacceptance, feeling unsafe due to school harassment, and peer bullying related to sexual orientation elevate risk in GLB adolescents for depression, anxiety, substance abuse, suicidal thoughts and
attempts, and social problems such as truancy, dropping out, running away, and homelessness. Mental health problems, sexual risk taking, or substance use may increase exposure to HIV and other STIs. Stigma may also impede access to healthcare in some communities. Thus, along with factors influencing exposure and susceptibility to health threats, stigma partly mediates elevated risk for health and mental health problems in GLB youth.

Nevertheless, most GLB youth are resilient, with good physical and mental health despite pervasive stress. Family connectedness and school support and safety are important protective factors against depression, suicidal thoughts and attempts, and substance abuse. GLB antiharassment policies and organizations such as genders and sexualities alliances (also sometimes called gay-straight alliances) and antibullying programs are associated with increased school safety for GLB youth. It is therefore important to reduce stigma, support acceptance, and promote resilient coping.

Health

Depression and Suicidality

Compared to their heterosexual peers, GLB youth and those who are not sure of their sexual orientation have higher prevalence of suicidality. Family rejection, bullying, and other victimization motivated by homophobia account statistically for increased depression and suicidal thoughts and attempts in GLB adolescents. Suicidal thoughts or attempts are highest during the interval following recognition of same-sex attraction or a same-sex sexual experience but prior to self-acceptance as gay.

Sexually Transmitted Infections

The epidemiology of STIs, related to specific sexual practices as well as prevalence of certain STIs in GLB communities, informs recommended counseling, screening, and treatment strategies. Anal intercourse has been shown to be the most efficient route of infection by hepatitis B (Chapter 385), cytomegalovirus (Chapter 282), and HIV (Chapter 302). Oral-anal and digital-anal contact can transmit enteric pathogens, such as hepatitis A. Unprotected oral sex also can lead to oropharyngeal disease in the receptive partner and gonococcal and nongonococcal urethritis in the insertive partner. Certain STIs,
particularly ulcerative diseases, such as syphilis and herpes simplex virus infection, facilitate spread of HIV.

Among U.S. adolescents and young adults, YMSM, and especially black YMSM, continue to face the greatest prevalence of HIV/AIDS. Although possible, female-to-female sexual transmission of HIV is inefficient, and females who only engage in sex with females are less likely than other youth to acquire an STI. However, boys and girls who identify as gay or lesbian may engage in sexual activity with partners of the other sex, so counseling and screening for all types of STIs are still relevant.

**Substance Abuse**

Compared with their heterosexual peers, GLB youth appear to use alcohol and other substances at higher rates, including more binge drinking and earlier onset and more rapid trajectory of substance use. More substantial substance use may be greatest in youth who do not identify as GLB but have same-sex attractions or engage in same-sex sexual behavior.

**Obesity and Disordered Eating**

Compared with heterosexual girls, lesbian and bisexual girls are generally more likely to be obese or overweight. In contrast, young gay and bisexual males are more likely to have body image concerns and to restrict eating or engage in compensatory weight loss strategies compared to heterosexual boys. Binge eating may also be more common in GLB youth.

**Psychosocial Problems**

Academic underachievement, truancy, and dropping out of school are frequently associated in GLB adolescents with homophobic victimization, harassment, violence, and feeling unsafe at school. Studies suggest that youth who eventually identify as GLB have higher rates than other youth of experiencing child abuse and of running away or being kicked out of their homes. GLB young people are overrepresented among homeless and runaway populations across the United States, which can expose them to drugs, sexual abuse and other health risks.
Recommendations for Care

Evaluation

The goal of GLB pediatric care is physical health, social and emotional well-being, and healthy development. Physicians should provide nonjudgmental care to all adolescents, including those who are GLB or questioning (see Chapter 133, Table 133.1). They should receive the age-appropriate history, examination, and anticipatory guidance recommended for adolescents in general. With some exceptions noted later, the physical examination and laboratory evaluation of GLB and questioning adolescents are the same as for any teenager. However, providers should appropriately screen for special potential medical and psychosocial threats to GLB teenagers’ health.

A nonjudgmental healthcare environment is important, with open communication and a positive relationship with youth and families. In the waiting room, written material about sexual orientation, support groups, and community resources will signal openness to discussing sexuality. Registration forms recognizing the possibility of same-gender parents signal a safe setting (e.g., forms can list parent/guardian #1, parent/guardian #2). Sexual history questions should avoid heterosexual assumptions (e.g., “Are you dating someone?” vs “Do you have a boyfriend/girlfriend?”). This is important at all ages. For example, asking a 6 yr old boy if he has a girlfriend may convey an unsupportive message if he discovers later that he would like a boyfriend. Explaining confidentiality and incorporating into each adolescent visit private time with no parent in the room (see Chapter 137) may facilitate discussing sexual orientation, as may use of appropriate health history forms such as the American Medical Association's Guidelines for Adolescent Prevention Services Questionnaire.

Clinicians should remember that any youth might be GLB whether or not they are identified or perceived as such, so clinicians should not presuppose a particular orientation. Competency in conveying sensitivity, acceptance, and respectfulness; effective communication skills; and appropriate attention to privacy and confidentiality (including practices related to billing and record requests) are fundamental to providing high-quality care. While remaining attuned to youth's preferences, explicit or implied, for discussing sexual orientation, providers can tactfully take the lead, if necessary, regarding any pressing areas of clinical concern.
Medical and Sexual Health

STIs are covered in Chapter 146, but issues specific to GLB youth are included here. Use of latex condoms for fellatio, and dental dams and cut-open latex condoms for anilingus and cunnilingus, should be discussed with adolescents. Recommendations also include use of latex condoms for sexual appliances. In addition, it is important to emphasize that people who have been using alcohol or other drugs are at increased likelihood for engaging in riskier sexual activity. It is important not to assume that a gay boy or lesbian girl who does not identify as bisexual has not had sex with someone of a different sex or gender. For example, lesbians can still have an unplanned pregnancy. Therefore, prevention counseling about unintended pregnancy is relevant to all adolescents. Similarly, youth who identify as heterosexual and whose attractions are not to those of the same sex or gender may still have sexual activity with a partner of the same sex or gender.

Although vaccination against hepatitis A and B is recommended for all children, it is particularly recommended that nonvaccinated adolescent males who are having sex or are likely to have sex with males receive catch-up vaccines. The same recommendation applies to the human papillomavirus (HPV) vaccine for males. The Centers for Disease Control and Prevention (CDC) recommends that males who are engaging in sexual activity with males have annual testing for HIV, hepatitis A, hepatitis B, syphilis, urethral gonorrhea and chlamydia (if engaging in insertive oral or anal intercourse), oral gonorrhea (if engaging in receptive oral intercourse), and rectal gonorrhea and chlamydia (if engaging in receptive anal intercourse).

Mental Health

Awareness of mental health and social problems is important when caring for GLB youth, as for all youth. Clinicians should monitor for depression, suicidality, anxiety, and substance abuse and know their community’s mental health resources. Minor psychosocial problems might be handled by referral to a support group for patients (e.g., GLSEN, formerly known as the Gay, Lesbian and Straight Education Network) or for parents and others (e.g., Parents, Families and Friends of Lesbians and Gays). In some communities, agencies and organizations serving the GLB community can help with social, educational, vocational, housing, and other needs.

Individuals or families who harbor negative attitudes may inquire about
mental health treatment to avert or change a homosexual or bisexual orientation. However, a GLB orientation is not an illness, and leading health organizations, including the American Academy of Pediatrics, American Academy of Family Physicians, Society for Adolescent Health and Medicine, American Academy of Child and Adolescent Psychiatry, and American Medical Association, have concluded that such change is neither possible nor warranted. It is important to distinguish between a GLB orientation, which is not a mental illness, and mental health problems (e.g., depression) for which GLB youth are at elevated risk. While understanding different families’ values, clinicians must recognize the morbidity and mortality associated with stigma and attempt to foster physical and emotional health. Individual or family therapy might be indicated.

Clinicians should also monitor for specific stressors, such as bullying and other homophobic victimization, family nonacceptance, and abuse. Failure to confront harassment constitutes tacit assent.

Anticipatory guidance, referral, and substance abuse treatment should be considered for the subset of GLB youth who use alcohol, drugs, or tobacco, some of whom may be using these to manage painful feelings related to conflicts over their sexuality.

Adolescents with serious psychiatric symptoms, such as suicidality, depression, and substance abuse, should be referred to mental health specialists with competency in treating GLB adolescents. It is essential to know how to recognize and manage psychiatric emergencies such as suicidal thoughts and attempts (see Chapter 40).

Institute of Medicine, Committee on Lesbian, Gay, Bisexual, and Transgender Health Issues and Research Gaps and Opportunities. *The health of lesbian, gay, bisexual, and

Transgender individuals have a gender identity that differs significantly from the sex they were assigned at birth (see Chapter 133). They may experience gender dysphoria, defined as clinically significant distress or impairment in social, school/occupational, or other important areas of functioning associated with incongruence between one's experienced/expressed gender and assigned gender, for at least 6 mo in duration. Gender-affirming care has been shown to alleviate gender dysphoria and may include psychological evaluation and supportive therapy, puberty suppression, feminizing or masculinizing hormone therapy, and surgery. Such care is guided by the Standards of Care for transsexual, transgender, and gender-nonconforming people set forth by the World Professional Association for Transgender Health (WPATH). In addition, the Endocrine Society has issued practice guidelines for endocrine treatment to alleviate gender dysphoria.

Transgender and gender-nonconforming children and adolescents have increased vulnerability to mental health concerns because of social stigma attached to gender nonconformity. Moreover, transgender and gender-nonconforming children and adolescents may present with general health concerns unrelated to their gender identity or gender expression, but may experience barriers to care that include a lack of cultural competence on the part of healthcare providers or the healthcare systems in which they practice. Therefore, to serve the youth and their families adequately, attention to both cultural and clinical competency is critical and should be improved. The American Psychological Association and the American Association of Child and Adolescent Psychiatrists have published practice guidelines to promote improved access to competent care.
Cultural and Clinical Competence

**Cultural competence** refers to the ability to communicate effectively with patients from various backgrounds. This includes appropriate assessment and clinical documentation of both gender identity (What is your current gender identity?) and sex assigned at birth (What sex were you assigned at birth [on your original birth certificate]?), use of preferred names and pronouns, and availability of all-gender bathrooms. It also includes recognition of and respect for gender diversity: children and adolescents may identify as girl, boy, boygirl, girlboy, transgender, genderqueer, nonbinary, gender fluid, gender questioning, or any other way in which they may describe their gender identity and expression (see Chapter 133). Particularly with children and adolescents, it is imperative not to label prematurely a young person's gender identity, but rather allow ample time for them to explore their gender identity and expression.

**Clinical competence** in transgender care refers to training and experience in providing gender-affirming care to facilitate gender identity development, alleviate any gender dysphoria, and promote resilience in the face of stigma. Care should ideally be provided by an interdisciplinary team or, alternatively, in consultation with other providers involved in the child or adolescent's care. This may include primary care providers, pediatric endocrinologists, and mental health professionals. The WPATH Standards of Care recommend that providers be competent in working with children and adolescents; be able to screen for coexisting mental health concerns; be knowledgeable about gender-nonconforming identities and expressions; and be knowledgeable and engaged in continuing education about the assessment and treatment of gender dysphoria.

**Gender Literacy**

For both providers and patients (child or adolescent and family), an up-to-date understanding of gender diversity is key. Much is yet to be learned about transgender identity development, but we do know that gender is not necessarily *binary*, and transgender and gender-nonconforming children and adolescents may identify and express their gender identity along a spectrum. The implication for care is that not all these children and adolescents need to change their gender role from male to female or female to male, and are in need of early medical interventions. Certainly, for some transgender and gender-nonconforming children and adolescents, these interventions are medically necessary and
lifesaving, and evidence to date indicates that for those who meet criteria for a DSM-5 diagnosis of gender dysphoria, treatment appears safe and effective in reducing gender dysphoria and optimizing mental health and well-being. Others, however, do not identify with the gender binary (i.e., do not identify as male or female, but rather as an alternative gender) and need a more individualized approach that may or may not include changes in gender role and/or any of the available medical interventions. For all young people, it is imperative to support them in the process of identity exploration and tolerate any ambiguity and uncertainty, as well as evaluate and treat their concerns in light of their overall child and adolescent development.

**Assessment**

The *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition* (DSM-5) outlines criteria for a diagnosis of gender dysphoria in children as well as in adolescents and adults (see Table 133.2). For children, these criteria must include a strong desire or insistence to be of the other gender (or some alternative gender that differs from one's assigned gender). For adolescents, this may include a marked incongruence between one's experienced/expressed gender and (anticipated) primary and/or secondary sex characteristics; a strong desire for the sex characteristics of the other gender (or some alternative gender that differs from one's assigned gender), and/or a strong desire to be treated as another gender.

There is considerable variation in the clinical presentation, severity, and persistence of gender dysphoria among children and adolescents. It is therefore important to obtain a history of gender identification and expression and monitor ongoing identity exploration and development. Coexisting mental health concerns of anxiety, depression, nonsuicidal self-injury, suicidal ideation, and suicide attempts are not uncommon and should be assessed. There also is a higher prevalence of autism spectrum disorder among children and adolescents presenting with gender dysphoria.

**Treatment**

Transgender and gender-nonconforming children and adolescents can benefit greatly from a nonjudgmental and empathetic stance, patient education about
gender diversity and the available options to alleviate gender dysphoria and affirm gender identity, access to community resources, and family support. Attention to behavioral problems and therapy for any mental health concerns caused by gender nonconformity and the attached social stigma should be incorporated into the treatment plan.

Treatment of gender dysphoria may include psychotherapy to reduce distress related to gender dysphoria or any other psychosocial difficulties. *Gender nonconformity in and of itself is not pathologic.* In addition, it is not ethical to try to change gender identity and expression to become more congruent with sex assigned at birth, because this has proved unsuccessful, particularly in the long term. Instead, psychotherapy (by a professional trained in transgender health) should support the unfolding process of identity exploration and development and assist the patient and family to manage any uncertainty and anxiety about the eventual outcome. Options to affirm gender identity include changes in gender role and expression, puberty suppression, feminizing or masculinizing hormones, and surgery. Changes in gender role may include changes in name and pronouns.

**Puberty suppression** with GnRH analogs, a reversible early medical intervention to reduce dysphoria by preventing the development of unwanted sex characteristics, is available as early as Tanner Stage 2. Feminizing or masculinizing *hormone therapy*, only partially reversible, is available and should be tailored to the somatic, emotional, and mental development of the adolescent. *Masculinizing chest surgery*, irreversible, is available preferably after ample experience living in a gender role congruent with the adolescent's gender identity. *Breast augmentation* is available, particularly after feminizing hormones have reached their maximum impact on breast growth. Hormone therapy or chest/breast surgery is indicated in patients with persistent, well-documented gender dysphoria who have the capacity to make a fully informed decision and to consent for treatment. *Genital surgery* (phalloplasty, metoidioplasty, vaginoplasty), irreversible, is available after living for a least 12 mo in a gender role congruent with the adolescent's gender identity, and preferably after the legal age of majority to give consent for medical procedures has been reached. For all these options, informed consent and support from family are critically important.

Early medical interventions have shown great promise in reducing gender dysphoria and optimizing psychosocial adjustment and well-being, but much remains unknown, particularly about the long-term effects of puberty
suppression. Moreover, gender identity and expression should be evaluated within the larger context of identity and human development, especially during the formative years of childhood and adolescence.

Many transgender people choose hormone therapy and do not undergo surgery of breast/chest or genitals. The implications for fertility and options for fertility preservation should be discussed and considered before hormone therapy and surgery. Indeed, there are transgender individuals who elect to have children and nurse the child after birth. Rather than using the term *breastfeeding*, the term *chest feeding* may be preferred. When transgender adults seek primary healthcare, attention must be focused on gender- as well as sex organ–specific preventive screening (e.g., Pap smear, mammography, prostate exam).

### Families

Family support is an important resource for transgender and gender-nonconforming youth and has been shown to buffer the negative impact of stigma on mental health. Family support also is a prerequisite for initiation of puberty suppression, feminizing or masculinizing hormone therapy, or any surgery before the age of legal majority has been reached. Providers are encouraged to include family in all aspects of treatment, while understanding that family members may be at different points in the process of coming to terms with having a transgender or gender-nonconforming loved one. Family members may benefit from online and community resources to educate themselves about gender diversity and to connect with similar others. Transgender and gender-nonconforming children and adolescents as well as their families are encouraged to learn as much as possible to be able to make fully informed decisions, in consultation with clinically competent transgender care providers, about the available behavioral and medical treatment options to affirm gender identity.

Klein DA, Paradise SL, Goodwin ET. Caring for transgender and gender-diverse persons: what clinicians should know. *Am

Adolescence is the first period of life where the major determinants of morbidity and mortality are *behavioral* rather than congenital or infectious. As adolescents make the transition from childhood to adulthood, they establish behaviors that affect both their current and future health. Adolescence is a time of immense biologic, psychological, and social change (see Chapter 132). Many of the psychological changes have a biologic substrate in the development and eventual maturation of the central nervous system, particularly the frontal lobe areas responsible for executive functioning (Fig. 136.1). In addition to cognitive development, there are both risk and protective factors for adverse adolescent health behaviors that are dependent on the social environment as well as the mental health of an adolescent (Table 136.1).

**FIG. 136.1** It has been speculated that the impact of puberty on arousal and motivation occurs before the maturation of the frontal lobes is complete. This gap may create a period of heightened vulnerability to problems in the regulation of affect and behavior, which might help to explain the increased potential in adolescence for risk taking, recklessness, and the onset of emotional and behavioral problems. (From Steinberg L:

Many adolescents continually confront the task of making healthy choices while struggling with impulsivity that can lead to unintentional consequences, such as injuries, sexually transmitted infections (STIs), or drug overdoses. Adolescents are also challenged with adopting behaviors that will affect their future adult health, such as eating nutritiously, engaging in physical activity, and choosing not to use tobacco. Environmental factors, such as family, peers, school, community, and religiosity, also contribute to adolescents' health and risk behaviors. The U.S. Centers for Disease Control and Prevention (CDC) **Youth Risk Behavior Surveillance Survey**, a school-based survey of a nationally representative sample of U.S. high school students, demonstrates that youth begin engaging in behaviors that place their health at risk during adolescence (Fig. 136.2).
FIG. 136.2  Selected health behaviors among 9th and 12th grade high school students. ENDs, Electronic nicotine delivery system. (Data from Centers for Disease Control and Prevention: 1991–2015 High school youth risk behavior survey data. [http://nccd.cdc.gov/youthonline](http://nccd.cdc.gov/youthonline).)

Although according to the 2015 CDC National Health Interview Survey (https://www.cdc.gov/nchs/nhis/shs/tables.htm), a probability sample survey conducted annually, an estimated 82% of 12-17 yr olds report excellent or very good health, 11% reported limitation in usual activities due to one or more chronic conditions, 10% missed 6-10 school days in the past year, 6% are uninsured, 6% have no usual place of healthcare, 10% have asthma, 12% have respiratory allergies, 10% have a learning disability, 14% have attention-deficit/hyperactivity disorder, and 18% take prescription medications routinely. In 2014 the mortality rate among adolescents 15-19 yr of age was 45 deaths per 100,000 population. While varying by gender, the leading causes of death overall among adolescents 15-19 yr of age are (1) unintentional injuries; (2) suicide; and (3) homicide (Table 136.2).

#2 | Intentional self-harm (suicide) | 13.0 | Intentional self-harm (suicide) | 4.2
#3 | Assault (homicide) | 11.2 | Malignant neoplasms | 2.5

Within the adolescent population, disparities in health occur. Adolescent health outcomes and behaviors vary among populations that can be defined by race or ethnicity, gender, education or income, disability, geographic location (e.g., rural or urban), or sexual orientation. Health disparities result from multiple factors, including poverty, environmental threats, inadequate access to healthcare, individual and behavioral factors, and educational inequalities (Table 136.3).

Access to Healthcare

Adolescents in the United States make fewer visits to physicians for ambulatory office visits than any other age group; school-age children and adolescents are more likely than younger children to have unmet health needs and delayed medical care. Adolescents who actually receive preventive care may still not have access to time alone with their provider to discuss confidential health issues such as STIs, HIV, or pregnancy prevention. Less than half (40%) of adolescents have time alone with their healthcare provider during a preventive healthcare visit; sexually experienced teens report sexual health discussions more often than nonsexually experienced teens, but the frequency is still low at 64% and 33.5% for sexually experienced females and males, respectively.

Young adults 18-24 yr are more likely to be insured with the 2010 Patient Protection and Affordable Care Act (ACA ). Currently, the ACA permits children to receive benefits from their parents' health plans through age 26 yr. Healthy People provides science-based, 10-yr national objectives for measuring and improving the health of all Americans by establishing benchmarks and monitoring progress over time. The Healthy People 2020 agenda includes 11 adolescent-specific objectives with a goal of improving the healthy development, health, safety, and well-being of adolescents and young adults over the next 10 yr (Table 136.4 ). This science-based initiative is centered around a framework for public health prevention priorities and actions to improve the health status of U.S. youth.

Table 136.4

Healthy People 2020 Adolescent Health (AH) Objectives

- **AH-1**: Increase the proportion of adolescents who have had a wellness checkup in the past 12 months
- **AH-2**: Increase the proportion of adolescents who participate in extracurricular and out-of-school activities
- **AH-3**: Increase the proportion of adolescents who are connected to a parent or other positive adult caregiver
  - **AH-3.1**: Increase the proportion of adolescents who have an adult in their lives with whom they can talk about serious problems
AH-3.2: Increase the proportion of parents who attend events and activities in which their adolescents participate

- **AH-4**: (Developmental) Increase the proportion of adolescents and young adults who transition to self-sufficiency from foster care

- **AH-5**: Increase educational achievement of adolescents and young adults
  - **AH-5.1 (Leading Health Indicator)**: Increase the proportion of students who graduate with a regular diploma 4 years after starting 9th grade
  - **AH-5.2**: Increase the proportion of students who are served under the Individuals with Disabilities Education Act who graduate high school with a diploma
  - **AH-5.3**: Increase the proportion of students whose reading skills are at or above the proficient achievement level for their grade
  - **AH-5.4**: Increase the proportion of students whose mathematics skills are at or above the proficient achievement level for their grade
  - **AH-5.5**: Increase the proportion of adolescents who consider their school work to be meaningful and important
  - **AH-5.6**: Decrease school absenteeism among adolescents due to illness or injury

- **AH-6**: Increase the proportion of schools with a school breakfast program

- **AH-7**: Reduce the proportion of adolescents who have been offered, sold, or given an illegal drug on school property

- **AH-8**: Increase the proportion of adolescents whose parents consider them to be safe at school

- **AH-9**: (Developmental) Increase the proportion of middle and high schools that prohibit harassment based on a student's sexual orientation or gender identity

- **AH-10**: Decrease the proportion of public schools with a serious violent incident

- **AH-11**: Reduce adolescent and young adult perpetration of, as well as victimization by, crimes
  - **AH-11.1**: Decrease the rate of minor and young adult perpetration of violent crimes
  - **AH-11.2**: Decrease the rate of minor and young adult perpetration of serious property crimes
AH-11.3: (Developmental) Decrease the percentage of counties and cities reporting youth gang activity

AH-11.4: (Developmental) Reduce the rate of adolescent and young adult victimization from crimes of violence

### Bibliography

CHAPTER 137

Delivery of Healthcare to Adolescents

Gale R. Burstein

Healthcare providers play an important role in nurturing healthy behaviors among adolescents, because the leading causes of death and disability among adolescents are preventable. Adolescence provides a unique opportunity to prevent or modify health conditions arising from behaviors that develop in the 2nd decade of life and that can lead to substantial morbidity and mortality, such as trauma, cardiovascular and pulmonary disease, type 2 diabetes, reproductive health disease, and cancer (see Chapter 132, Table 132.4).

Health systems in each community should be in place to ensure comprehensive and high-quality care to adolescents. Health insurance coverage that is affordable, continuous, confidential, and not subject to exclusion for preexisting conditions should be available for all adolescents and young adults. Comprehensive, coordinated benefits should meet the developmental needs of adolescents, particularly for reproductive, mental health, dental, and substance abuse services. Safety net providers and programs that provide confidential services, such as school-based health centers, federally qualified health centers, family planning services, and clinics that treat sexually transmitted infections (STIs) in adolescents and young adults, need to have assured funding for viability and sustainability. Quality-of-care data should be collected and analyzed by age so that the performance measures for age-appropriate healthcare needs of adolescents are monitored. Affordability is important for access to preventive services. Family involvement should be encouraged, but confidentiality and adolescent consent are critically important. Healthcare providers, trained and experienced in adolescent care, should be available in all communities. Healthcare providers should be adequately compensated to support the range and intensity of services required to address the developmental and health service needs of adolescents. The development and
dissemination of provider education about **adolescent preventive health guidelines** have been demonstrated to improve the content of recommended care (Table 137.1). The ease of recognition or expectation that an adolescent's needs can be addressed in a setting relates to the **visibility and flexibility** of sites and services. Staff at sites should be approachable, linguistically capable, and culturally competent. Health services should be coordinated to respond to goals for adolescent health at the local, state, and national levels. The coordination should address service financing and delivery in a manner that reduces disparities in care.

CDC recommends universal, voluntary HIV screening of all sexually active people, beginning at age 13 yr. The American Academy of Pediatrics recommends offering routine HIV screening to all adolescents at least once by 16-18 yr of age and to those younger if at risk. US Preventive Services Task Force recommends offering routine HIV screening to all adolescents age 15 yr and older at least once and to those younger if at risk. Patients who test positive for HIV should receive prevention counseling and referral to care before leaving the testing site.

Refer to specific guidance by age as listed in Bright Futures guidelines.

HIV, Human immunodeficiency virus; STI, sexually transmitted infection.

Although most adolescents in the United States have seen a healthcare provider in the past year and report a usual source of healthcare, adolescents are less likely to receive preventive care services. According to the 2011 National Health Interview Survey, an estimated 90% of 12-17 yr old U.S. adolescents had 1 or more contacts with a healthcare professional in the past year, 98% identify a usual source of care at a physician's office or clinic, and 17% made at least 1 emergency department visit in the past year. Uninsured adolescents are the least likely to receive care. In 2015, 63% of people under age 19 yr were covered at some point during the year by private insurance, and 43% of children had public health insurance at some point during 2015. However, even among adolescents who are fully insured with a usual source of care, most do not receive preventive healthcare. An analysis of claims data from a large Minnesota health plan with approximately 700,000 members found that among patients age 11-18 yr who were enrolled for at least 4 yr between 1998 and 2007, few received preventive care visits. One third of adolescents had no preventive care visits from age 13 through 17 yr, and another 40% had only a single such visit. Nonpreventive care visits were more frequent in all age-groups, averaging about 1 per yr at age 11 yr, climbing to about 1.5 per yr at age 17 yr. Among older adolescents, females had both more preventive care and more nonpreventive care visits than did males.

The Patient Protection and Affordable Care Act (ACA), enacted in March 2010, has expanded access to both commercial health plans and Medicaid for
young adults age 19-26 yr (Fig. 137.1). From June 2010 through June 2012, the proportion of young adults with insurance increased from 65.7% to 73.8%. Currently, ACA provisions require that commercial health plans (1) continue dependent coverage to 26 yr, regardless of the young adult's financial or dependent status, marriage, or educational enrollment; (2) mandate university and college student health plans to enhance consumer protections for students; (3) provide financial assistance for young adults to enroll into health insurance exchanges with incomes ranging from 133–399% of the federal poverty level in Medicaid expansion states; and (4) offer preventive healthcare services free of any cost sharing, deductibles, or copayments. In states that have expanded Medicaid coverage, all adults with incomes <133% of the federal poverty level are eligible to enroll.

![Graph showing percentage of adults age 19-25 yr with health insurance by coverage type and percentage uninsured at the time of the interview: United States, 1997–September, 2012. Note: Estimates for 2012 are based on data collected in January through September. Data are based on household interviews of a sample of the civilian noninstitutionalized population. (Data from CDC/NCHS, National Health Interview Survey, 1997–2012, Family Core Component.)](image)

(Data from CDC/NCHS, National Health Interview Survey, 1997–2012, Family Core Component.)

The complexity and interaction of physical, cognitive, and psychosocial developmental processes during adolescence require sensitivity and skill on the part of the health professional (see Chapter 132). Health education and promotion, as well as disease prevention, should be the focus of every visit. In 2017 the American Academy of Pediatrics (AAP) in collaboration with the U.S.
Department of Health and Human Services, Health Resources and Services Administration, Maternal and Child Health Bureau, published the 4th edition of *Bright Futures: Guidelines for Health Supervision of Infants, Children, and Adolescents*, which offers providers a strategy for delivery of adolescent preventive health services with screening and counseling recommendations for early, middle, and late adolescence (Table 137.2). *Bright Futures* is rooted in the philosophy of preventive care and reflects the concept of caring for children in a “medical home.” These guidelines emphasize effective partnerships with parents and the community to support the adolescent's health and development.

† Centers for Disease Control and Prevention recommends universal, voluntary HIV screening of all sexually active people, beginning at age 13 yr. American Academy of Pediatrics recommends routine HIV screening offered to all adolescents at least once by 16-18 yr of age and to those younger if at risk. U.S. Preventive Services Task Force recommends routine HIV screening offered to all adolescents age 15 yr and older at least once and to those younger if at risk. Patients who test positive for HIV should receive prevention counseling and referral to care before leaving the testing site.

NA, Not applicable; NAAT, nucleic acid amplification test; STIs, sexually transmitted infections.

Adapted from Hagan JF, Shaw JS, Duncan PM, editors: *Bright Futures: guidelines for health supervision of infants, children, and adolescents*, ed 4, Elk Grove Village, IL, 2017, American
The Centers for Disease Control and Prevention (CDC) Advisory Committee on Immunization Practices (ACIP) currently recommends routine adolescent vaccines for universal administration beginning at the 11-12 yr old visit, or as soon as possible, (a) tetanus–diphtheria–acellular pertussis vaccine (Tdap), (b) the meningococcal conjugate vaccine (MCV4) with a booster at age 16 yr, and (c) the human papillomavirus vaccine (HPV) series (see Chapter 197). ACIP recommends annual influenza vaccination and hepatitis A virus (HAV) vaccination to adolescents and young adults who have not previously received the HAV vaccine series if immunity against HAV is desired or for those at increased risk for infection, such as men who have sex with men (MSM), injection drug users (IDU), and those with chronic liver disease or clotting factor disorders, or who live in areas that target older children for HAV vaccine.

The time spent on various elements of the screening will vary with the issues that surface during the assessment. For gay and lesbian youth (see Chapter 134), emotional and psychological issues related to their experiences, from fear of disclosure to the trauma of homophobia, may direct the clinician to spend more time assessing emotional and psychological supports in the young person’s environment. For youth with chronic illnesses or special needs, the assessment of at-risk behaviors should not be omitted or deemphasized by assuming they do not experience the “normal” adolescent vulnerabilities.

137.1

Legal Issues

Gale R. Burstein

The rights of an individual, including those of adolescents, vary widely between nations. In the United States, the right of a minor to consent to treatment without parental knowledge differs between states and is governed by state-specific
minor consent laws. Some consent laws are based on a minor's status, such as minors who are emancipated, parents, married, pregnant, in the armed services, or mature. In some states, minors can be considered emancipated if they are or have served in the armed services or are living apart from parents and are economically independent through gainful employment. A mature minor is a minor who is emotionally and intellectually mature enough to give informed consent and who lives under the supervision of a parent or guardian. Courts have held that if a minor is mature, a physician is not liable for providing beneficial treatment. There is no formal process for recognition of a mature minor. The determination is made by the healthcare provider.

Some minor consent laws are based on services a minor is seeking, such as emergency care, sexual healthcare, substance abuse, or mental healthcare (Table 137.3). All 50 states and the District of Columbia explicitly allow minors to consent for their own health services for STIs. Approximately 25% of states require that minors be a certain age (generally 12-14 yr) before they can consent for their own care for STIs. No state requires parental consent for STI care or requires that providers notify parents that an adolescent minor child has received STI services, except in limited or unusual circumstances.

### Table 137.3

**Types of Minor Consent Statutes or Rules of Common Law That Allow for Medical Treatment of a Minor Patient Without Parental Consent**

<table>
<thead>
<tr>
<th>LEGAL EXCEPTIONS TO INFORMED CONSENT REQUIREMENT</th>
<th>MEDICAL CARE SETTING</th>
</tr>
</thead>
</table>
| The “emergency” exception                       | • The child is suffering from an emergent condition that places his or her life or health in danger.  
• The child's legal guardian is unavailable or unable to provide consent for treatment or transport.  
• Treatment or transport cannot be safely delayed until consent can be obtained.  
• The professional administers only treatment for emergent conditions that pose an immediate threat to the child. |
| The “emancipated minor” exception               | • Married  
• Economically self-supporting and not living at home  
• Active-duty status in the military  
• In some states, a minor who is a parent or pregnant  
• Some states might require a court to declare the emancipation of a minor. |
<p>| The “mature”                                   | Most states recognize a mature minor, in which a minor, usually ≥14 yr, displays sufficient |</p>
<table>

</tr>
<tr>
<td>• Pregnancy and contraceptive services</td>
<td>• Sexually transmitted infection testing and treatment</td>
</tr>
<tr>
<td>• Drug and alcohol addiction treatment</td>
<td></td>
</tr>
</tbody>
</table>

Minors’ right to consent for **contraceptive services** varies from state to state. Almost 50% of states and the District of Columbia explicitly authorize all minors to consent for their own contraceptive services; and 50% of states permit minors to consent for their own contraceptive services under specific circumstances, such as being married, a parent, currently or previously pregnant, over a certain age, or a high school graduate, or per physician's discretion.

A minor's right to consent for **mental healthcare** and **substance abuse** treatment services vary by state and age of minor, whether care is medical vs nonmedical (e.g., counseling), and whether care is delivered as an inpatient vs outpatient basis. Minor consent laws often contain provisions regarding confidentiality and disclosure, even when general state consent laws do not have such provisions.

The **confidentiality** of medical information and records of a minor who has consented for his or her own reproductive healthcare is governed by numerous federal and state laws. Laws in some states explicitly protect the confidentiality of STI or contraceptive services for which minors have given their own consent and do not allow disclosure of the information without the minor's consent. In other states, laws grant physicians discretion to disclose information to parents.

The confidentiality of medical information and records of a minor who has consented for his or her own healthcare is also governed by numerous federal and state laws. Laws in some states explicitly protect the confidentiality of STI, contraceptive, or mental health services for which minors have given their own consent, and do not allow disclosure of the information without the minor's consent. In other states, laws grant physicians discretion to disclose information to parents. Title X and Medicaid both provide confidentiality protection for family planning services provided to minors with funding from these programs.

Federal regulations issued under the Federal Health Insurance Portability and Accountability Act of 1996, known as the **HIPAA Privacy Rule**, defer to state and “other applicable laws” with respect to the question of whether parents have
access to information about care for which a minor has given consent. Thus, both the state laws that either prohibit or permit disclosure of confidential information and the federal Title X and Medicaid laws that protect the confidentiality of care for adolescents are important under the HIPAA Privacy Rule in determining when confidential information about health services for minors can be disclosed to parents.

Billing for confidential services is complex. Commercial health plans send home an explanation of benefit (EOB) to the primary insured or the primary beneficiary, listing services rendered by the provider and reimbursed by the health plan. An EOB documenting that confidential health services were rendered to their adolescent dependent that is received by a parent may disclose those services. In addition, copayments automatically generated with certain billing codes for office visits and medications can be a barrier for adolescents receiving care, including treatment.

Providers may elect to establish a policy of discussing with their adolescent patients when medical records and other information will be disclosed and developing a mechanism to alert office staff as to what information in the chart is confidential. For legal and other reasons, a chaperone should be present whenever an adolescent female patient is examined by a male physician.

Screening Procedures

Gale R. Burstein

Interviewing the Adolescent

The preparation for a successful interview with an adolescent patient varies based on the history of the relationship with the patient. Patients (and their parents) who are going from preadolescence to adolescence while seeing the same provider should be guided through the transition. Although the rules for confidentiality are the same for new and continuing patients, the change in the physician–patient relationship, allowing more privacy during the visit and more autonomy in the health process, may be threatening for the parent as well as the adolescent. For new patients, the initial phases of the interview are more challenging given the need to establish rapport rapidly with the patient in order to meet the goals of the encounter. Issues of confidentiality and privacy should be explicitly stated along with the conditions under which that confidentiality
may need to be altered, that is, in life- or safety-threatening situations. For new patients, the parents should be interviewed with the adolescent or before the adolescent to ensure that the adolescent does not perceive a breach of confidentiality. The clinician who takes time to listen, avoids judgmental statements and the use of street jargon, and shows respect for the adolescent's emerging maturity will have an easier time communicating with the adolescent. The use of open-ended questions, rather than closed-ended questions, will further facilitate history taking. (The closed-ended question, “Do you get along with your father?” leads to the answer “yes” or “no,” in contrast to the question, “What might you like to be different in your relationship with your mother?” which may lead to an answer such as, “I would like her to stop always worrying about me.”)

The goals of the interview or clinical encounter are to establish an information base, identify problems and issues from the patient's perspective, and identify problems and issues from the perspective of the clinician, based on knowledge of the health and other issues relevant to the adolescent age-group. The adolescent should be given an opportunity to express concerns and the reasons for seeking medical attention. The adolescent as well as the parent should be allowed to express the strengths and successes of the adolescent, in addition to communicating problems.

The effectiveness of an interview can be compromised when the interviewer is distracted by other events or individuals in the office, when extreme time limitations are obvious to either party, or when there is expressible discomfort with either the patient or the interviewer. The need for an interpreter when a patient is hearing impaired or if the patient and interviewer are not language compatible provides a challenge but not necessarily a barrier under most circumstances (see Chapter 11). Observations during the interview can be useful to the overall assessment of the patient's maturity, presence or absence of depression, and the parent–adolescent relationship. Given the key role of a successful interview in the screening process, adequate training and experience should be sought by clinicians providing comprehensive care to adolescent patients.

Psychosocial Assessment

A few questions should be asked to identify the adolescent who is having difficulty with peer relationships (Do you have a best friend with whom you
can share even the most personal secret?), self-image (Is there anything you would like to change about yourself?), depression (What do you see yourself doing 5 yr from now?), school (How are your grades this year compared with last year?), personal decisions (Are you feeling pressured to engage in any behavior for which you do not feel you are ready?), and an eating disorder (Do you ever feel that food controls you, rather than vice versa?). Bright Futures materials provide questions and patient encounter forms to structure the assessments. The HEADS/SF/FIRST mnemonic, basic or expanded, can be useful in guiding the interview if encounter forms are not available (Table 137.4). Based on the assessments, appropriate counseling or referrals are recommended for more thorough probing or for in-depth interviewing.

### Table 137.4
Adolescent Psychosocial Assessment: HEADS/SF/FIRST Mnemonic

| H ome. | Space, privacy, frequent geographic moves, neighborhood |
| E ducation/School. | Frequent school changes, repetition of a grade/in each subject, teachers' reports, vocational goals, after-school educational clubs (e.g., language, speech, math), learning disabilities |
| A buse. | Physical, sexual, emotional, verbal abuse; parental discipline |
| D rugs. | Tobacco, electronic cigarettes or vaping devices, alcohol, marijuana, inhalants, “club drugs,” “rave” parties, others; drug of choice, age at initiation, frequency, mode of intake, rituals, alone or with peers, quit methods, number of attempts |
| S afety. | Seat belts, helmets, sports safety measures, hazardous activities, driving while intoxicated |
| S exuality/S exual Identity. | Reproductive health (use of contraceptives, presence of sexually transmitted infections, feelings, pregnancy) |
| F amily and F riends |
  | Family: Family constellation; genogram; single/married/separated/divorced/blended family; family occupations and shifts; history of addiction in first- and second-degree relatives; parental attitude toward alcohol and drugs; parental rules; chronically ill, physically or mentally challenged parent |
  | Friends: Peer cliques and configuration (“preppies,” “jocks,”
“nerds,” “computer geeks,” cheerleaders), gang or cult affiliation

**Image.** Height and weight perceptions, body musculature and physique, appearance (including dress, jewelry, tattoos, body piercing as fashion trends or other statement)

**Recreation.** Sleep, exercise, organized or unstructured sports, recreational activities (television, video games, computer games, internet and chat rooms, church or community youth group activities [e.g., Boy (BSA)/Girl Scouts; Big Brother/Sister groups, campus groups]). How many hours per day, days per week involved?

**Spirituality and Connectedness.** Use HOPE* or FICA † acronym; adherence, rituals, occult practices, community service or involvement

**Threats and Violence.** Self-harm or harm to others, running away, cruelty to animals, guns, fights, arrests, stealing, fire setting, fights in school

---

* HOPE, H ope or security for the future; o rganized religion; p ersonal spirituality and p ractices; e ffects on medical care and end-of-life issues.
† FICA, Faith beliefs; importance and influence of faith; community support.

---

**Physical Examination**

**Vision Testing**

The pubertal growth spurt may involve the optic globe, resulting in its elongation and myopia in genetically predisposed individuals (see Chapter 636). Vision testing should therefore be performed to detect this problem before it affects school performance.

**Audiometry**

Highly amplified music of the kind enjoyed by many adolescents may result in hearing loss or tinnitus (see Chapter 654). A hearing screening is recommended
by the *Bright Futures* guidelines for adolescents who are exposed to loud noises regularly, have had recurring ear infections, or report problems.

**Blood Pressure Determination**

Criteria for a diagnosis of hypertension are based on age-specific norms that increase with pubertal maturation (see Chapter 449). An individual whose blood pressure (BP) exceeds the 95th percentile for his or her age is suspect for having hypertension, regardless of the absolute reading. Those adolescents with BP between the 90th and 95th percentiles should receive appropriate counseling relative to weight and have a follow-up examination in 6 mo. Those with BP above the 90th percentile should have their BP measured on 3 separate occasions to determine the stability of the elevation before moving forward with an intervention strategy. The technique is important; false-positive results may be obtained if the cuff covers less than two thirds of the upper arm. The patient should be seated, and an average should be taken of the 2nd and 3rd consecutive readings, using the change rather than the disappearance as the diastolic pressure. Most adolescents with BP elevation have labile hypertension. If BP is below 2 standard deviations (SD) for age, anorexia nervosa and Addison disease should be considered.

**Scoliosis**

See Chapter 699.

Approximately 5% of male and 10–14% of female adolescents have a mild curvature of the spine. This is 2-4 times the rate in younger children. Scoliosis is typically manifested during the peak of the height velocity curve, at approximately 12 yr in females and 14 yr in males. Curves measuring >10 degrees should be monitored by an orthopedist until growth is complete.

**Breast Examination**

See Chapters 141 and 556.

Visual inspection of the young and middle adolescent female adolescent's breasts is performed to evaluate progression of sexual maturation and provide reassurance about development.
Scrotum Examination

Visual inspection of the young and middle adolescent male testicles is performed to evaluate progression of sexual maturation and provide reassurance about development. The peak incidence of germ cell tumors of the testes is in late adolescence and early adulthood. Palpation of the testes may have an immediate yield and should serve as a model for instruction of self-examination. Because varicoceles often appear during puberty, the examination also provides an opportunity to explain and reassure the patient about this entity (see Chapter 560).

Pelvic Examination

See Chapter 563.

Laboratory Testing

The increased incidence of iron-deficiency anemia after menarche directs the performance of a hematocrit annually in females with moderate to heavy menses. The reference standard for this test changes with progression of puberty, as estrogen suppresses erythropoietin (see Chapter 474). Populations with nutritional risk should also have the hematocrit monitored. Androgens have the opposite effect, causing the hematocrit to rise during male puberty; sexual maturity rating (SMR) 1 males have an average hematocrit of 39%, whereas those who have completed puberty (SMR 5; see Chapter 132) have an average value of 43%. Tuberculosis (TB) testing is important in adolescents with risk factors, such as an adolescent with HIV, living in the household with someone with HIV, the incarcerated or homeless adolescent, adolescents from a country where TB is common, or those with other risk factors, because puberty has been shown to activate this disease in those not previously treated. Hepatitis C virus (HCV) screening should be offered to adolescents who report risk factors, such as IDU, received blood products or organ donation before 1992, or long-term hemodialysis. Almost 10% of all HCV cases reported to CDC in 2015 were among 15-24 yr olds. CDC HCV surveillance data demonstrates that from 2006 to 2014, the number of reported HCV infections among females of reproductive age (15-44 yrs) doubled. Nearly half of those cases were among females 15-30 yrs of age. Two thirds (67%) of those with a known risk factor reported intravenous drug use.
Sexually active adolescents should undergo screening for STIs per CDC guidelines, regardless of symptoms (see Chapter 146). There are clear indications for chlamydia and gonorrhea screening of females ≤24 yr old, but less sufficient evidence to support routine screening in young men. Based on feasibility, efficacy, and cost-effectiveness, evidence is insufficient to recommend routine chlamydia screening in all sexually active young men. However, screening of sexually active young males should be considered in clinical settings associated with high prevalence of chlamydia (e.g., adolescent clinics, correctional facilities, sexually transmitted disease clinics) and should be offered to all young MSM. HIV screening should be discussed and offered at least once to all adolescents aged 15-18 yr and to younger and older adolescents who are at increased risk. Routine screening of adolescents who are asymptomatic for certain STIs (e.g., syphilis, trichomoniasis, herpes simplex virus, HPV) is not recommended. However, young MSM and pregnant adolescent females might require more thorough evaluation for all sexually transmitted diseases. Because cervical cancer incidence is low and complications from procedures may outweigh benefits of screening adolescent females, cervical cancer screening should not begin until age 21 yr.

Bibliography

Centers for Disease Control and Prevention. The recommended immunization schedule for children and adolescents aged 18 years or younger, United States.

English A, Park MJ. Access to health care for young adults: the Affordable Care Act is making a difference. Center for Adolescent Health and the Law; and San Francisco, National Adolescent Health and Young Adult Information Center: Chapel Hill, NC; 2012.

The importance of successfully transitioning the care of adolescents with special healthcare needs (SHCN) from pediatric to adult services has been recognized for more than 2 decades. Successful transition is associated with improved health outcomes and quality of life; poorly managed transition may lead to loss of a medical home and worsening of chronic disease control and previous care.

The American Academy of Pediatrics, in conjunction with other key professional societies, published detailed, comprehensive guidelines for incorporating transition services into the medical home for all adolescents, regardless of the presence or absence of SHCN. These guidelines are based on expert opinion because the evidence on transition outcomes is limited. This clinical report emphasizes that transition encompasses much more than simply the transfer of care to another provider. The guidelines go beyond recommendations for the pediatric medical home by providing guidance and practice-based resources for implementing elements of transition support in family medicine and internal medicine practices. This includes providing assistance for the patient in adapting to an adult model of healthcare delivery. Table 138.1 represents the key elements of healthcare transition. Tools to assist providers with these steps are available online from the National Center for Health Care Transition Improvement (www.gottransition.org).

Table 138.1

**Key Elements of the Transition of Healthcare Process**

- *Written transition policy* to be shared with youth, families, providers, and staff, explaining the process and the responsibilities of all team members
- **Transitioning youth registry** to track the progress of each patient through the transition process
- **Longitudinal readiness checklists** assessing the youth's ability for independence, self-management, and communicating with the adult healthcare system, as well as the family's readiness to assist the patient in achieving these goals
- **Written transition plan** documenting the steps to be conducted to meet the needs identified in the readiness assessment, as well as identifying appropriate adult care resources
- For youth with SHCN, expanded transition services, including attention to insurance, entitlements, guardianship, and vocational needs, in addition to adult subspecialty care
- Appropriate communication between the pediatric and adult medical home and subspecialists, including a **portable medical summary** and care plan delivered to the patient and caregivers
- Transfer of care, within the 18-21 yr old range, to adult providers, to whom pediatric providers continue to serve as a resource until transition is complete

The process begins with the development of a transition policy and its dissemination to all families of young adolescents, ensuring that families understand that transition planning will be an element of health maintenance and chronic care management visits throughout the adolescent years. By middle adolescence, a transition plan should be developed with the youth and family caregivers and updated at subsequent visits until the patient is ready for implementation of the adult care model in early adulthood. Periodic **readiness assessments** are key to plan and anticipate challenges. Critical to the transition process is **skills training** for the adolescent in communication, self-advocacy, and self-care. Some youth with SHCN depend on caregivers for navigating the healthcare system on their behalf, and it is not realistic to expect increased independence. For these youth, addressing guardianship, long-term care planning, and advanced directives are important. **Care coordination** has been found to facilitate navigation and engagement in an adult-oriented health system, especially for adolescents with SHCN. The goal is to help all youth maximize their potential as they become young adults.

Violent Behavior

Michael N. Levas, Marlene D. Melzer-Lange

Violence is recognized by the World Health Organization (WHO) as a leading worldwide public health problem. WHO defines violence as “the intentional use of physical force or power, threatened or actual, against oneself, another person, or against a group or community that either results in or has a high likelihood of resulting in injury, death, psychologic harm, maldevelopment or deprivation” (see Chapter 14). Youths may be perpetrators, victims, or observers of violence (or any combination of the 3 roles), with varying severity of impact on the individual, family, and larger community. Risk factors for youth violence include poverty, relative social disadvantage, war, substance abuse, mental health disorders, and poor family functioning.

Epidemiology

In 2015, homicide in the United States was the 3rd leading cause of death for 10-24 yr olds, totaling 4,979 deaths, which were largely males (87%) killed by a handgun (90.1%). The 2015 homicide rate for teens ages 12-17 yr was 3.1/100,000 youth, down 65% from 8.4/100,000 youth in 1993. WHO reports that other than the United States, where the youth and young adult homicide rate was 11 per 100,000, most countries with homicide rates above 10 per 100,000 are developing nations or countries with rapid socioeconomic changes. In the United States the prevalence of behaviors that contribute to violence has not decreased since 1999; fighting, weapon carrying, and gang involvement remain prevalent among youth. Gang-related homicides among youth in 5 major U.S. cities are more likely to involve young (15-19 yr) males (80%), racial/ethnic minorities (73%), and a firearm (90%) in comparison to homicides unrelated to gang activity. In addition, gang homicides are more likely to occur in public
places, in the afternoon/evening hours, and rarely are related to drug trade/use. Furthermore, the rate of homicide in youth had been declining but showed an increase in 2015 (Fig. 139.1).

![US Homicides and age-adjusted rates: youth 10 to 19 years of age 1999–2015](http://www.cdc.gov/ncipc/wisqars)

Adolescent reports of **physical fighting** have decreased from 42% in 1991 to 23% in 2015. Violence at U.S. schools remains a significant problem, however, with 7.8% of students reporting being in a physical fight on school property 1 or more times in the preceding 12 mo. The 2015 Youth Risk Behavior Surveillance System reported 16.2% of youths overall carried a weapon such as a gun, knife, or club in the last 30 days; 4.1% carried the weapon to school; and 6.0% reported being threatened or injured with a type of weapon on school property. Males are more likely than females to carry a gun or weapon and therefore may need more support and engagement at home and at school. **Weapon carrying** is highest among white males overall, which may begin as early as 9th grade. These violence-related behaviors at school affect the general students' perception of safety. More than 5.6% of students did not go to school on 1 or more days in the preceding 30 days because they felt it was unsafe. School-based prevention programs initiated at the elementary school level have been found to decrease
violent behaviors in students. Increased surveillance of students is warranted both on and around school property to improve student safety.

**Dating violence** (or intimate partner violence) occurs between 2 people in a close relationship and can be physical (punching, kicking, hitting, shoving), emotional (shaming, bullying, controlling, stalking), or sexual (forcing partner to engage in a sexual act when he/she does not consent to it). Incidents of dating violence often occur during the adolescent years, with 22.4% of women and 15% of men experiencing some type of partner violence between the ages of 11 and 17 yr. The highest prevalence rates are seen in black students and older students. It may start with teasing, name calling, or shaming but often progresses electronically, as frequent calls, texting, or posting sexual pictures of a partner on social media. Risk factors for being a victim of dating violence includes those who use alcohol, believe dating violence is acceptable, have lack of parental supervision, or have a friend who is in a violent relationship. Most teens do not report the behaviors due to fear of retaliation from the partner. Teens who are victims of dating violence are more likely to experience decreased school performance, have thoughts about suicide, use drugs and alcohol, develop an eating disorder, experience depression, and are more likely to be victimized during college. School-based prevention programs that address attitudes and behaviors linked with dating violence, such as **Safe Dates** and **Dating Matters**, offer training experiences to change social norms among teens.

**Etiology**

WHO places youth violence in a model within the context of 3 larger types of violence: self-inflicted, interpersonal, and collective. **Interpersonal violence** is subdivided into violence largely between family members or partners and includes child abuse. **Community violence** occurs between individuals who are unrelated. **Collective violence** incorporates violence by people who are members of an identified group against another group of individuals with social, political, or economic motivation. The types of violence in this model have behavioral links, such that child abuse victims are more likely to experience violent and aggressive interpersonal behavior as adolescents and adults. Overlapping risk factors for the types of violence include firearm availability, alcohol use, and socioeconomic inequalities. The benefit to identifying common risk factors for the types of violence lies in the potential for intervening with prevention efforts and gaining positive outcomes for more than 1 type of violent behavior. The
The identified risk factors for youth violence include poverty, association with delinquent peers, poor school performance or low education status, disconnection from adult role models or mentors, prior history of violence or victimization, poor family functioning, childhood abuse, substance abuse, and certain mental health disorders. The most common disorders associated with aggressive behavior in adolescents are mental retardation, learning disabilities, moderately severe language disorders, and mental disorders such as attention-deficit/hyperactivity disorder (ADHD) and mood disturbances. The link between severe mental illness and violent behaviors is strongest for those with coexisting alcohol or substance abuse or dependence.

Inability to master prosocial skills such as the establishment and maintenance of positive family/peer relations and poor resolution of conflict may put adolescents with these disorders at higher risk of physical violence and other risky behaviors. Conduct disorder and oppositional defiant disorder are
specific psychiatric diagnoses whose definitions are associated with violent behavior (Table 139.1). They occur with other disorders such as ADHD (see Chapter 49) and increase an adolescent's vulnerability for juvenile delinquency, substance use or abuse, sexual promiscuity, adult criminal behavior, incarceration, and antisocial personality disorder. Other co-occurring risk factors for youth violence include use of anabolic steroids, gang tattoos, belief in one's premature death, preteen alcohol use, and placement in a juvenile detention center.

**Table 139.1**

<td>Diagnosed by a mental health practitioner</td>
<td>Adjudicated in the legal system</td>
</tr>
</tbody>
</table>

**Diagnosis**

The assessment of an adolescent at risk or with a history of violent behavior or victimization should be a part of the health maintenance visit of all adolescents. The answers to questions about recent history of involvement in a physical fight, carrying a weapon, or firearms in the household, as well as concerns that the
adolescent may have about personal safety, may suggest a problem requiring a more in-depth evaluation. The **FISTS** mnemonic provides guidance for structuring the assessment (Table 139.2). The additional factors of physical or sexual abuse, serious problems at school, poor school performance and attendance, multiple incidents of trauma, substance use, and symptoms associated with mental disorders are indications for evaluation by a mental health professional. In a situation of acute trauma, assault victims are not always forthcoming about the circumstances of their injuries for fear of retaliation or police involvement. Stabilization of the injury or the gathering of forensic evidence in sexual assault is the treatment priority; however, once this is achieved, addressing a more comprehensive set of issues surrounding the assault is appropriate.

**Table 139.2**

</tr>
</tbody>
</table>

**Treatment**

In the patient with acute injury secondary to violent assault, the treatment plan should follow standards established by the American Academy of Pediatrics model protocol, which includes the stabilization of the injury, evaluation and
treatment of the injury, evaluation of the assault circumstance, psychological evaluation and support, social service evaluation of the circumstance surrounding the assault, and a treatment plan on discharge that is designed to protect the adolescent from subsequent injury episodes, prevent retaliation, and minimize the development of psychological disability. Victims as well as witnesses of violence are at risk for posttraumatic stress disorder and future aggressive or violent behavior. Utilizing a trauma-informed care approach enables providers to help these victims and witnesses so that they can develop linkages to recovery and resilience. **Hospital-based violence intervention programs** have shown success by supporting youth who have sustained a violent injury in the emergency department, hospital, or community.

Multiple treatment modalities are used simultaneously in managing adolescents with persistent violent and aggressive behavior and range from cognitive-behavioral therapy involving the individual and family to specific family interventions (parent management training, multisystemic treatment) and pharmacotherapy. Treatment of comorbid conditions, such as ADHD, depression, anxiety, and substance abuse, appears to reduce aggressive behavior.

**Prevention**

The WHO recognizes a multifactorial approach to prevention: parenting and early childhood development strategies; school-based academic and social skills development strategies, strategies for young people at higher risk of or already involved in violence, and community-and society-level strategies (Table 139.3). **Parenting and early childhood development approaches** concentrate on working with families to provide nonviolent parenting through home visitation and parent groups as well as teaching coping strategies and nonviolent conflict resolution for all children and families. **School-based social skills development strategies** focus on students' families and peer relationships, especially those with the potential to trigger aggressive or violent responses. Solutions include improving skills in coping or problem solving in bullying, peer mediation, dating violence prevention, and after-school programs. **Strategies for young people at higher risk of, or already involved in, violence** include therapeutic mental health approaches, crime victim services, vocational training, mentoring, and gang intervention. These youth are at highest risk for repeat injury or incarceration. **Community- and societal-level approaches** include broader advocacy and legislative actions, as well as changing the cultural norm toward
violent behaviors.

+, Promising (strategies that include 1 or more programs supported by at least 1 well-designed study showing prevention of perpetration and/or experiencing of youth violence, or at least 2 studies showing positive changes in key risk or protective factors for youth violence).

?, Unclear because of insufficient evidence (strategies that include 1 or more programs of unclear effectiveness).

+/−, Unclear because of mixed results (strategies for which the evidence is mixed; some programs have a significant positive effect and others a significant negative effect on youth violence).

A specific prevention strategy can incorporate several approaches, such as the handgun/firearm prevention recommendations that include gun-lock safety, public education, and legislative advocacy. Other efforts are directed toward establishing a national database to track and define the problem of youth violence. The National Violent Death Reporting System collects and analyzes violent death data from 40 states and aims to improve surveillance of current trends, to share information state to state, to build partnerships among state and community organizations, and to develop and implement prevention and intervention programs. The Centers for Disease Control and Prevention characterizes specific successful prevention programs and summarizes program content on its website (www.cdc.gov).

**Bibliography**

Hahn R, Fuqua-Whitley D, Wethington H, et al. The

Substance Abuse and Mental Health Services Administration.

Although varying in percentages by nation and culture, a substantial proportion of adolescents will engage in the use of a wide range of substances, including alcohol, tobacco, natural and synthetic marijuana, opiates, and stimulants. Their reactions to and the consequences of these exposures are influenced by a complex interaction among biologic and psychosocial development, environmental messages, legality, and societal attitudes. The potential for adverse outcomes even with occasional use in adolescents, such as motor vehicle crashes and other injuries, is sufficient justification to consider any drug use in adolescents a considerable risk.

Individuals who initiate drug use at an early age are at a greater risk for becoming addicted than those who try drugs in early adulthood. Drug use in younger adolescents can act as a substitute for developing age-appropriate coping strategies and enhance vulnerability to poor decision-making. First use of the most commonly used drug (alcohol) occurs before age 18 yr, with 88% of people reporting age of first alcohol use at <21 yr old, the legal drinking age in the United States. Interestingly, inhalants have been identified as a popular first drug for youth in 8th grade (age 13-14 yr).

When drug use begins to negatively alter functioning in adolescents at school and at home, and risk-taking behavior is seen, intervention is warranted. Serious drug use is a pervasive phenomenon and infiltrates every socioeconomic and cultural segment of the population. It is one of the costliest and most challenging public health problems facing all societies and cultures. The challenge to the clinician is to identify youths at risk for substance abuse and offer early intervention. The challenge to the community and society is to create norms that decrease the likelihood of adverse health outcomes for adolescents and promote and facilitate opportunities for adolescents to choose healthier and safer options.
Recognizing those drugs with the greatest harm, and at times focusing on harm reduction with or without abstinence, is an important modern approach to adolescent substance abuse (Figs. 140.1 and 140.2).

**FIG. 140.1** Mean harm scores for 20 substances as determined by an expert panel based on 3 criteria: physical harm to user; potential for dependence; and effect on family, community, and society. Classification under the Misuse of Drugs Act, when appropriate, is shown by the color of each bar. Class A drugs are deemed potentially most dangerous; class C least dangerous. (From Nutt D, King LA, Saulsbury W, et al: Development of a rational scale to access the harm of drugs of potential misuse, *Lancet* 369:1047–1053, 2007.)
Etiology

Substance abuse has multifactorial origins (Fig. 140.3). Biologic factors, including genetic predisposition, are established contributors. Behaviors such as
rebelliousness, poor school performance, delinquency, and criminal activity and personality traits such as low self-esteem, anxiety, and lack of self-control are frequently associated with or predate the onset of drug use. Psychiatric disorders often coexist with adolescent substance use. Conduct disorders and antisocial personality disorders are the most common diagnoses coexisting with substance abuse, particularly in males. Teens with depression (see Chapter 39.1), attention deficit disorder (Chapter 49), anxiety (Chapter 38), and eating disorders (Chapter 41) have high rates of substance use. The determinants of adolescent substance use and abuse are explained using numerous theoretical models, with factors at the individual level, the level of significant relationships with others, and the level of the setting or environment. Models include a balance of risk and protective or coping factors contributing to individual differences among adolescents with similar risk factors who escape adverse outcomes.

Risk factors for adolescent *drug use* may differ from those associated with adolescent *drug abuse*. Adolescent use is more commonly related to social and peer factors, whereas abuse is more often a function of psychological and biologic factors. The likelihood that an otherwise normal adolescent would experiment with drugs may depend on the availability of the drug to the adolescent, the perceived positive or otherwise functional value to the adolescent, the perceived risk associated with use, and the presence or absence of restraints, as determined by the adolescent's cultural or other important value systems. An adolescent who abuses drugs may have genetic or biologic factors coexisting with dependence on a particular drug for coping with day-to-day activities.

Specific historical questions can assist in determining the severity of the drug problem through a rating system (*Table 140.1*). The type of drug used (marijuana vs heroin), the circumstances of use (alone or in a group setting), the frequency and timing of use (daily before school vs occasionally on a weekend), current mental health status, and general functional status, including sleep habits and screen use, should all be considered in evaluating any child or adolescent found to be using a drug. The stage of drug use/abuse should also be considered (*Table 140.2*). A teen may spend months or years in the experimentation phase trying a variety of illicit substances, including the most common drugs: cigarettes, alcohol, and marijuana. Often it is not until regular use of drugs resulting in negative consequences (problem use) that the teen is identified as having a problem, either by parents, friends, teachers, or a healthcare provider. Certain protective factors play a part in buffering the risk factors as well as assisting in anticipating the long-term outcome of experimentation. Having emotionally supportive parents with open communication styles, involvement in organized school activities, having mentors or role models outside the home, and recognition of the importance of academic achievement are examples of the important protective factors.

### Table 140.2

**Stages of Adolescent Substance Abuse**

<table>
<thead>
<tr>
<th>STAGE</th>
<th>DESCRIPTION</th>
</tr>
</thead>
</table>
| 1 | Potential for abuse  
- Decreased impulse control  
- Need for immediate gratification  
- Available drugs, alcohol, inhalants  
- Need for peer acceptance |
| 2 | Experimentation: learning the euphoria  
- Use of inhalants, tobacco, marijuana, and alcohol with friends  
- Few, if any, consequences  
- Use may increase to weekends regularly  
- Little change in behavior |
| 3 | Regular use: seeking the euphoria  
- Use of other drugs, e.g., stimulants, LSD, sedatives  
- Behavioral changes and some consequences  
- Increased frequency of use; use alone  
- Buying or stealing drugs |
| 4 | Regular use: preoccupation with the “high”  
- Daily use of drugs  
- Loss of control  
- Multiple consequences and risk taking  
- Estrangement from family and “straight” friends |
| 5 | Burnout: use of drugs to feel normal  
- Polysubstance use/cross-addiction  
- Guilt, withdrawal, shame, remorse, depression  
- Physical and mental deterioration  
- Increased risk taking, self-destructive, suicidal |

### Epidemiology

Alcohol, cigarettes, and marijuana are the most commonly reported substances used among U.S. teens (Table 140.3). The prevalence of substance use and associated risky behaviors vary by age, gender, race/ethnicity, and other
sociodemographic factors. Younger teenagers tend to report less use of drugs than do older teenagers, except for inhalants (in 2016, 4.4% in 8th grade, 2.8% in 10th grade, 1.0% in 12th grade). Males have higher rates of both licit and illicit drug use than females, with greatest differences seen in their higher rates of frequent use of smokeless tobacco, cigars, and anabolic steroids. For a number of years, black 12th graders have reported lifetime, annual, 30-day, and daily prevalence levels for nearly all drugs that were lower than those for white or Hispanic 12th graders. That is less true today, with levels of drug use among blacks more similar to the other groups.

---

**Notes:**

- **a** The proportional change is the percent by which the most recent year deviates from the peak year (or the low year) for the drug in question. Thus, if a drug was at 20% prevalence in the peak year and declined to 10% prevalence in the most recent year, this would reflect a proportional decline of 50%.

- **b** Question was discontinued among 8th and 10th graders in 2012.

- **c** In 2013, for the questions on the use of amphetamines, the text was changed on 2 of the questionnaire forms for 8th and 10th graders and 4 of the questionnaire forms for 12th graders. This change also impacted the any illicit drug indices. Data presented here include only the changed forms beginning in 2013.

- **d** In 2014, the text was changed on 1 of the questionnaire forms for 8th, 10th, and 12th graders to include “Molly” in the description. The remaining forms were changed in 2015. Data for both versions of the question are presented here.
Notes: “—” indicates data not available; “‡” indicates a change in the question text. When a question change occurs, peak levels after that change are used to calculate the peak year to current year difference.

Values in **bold** equal peak levels since 1991. Values in *italics* equal peak level before wording change. Underlined values equal lowest level since recent peak level.

Level of significance of difference between classes: s = .05, ss = .01, sss = .001.

Any apparent inconsistency between the change estimate and the prevalence estimates for the 2 most recent years is caused by rounding.

The distribution of annual marijuana use by race/ethnicity varies by grade level. In all 3 grades, prevalence is highest among Hispanic students. Differences in prevalence across the groups are proportionately largest in 8th grade (13% for Hispanics, 7.8% for whites), somewhat smaller in 10th grade (27% for Hispanics, 24% for whites), and negligible in 12th grade (37% for Hispanics, 35% for whites). Blacks fall between whites and Hispanics in 8th and 10th grade but are slightly below them in 12th grade (35%).

The number of 12th graders who report using any of the prescription psychotherapeutic drugs, including amphetamines, sedatives (barbiturates), tranquilizers, and narcotics other than heroin, decreased in 2016 (*Table 140.4*). Prevalence was 18.0%, 12.0%, and 5.4% for lifetime, annual, and 30-day use, respectively, indicating that a substantial portion of adolescents still use prescription drugs nonmedically. Rural adolescents were 26% more likely than urban adolescents to have used prescription drugs nonmedically. Use was associated with decreased health status, major depressive episode(s), and other drug use (marijuana, cocaine, hallucinogens, inhalants) and alcohol use. In a large-scale study of 16,209 adolescent exposures to prescription drugs, 52.4% were females, and the mean age was 16.6 yr. The 5 most frequently misused or abused drugs were hydrocodone (32%), amphetamines (18%), oxycodone (15%), methylphenidate (14%), and tramadol (11%). Many of these drugs can be found in the parents' home, some are over-the-counter (OTC) drugs (dextromethorphan, pseudoephedrine), whereas others are purchased from drug dealers at schools and colleges. Teen users of nonmedical opioids use other substances concurrently. Most frequently, teens combine opioids with marijuana, alcohol, cocaine, and tranquilizers, putting them at risk for serious complications and overdose.
Clinical Manifestations

Although manifestations vary by the specific substance of use, adolescents who use drugs often present in an office setting with no obvious physical findings. Drug use is more frequently detected in adolescents who experience trauma such as motor vehicle crashes, bicycle injuries, or violence. Eliciting appropriate historical information regarding substance use, followed by blood alcohol and urine drug screens, is recommended in emergency settings. Although waning in popularity, the illicit substances known as “club drugs” still need to be...
considered in the differential diagnosis of a teen with an altered sensorium (Table 140.5). An adolescent presenting to an emergency setting with an impaired sensorium should be evaluated for substance use as a part of the differential diagnosis (Table 140.6). Screening for substance use is recommended for patients with psychiatric and behavioral diagnoses. Other clinical manifestations of substance use are associated with the route of use; intravenous drug use is associated with venous “tracks” and needle marks, and nasal mucosal injuries are associated with nasal insufflation of drugs. Seizures can be a direct effect of drugs such as cocaine, synthetic marijuana, and amphetamines or an effect of drug withdrawal in the case of barbiturates or tranquilizers.

* Depends on dose.
Concentrations that are sufficiently high can give positive results for amphetamine because of cross-reactions.

Flunitrazepam can give positive results for benzodiazepines; ketamine can give positive results for phencyclidine.

DEA, U.S. Drug Enforcement Agency, currently reviewing possibility of flunitrazepam being placed into schedule of the U.S. Controlled Substance Act; GC/MS, gas chromatography–mass spectroscopy. Duration, half-life, and peak plasma are probably different after high or sequential doses because of nonlinear kinetics; ND, not determined in humans.

</table>

Screening for Substance Abuse Disorders

In a primary care setting the annual health maintenance examination provides an opportunity for identifying adolescents with substance use or abuse issues. The direct questions as well as the assessment of school performance, family relationships, and peer activities may necessitate a more in-depth interview if there are suggestions of difficulties in those areas. Several self-report screening questionnaires also are available, with varying degrees of standardization, length, and reliability. The CRAFFT mnemonic is specifically designed to screen for adolescents' substance use in the primary setting (Table 140.7). Privacy and confidentiality must be established when asking the teen about specifics of their substance experimentation or use. Interviewing the parents can provide additional perspective on early warning signs that go unnoticed or disregarded by the teen. Examples of early warning signs of teen substance use are change in mood, appetite, or sleep pattern; decreased interest in school or school performance; loss of weight; secretive behavior about social plans; or valuables such as money or jewelry missing from the home. The use of urine drug screening is recommended when select circumstances are present: (1) psychiatric symptoms to rule out comorbidity or dual diagnoses, (2) significant changes in school performance or other daily behaviors, (3) frequently occurring accidents, (4) frequently occurring episodes of respiratory problems, (5) evaluation of serious motor vehicular or other injuries, and (6) as a monitoring procedure for a recovery program. Table 140.8 shows common tests used for detection by substance, along with the approximate retention time between use and identification in the urine. Most initial screening uses an immunoassay method, such as the enzyme-multiplied immunoassay technique, followed by a confirmatory test using highly sensitive, highly specific gas chromatography–mass spectrometry. The substances that can cause false-positive results should be considered, especially when there is a discrepancy between the physical findings and the urine drug screen result. In 2007 the American of Academy of Pediatrics (AAP) released guidelines that strongly discourage routine home-based or school-based testing.

Table 140.7

CRAFFT Mnemonic Tool
• Have you ever ridden in a car driven by someone (including yourself) who was high or had been using alcohol or drugs?
• Do you ever use alcohol or drugs to relax, feel better about yourself or fit in?
• Do you ever use alcohol or drugs while you are by yourself (alone)?
• Do you ever forget things you did while using alcohol or drugs?
• Do your Family or friends ever tell you that you should cut down on your drinking or drug use?
• Have you ever gotten into trouble while you were using alcohol or drugs?

Diagnosis

The *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5) no longer identifies substance use disorders as those of *abuse* or of *dependence*. A substance use disorder is defined by a cluster of cognitive, behavioral, and physiologic symptoms that indicate that an adolescent is using a substance even though there is evidence that the substance is harming the adolescent. Even after detoxification, a substance use disorder may leave persisting changes in brain circuits with resulting behavioral changes. There are 11 criteria that describe a pathologic pattern of behaviors related to use of the substance, falling into 4 categories: impaired control, social impairment, increased risk, and pharmacologic criteria. The 1st category, **impaired control**, describes an individual taking increasing amounts of the substance who expresses a persistent desire to decrease use, with unsuccessful efforts. The individual may spend a great deal of time obtaining the substance, using the substance, or recovering from its effects and expresses an intense desire for the drug, usually in settings where the drug had been available, such as a specific type of social situation. The 2nd cluster of criteria (5-7) reflects **social impairment**, including the inability to perform as expected in school, at home, or at a job; increasing social problems; and withdrawing from the family. The 3rd cluster of 2 criteria addresses **increased risk** associated with use of the substance, and the 4th cluster includes 2 criteria addressing **pharmacologic responses** (tolerance and/or withdrawal). The total number of criteria present is associated with a determination of a *mild*, *moderate*, or *severe* disorder.

These criteria may have limitations with adolescents because of differing patterns of use, developmental implications, and other age-related consequences. Adolescents who meet diagnostic criteria should be referred to a program for substance use disorder treatment unless the primary care physician has additional training in addiction medicine.
Complications

Substance use in adolescence is associated with comorbidities and acts of juvenile delinquency. Youth may engage in other high-risk behaviors such as robbery, burglary, drug dealing, or prostitution for the purpose of acquiring the money necessary to buy drugs or alcohol. Regular use of any drug eventually diminishes judgment and is associated with unprotected sexual activity with its consequences of pregnancy and sexually transmitted infections, including HIV, as well as physical violence and trauma. Drug and alcohol use is closely associated with trauma in the adolescent population. Several studies of adolescent trauma victims have identified cannabinoids and cocaine in blood and urine samples in significant proportions (40%), in addition to the more common identification of alcohol. Any use of injected substances involves the risk of hepatitis B and C viruses as well as HIV (see Chapter 302).

Treatment

Adolescent drug abuse is a complex condition requiring a multidisciplinary approach that attends to the needs of the individual, not just drug use. Fundamental principles for treatment include accessibility to treatment; utilizing a multidisciplinary approach; employing individual or group counseling; offering mental health services; monitoring of drug use while in treatment; and understanding that recovery from drug abuse/addiction may involve multiple relapses. For most patients, remaining in treatment for a minimum period of 3 mo will result in a significant improvement.

Prognosis

For adolescent substance abusers who have been referred to a drug treatment program, positive outcomes are directly related to regular attendance in posttreatment groups. For males with learning problems or conduct disorder, outcomes are poorer than for those without such disorders. Peer use patterns and parental use have a major influence on outcome for males. For females, factors such as self-esteem and anxiety are more important influences on outcomes. The chronicity of a substance use disorder makes relapse an issue that must always be considered when managing patients after treatment, and appropriate
assistance from a health professional qualified in substance abuse management should be obtained.

## Prevention

Preventing drug use among children and teens requires prevention efforts aimed at the individual, family, school, and community levels. The National Institute on Drug Abuse (NIDA) of the U.S. National Institutes of Health has identified essential principles of successful prevention programs. Programs should enhance **protective factors** (parent support) and reduce **risk factors** (poor self-control); should address all forms of drug abuse (legal and illegal); should address the specific type(s) of drug abuse within an identified community; and should be culturally competent to improve effectiveness (Table 140.9). The highest-risk periods for substance use in children and adolescents are during life transitions, such as the move from elementary school to middle school, or from middle school to high school. Prevention programs need to target these emotionally and socially intense times for teens to adequately anticipate potential substance use or abuse. Examples of effective research-based drug abuse prevention programs featuring a variety of strategies are listed on the NIDA website ([www.drugabuse.gov](http://www.drugabuse.gov)), and on the Center for Substance Abuse Prevention website ([www.prevention.samhsa.gov](http://www.prevention.samhsa.gov)).

From National Institute on Drug Abuse: *Preventing drug use among children and adolescents: a research-based guide for parents, educators, and community leaders*, NIH Pub No 04-4212(B), ed 2, Bethesda, MD, 2003, NIDA.
Alcohol

Cora Collette Breuner

Alcohol is the most widely used substance of abuse among America's youth, and a higher proportion use alcohol than use tobacco or other drugs, but the numbers are trending down. According to the 2016 Monitoring the Future (MTF) study, 19.9% (down from 27.6%) of 10th graders reported using alcohol in the past 30 days. Early initiation of alcohol use increases the risk for a variety of developmental problems during adolescence and is frequently an indicator of future substance use. Drinking by children, adolescents, and young adults has serious negative consequences for the individuals, their families, their communities, and society as a whole. Underage drinking contributes to a wide range of costly health and social problems, including motor vehicle crashes (the greatest single mortality risk for underage drinkers); suicide; interpersonal violence (e.g., homicides, assaults, rapes); unintentional injuries such as burns, falls, and drowning; brain impairment; alcohol dependence; risky sexual activity; academic problems; and alcohol and drug poisoning. On average, alcohol is a factor in the deaths of approximately 4,300 youths in the United States per year, shortening their life by an average of 60 yr.

According to the Centers for Disease Control and Prevention (CDC) 2015 Youth Risk Behavior Survey (YRBS), 63.2% of students had had at least 1 drink of alcohol on at least 1 day during their life (i.e., ever drank alcohol). The prevalence of having ever drunk alcohol was higher among female (65.3%) than male (61.4%) students; higher among black female (57.9%) and Hispanic female (68.6%) than black male (51.0%) and Hispanic male (63.4%) students, respectively; and higher among female (53.0%) than male (48.9%) 9th graders.

The prevalence of having ever drunk alcohol was higher among white (65.3%) and Hispanic (65.9%) than black (54.4%) students, higher among white female (66.7%) and Hispanic female (68.6%) than black female (57.9%) students, and higher among white male (64.0%) and Hispanic male (63.4%) than black male (51.0%) students.

The prevalence of having ever drunk alcohol was higher among 10th graders (60.8%), 11th graders (70.3%), and 12th graders (73.3%) than 9th graders.
(50.8%); higher among 11th-grade female (72.1%) and 12th-grade female (75.2%) than 9th-grade female (53.0%) and higher among 10th-grade male (58.8%), 11th-grade male (68.7%), and 12th-grade male (71.5%) than 9th-grade male (48.9%) students.

Multiple factors can affect a young teen's risk of developing a drinking problem at an early age (Table 140.10). One third of high school seniors admit to combining drinking behaviors with other risky behaviors, such as driving or taking additional substances. Binge drinking remains especially problematic among the older teens and young adults; 31% of high school seniors report having 5 or more drinks in a row in the last 30 days. Higher use is seen in males (23.8%) than in females (19.8%), and whites (24.0%) and Hispanics (24.2%) than in blacks (12.4%). Teens with binge-drinking patterns are more likely to be assaulted, engage in high-risk sexual behaviors, have academic problems, and be injured than those teens without binge drinking patterns.

**Table 140.10**

**Risk Factors for a Teen Developing a Drinking Problem**

**Family Risk Factors**

- Low parental supervision
- Poor parent to teen communication
- Family conflicts
- Severe or inconsistent family discipline
- Having a parent with an alcohol or drug problem

**Individual Risk Factors**

- Poor impulse control
- Emotional instability
- Thrill-seeking behaviors
- Behavioral problems
- Perceived risk of drinking is low
- Begins drinking before age 14 yr
Alcohol contributes to more **deaths** in young individuals in the United States than all the illicit drugs combined. Among studies of adolescent trauma victims, alcohol is reported to be present in 32–45% of hospital admissions. Motor vehicle crashes are the most frequent type of event associated with alcohol use, but the injuries spanned several types, including self-inflicted wounds.

Alcohol is often mixed with energy drinks (caffeine, taurine, sugars), which can result in a spectrum of alcohol-related negative behaviors. **Caffeine** may counter the sedative effects of alcohol, resulting in more alcohol consumption and a perception of not being intoxicated, thus leading to risk-taking behavior such as driving while intoxicated. In addition, aggressive behavior, including sexual assaults and motor vehicle or other injuries, has been reported. Both alcohol and caffeine overdoses have also been reported.

**Pharmacology and Pathophysiology**

Alcohol (ethyl alcohol or ethanol) is rapidly absorbed in the stomach and is transported to the liver and metabolized by 2 pathways. The primary metabolic pathway contributes to the excess synthesis of triglycerides, a phenomenon that is responsible for producing a **fatty liver**, even in those who are well nourished. Engorgement of hepatocytes with fat causes necrosis, triggering an inflammatory process (**alcoholic hepatitis**), later followed by fibrosis, the hallmark of **cirrhosis**. Early hepatic involvement may result in elevation in γ-glutamyltransferase (GGT) and serum glutamic-pyruvic transaminase (alanine transaminase). The 2nd metabolic pathway, which is utilized at high serum alcohol levels, involves the microsomal enzyme system of the liver, in which the cofactor is reduced nicotinamide-adenine dinucleotide phosphate. The net effect of activation of this pathway is to decrease metabolism of drugs that share this system and to allow for their accumulation, enhanced effect, and possible toxicity.

**Clinical Manifestations**

Alcohol acts primarily as a central nervous system (CNS) depressant. It produces euphoria, grogginess, talkativeness, impaired short-term memory, and an increased pain threshold. Alcohol's ability to produce vasodilation and hypothermia is also centrally mediated. At very high serum levels, respiratory
depression occurs. Its inhibitory effect on pituitary antidiuretic hormone release is responsible for its diuretic effect. The gastrointestinal (GI) complications of alcohol use can occur from a single large ingestion. The most common is acute erosive gastritis, manifesting as epigastric pain, anorexia, vomiting, and hemepositive stools. Less frequently, vomiting and mid-abdominal pain may be caused by acute alcoholic pancreatitis; diagnosis is confirmed by the finding of elevated serum amylase and lipase levels.

**Diagnosis**

Primary care settings provide the opportunity to screen teens for alcohol use or problem behaviors. Brief alcohol screening instruments such as CRAFFT (see Table 140.7) or AUDIT (Alcohol Use Disorders Identification Test, Table 140.11) perform well in a clinical setting as techniques to identify alcohol use disorders. A score of ≥8 on the AUDIT questionnaire identifies people who drink excessively and who would benefit from reducing or ceasing drinking. Teenagers in the early phases of alcohol use exhibit few physical findings. Recent use of alcohol may be reflected in elevated GGT and aspartate transaminase levels.

</table>
* Score $\geq 8 = \text{problem drinking.}$

In acute care settings the **alcohol overdose syndrome** should be suspected in any teenager who appears disoriented, lethargic, or comatose. Although the distinctive aroma of alcohol may assist in diagnosis, confirmation by analysis of blood is recommended. At levels $>200 \text{ mg/dL}$, the adolescent is at risk of death, and levels $>500 \text{ mg/dL}$ (median lethal dose) are usually associated with a fatal outcome. When the level of obtundation appears excessive for the reported blood alcohol level, head trauma, hypoglycemia, or ingestion of other drugs should be considered as possible confounding factors.

**Treatment**

The usual mechanism of death from the alcohol overdose syndrome is **respiratory depression**, and artificial ventilatory support must be provided until the liver can eliminate sufficient amounts of alcohol from the body. In a patient without alcoholism, it generally takes 20 hr to reduce the blood level of alcohol from 400 mg/dL to zero. Dialysis should be considered when the blood level is $>400 \text{ mg/dL}$. As a follow-up to acute treatment, referral for treatment of the alcohol use disorder is indicated. Group counseling, individualized counseling, and multifamily educational intervention have proved to be effective interventions for teens.

Cigarettes

Tobacco use and addiction almost always start in childhood or adolescence, a period when the brain has heightened susceptibility to nicotine addiction. Nearly 90% of adult smokers began smoking before age 18. Factors associated with youth tobacco use include exposure to smokers (friends, parents), tobacco availability, low socioeconomic status, poor school performance, low self-esteem, lack of perceived risk of use, and lack of skills to resist influences to use tobacco.

From 2011–2017, among all US high school students, current use of cigarettes decreased from 15.8% to 7.6%. During the same time period, however, current use of e-cigarettes and hookah (water pipes used to smoke tobacco) increased significantly among middle and high school students. In 2017, e-cigarettes (11.7%) were the most commonly used tobacco product among high school students. Cigars (7.7%) and cigarettes (7.6%) were the second and third most commonly used tobacco products among high school students, followed by smokeless tobacco (5.5%), hookah (3.3%), and pipe tobacco (0.8%).

Tobacco use is associated with other high-risk behaviors. Teens who smoke are more likely than nonsmokers to use alcohol and engage in unprotected sex, are 8 times more likely to use marijuana, and are 22 times more likely to use cocaine.

Tobacco is used by teens in all regions of the world, although the form of tobacco used differs. In the Americas and Europe, cigarette smoking is the predominant form of tobacco use, followed by cigars and smokeless tobacco; in the Eastern Mediterranean, hookah use is prevalent; in Southeast Asia, smokeless tobacco products are used; in the Western Pacific, betel nut is chewed with tobacco; and pipe, snuff, and rolled tobacco leaves are used in Africa. Cigarette use by teens in low- and middle-income nations is increasing.

Pharmacology

Nicotine, the primary active ingredient in cigarettes, is addictive. Nicotine is absorbed by multiple sites in the body, including the lungs, skin, GI tract, and buccal and nasal mucosa. The action of nicotine is mediated through nicotinic acetylcholine receptors located on noncholinergic presynaptic and postsynaptic sites in the brain and causes increased levels of dopamine. Nicotine also stimulates the adrenal glands to release epinephrine, causing an immediate
elevation in blood pressure, respiration, and heart rate. The dose of nicotine delivered to the user in a cigarette depends on a variety of factors, including puffing characteristics. A smoker typically takes 10 puffs within the span of 5 minutes and absorbs 1-2 mg of nicotine (range: 0.5–3 mg). Cotinine, the major metabolite of nicotine, has a biologic half-life of 19-24 hr and can be detected in urine, serum, and saliva.

**Clinical Manifestations**

Cigarettes are addictive by design and result in life-shortening diseases in half their long-term users. Each year, approximately 480,000 deaths are attributable to smoking, responsible for 1 of every 5 deaths and 1 of every 3 cancer deaths in the United States. Cigarette smoking has severe adverse health consequences for youth and young adults, including increased prevalence of chronic cough, sputum production, wheezing, and worsening asthma. Smoking during pregnancy increases prenatal and perinatal morbidity and mortality, either causing or exacerbating the risks of preterm birth, low birthweight, congenital malformations, stillbirth, and sudden infant death syndrome (SIDS). Withdrawal symptoms, including irritability, decreased concentration, increased appetite, and strong cravings for tobacco, can occur when adolescents try to quit.

**Electronic Cigarettes (E-Cigarettes)**

E-cigarettes, also known as electronic nicotine delivery systems (ENDS), are handheld devices that produce an aerosol created from a solution of nicotine, flavoring chemicals, propylene glycol, and often other constituents unknown and unadvertised to the consumer. There is wide variability in terminology, product design, and engineering of these products, with alternative names including e-cigs, electronic cigars, electronic hookah, e-hookah, personal vaporizers, vape pens, and vaping devices. The industry continues to develop new products, such as JUUL, which contain nicotine but may not be recognized as a tobacco product by teens. The unique flavors offered in e-cigarette solution, the majority of which are confectionary in nature and appealing to children, have been shown to encourage youth experimentation, regular use, and addiction.

Adverse effects to users include dry cough, throat irritation, and lipoid pneumonia. Nonusers could be impacted by the secondhand and thirdhand
aerosol (residual nicotine and other chemicals left on surfaces), which have been shown to contain known toxicants, including nicotine, carcinogens, and metal particles. Rates of acute nicotine poisoning have increased from unintentional exposure of children to the concentrated nicotine–containing e-cigarette solution. Studies of adolescents suggest a strong association between e-cigarette use at baseline and progression to traditional cigarette smoking. E-cigarettes may contribute to subsequent cigarette use through nicotine addiction and social normalization of smoking behaviors.

E-cigarettes are not U.S. Food and Drug Administration (FDA) approved and have not been shown to be safe or effective for smoking cessation treatment. Unless the quality of the evidence improves, adolescent smokers interested in quitting should seek and be referred to evidence-based treatments. In August 2016 the FDA finalized a rule that extends its regulatory authority to all tobacco products, including e-cigarettes, affecting how these products are manufactured, marketed, and sold. It requires manufacturers to report product ingredients and undergo the agency's premarket review to receive marketing authorization. In 2017, however, the FDA delayed implementation of this rule until 2022, allowing e-cigarettes (as of April 2019) to remain on the market without premarket review.

**Hookah**

Hookah (water pipe) smoking uses specially treated tobacco that comes in a variety of flavors. Emerging evidence indicates that hookah may involve comparable health risks to cigarettes, including nicotine dependence. Both human and machine simulation studies of hookah use consistently find that smoke content and user toxicant exposure, including carbon monoxide, tar, and nicotine, are at least comparable to that of cigarettes. Secondhand smoke from hookahs can be a health risk for nonsmokers exposed to harmful toxicants.

**Treatment**

Tobacco prevention interventions delivered in pediatric settings, including individual encounters or connection to educational materials, can reduce the risk for smoking initiation in school-age children and adolescents. Messages should be clear, personally relevant, and age appropriate. Adolescents may be more
responsive to messages that emphasize the effects of tobacco use on appearance, breath, and sports performance; lack of benefit for weight loss; monetary cost of tobacco addiction; and deceptive marketing by the tobacco industry.

The approach to smoking cessation in adolescents includes the 5 A s (ask, advise, assess, assist, and arrange) and use of nicotine replacement therapy (NRT) in addicted teens who are motivated to quit. Consensus panels recommend the 5 As, although evidence of efficacy in adolescents is limited. Studies of the NRT patch in adolescents suggest a positive effect on reducing withdrawal symptoms; pharmacotherapy should be combined with behavioral therapy to increase cessation and lower relapse rates. In a limited number of studies, cessation rates of 15% were reported at 3 and 6 mo. NRT is also available as a gum, inhaler, nasal spray, lozenge, or microtab (Table 140.12). Medications such as bupropion and varenicline improve smoking cessation rates in adults but are not FDA approved for use in adolescents <18 yr old. Preliminary studies in adolescents report cessation efficacy with 150 mg of bupropion twice daily. In postmarketing surveillance, suicidal ideation and suicide have been reported among patients taking bupropion and varenicline.

† None is FDA approved for use in patients younger than 18 yr.

Pediatric clinicians can connect patients to effective behavioral interventions, including telephone, text message, smartphone app, internet, and community-based resources. Free telephone-based treatment (1-800-QUIT-NOW) has been shown to improve smoking cessation rates. Smoke-free TXT, offered by the National Cancer Institute, engages teens to quit smoking using free, daily text messaging. Teens can sign up online (teen.smokefree.gov) or text QUIT to iQUIT (47848). A smartphone-based app, QuitSTART, helps teens track cravings, monitor moods, use cessation tips, and follow quitting attempts. The American Lung Association's Not-On-Tobacco Program (NOT) is a nationally recognized best-practice model for teen smoking cessation (see www.lung.org).

Bibliography

Marijuana (cannabis, pot, weed, hash, grass), derived from the Cannabis sativa hemp plant, is the most commonly abused illicit drug. The main active chemical, tetrahydrocannabinol (THC), is responsible for its hallucinogenic properties. THC is absorbed rapidly by the nasal or oral routes, producing a peak of subjective effect at 10 min and 1 hr, respectively. Marijuana is generally smoked as a cigarette (reefer, joint) or in a pipe. Although there is much variation in content, each cigarette contains 8–10% THC. Another popular form that is smoked, a “blunt,” is a hollowed-out small cigar refilled with marijuana. Marijuana products (hash oil or leaf) can also be used in some vaping devices or hookah pens. Hashish is the concentrated THC resin in a sticky black liquid or oil. Although marijuana use by U.S. teens has declined in the last decade, 23.1% of high school students have used marijuana at least once during the previous 30 days, and current marijuana use is highest in black males and high school seniors. About 8% of students report having tried marijuana before age 13, with a range of 4.3–18.5% across various states, indicating the need for early prevention efforts. Adolescents living in states where medical marijuana is legal
report a higher use of cannabis “edibles.” It is important to recognize that as perceived harm drops, marijuana use increases (Fig. 140.4).

![Graph showing perceived harm and marijuana use over time]

**Fig. 140.4** As the perceived harm of marijuana drops, use goes up. The 36.4% using in 2013 equates to about 11 students in the average class. (From NIH National Institute on Drug Abuse.)

**Clinical Manifestations**

In addition to the “desired” effects of elation and euphoria, marijuana may cause impairment of short-term memory, poor performance of tasks requiring divided attention (e.g., those involved in driving), loss of critical judgment, decreased coordination, and distortion of time perception (Table 140.13). Visual hallucinations and perceived body distortions occur rarely, but “flashbacks” or recall of frightening hallucinations experienced under marijuana's influence may occur, usually during stress or with fever.

**Table 140.13**

**Acute and Chronic Adverse Effects of Cannabis Use**

**Acute Adverse Effects**

- Anxiety and panic, especially in naïve users
• Psychotic symptoms (at high doses)
• Road crashes if a person drives while intoxicated

**Chronic Adverse Effects**

• Cannabis dependence syndrome (in about 1 in 10 users)
• Chronic bronchitis and impaired respiratory function in regular smokers
• Psychotic symptoms and disorders in heavy users, especially those with a history of psychotic symptoms or a family history of these disorders
• Impaired educational attainment in adolescents who are regular users
• Subtle cognitive impairment in those who are daily users for 10 yr or more

Smoking marijuana for a minimum of 4 days/wk for 6 mo appears to result in dose-related suppression of plasma testosterone levels and spermatogenesis, prompting concern about the potential deleterious effect of smoking marijuana before completion of pubertal growth and development. There is an antiemetic effect of oral THC or smoked marijuana, often followed by appetite stimulation, which is the basis of the drug's use in patients receiving cancer chemotherapy. Although the possibility of teratogenicity has been raised because of findings in animals, there is no evidence of such effects in humans.

An amotivational syndrome has been described in long-term marijuana users who lose interest in age-appropriate behavior; proof of the causative relationship remains equivocal. Chronic use is associated with increased anxiety and depression, learning problems, poor job performance, hyperemesis, and respiratory problems such as pharyngitis, sinusitis, bronchitis, and asthma (see Table 140.13).

The cannabinoid hyperemesis syndrome is characterized by recurrent episodes of vomiting associated with abdominal pain and nausea; patients often find relief by taking a hot shower or bath. Cannabis use has been chronic (>1-2 yr) and frequent (multiple times per week). Treatment includes stopping marijuana use, antiemetics, and topical capsaicin.

The increased THC content of marijuana of 5-15–fold compared to that of the
1970s is related to the observation of a withdrawal syndrome, occurring 24-48 hr after discontinuing the drug. Heavy users experience malaise, irritability, agitation, insomnia, drug craving, shakiness, diaphoresis, night sweats, and GI disturbance. The symptoms peak by the 4th day and resolve in 10-14 days. Certain drugs may interact with marijuana to potentiate sedation (alcohol, diazepam) and stimulation (cocaine, amphetamines) or may be antagonistic (propranolol, phenytoin).

Behavioral interventions, including cognitive-behavioral therapy (CBT) and motivational incentives, have shown to be effective in treating marijuana dependency.

**Synthetic Marijuana**

Spice, K2, crazy clown, aroma, black mamba, blaze, dream, and funky monkey are some of the common street names for synthetic marijuana, which is a mixture of herbs or plant materials that have been sprayed with artificial chemicals similar to THC, the psychoactive ingredient in marijuana. One active group of chemicals is the carboxamides, which are not detected by standard assays to detect THC. In the United States the chemicals in “Spice” are designated a Schedule I controlled substance (as is marijuana) by the Drug Enforcement Administration (DEA), thereby making it illegal to sell, buy, or possess them. Nonetheless, synthetic marijuana is the 2nd most common illicit drug used by high school seniors. More than 10% of high school seniors used synthetic marijuana in the last year.

Synthetic marijuana is mainly used by smoking, or mixed with marijuana, or brewed as a tea for drinking. The chemicals in synthetic marijuana affect the same receptors as THC and produce similar effects as seen in cannabis use, such as relaxation, elevated mood, and altered perception. In addition, sympathomimetic symptoms are quite common and are the cause of significant toxicity. Symptoms of intoxication include vomiting, tachycardia, hypertension, hyperthermia, confusion, extreme anxiety, profuse sweating, agitation, aggression, dysphoria, hallucinations, seizures, rhabdomyolysis, dystonia, unresponsiveness, confusion, catatonia, “zombie-like” behaviors, and myocardial ischemia. In response to legislation to ban the chemicals in OTC synthetic marijuana products, manufacturers alter and substitute the chemicals in the product, keeping it on the legal market and leaving teens particularly vulnerable to potential health effects.
Synthetic marijuana are not detected by standard toxicology screening but can be identified in specialized laboratories.

Bibliography

Lynne-Landsman SD, Livingston MD, Wagenaar AC. Effects of state medical marijuana laws on adolescent marijuana use.

Simonetto DA, Oxentenko AS, Herman ML, Szostek JH.
Inhalants, found in many common household products, comprise a diverse group of volatile substances whose vapors can be inhaled to produce psychoactive effects. The practice of inhalation is popular among younger adolescents and decreases with age. Young adolescents are attracted to these substances because of their rapid action, easy availability, and low cost. Products that are abused as inhalants include volatile solvents (paint thinners, glue, e-cigarette solvents known as “dripping,” toluene, acetone, refrigerants, gasoline, cleaning fluids, correction fluids), aerosols (spray paint, nitrous oxide, hair spray), gases (propane tanks, lighter fluid), nitrites (“poppers” or “video head cleaner”), and propellants used in whipped cream dispensers. The most popular inhalants among young adolescents are glue, shoe polish, and spray paint. The various products contain a wide range of chemicals with serious adverse health effects (Table 140.14). Huffing, the practice of inhaling fumes, can be accomplished using a paper bag containing a chemical-soaked cloth, spraying aerosols directly into the nose/mouth, or using a balloon, plastic bag, or soda can filled with fumes. The percentage of adolescents using inhalants has remained stable, with 5.8% of high school students reporting having ever used inhalants. Eighth and 9th graders report highest use, suggesting targeted prevention strategies for this age-group.

**Table 140.14**

**Hazards of Chemicals Found in Commonly Abused Inhalants**
Amyl nitrite, butyl nitrite ("poppers," "video head cleaner"): sudden sniffing death syndrome, suppressed immunologic function, injury to red blood cells (interfering with oxygen supply to vital tissues)

Benzene (found in gasoline): bone marrow injury, impaired immunologic function, increased risk of leukemia, reproductive system toxicity

Butane, propane (found in lighter fluid, hair and paint sprays): sudden sniffing death syndrome via cardiac effects, serious burn injuries (because of flammability)

Freon (used as a refrigerant and aerosol propellant): sudden sniffing death syndrome, respiratory obstruction and death (from sudden cooling/cold injury to airways), liver damage

Methylene chloride (found in paint thinners and removers, degreasers): reduction of oxygen-carrying of blood, changes to the heart muscle and heartbeat

Nitrous oxide ("laughing gas"), hexane: death from lack of oxygen to the brain, altered perception and motor coordination, loss of sensation, limb spasms, blackouts caused by blood pressure changes, depression of heart muscle functioning

Toluene (found in gasoline, paint thinners and removers, correction fluid): brain damage (loss of brain tissue mass, impaired cognition, gait disturbance, loss of coordination, loss of equilibrium, limb spasms, hearing and vision loss), liver and kidney damage

Trichloroethylene (found in spot removers, degreasers): sudden sniffing death syndrome, cirrhosis of the liver, reproductive complications, hearing and vision damage

Clinical Manifestations

The major effects of inhalants are psychoactive (Table 140.15). The intoxication lasts only a few minutes, so a typical user will huff repeatedly over an extended period (hours) to maintain the high. The immediate effects of inhalants are similar to alcohol: euphoria, slurred speech, decreased coordination, and dizziness. Toluene, the main ingredient in model airplane glue and some rubber cements, causes relaxation and pleasant hallucinations for up to 2 hr. Euphoria is followed by violent excitement; coma may result from prolonged or rapid inhalation. Volatile nitrites, such as amyl nitrite, butyl nitrite, and related compounds marketed as room deodorizers, are used as euphoriant, enhancers of
musical appreciation, and sexual enhancements among older adolescents and young adults. They may result in headaches, syncope, and lightheadedness; profound hypotension and cutaneous flushing followed by vasoconstriction and tachycardia; transiently inverted T waves and depressed ST segments on electrocardiography; methemoglobinemia; increased bronchial irritation; and increased intraocular pressure. There may be dermatologic findings, including perianal/perioral dermatitis ("huffer rash"), frostbite, and contact dermatitis, as well as epistaxis, nasal ulcers, and conjunctivitis.

### Complications

Model airplane glue is responsible for a wide range of complications, related to chemical toxicity, to the method of administration (in plastic bags, with resultant suffocation), and to the dangerous setting in which the inhalation occurs (inner-city roof tops). Common neuromuscular changes reported in chronic inhalant abusers include difficulty coordinating movement, gait disorders, muscle tremors, and spasticity, particularly in the legs (Table 140.16). Chronic use may cause pulmonary hypertension, restrictive lung defects or reduced diffusion capacity, peripheral neuropathy, hematuria, tubular acidosis, and possibly cerebral and cerebellar atrophy. Chronic inhalant abuse has long been linked to widespread brain damage and cognitive abnormalities that can range from mild impairment (poor memory, decreased learning ability) to severe dementia. High-frequency inhalant users were significantly more likely than moderate- and low-
frequency users to experience adverse consequences of inhalant intoxication, such as behavioral, language, and memory problems. Certain risky behaviors and consequences, such as engaging in unprotected sex or fighting while high on inhalants, were dramatically more common among high-frequency than low-frequency inhalant users. Death in the acute phase may result from cerebral or pulmonary edema or myocardial involvement (Table 140.16).

**Diagnosis**

Diagnosis of inhalant abuse is difficult because of the ubiquitous nature of the products and decreased parental awareness of the dangers. In the primary care setting, providers need to ask parents if they have witnessed any unusual behaviors in their teen; noticed high-risk products in the teen's bedroom; seen paint on the teen's hands, nose, or mouth; or found paint- or chemical-coated rags. Complete blood count, coagulation studies, and hepatic and renal function
studies may identify the complications. In extreme intoxication, a user may manifest symptoms of restlessness, general muscle weakness, dysarthria, nystagmus, disruptive behavior, and occasionally hallucinations. Toluene is excreted rapidly in the urine as hippuric acid, with the residual detectable in the serum by gas chromatography.

**Treatment**

Treatment is generally supportive and directed toward control of arrhythmia and stabilization of respirations and circulation. Withdrawal symptoms do not usually occur.

Hallucinogens

Cora Collette Breuner

Keywords

LSD
MDMA
PCP

Several naturally occurring and synthetic substances are used by adolescents for their hallucinogenic properties. They have chemical structures similar to neurotransmitters such as serotonin, but their exact mechanism of action remains unclear. Lysergic acid diethylamide (LSD) and methylenedioxymethamphetamine (MDMA) are the most commonly reported hallucinogens used. 251-NBOMe (“N-Bomb”) is a new designer drug that interacts with the 5HT-2a receptor and has sympathomimetic and hallucinogenic properties.

Lysergic Acid Diethylamide

LSD (acid, big “d,” blotters) is a very potent hallucinogen that is made from lysergic acid found in ergot, a fungus that grows on rye and other grains. Its high potency allows effective doses to be applied to absorbent paper, or it can be taken as a liquid or a tablet. The onset of action can be 30-60 min, and it peaks at 2-4 hr. By 10-12 hr, individuals return to the predrug state. Among U.S. 12th
Clinical Manifestations

The effects of LSD can be divided into 3 categories: somatic (physical effects), perceptual (altered changes in vision and hearing), and psychic (changes in sensorium). The common somatic symptoms are dizziness, dilated pupils, nausea, flushing, elevated temperature, and tachycardia. The sensation of synesthesia, or “seeing” smells and “hearing” colors, as well as major distortions of time and self, have been reported with high doses of LSD. Delusional ideation, body distortion, and suspiciousness to the point of toxic psychosis are the more serious of the psychic symptoms. LSD is not considered to be an addictive drug because it does not typically produce drug-seeking behavior.

Treatment

An individual is considered to have a “bad trip” when the sensory experiences causes the user to become terrified or panicked. These episodes should be treated by removing the individual from the aggravating situation and placing him in a quiet room with a calming friend. In situations of extreme agitation or seizures, use of benzodiazepines may be warranted. “Flashbacks” or LSD-induced states after the drug has worn off and tolerance to the effects of the drug are additional complications of its use.

Methylenedioxymethamphetamine

MDMA (“X,” Ecstasy, Molly), a phenylisopropylamine hallucinogen, is a synthetic compound similar to hallucinogenic mescaline and the stimulant methamphetamine. Like other hallucinogens, this drug is proposed to interact with serotonergic neurons in the central nervous system (CNS). It is the preferred drug at “raves,” all-night dance parties, and is also known as one of the “club drugs” along with γ-hydroxybutyrate (GHB) and ketamine (see Table 140.5). Between 2009 and 2010, past-year use of MDMA increased among U.S. 8th and 10th graders but then declined in both grades. Nationwide, the prevalence of having ever used MDMA was 8.4% of college students. In 2016, MDMA use by blacks (2.2%) in 12th grade was lower than for Hispanics (2.8%) or whites (3.3%).
Clinical Manifestations

Euphoria, a heightened sensual awareness, and increased psychic and emotional energy are acute effects. Compared to other hallucinogens, MDMA is less likely to produce emotional lability, depersonalization, and disturbances of thought. Nausea, jaw clenching, teeth grinding, and blurred vision are somatic symptoms, whereas anxiety, panic attacks, and psychosis are the adverse psychiatric outcomes. A few deaths have been reported after ingestion of the drug. In high doses, MDMA can interfere with the body's ability to regulate temperature. The resultant hyperthermia in association with vigorous dancing at a “rave” has resulted in severe liver, kidney, and cardiovascular system failure and death. There are no specific treatment regimens recommended for acute toxicity.

Chronic MDMA use can lead to changes in brain function, affecting cognitive tasks and memory. These symptoms may occur because of MDMA's effects on neurons that use serotonin as a neurotransmitter. The serotonin system plays an important role in regulating mood, aggression, sexual activity, sleep, and sensitivity to pain. A high rate of dependence has been found among MDMA users. MDMA exposure may be associated with long-term neurotoxicity and damage to serotonin-containing neurons. In nonhuman primates, exposure to MDMA for only 4 days caused damage to serotonin nerve terminals that was evident 6-7 yr later. There are no specific pharmacologic treatments for MDMA addiction. Drug abuse recovery groups are recommended.

Phencyclidine

Phencyclidine (PCP) (sternyl, angel dust, hog, peace pill, sheets) is an arylcyclohexalamine whose popularity is related in part to its ease of synthesis in home laboratories. One of the by-products of home synthesis causes cramps, diarrhea, and hematemesis. It is a “dissociative drug” that produces feelings of detachment from the surrounding environment and self. The drug is thought to potentiate adrenergic effects by inhibiting neuronal reuptake of catecholamines. PCP is available as a tablet, liquid, or powder, which may be used alone or sprinkled on cigarettes (joints). The powders and tablets generally contain 2-6 mg of PCP, whereas joints average 1 mg for every 150 mg of tobacco leaves, or approximately 30-50 mg per joint. The prevalence of PCP use (hallucinogenic drug) among U.S. 12th graders was 1.3%.
Clinical Manifestations

The clinical manifestations are dose related and produce alterations of perception, behavior, and autonomic functions. Euphoria, nystagmus, ataxia, and emotional lability occur within 2-3 min after smoking 1-5 mg and last for 4-6 hr. At these low doses the user is likely to experience shallow breathing, flushing, generalized numbness of extremities, and loss of motor coordination. Hallucinations may involve bizarre distortions of body image that often precipitate panic reactions. With doses of 5-15 mg, a toxic psychosis may occur, with disorientation, hypersalivation, and abusive language lasting for >1 hr. Hypotension, generalized seizures, and cardiac arrhythmias typically occur with plasma concentrations of 40-200 mg/dL. Death has been reported during psychotic delirium, from hypertension, hypotension, hypothermia, seizures, and trauma. The coma of PCP may be distinguished from that of the opiates by the absence of respiratory depression; the presence of muscle rigidity, hyperreflexia, and nystagmus; and lack of response to naloxone. PCP psychosis may be difficult to distinguish from schizophrenia. In the absence of a history of use, the diagnosis depends on urinalysis.

Treatment

Management of the PCP-intoxicated patient includes placement in a darkened, quiet room on a floor pad, safe from injury. Acute alcohol intoxication may also be present. For recent oral ingestion, gastric absorption is poor, and induction of emesis or gastric lavage is useful. Diazepam, in a dose of 5-10 mg orally or 2-5 mg intravenously, may be helpful if the patient is agitated and not comatose. Rapid excretion of the drug is promoted by acidification of the urine. Supportive therapy of the comatose patient is indicated with particular attention to hydration, which may be compromised by PCP-induced diuresis. Inpatient and/or behavioral treatments can be helpful for chronic PCP users.

Bibliography

140.6

Cocaine

Cora Collette Breuner

Cocaine, an alkaloid extracted from the leaves of the South American Erythroxylum coca, is supplied as the hydrochloride salt in crystalline form. With snorting, it is rapidly absorbed into the bloodstream from the nasal
mucosa, detoxified by the liver, and excreted in the urine as benzoylecgonine. Smoking the cocaine alkaloid (freebasing) involves inhaling the cocaine vapors in pipes, or cigarettes mixed with tobacco or marijuana. Accidental burns are potential complications of this practice. With crack cocaine, the crystallized rock form, the smoker feels “high” in <10 sec. The risk of addiction with this method is higher and more rapidly progressive than from snorting cocaine. Tolerance develops, and the user must increase the dose or change the route of administration, or both, to achieve the same effect. To sustain the high, cocaine users repeatedly use cocaine in short periods of time known as “binges.” Drug dealers often place cocaine in plastic bags or condoms and swallow these containers during transport. Rupture of a container produces a sympathomimetic crisis (see Table 140.6). Cocaine use among U.S. high school students has decreased in the last decade, as noted in the MTF 2016 data, with 3.7% of 12th graders having tried the drug (any route) at least once.

Clinical Manifestations

Cocaine is a strong CNS stimulant that increases dopamine levels by preventing reuptake. Cocaine produces euphoria, increased motor activity, decreased fatigability, and mental alertness. Its sympathomimetic properties are responsible for pupillary dilation, tachycardia, hypertension, and hyperthermia. Snorting cocaine chronically results in loss of sense of smell, nosebleeds, and chronic rhinorrhea. Injecting cocaine increases risk for HIV infection. Chronic abusers experience anxiety, irritability, and sometimes paranoid psychosis. Lethal effects are possible, especially when cocaine is used in combination with other drugs, such as heroin, in an injectable form known as a “speedball.” Cocaine, when taken with alcohol, is metabolized by the liver to produce cocaethylene, a substance that enhances the euphoria and is associated with a greater risk of sudden death than cocaine alone. Pregnant adolescents who use cocaine place their fetus at risk of premature delivery, complications of low birthweight, and possibly developmental disorders.

Treatment

There are no FDA-approved medications for treatment of cocaine addiction. CBT has been shown to be effective when provided in combination with
additional services and social support. Oral sustained-release dexamfetamine has been shown to be partially effective in adults with cocaine dependence.

Bibliography

140.7

Amphetamines

*Cora Collette Breuner*

Methamphetamine, commonly known as “ice,” is a nervous system stimulant and schedule II drug with a high potential for abuse. Most of the methamphetamine currently abused is produced in illegal laboratories. It is a white, odorless, bitter-tasting powder that is particularly popular among adolescents and young adults because of its potency and ease of absorption. It can be ingested orally, smoked, needle-injected, or absorbed across mucous membranes. Amphetamines have multiple CNS effects, including release of neurotransmitters and an indirect catecholamine agonist effect. In recent years, there has been a general decline of methamphetamine use among high school students. In the 2012 MTF Study, 1.1% of 12th graders reported using
methamphetamine at least once, reflecting a steady decline in use.

**Clinical Manifestations**

Methamphetamine rapidly increases the release and blocks the reuptake of dopamine, a powerful “feel good” neurotransmitter (Table 140.17). The effects of amphetamines can be dose related. In small amounts, amphetamine effects resemble other stimulants: increased physical activity, rapid and/or irregular heart rate, increased blood pressure, and decreased appetite. High doses produce slowing of cardiac conduction in the face of ventricular irritability. Hypertensive and hyperpyrexic episodes can occur as seizures (see Table 140.6). Binge effects result in the development of psychotic ideation with the potential for sudden violence. Cerebrovascular damage, psychosis, severe receding of the gums with tooth decay, and infection with HIV and hepatitides B and C can result from long-term use. A withdrawal syndrome is associated with amphetamine use, with early, intermediate, and late phases (Table 140.17). The early phase is characterized as a “crash” phase with depression, agitation, fatigue, and desire for more of the drug. Loss of physical and mental energy, limited interest in the environment, and anhedonia mark the intermediate phase. In the final phase, drug craving returns, often triggered by particular situations or objects.

### Treatment

Acute agitation and delusional behaviors can be treated with haloperidol or droperidol. Phenothiazines are contraindicated and may cause a rapid drop in blood pressure or seizure activity. Other supportive treatment consists of a cooling blanket for hyperthermia and treatment of the hypertension and arrhythmias, which may respond to sedation with lorazepam or diazepam. For the chronic user, comprehensive CBT interventions have been demonstrated as effective treatment options.

### Bibliography

Stimulant Abuse and Diversion

Cora Collette Breuner

In MTF 2016, 6.4% of 12th graders reported using OTC diet pills in their lifetime, and 2.1% in the past 30 days. These include nonprescription stimulants of 2 general types: pseudoamphetamines, usually sold by internet/mail order, and OTC stimulants, primarily diet and “stay-awake” pills. These drugs usually contain caffeine, ephedrine, and/or phenylpropanolamine. Stay-awake pills were used less often in 2016, with 3.6% of 12th graders reporting lifetime use and a 30-day prevalence of 1.7%. Even fewer students indicated use of look-alike products (2.3% lifetime and 0.9% monthly prevalence).

The misuse of a stimulant medication, defined as taking a stimulant not prescribed by a health care provider and not in accordance with health care provider guidance, has been growing over the past 2 decades, with a surge in prevalence rates of nonprescription stimulant use among both adolescents and young adults in the past 10 years. Nonprescription use of methylphenidate (MPH) in 2000 was 1.2%, increasing to 2% for MPH and 7.5% for nonprescription mixed amphetamine salts (AMPs) in 2015.

The majority of nonprescription stimulant users reported obtaining the drugs by diversion, a process for obtaining the drug from peers. Diversion occurs quite often and can begin in childhood, adolescence, or young adulthood. Lifetime rates of diversion ranged from 16–29% of students with stimulant prescriptions. One survey reported that 23.3% of middle and high school students taking prescribed stimulants had been solicited to divert their medication to others at a rate that increased from middle to high school. It has been shown that 54% of college students prescribed stimulants for attention-deficit/hyperactivity disorder (ADHD) had been approached to divert their medication.

In U.S. college students, nonprescription use of stimulants (Ritalin, Adderall, Dexedrine) is more prevalent among particular subgroups (male, white, members of fraternities/sororities, with lower grade point averages, more likely to use alcohol, cigarettes, marijuana, MDMA, or cocaine) and types of colleges (northeastern region, with more competitive admission standards). Lifetime
prevalence of nonprescription stimulant use was 6.9% and past-month prevalence 2.1%. According to a survey of 334 ADHD-diagnosed college students taking prescription stimulants, 25% misused their own prescription medications. Scholastic pressures, including the need to succeed academically, and persistent social and financial demands place many students at an increased risk for misuse of various drugs, especially at the end of school terms. A web-based survey of medical and health profession students found that the most common reason for nonprescription stimulant use was to focus and concentrate during studying.

**Clinical Manifestations**

Misuse of stimulants is associated with psychosis, seizures, myocardial infarction, cardiomyopathy, and even sudden death. Intentional misuse of MPH or AMPs in combination with other substances leads to adverse medical consequences. One study revealed an increase in emergency department (ED) visits involving AMP misuse from 862 in 2006 to 1,489 in 2011. Importantly, 14% of the ED visits for stimulant use were associated with cardiovascular (CV) events. Psychosis includes visual hallucinations, delusions, anorexia, flattening of affect, and insomnia mediated by dopaminergic excess. The CV effects include hypertension, arrhythmias, tachycardia, cardiomyopathy, cardiac dysrhythmias, necrotizing vasculitis, and CV accidents. Case reports include serious CV adverse drug reactions (ADRs), sudden death, and psychiatric disorders. Many patients report sleep difficulties (72%), irritability (62%), dizziness and lightheadedness (35%), headaches (33%), stomach aches (33%), and sadness (25%). Other health risks include loss of appetite, weight loss, and nervousness. Many users are involved in heavy episodic alcohol use while using MPH or AMPs. Most users of MPH or AMPs are unaware of these adverse effects and predominantly “feel good” about taking these medications.

Despite reports that MPH misuse is a healthcare issue, >82% of primary care physicians did not suspect misuse of prescribed ADHD medication in one report, and <1% thought that their patients were diverting prescribed ADHD medication. Improved monitoring for malingering and patient misuse may assist stopping diversion of these medications. ADHD diagnosis should be confirmed in those requesting ADHD medication, and they should be screened for use of other drugs.
Treatment

Treatment for nonprescription stimulant overdose is similar as that for amphetamine overdose. Haloperidol or droperidol is recommended for acute agitation and delusional behaviors. Phenothiazines are contraindicated and may cause a rapid drop in blood pressure or seizure activity. Hyperthermia may require use of a cooling blanket, and sedation with a benzodiazepine is recommended for treatment of the hypertension and arrhythmias. In those with chronic use, inpatient or outpatient substance abuse interventions utilizing CBT has been shown to be the most effective treatment option.

Monitoring of the diversion and misuse of pharmaceutical stimulants must be a priority. More data need to be obtained on the prevalence, patterns, and harmful effects in adolescents and young adults.

National Institute on Drug Abuse. *Commonly abused prescription drugs*.

**140.9**

**Opiates**

*Cora Collette Breuner*

*Heroin* is a highly addictive synthetic opiate drug made from a naturally occurring substance (*morphine*) in the opium poppy plant. It is a white or brown powder that can be injected (intravenously or subcutaneously), snorted/sniffed, or smoked. Intravenous (IV) injection produces an immediate effect, whereas effects from the subcutaneous route occur in minutes, and from snorting, in 30 minutes. After injection, heroin crosses the blood-brain barrier, is converted to morphine, and binds to opiate receptors. Tolerance develops to the euphoric effect, and the chronic user must take more heroin to achieve the same intense effect. Heroin use among U.S. teens peaked in the mid-1990s but is resurgent in some suburban communities, as is the use of *prescription opioids* found in the home. Nationwide, 2.9% of high school students report having tried heroin at least once. Highest use is seen in black males, with a growing prevalence in suburban high school students; ranges vary from 0.8% to 5.3% across large urban, suburban, and rural school districts. *Fentanyl* is a more potent opiate and is responsible for many opiate overdoses. *Recreational (illegal) use of prescription opiate medications by oral or injection (dissolving the pill) is a major source of opiate addiction and opiate overdoses.*
Clinical Manifestations

The clinical manifestations are determined by the purity of the heroin or its adulterants, combined with the route of administration. The immediate effects include euphoria, diminution in pain, flushing of the skin, and pinpoint pupils (see Table 140.17). An effect on the hypothalamus is suggested by the lowering of body temperature. The most common dermatologic lesions are the “tracks,” the hypertrophic linear scars that follow the course of large veins. Smaller, discrete peripheral scars, resembling healed insect bites, may be easily overlooked. The adolescent who injects heroin subcutaneously may have fat necrosis, lipodystrophy, and atrophy over portions of the extremities. Attempts to conceal these stigmata may include amateur tattoos in unusual sites. Skin abscesses secondary to unsterile techniques of drug administration are usually found. There is a loss of libido; the mechanism is unknown. The chronic heroin user may resort to prostitution to support the habit, thus increasing the risk of sexually transmitted diseases (including HIV), pregnancy, and other infectious diseases. Constipation results from decreased smooth muscle propulsive contractions and increased anal sphincter tone. The absence of sterile technique in injection may lead to cerebral microabscesses or endocarditis, usually caused by *Staphylococcus aureus* or *Pseudomonas aeruginosa*. Abnormal serologic reactions are also common, including false-positive Venereal Disease Research Laboratories and latex fixation tests. Infectious complications are usually not seen with oral prescription opioid use unless the pills are dissolved and injected.

Withdrawal

After ≥8 hr without heroin, the addicted individual undergoes a series of physiologic disturbances over 24-36 hr, referred to collectively as “withdrawal” or the abstinence syndrome (see Table 140.17). The earliest sign is yawning, followed by lacrimation, mydriasis, restlessness, insomnia, “goose flesh,” cramping of the voluntary musculature, bone pain, hyperactive bowel sounds and diarrhea, tachycardia, and systolic hypertension. Although the administration of methadone is the most common method of detoxification, the addition of buprenorphine, an opiate agonist-antagonist, is available for detoxification and maintenance treatment of heroin and other opiates. Buprenorphine has the advantage of offering less risk of addiction, overdose, and withdrawal effects, and can be dispensed in the privacy of a physician's office.
Combined with behavioral interventions, it has a greater success rate of detoxification. A combination drug, buprenorphine plus naloxone, has been formulated to minimize abuse during detoxification. Clonidine and tramadol have also been used to manage opioid withdrawal.

Drugs used to treat opioid use disorder, a chronic relapsing problem, traditionally include methadone maintenance and buprenorphine. Abuse-deterrent opioid pill formulations (when pain control requires an opioid) include pills resistant to crushing that form a viscous gel when dissolved or pills with a sequestered opioid antagonist (naltrexone).

**Overdose Syndrome**

The overdose syndrome is an acute reaction after administration of an opiate. It is the leading cause of death among drug users. The clinical signs include stupor or coma, seizures, miotic pupils (unless severe anoxia has occurred), respiratory depression, cyanosis, and pulmonary edema. The differential diagnosis includes CNS trauma, diabetic coma, hepatic (and other) encephalopathy, Reye syndrome, and overdose of alcohol, barbiturates, PCP, or methadone. Diagnosis of opiate toxicity is facilitated by IV administration of naloxone, 0.01 mg/kg (2 mg is a common initial dose for an adolescent), which causes dilation of pupils constricted by the opiate. Diagnosis is confirmed by the finding of morphine in the serum.

**Treatment**

Treatment of acute heroin overdose consists of maintaining adequate oxygenation and continued administration of naloxone, a pure opioid antagonist. It may be given intravenously, intramuscularly, subcutaneously, as a nasal spray, or by endotracheal tube. Naloxone has an ultrarapid onset of action (1 min) and duration of action of 20-60 min. Naloxone is often available in the field, carried by first responders. Take-home naloxone may also be given to drug users, their family, or friends; such programs have been effective in treating overdoses. If there is no response, other etiologies for the respiratory depression must be explored. Naloxone may have to be continued for 24 hr if methadone, rather than shorter-acting heroin, has been taken. Admission to the intensive care unit is indicated for patients who require continuous naloxone infusions.
(rebound coma, respiratory depression) and for those with life-threatening arrhythmias, shock, and seizures.

140.10
Bath Salts

Cora Collette Breuner

Bath salts refers to a group of previously OTC, but now illicit, substances containing 1 or more synthetic chemicals similar to cathinone , an amphetamine-like stimulant found in the khat plant. The bath salts, marketed under brand names (e.g., Lunar Wave, Cloud Nine, Vanilla Sky), are sold online
or in drug paraphernalia stores as a white or brown crystalline powder and can be ingested, inhaled, or injected. The most current information about teen use of bath salts is from the 2016 MTF survey of 8th, 10th, and 12th graders, who report use of 0.9%, 0.8%, and 0.8%, respectively. The synthetic cathinones found in bath salts include methylone, mephedrone, and 3,4-methylenedioxypyrovalerone (MDPV), all of which are chemically similar to amphetamines and MDMA (Ecstasy).

**Clinical Manifestations**

The chemicals in bath salts raise brain dopamine levels, causing the user to feel a surge of euphoria, with increased sociability and sex drive. In addition, the user may experience a surge in norepinephrine, causing reactions such as an elevated heart rate, chest pain, vasoconstriction, diaphoresis, hyperthermia, dilated pupils, seizures, arrhythmias, and high blood pressure. Users also experience psychiatric symptoms such as aggressive behavior, panic attacks, paranoia, psychosis, delirium, self-mutilation, and hallucinations caused by elevated serotonin levels. Intoxication from bath salts may cause excited delirium syndrome, which includes dehydration, rhabdomyolysis, and kidney failure.

**Treatment**

Treatment of overdose should be directed at specific complications but often includes benzodiazepines or propofol for agitation and other neuropsychiatric manifestations. The synthetic cathinones in bath salts are highly addictive, triggering intense cravings in those who consume them frequently. This may result in dependence, tolerance, and strong withdrawal symptoms, as seen in other highly addictive substances. The sale of 2 of the synthetic cathinones, mephedrone and MDPV, is illegal in the United States.

**Bibliography**

Bibliography

National Institute on Drug Abuse. *NIDA infofacts: club drugs (GHB, ketamine, and Rohypnol)*.

Breast development is often the first visible sign of puberty in the adolescent female. Pediatric practitioners must be able to distinguish normal breast development, including normal variants, from pathologic breast disorders. Visual inspection of the breast tissue should routinely be a component of the young adolescent's general physical examination. Breast development during puberty is described using the Sexual Maturity Rating (SMR) scale, progressing from SMR 1 to SMR 5 as the breast becomes more mature (see Chapter 132, Fig. 132.2).

**Female Disorders**

See Chapter 566.

**Male Disorders**

*Pubertal gynecomastia* occurs in up to 65% of healthy adolescent males (see Chapter 603). Although this finding has long been attributed to a transient imbalance of estrogen and androgen concentrations, this biochemical imbalance has not been clearly demonstrated. Recent studies suggest that elevations of insulin-like growth factor (IGF)-I may have a stronger association. Onset typically is between 10 and 13 yr, peaking at SMR 3-4. Careful physical examination is essential to distinguish between *true gynecomastia*, characterized by a discrete disk of palpable glandular tissue under the nipple-areolar complex, and *pseudogynecomastia*, characterized by more diffuse, bilateral adiposity of the anterior chest wall. Physiologic gynecomastia regresses
spontaneously in up to 90% of adolescents within 18-24 mo. Reassurance and continued observation are recommended in most patients; surgery may be indicated in severe or persistent cases. No medical therapies for gynecomastia have been approved for use in adolescents by the U.S. Food and Drug Administration. Small, noncontrolled trials of antiestrogens, such as tamoxifen, appear promising, but more evidence is needed. Conditions associated with nonphysiologic gynecomastia include endocrine disorders, liver disease, neoplasms, chronic disease, and trauma. Although dozens of medications are implicated as possible causes of gynecomastia, convincing evidence exists only for a few, including several antiandrogens and other exogenous hormones, antiretrovirals, and histamine$_2$ receptor blockers. Calcium channel blockers, certain antipsychotics, proton pump inhibitors, lavender, and tea tree oil may be causative. Among drugs of abuse, alcohol, opioids, and anabolic steroids may be associated with gynecomastia, but minimal evidence supports an association with marijuana or amphetamines.

Other breast pathology in males is uncommon. Benign masses such as neurofibromas, lipomas, and dermoid cysts have been reported in the male breast. Males with Klinefelter syndrome have an elevated risk of breast cancer (see Chapter 601), but this malignancy is otherwise exceedingly rare in adolescents.

Menstrual Problems

Krishna K. Upadhya, Gina S. Sucato

See also Chapter 565.

Menstrual disturbances, including delayed onset, irregularity, heavy flow, and pain, occur in 75% of females during adolescence. Menstrual problems vary in presentation. For adolescents with minor variations from normal (Table 142.1), an explanation of symptoms and reassurance may be all that is needed. Severe dysmenorrhea or prolonged menstrual bleeding can be not only frightening, but a cause of persistent morbidity requiring more aggressive management, potentially including referral to a specialist in adolescent gynecology.

</tbody>
</table>

* Adolescents with 2 or more cycles outside this range or who skip their period for 3 consecutive mo warrant evaluation.

Normal Menstruation

Data from many countries, including the United States, suggest that the average age of menarche, or first menses, varies according to ethnic origin and socioeconomic status. There is often a close concordance of the age at menarche between mother and daughter, suggesting that genetic factors are determinants in addition to individual factors such as weight, exercise level, and chronic medical
conditions. The age of menarche has declined in countries and populations experiencing improved nutritional standards and other living conditions. In U.S. females, the average age of menarche, 12.5 years, has been relatively stable over the last few decades; it is slightly older for non-Hispanic whites, and slightly younger for non-Hispanic blacks and Hispanic Americans.

Menarche typically occurs within 2-3 yr of the onset of breast budding (thelarche), which is the 1st sign of puberty in most females. Menarche usually occurs during breast sexual maturity rating (SMR; i.e., Tanner stage) 4. Periods gradually become more regular, initially with longer cycle lengths ranging between 21 and 45 days. The older the age at which menarche occurs, the longer it takes for consistently ovulatory cycles to be established. However, for most adolescents, by 3 yr after menarche, menstrual cycles are similar to that of adults: between 21 and 35 days long.

**Menstrual Irregularities**

In young adolescents, many variations in menstruation are explained by anovulation that results from immaturity of the hypothalamic-pituitary-ovarian axis governing menstrual cyclicity. Significant deviations from normal should prompt a search for organic pathology in a logical and cost-effective manner. An accurate menstrual history is an important, but often lacking, 1st step toward a diagnosis. At menarche, all patients should be encouraged to track their periods, which several free smartphone and tablet applications can facilitate.

Previously, a range of terms has been used to describe abnormal menstrual bleeding. These include “menorrhagia” to indicate regularly occurring bleeding that was excessive in amount or duration, and “metrorrhagia” to indicate irregular bleeding between periods. Such terms are imprecise, confusing, and not linked to any specific underlying pathology. Abnormal uterine bleeding (AUB) is the preferred term for uterine bleeding that is abnormal in regularity, volume, frequency, or duration. AUB is further specified by adding terms that describe the bleeding as heavy menstrual bleeding, or intermenstrual bleeding. A qualifying letter is added to indicate the etiology of the abnormal bleeding. Of the 9 categories of etiologies, the 3 most relevant to adolescents are ovulatory dysfunction (AUB-O), previously referred to as “dysfunctional uterine bleeding” and discussed in Chapter 142.2; coagulopathy (AUB-C); and not yet classified (AUB-N).

In addition to a standard medical history noting hospitalizations, chronic
illness, and medication use, a complete history for evaluating a patient with menstrual irregularity should include the timing of pubertal milestones, such as onset of pubic and axillary hair and breast development; a detailed patient menstrual history; age of menarche and overall menstrual pattern of mother and sisters; and a family history of gynecologic problems. The complete review of systems should elicit any changes in headache pattern or vision; the presence of galactorrhea; and any changes in skin, hair, or bowel patterns. Changes in diet, level of exercise, and sports participation are also important factors when generating a differential diagnosis. As with all adolescent visits, the patient should be interviewed alone, and the confidential history should assess substance use, consensual sexual activity, forced sexual behavior, abuse, and other psychosocial stressors.

In addition to the basic growth parameters of weight, height, blood pressure, heart rate, and body mass index, a careful review of the patient's growth chart is indicated. Physical examination should document SMR; signs of androgen excess, such as hirsutism or severe acne; and signs suggestive of an eating disorder (see Chapter 41), such as lanugo or knuckle calluses. A careful external genital examination should be performed, but in the absence of sexual activity, an internal pelvic examination is rarely necessary. If being considered for the young adolescent, an internal exam should be performed by a physician with expertise in this age-group using proper equipment and technique. Transabdominal pelvic ultrasound can be a useful adjunct for evaluating anatomic abnormalities in the adolescent; when indicated, MRI can provide greater detail of pelvic anatomy.

142.1

Amenorrhea

Krishna K. Upadhya, Gina S. Sucato

Keywords
Amenorrhea, the absence of menstruation, generally requires evaluation at age 15 yr, or if there has been no menstruation within 3 yr of the onset of puberty (primary amenorrhea), or if there has been no menstruation for the length of 3 previous cycles in a postmenarchal patient (secondary amenorrhea). However, the following caveats exist: lack of any pubertal signs by age 13 yr in a girl should prompt evaluation for pubertal delay; in sexually active patients, or those with other symptoms suggesting pathology, evaluation should be initiated without waiting for 3 missed cycles; in patients whose breast development started between age 8 and 9 yr, observation for >3 yr may be warranted in some cases, given data suggesting that the age of thelarche has decreased but the age of menarche has not. Conversely, expectant management with close follow-up can be considered in a patient whose history, physical examination (showing some signs of pubertal development), and family history suggest constitutional delay of puberty.

The differential diagnosis of amenorrhea is broad (Table 142.2) and requires a careful history and physical exam to guide any necessary diagnostic studies. Key to the evaluation is understanding the timing and tempo of the patient's pubertal milestones. The evaluation of a patient presenting with amenorrhea should begin by ascertaining whether she has ever had any prior menstrual bleeding. Some aspects of the evaluation of both primary and secondary amenorrhea are identical; conditions that can interrupt the menstrual cycle can also prevent menarche. In females with primary amenorrhea, however, genetic and anatomic conditions must also be considered (Table 142.3).

History and Physical Examination

Important elements of the history include dietary intake, exercise level, and a thorough review of any ongoing symptoms, including fever, headache, vision changes, chronic respiratory or gastrointestinal (GI) complaints, changes in bowel history, galactorrhea, changes in hair or nails, excessive body hair, severe acne, unexplained musculoskeletal complaints, and changes in vaginal discharge (which can disappear in females who are hypoestrogenic for reasons such as poor caloric intake). Any underlying medical conditions and the adequacy of their control should be noted, as well as the presence of any renal or skeletal anomalies, some of which may be associated with reproductive system anomalies. Medications, particularly those for psychiatric conditions, should be documented. Family history of menarcheal age, eating disorders (see Chapter 41), and polycystic ovary syndrome (PCOS; see Chapter 567) should be elicited. A thorough social history is necessary, especially concerning the presence or absence of sexual activity or abuse (see Chapter 16.1).

Physical examination should begin with careful attention to growth chart trajectories. In addition to a search for undiagnosed systemic disease, clues to an eating disorder, thyroid disease, or hyperandrogenism should be sought. The exam should assess for body mass index, orthostatic pulses, blood pressure, abnormal dentition, anosmia or hyposmia (suggestive of Kallmann syndrome; see Chapter 601.2), parotid enlargement, thyroid gland palpation, hepatosplenomegaly or other abdominal mass, lymphadenopathy, presence or absence of breast tissue (by palpation, not inspection), and SMR (see Chapter 132). Skin examination should note any lanugo, dry or doughy skin, loss of hair from scalp or eyebrows, striae, acanthosis nigricans, or acne. The genital exam should note SMR and appearance of the vagina, which should be pink and moist; thin, dry, reddened mucosa suggests estrogen deficiency. The clitoral width should be <1 cm. In the patient with primary amenorrhea, vaginal patency can be assessed painlessly using a slender saline-moistened swab and careful avoidance of the hymen. If physical assessment of the cervix and uterus is not tolerated, a pelvic ultrasound is advisable in patients with primary amenorrhea, followed by MRI if more detail is needed.
Laboratory Studies

A urine pregnancy test, serum levels of prolactin, thyroid-stimulating hormone, and follicle-stimulating hormone (FSH) are reasonable to measure in all patients presenting with amenorrhea (Fig. 142.1). Elevation of FSH (>30 mIU/mL) in an amenorrheic female suggests ovarian insufficiency, and if confirmed with repeat testing, should be followed with a pelvic ultrasound, karyotype, and specialist referral. Diagnostic tests in the patient presenting with amenorrhea should be tailored to her history and physical exam (Table 142.4).

activities
Pelvic ultrasound (if bleeding persists despite treatment)

* In patients with signs or symptoms suggestive of polycystic ovary syndrome, such as acne, hirsutism, obesity, acanthosis nigricans, and a history of infrequent menses.

† Any abnormalities should be followed with a ristocetin-induced platelet aggregation and von Willebrand factor multimers. Testing in the 1st 3 days of menses and before any estrogen treatment is started minimizes the chances of false-negative tests. Repeat testing can be warranted in patients for whom there is a high pretest suspicion.

In patients with signs of androgen excess (e.g., severe acne or hirsutism) or other physical stigmata associated with PCOS (rapid pubertal weight gain, acanthosis nigricans) consider measuring levels of 17-hydroxyprogesterone (17-OHP) (collected in the morning, approximately 8 AM), free and total testosterone, dehydroepiandrosterone sulfate (DHEAS), and androstenedione. PCOS affects up to 15% of females; diagnostic criteria for adolescents are controversial but include variations of menstrual irregularity (ranging from amenorrhea to AUB) and physical or biochemical evidence of androgen excess. The interpretation of polycystic ovarian morphology identified on ultrasound in adolescents can be challenging, and an ultrasound is not necessary for diagnosis in adolescents.
With the exceptions of pregnancy, constitutional delay, and imperforate hymen, conditions causing primary amenorrhea are associated with reduced fertility; thus their diagnosis may cause profound emotional responses in patients and families. Therefore, before ordering studies to confirm these diagnoses (e.g., karyotype, MRI of reproductive anatomy), the clinician should carefully consider the implications and be prepared to refer to specialists with experience managing the long-term treatment of such diagnoses.

In patients presumed to have hypothalamic amenorrhea, based on prepubertal luteinizing hormone (LH) and low FSH levels using an ultrasensitive assay and consistent history and physical exam, MRI of the brain is not necessary in all patients. However, MRI should be considered for patients presenting with a headache history that is a change from baseline, persistent emesis, change in thirst, urination, or vision, elevated prolactin or galactorrhea, or other neurologic symptoms.

**Treatment**

Treatment for amenorrhea varies widely depending on the underlying cause. Many diagnoses require referral to clinicians in specialties such as endocrinology, adolescent medicine, gynecology, and other surgical subspecialists; often, collaboration with other disciplines such as psychology or nutrition is also indicated. For patients with PCOS, the mainstay of treatment is suppression of ovarian androgens (typically with combined hormonal contraception, i.e., estrogen and progestin) and lifestyle modifications to decrease obesity and insulin resistance. Patients with abnormal glucose tolerance may benefit from the addition of metformin. Spironolactone, an androgen receptor blocker, can also be used to reduce androgen effects, including hirsutism. Because of the high prevalence of metabolic syndrome in PCOS, evaluation of comorbid diabetes and hyperlipidemia with periodic lipid screening and oral glucose tolerance testing should be considered, particularly for obese patients, those with familial risk factors, and those with other signs such as acanthosis nigricans and hypertension. For patients with eating disorders or other conditions of energy imbalance that render them hypoestrogenic, normalizing weight and improving nutritional status are the keys to treatment. Initiation of hormonal therapy is not recommended routinely in these patients. However, for those who remain amenorrheic after a trial of nutritional and activity modification, short-term use of transdermal estrogen therapy.
may be considered to protect bone health. For females with amenorrhea based on ovarian insufficiency (or absence), exogenous hormones are required for all pubertal development. Experts recommend starting at age 10-12 yr with low-dose transdermal estrogen, progressing to increased doses of estrogen and cyclic progestin. Continued maintenance therapy can be accomplished with higher-dose combination products, as found in typical combined hormonal contraceptive pills, patches, and rings.

For patients with secondary amenorrhea, use of hormones to bring on monthly bleeding (e.g., with combined hormonal contraception) in the absence of a clear indication (e.g., PCOS, contraception) is not recommended, because this will mask the patient's subsequent menstrual pattern. However, in patients with normal postpubertal estrogen levels, progesterone can be useful to periodically (every 4-12 wk) induce shedding of the endometrial lining to avoid buildup and subsequent heavy menses. One commonly used regimen is medroxyprogesterone, 10 mg daily for the 1st 12 days of the month.

Bibliography

Abnormal uterine bleeding (AUB) is a broad term used to describe any menstrual bleeding pattern that is outside what is considered physiologic. Clinicians are encouraged to categorize the abnormal pattern based on the patient's complaint, which will usually be menses that are irregular (AUB/IMB: intermenstrual bleeding) or heavy (AUB/HMB: heavy menstrual bleeding).

Irregular Menstrual Bleeding

The American Academy of Pediatrics (AAP) advocates treating menstrual status as a vital sign at routine visits. Although menses are frequently irregular in the early postmenarcheal years, further evaluation is necessary when menstrual patterns vary too widely from what is normal for age. Even in the 1st postmenarcheal year, menses should not be less frequent than every 45 days. Menses become increasingly regular with age, and by 3 years after menarche
typically occur every 21-35 days, lasting 3-7 days. An adolescent's personal cycle duration is usually established by age 19 or 20 yr.

Adolescents rarely present with complaints of unusually short or light menses. However, short, light, or infrequent menses should be evaluated similarly to secondary amenorrhea. Females whose menses are excessive are much more likely to come to attention for AUB.

In the early postmenarcheal years, the most common cause of AUB in adolescents is anovulation caused by immaturity of the hypothalamic-pituitary-ovarian axis. In the absence of a mid-cycle surge of LH to stimulate ovulation, there is no corpus luteum production of progesterone. Without the stabilizing effects of progesterone on the endometrial lining, there is increased risk of irregular bleeding. Irregular bleeding because of anovulation, in the absence of anatomic, systemic, or endocrinologic disease, is categorized as AUB caused by ovulatory dysfunction (AUB-O; previously referred to as dysfunctional uterine bleeding). Although it is the most common cause of abnormal menstrual bleeding in adolescents, AUB-O is a diagnosis of exclusion. In generating a differential diagnosis, it is important to remember that most conditions that lead to amenorrhea can cause anovulation first, and anovulation is a key risk for heavy irregular bleeding. Table 142.5 lists the causes of AUB.

Unscheduled bleeding during the use of hormonal contraception frequently occurs, particularly with progestin-only methods. Common causes include medication nonadherence, interacting medications (prescribed or over-the-counter), and smoking. Patients should be reassured such bleeding is benign and not an indication to stop an otherwise satisfactory contraceptive method.

**Heavy and Prolonged Menstrual Bleeding**

Irregular bleeding, particularly that resulting from anovulation, can be long and heavy (Table 142.5). However, in patients who have regular, cyclic menses that are long and/or heavy, particularly if menses are heavy from the onset of menarche, a hematologic cause should be strongly considered. **Von Willebrand disease** and coagulation disorders are found in up to 13% and 20%, respectively, of women with heavy menstrual bleeding; prevalence goes up significantly among women with bleeding severe enough to warrant hospitalization. Other symptoms suggestive of bleeding disorders include *flooding* (changing a pad or tampon more than hourly), passing clots larger than 1 inch in diameter, menses longer than 7 days, a history of hemorrhagic ovarian cysts, excessive bleeding from wounds or postoperatively, and first-degree relatives with heavy menses or
epistaxis requiring medical treatment.

**Laboratory Findings**

*Table 142.4* lists laboratory tests to be considered in patients with long, heavy bleeding. Females with persistent heavy bleeding despite negative testing should be referred to a hematologist for testing for platelet function disorders, factor deficiencies, and other less common disorders. In the initial evaluation, rapidity of blood loss in conjunction with the hemoglobin establishes the **severity of the bleeding**: mild (hemoglobin > 10 g/dL), moderate (hemoglobin 8-10 g/dL), or severe (hemoglobin < 8 g/dL).

**Treatment**

In **mild** bleeding, iron supplementation is recommended, and the patient should keep a menstrual calendar to follow the subsequent flow patterns. Nonsteroidal antiinflammatory drugs (NSAIDs; e.g., naproxen) are more effective than placebo in treating heavy bleeding and also would help treat any concurrent dysmenorrhea. Active bleeding typically responds well to cycling with any combined hormonal contraceptive (containing estrogen and progestin) method starting with twice-daily dosing if needed until bleeding stops. Patients with estrogen contraindications can be treated with progestins alone, such as medroxyprogesterone or norethindrone acetate, 10 mg orally (PO) per day, either continuously or for 12 days per month. The latter regimen will be followed by monthly bleeding.

With **moderate** anemia, any of the hormonal regimens above can be used. However, it may be necessary to start with 3-4 combined oral contraceptive (COC) pills (or 3-4 doses of medroxyprogesterone 10 mg) per day, with additional medication to control nausea. The dose can usually be tapered to daily dosing over the next 2 wk. Patients with ongoing rapid bleeding, syncope or lightheadedness, or hemodynamic instability should be treated in the hospital, as should most patients with a hemoglobin of <8 g/dL.

Patients with **severe** anemia should be treated with 1 of the hormone tapers described above, in addition to fluid or blood products as indicated; it is advisable to draw necessary laboratory studies before transfusion. Patients with emesis or other significant symptoms may be treated initially with conjugated
estrogens, 25 mg intravenously (IV) every 4-6 hr for 1-2 days. A COC or progestin regimen should be added within the 1st day because progestin is needed to stabilize the endometrial lining and can be used as maintenance therapy after hospital discharge. In the exceptionally rare case of a patient whose bleeding cannot be controlled hormonally, options for gynecologic interventions include intrauterine Foley balloon placement or uterine packing to tamponade the uterus mechanically. Dilation and curettage, performed frequently in adult women, is almost never indicated in adolescents and can increase blood loss in women with bleeding disorders.

Hormonal treatment for AUB should continue for at least 3-6 mo, depending on the patient's age, prior menstrual history, and severity of presentation, before reassessing the need for ongoing therapy. Additional options for maintenance therapy include combined hormonal transdermal patches and vaginal rings; depot medroxyprogesterone acetate, 150 mg intramuscularly (IM) or 104 mg subcutaneously (SC) every 3 mo; and placement of a levonorgestrel intrauterine device (IUD), depending on the patient's concurrent need for long-term contraception. For patients who choose to avoid hormonal therapy, tranexamic acid, 1,300 mg PO 3 times daily, can be used for up to the 1st 5 days of menses in patients who do not have an increased risk of thrombosis.

For young women with bleeding disorders, formulation of a long-term treatment plan is best done in collaboration with the patient's hematologist. Females with a known bleeding disorder may be up to 5 times more likely to develop heavy menstrual bleeding. Therefore, it can be helpful while the patient is still premenarcheal to put a proactive plan in place in the event of acute heavy menstrual bleeding, which can occur with a patient's first menstrual period.

### 142.3

**Dysmenorrhea**

*Krishna K. Upadhya, Gina S. Sucato*

**Keywords**

dysmenorrhea

endometriosis

Dysmenorrhea, painful uterine cramps that precede and accompany menses, occur in up to 90% of women age 17-24. Although dysmenorrhea is frequently severe enough to interfere with school and other activities, many adolescents undertreat their symptoms, and fewer still seek medical care for relief.

Dysmenorrhea may be primary or secondary. **Primary dysmenorrhea**, characterized by the absence of any specific pelvic pathologic condition, is by far the more commonly occurring form, accounting for approximately 90% of
cases. After ovulation, withdrawal of progesterone results in synthesis of prostaglandins by the endometrium, which stimulates local vasoconstriction, uterine ischemia and pain, and smooth muscle contraction, explaining both uterine and GI symptoms. Because of the association with ovulation, primary dysmenorrhea typically presents at least 12 mo after menarche.

**Secondary dysmenorrhea** results from underlying pathology, such as anatomic abnormality, or infection, such as pelvic inflammatory disease. However, the most common cause of secondary dysmenorrhea in adolescents is **endometriosis**, a condition in which implants of endometrial tissue are found outside the uterus, usually near the fallopian tubes and ovaries. Often, other family members have endometriosis. Although characteristically there is severe pain at menses, adolescents can present with noncyclic pain as well.

Although primary dysmenorrhea is almost always the cause, a careful history and physical examination are required for adolescents who present with pelvic pain. An internal pelvic exam is not required in females who are not sexually experienced and whose presentation is consistent with primary dysmenorrhea. Constipation can vary cyclically in many females, especially those with irritable bowel syndrome, and often significantly contributes to the pain. **Mittelschmerz**, brief severe pain with ovulation, occurs at mid-cycle and can explain what initially appeared to be noncyclic pelvic pain. Table 142.6 lists the differential diagnosis and “red flags” for secondary dysmenorrhea. Ovarian cysts, a frequent concern of families, are usually transient and painless.

**Table 142.6**

<tbody>
<tr>
<td><strong>PRESENTATION</strong></td>
</tr>
<tr>
<td>Primary: Crampy pelvic pain may be accompanied by aching/heaviness in lower back and upper thighs, nausea, emesis, diarrhea, headache, mastalgia, fatigue, and dizziness; symptoms begin at or shortly before onset of menstrual flow and last 1-3 days.</td>
</tr>
<tr>
<td>Endometriosis and adenomyosis †: Increasingly severe dysmenorrhea despite adequate therapy; pain exacerbated during menses can occur acyclically as well.</td>
</tr>
<tr>
<td>Müllerian anomalies: Pain begins at or shortly after menarche and occurs with bleeding;</td>
</tr>
</tbody>
</table>
with partial outflow obstruction presence of **known renal tract anomaly** (often coexists with müllerian anomaly). to identify some lesions (e.g., obstructed hemivagina). *Found in 8% of adolescents who underwent laparoscopy for persistent pelvic pain.*

**Pelvic inflammatory disease**

Abrupt onset of dysmenorrhea more severe than baseline in a sexually active adolescent; presentation can range from mild discomfort to acute abdomen.

Clinical diagnosis made by findings of uterine or adnexal tenderness on bimanual pelvic examination (see Chapter 146); supporting features include dysuria, dyspareunia, **vaginal discharge**, fever, and increased white blood cell count.

**Pregnancy complication**

Coincident pain and bleeding may be misdiagnosed as dysmenorrhea.

Urine test positive for human chorionic gonadotropin.

*Bold* entries indicate "red flags" for diagnosis.

† Adenomyosis is the presence of endometrial tissue within the uterine myometrium.

Treatment for primary dysmenorrhea is aimed at preventing or decreasing prostaglandin production. The mainstay of treatment is prostaglandin synthetase inhibition with NSAIDs (Table 142.7) beginning at, or preferably the day before, menstruation. High doses of around-the-clock treatment are rarely needed for more than the 1st 2 days. More data are needed to make specific treatment recommendations regarding exercise, but females should be reassured that participation in usual sports and extracurricular activities is not only permissible but a benchmark of adequate treatment.

Use with caution in patients with impaired renal or liver dysfunction, heart failure, or a history of GI bleeding or ulcer. Full prescribing information can be found at: http://www.accessdata.fda.gov/drugsatfda_docs/label/2011/020998s033,021156s003lbl.pdf.

DMPA, Depot medroxyprogesterone acetate; LARC, long-acting reversible contraceptive; NSAIDs, nonsteroidal antiinflammatory drugs.

For those adolescents whose pain does not respond to optimally dosed NSAIDs, or who also require contraception, the currently available forms of hormonal contraception will improve dysmenorrhea. A number of trials have investigated adjuvant treatments including heat, aromatherapy, acupressure, acupuncture, transcutaneous nerve stimulation, herbal remedies, yoga, and dietary supplements; however, the mainstay second-line treatment is hormones. The mechanisms are not fully delineated but are presumed to include elimination of progesterone production from the corpus luteum for those methods that prevent ovulation, and decreased prostaglandin production from the diminished endometrial lining. Up to 3 cycles may be required to appreciate the full benefit. Methods and regimens that eliminate a placebo interval may provide better relief. Females whose pain persists despite more than 3 mo of adequate hormonal therapy require further evaluation and treatment.

Premenstrual Syndrome and Premenstrual Dysphoric Disorder
Keywords

premenstrual syndrome
PMS
premenstrual dysphoric disorder
PMDD

**Premenstrual dysphoric disorder (PMDD)** is a depressive disorder that is distinguished from other depressive disorders by its timing. Symptoms of anxiety and depressed mood begin in the luteal phase of the menstrual cycle (i.e., in the 2nd half, after ovulation) and improve within a few days after the onset of menses. PMDD causes significant distress and functional impairment and may be accompanied by physical and behavioral symptoms. PMDD occurs in 2–6% of menstruating females worldwide. Based on a large body of scientific evidence, it has been included in the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition* (DSM-5) as a distinct, treatment-responsive, depressive disorder (Table 142.8). PMDD is distinguished from **premenstrual syndrome (PMS)**, which has similar timing and occurs in up to 30% of adolescents, by the severity and consequences of the affective symptoms. Premenstrual symptoms are precipitated by ovulation; symptoms recur in the luteal phase and should disappear at the end of menstruation. Up to half of women who report PMS do not meet diagnostic criteria for PMDD when symptoms are rated prospectively. Consequently, use of a menstrual calendar to document symptoms prospectively is necessary, because it is important to distinguish PMDD from anxiety, depression, or another mental health disorder, the symptoms of which are exacerbated cyclically but occur throughout the cycle.

**Table 142.8**

Criteria for Premenstrual Dysphoric Disorder
A. In the majority of menstrual cycles, at least 5 symptoms must be present in the final week before the onset of menses, start to *improve* with a few days after the onset of menses, and become *minimal* or absent in the week post menses.

B. One (or more) of the following symptoms must be present:
   1. Marked affective lability (e.g., mood swings; feeling suddenly sad or tearful, or increased sensitivity to rejection).
   2. Marked irritability or anger or increased interpersonal conflicts.
   3. Marked depressed mood, feelings of hopelessness, or self-deprecating thoughts.
   4. Marked anxiety, tension, and/or feelings of being keyed up or on edge.

C. One (or more) of the following symptoms must additionally be present, to reach a total of 5 symptoms when combined with symptoms from criterion B above.
   1. Decreased interest in usual activities (e.g., work, school, friends, and hobbies).
   2. Subjective difficulty in concentration.
   3. Lethargy, easy fatigability, or marked lack of energy.
   4. Marked change in appetite; overeating; or specific food cravings.
   5. Hypersomnia or insomnia.
   6. A sense of being overwhelmed or out of control.
   7. Physical symptoms such as breast tenderness or swelling, joint or muscle pain, a sensation of “bloating,” or weight gain.

*Note:* The symptoms in criteria A-C must have been met for most menstrual cycles that occurred in the preceding year.

D. The symptoms are associated with clinically significant distress or interference with work, school, usual social activities, or relationships with others (e.g., avoidance of social activities; decreased productivity and efficiency at work, school, or home).

E. The disturbance is not merely an exacerbation of the symptoms of another disorder, such as major depressive disorder, panic disorder, persistent depressive disorder (dysthymia), or a personality disorder (although it may co-occur with any of these disorders).

F. Criterion A should be confirmed by prospective daily ratings during at least
2 symptomatic cycles. *(Note: The diagnosis may be made provisionally prior to this confirmation).*

G. The symptoms are not attributable to the physiological effects of a substance (e.g., a drug of abuse, a medication, other treatment) or another medical condition (e.g., hyperthyroidism).

From *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition* (Copyright 2013), American Psychiatric Association, pp 171–172.

Treatment success is gauged by improvement in patient symptoms. In mild cases of PMS, adolescents may have adequate relief following education about the relationship of symptoms to the menstrual cycle and instruction on stress management techniques, including exercise. There is not strong evidence supporting the effectiveness of most combined hormonal contraceptive methods for PMS, particularly in adolescents. However, some experts suggest this treatment option for those patients who also have dysmenorrhea or contraceptive needs.

The treatment option for severe PMS and PMDD with the most supportive evidence is use of selective serotonin reuptake inhibitors (SSRIs), which are first-line therapy for adult women. In contrast to the treatment of depression, SSRIs can be rapidly effective for PMDD and thus can be prescribed either continuously or intermittently, beginning at ovulation (or whenever in the luteal phase symptoms begin) and ending when symptoms resolve. Adolescents can be prescribed the standard doses used for adults, such as fluoxetine, 20 mg PO daily.

**Bibliography**

The untoward consequences of sexual activity, including unintended pregnancy (see Chapter 144) and sexually transmitted infections (STIs; Chapter 146), are experienced by adolescents at unacceptably high rates. Adolescents often do not seek reproductive healthcare until 6-12 mo after initiating sex; many will become pregnant and/or acquire an STI during this interval. Early and appropriate counseling and educational interventions with adolescents, including direct discussion of unwanted pregnancy and STI prevention, can decrease risky sexual behavior; adolescents who plan sexual initiation are 75% more likely to use contraception at sexual debut. Therefore, appropriate counseling and provision of contraception as warranted are a critical component in comprehensive healthcare for adolescents.

Contraceptive Effectiveness

To decrease rates of unintended pregnancy, the American Academy of Pediatrics (AAP) and American College of Obstetricians and Gynecologists (ACOG) recommend adolescents use the most effective forms of reversible contraception. Comparing typical effectiveness of contraceptive methods the chart illustrates a tiered system of contraceptive methods ranging from more effective to less effective methods (Fig. 143.1). These tiers are categorized by typical-use failure rates, which reflect the effectiveness of a method for the average person who may not consistently use the method or may not always use the method correctly (Table 143.1). For example, for oral contraceptive pills, the typical-use failure rate is 7%, whereas the perfect-use failure rate is <1%. Tier 1 methods, the most effective, include those with failure rates of <1 pregnancy per 100 women in a year of typical use, and reversible Tier 1 methods include
intrauterine devices (IUDs) and implants. **Tier 2** methods have failure rates of 4-7 pregnancies per 100 women in a year of typical use and include injectable contraception, oral contraceptive pills, contraceptive patch, and vaginal ring. **Tier 3** methods have failure rates of >13 pregnancies per 100 women per year of typical use and include the male and female condom, the diaphragm, withdrawal, the sponge, fertility awareness–based methods, and spermicides.

### 143.1

**Contraceptive Use**

*Tara C. Jatlaoui, Yokabel Ermias, Lauren B. Zapata*

**Keywords**

- sexual activity
- sexual debut
Sexual Activity

According to the Youth Risk Behavior Surveillance System 2015, 41.2% of U.S. high school students had ever had sexual intercourse and approximately one-third reported being currently sexually active.

Although U.S. teens and European teens have similar levels of sexual activity and ages of sexual debut, U.S. teens are less likely to use contraception and less likely to use the most effective methods. Teen pregnancy rates have been declining worldwide as a result of delayed initiation of sexual activity and increased contraceptive use. Despite declines, the United States still had the highest 2013 teen birthrate in the Western industrialized world, with 26.5 live births per 1,000 females aged 15-19 yr (Fig. 143.2). This is almost 1.5 times higher than the 2013 teen birthrate in the United Kingdom, which has the highest rate in Western Europe, and almost 8 times higher than the teen birthrate in Switzerland, which has the lowest rate in Western Europe. In 2011, of the 574,000 teen pregnancies in the United States, 75% were unintended, indicating an unmet need for reliable, effective contraception that teens will correctly and consistently use.

Use of Contraception Among Teens

According to the National Survey of Family Growth, 2011–2013, virtually all sexually experienced teens have used some method of contraception in the past. The most commonly used method by teenage females is the condom, followed by withdrawal (both least effective methods) and then the pill (a moderately effective method). IUDs and implants, the most effective reversible methods, are only used by 4.3% of female contraceptive users age 15-19 yr. Use of contraception at first sex has greatly increased over the last 50 yr. As of 2010, the condom is the most common method used at first sex, reported by >75% of males and females. Factors associated with contraception use at first sex include increasing age among teens up to age 17 yr; time spent in college; and planning their sexual debut.

More than half of sexually experienced female teens are currently using the most effective reversible contraceptives or moderately effective contraceptive methods. U.S. teens' use of hormonal methods at last intercourse is less frequent compared to teens in other developed countries: 52% of U.S. teens, 56% of Swedish 18-19 yr olds, 67% of French 15-19 yr olds, 72% of British 16-19 yr olds, and 73% of Canadian 15-19 yr olds use hormonal methods. A higher likelihood of female current contraceptive use is associated with older age at sexual initiation, aspirations for higher academic achievement, acceptance of one's own sexual activity, and a positive attitude toward contraception. Despite the importance of dual protection to protect against both unwanted pregnancy and STIs, only 21.3% of sexually active female U.S. teens are using condoms in addition to another, more effective contraceptive method.

counseling
effectiveness
typical-use failure rates
confidentiality
teen-friendly

The health screening interview during the adolescent preventive visit offers opportunities to identify and discuss unsafe sexual practices among all adolescents and to identify and reinforce safe sexual behaviors, including abstinence (see Chapter 137). Adolescents with medical conditions, either chronic or acute, are particularly vulnerable to having sexual and reproductive health omitted from their visits, although they have similar sexual health and contraceptive needs as healthy adolescents (see Chapter 734). Their comorbidities or concurrent medication use may make unintended pregnancy an
increased health risk and may also reduce contraceptive options. The U.S. Medical Eligibility Criteria for Contraceptive Use outlines medical conditions associated with increased risk for adverse health events as a result of pregnancy and also provides recommendations for who can safely use specific contraceptive methods.

The goals of counseling with adolescents are to (1) understand adolescent experiences, preferences, perceptions, and misperceptions about pregnancy and use of contraceptives; (2) help adolescents put unprotected intercourse risk in a personal perspective; (3) educate adolescents about the various methods available using information that is medically accurate, balanced, and provided in a nonjudgmental manner; and (4) help adolescents choose a safe and effective method that can either be provided on site or be easily obtained through prescription or by referral. Counseling should include a review of all contraceptive methods available that the adolescent can use safely (see U.S. Medical Eligibility Criteria), starting with the most effective methods. Long-acting reversible contraception (IUDs and implants) is a safe and effective option for many adolescents, including those who have not been pregnant or given birth. The adolescent should be counseled about method effectiveness using typical-use failure rates. It is important to ask about use of withdrawal because 60% of female teens have used it for contraception and it has a typical-use failure rate of 20%. Abstinence should also be discussed as an option even if teens have engaged in sexual intercourse in the past. Situational abstinence may be the best option if they do not have another method available at a particular time.

Necessary concepts to address while discussing individual methods include how effective the method is, how long the method works, what behaviors are required for correct and consistent use, what side effects may be seen, any noncontraceptive benefits of the method (e.g., reduced menstrual bleeding, protection from STIs), and what signs or symptoms of complications should prompt a return visit. Reviewing common side effects allows teens to anticipate and cope with any changes with reassurance and may avoid method discontinuation. Weighing the possibility of certain side effects with the possibility of an unintended pregnancy may also help with the conversation. It is also important to address any specific misperceptions teens may have for certain contraceptives regarding side effects, effectiveness, or any other concept discussed.

Once an adolescent chooses a method, the provider and adolescent should
discuss clear plans on correct and consistent use of the chosen method and strategies for appropriate follow-up (Table 143.1). Providers should help the adolescent consider potential barriers to correct and consistent use (e.g., forgetting to take a pill daily) and develop strategies to deal with each barrier (e.g., use of reminder systems such as daily text messages or phone alarms). The provider should assess whether the teen understood the information discussed and may confirm by asking the teen to repeat back key concepts.

The U.S. Selected Practice Recommendations for Contraceptive Use provides guidance for providers regarding when to start contraception, how to be certain the woman is not pregnant at contraception initiation, and what examinations and tests are recommended before initiating contraception. Generally, women may start a contraceptive method other than an IUD at any time, and an IUD may be placed when a provider is reasonably certain that a woman is not pregnant. Most women do not require any exams or tests before initiating contraception. A pelvic examination is only required for placement of an IUD, unless otherwise indicated. STI screening is appropriate at IUD placement once sexual activity has begun, but most women do not require additional screening if they have been recently screened according to CDC sexually transmitted disease (STD) treatment guidelines. Gonorrhea and chlamydia screening using a self- or provider-collected vaginal swab or urine sample is recommended unless symptoms require a pelvic exam. IUD placement should not be delayed to receive screening results. ACOG guidelines recommend that the female teen should first visit a gynecologist between age 13 and 15 yr, unless necessary at an earlier age. This visit aims to establish rapport, educate the patient and parents or guardian on healthy sexual development, and provide routine preventive services. Cervical cancer screening is not recommended until age 21.

Providers should offer confidential services to adolescents and observe all relevant state laws and legal obligations (e.g., notification or reporting of sexual abuse). Chapter 137 discusses confidentiality and consent issues related to contraceptive management. Providers should also encourage adolescents to involve parents or guardians in their healthcare decisions, while giving parents clear information on their teen's right to confidentiality, privacy, and informed consent. All services should be provided in a youth-friendly manner, meaning that they are accessible, equitable, acceptable, appropriate, comprehensive, effective, and efficient. Resources are available that describe ways to ensure a teen-friendly reproductive health visit.

### 143.3

**Long-Acting Reversible Contraception**
Long-acting reversible contraception (LARC) includes 4 levonorgestrel (LNG) IUDs, the copper (Cu) IUD, and the etonogestrel subdermal implant. LARC methods are the only Tier 1 methods that are reversible (see Fig. 143.1). Considered “forgettable” contraception, LARC does not require frequent office or pharmacy visits and does not depend on user compliance for effectiveness. In the Contraceptive CHOICE Project in St. Louis, MO, >9,000 women were given the contraceptive method of their choice at no cost and were followed for 2-3 yr. The failure rates among women who used oral contraceptive pills, transdermal patch, or vaginal ring were >20 times higher than the failure rates for women using a LARC method. Acceptance, continuation, and satisfaction in this project were also higher among adolescents using LARC compared with adolescents using non-LARC methods. ACOG and AAP support the use of LARC methods for adolescents. The U.S. Medical Eligibility Criteria supports safe use of both IUDs and implants for adolescents and nulliparous women. Implants are considered category 1 for all ages, and IUDs are considered category 2 for women <20 yr old and for nulliparous women (Table 143.2).

</tr>
</tbody>
</table>
Intrauterine Devices

IUDs are small, flexible, plastic objects introduced into the uterine cavity through the cervix. They differ in size, shape, and the presence or absence of pharmacologically active substances. In the United States, 5 IUDs are currently approved by the Food and Drug Administration (FDA): the CuT380A (Paragard) and 4 LNG IUDs (Liletta, Kyleena, Mirena, and Skyla). The effectiveness of the Cu IUD is enhanced by the copper ions released into the uterine cavity, with possible mechanisms including inhibition of sperm transport and prevention of implantation; this IUD is effective for at least 10 yr.

The LNG IUDs also have various actions, from thickening of cervical mucus and inhibiting sperm survival to suppressing the endometrium. LNG IUDs are effective for at least 3 and 5 years. All IUDs have typical-use failure rates of <1% (see Fig. 143.1).

Common misconceptions of IUDs among healthcare providers are that IUDs cause infections, infertility, and generally are not safe for teens or nulliparous women to use; these misconceptions are a barrier to teens accessing these highly effective and acceptable methods. IUDs do not increase risk of infertility and may be inserted safely in teens as well as nulliparous women (category 2; see Table 143.2).

Although early studies suggested an increased risk for upper genital tract infection, theoretically as a result of passing a foreign body through the cervix, newer work has refuted these earlier concerns. Therefore, clinicians are encouraged to consider use of IUDs in adolescents despite relatively high prevalence rates of STIs in this population. Teens should be screened for gonorrhea and chlamydia at or before IUD placement, although placement should not be delayed if results have not returned and there are no signs of current infection (e.g., purulent discharge, erythematous cervix). If STI testing is positive with an IUD in place, the patient may be treated without removing the IUD if she wants to continue the method. Evidence from 2 systematic reviews did not find benefit in routinely administering misoprostol to women undergoing routine IUD placement to decrease pain or improve provider ease of insertion.
paracervical block with lidocaine may reduce patient discomfort during placement and, along with other medications (e.g., NSAIDs, anxiolytics), may be considered on an individual patient basis, but these are not routinely recommended.

## Implants

Currently, one contraceptive implant is available in the United States. Originally FDA approved in 2006, the single rod that releases 60 µg/day of etonogestrel has been updated to a radiopaque rod with a new inserter. This progestin-only method keeps etonogestrel at steady serum levels for at least 3 yr and primarily works to inhibit ovulation. Similar to the levonorgestrel IUD, the progestin acts on the uterus to cause an atrophic endometrium and thicken cervical mucus to block sperm penetration; its typical-use failure rate is also <1% (see Fig. 143.1). Unlike the IUD, no pelvic exam is required for insertion. A trained provider can quickly place or remove the implant in the upper arm under local anesthesia. Common side effects include amenorrhea, irregular bleeding, or infrequent bleeding, and less often, prolonged or frequent bleeding. One potential unique complication of this method relates to localized infection and other side effects after implantation, such as bleeding, hematoma, or scarring, and if inserted too deeply into the muscle, neural damage or migration; however, these events are rare, occurring in <1% of patients. Minor side effects, such as bruising or skin irritation, are more common but most often resolve without treatment.

## Bibliography

Several progestin-only contraceptive methods are available and include the LNG IUDs and implant (see Chapter 143.3), as well as an injectable and progestin-only pills. These methods do not contain estrogen and may be useful for teens with contraindications to estrogen (Table 143.3) and are considered generally safe for use in teens (category 1 or 2; see Table 143.2). Progestins thicken cervical mucus to block sperm entry into the uterine cavity as well as induce an atrophic endometrium leading to either amenorrhea or less menstrual blood loss; the implant and injectable additionally suppress ovulation. Teens should be provided anticipatory counseling regarding bleeding irregularities that may normally occur in the 1st 3-6 mo of hormonal contraception use.

<table>
<thead>
<tr>
<th>Conditions Classified as Category 3 and 4 for Combined Hormonal Contraceptive Use</th>
</tr>
</thead>
<tbody>
<tr>
<td>Category 4</td>

</tbody>
</table>
Complicated valvular heart disease
Current breast cancer
Severe decompensated cirrhosis
Deep venous thrombosis/pulmonary embolism (acute; history, not on anticoagulation or on established therapy for at least 3 mo with higher risk recurrence; major surgery with prolonged immobilization)
Complicated diabetes with nephropathy, retinopathy, neuropathy, or other vascular disease or duration of diabetes >20 yr
Migraine with aura
Hypertension (blood pressure >160/100 mm Hg) or hypertension with vascular disease
Ischemic heart disease (history of or current)
Hepatocellular adenoma
Malignant liver tumor
Peripartum cardiomyopathy (diagnosed <6 mo prior or with moderately or severely impaired cardiac function)
Postpartum <21 days
History of cerebrovascular accident
Systemic lupus erythematosus with positive antiphospholipid antibodies
Thrombogenic mutations
Viral hepatitis (acute or flare)

**Category 3**

Past breast cancer with no evidence of disease for 5 yr
Breastfeeding and <1 mo postpartum
Deep venous thrombosis/pulmonary embolism (history of DVT/PE with lower risk recurrence)
Gallbladder disease (current, medically treated)
History of malabsorptive bariatric surgery
History of cholestasis and past combined oral contraceptive–related
Hypertension (adequately controlled or blood pressure <160/100 mm Hg)
Peripartum cardiomyopathy with mild impairment or >6 mo
Postpartum 21-42 days with other risk factors for venous thromboembolism
Drug interactions (Ritonavir-boosted protease inhibitors; certain anticonvulsants; rifampin or rifabutin)
Depo-Provera

An injectable progestin, depot medroxyprogesterone acetate (DMPA, Depo-Provera) is a Tier 2 contraceptive method available as a deep intramuscular (IM) injection (150 mg), or as a subcutaneous (SC) injection (104 mg) with typical-use failure rates of 4% (see Table 143.1). Both preparations must be readministered every 3 mo (13 wk) and act to inhibit ovulation. DMPA is particularly attractive for adolescents who have difficulty with compliance, are intellectually or physically impaired, and are chronically ill or have a condition for which estrogen use is not recommended. Common concerns with DMPA include bleeding changes, bone effects, and weight gain. After 1 yr of use, 50% of DMPA users develop amenorrhea, which may be an added advantage for teens with heavy menstrual bleeding, dysmenorrhea, anemias, or blood dyscrasias, or for those with impairments that make hygiene difficult. Although studies have demonstrated bone mineral density (BMD) loss in adolescents, potentially increasing their risk for osteoporosis later in life, other studies have found that BMD is recovered after discontinuation of this method, and it is thus considered safe for use in this population. Healthcare providers may want to consider a contraceptive containing estrogen in teens who are already at high risk for low BMD, such as those receiving chronic corticosteroid therapy or those with eating disorders (see Chapter 726). Although the FDA issued a black box warning in 2004, AAP and ACOG do not recommend limiting DMPA use to 2 yr for all women and do not recommend routine BMD screening for females using DMPA. Early weight gain may be predictive of progressive gain over time; thus those teens gaining weight in the 1st 3-6 mo should consider another method.

Progestin-Only Pills

Progestin-only oral contraceptive pills (POPs) are available for the adolescent in whom the use of estrogen is potentially harmful, such those with active liver disease, replaced cardiac valves, or hypercoagulable states (see Table 143.3). POPs (mini pills) are quickly effective after 2 days of initiation in thickening cervical mucus, but are less reliable in inhibiting ovulation. Effects are short-
lived, and pill-taking must be punctual, which may be difficult for teens. If a pill is >3 hr late from normal time, an unintended pregnancy may occur. POPs have a typical-use failure rate of 7% (see Table 143.1 ). Acceptance by adolescents is limited by the necessity of taking the pill at the same time daily and bleeding irregularities, including amenorrhea and breakthrough bleeding.

combined hormonal contraceptives
oral contraceptive pills
combined pills
patch
ring

Combined hormonal contraceptives (CHCs) are methods that include an estrogenic substance in combination with a progestin; methods available in the United States include several formulations of combined oral contraceptives (COCs), a transdermal patch, and a vaginal ring. The major mechanism of action of the estrogen-progestin combination is to prevent the surge of luteinizing hormone and thereby inhibit ovulation. Additional effects to the reproductive tract include thickening of the cervical mucus, which prevents sperm penetration, and thinning of the endometrial lining, which may decrease menstrual blood loss. Typical-use failure rates for all CHCs are the same at 7%.

The COCs, patch, and vaginal ring are classified together as CHCs in the U.S. Medical Eligibility Criteria for Contraceptive Use, and recommendations mostly
consider estrogen exposure for a given condition or characteristic (see Table 143.3). Venous thromboembolism, hepatic adenomas, myocardial infarction, and stroke are some of the more serious potential complications of exogenous estrogen use. These serious adverse events are exceedingly rare in adolescents. Even though teenage smokers who use oral contraceptives have more than twice the risk of myocardial infarction, the likelihood of its occurrence is very small, and thus clinically insignificant, compared to the risk of dying from other pregnancy-related complications.

**Combined Oral Contraceptives**

Oral contraceptive pills (OCs) can be either COCs or progestin-only pills and are commonly referred to as “the pill.” The pill is one of the most common contraceptive methods used among women of all ages. To decrease risk of pregnancy and increase continuation, providers are encouraged to provide OCs at the time of patient presentation to start immediately rather than waiting for next menses, as long as the provider is reasonably sure that the patient is not pregnant. Providers are also encouraged to provide up to 13 pill packs at a time, based on evidence that more pill packs given is associated with higher continuation rates. Advanced provision of emergency contraceptive pills is also recommended should patients miss pills and have unprotected sex. The effectiveness of COCs depends on compliance, and unfortunately, adolescents may forget to take a pill each day. Figs. 143.3 and 143.4 list the rules for missed pills or following vomiting or diarrhea.
FIG. 143.3  Recommended actions after late or missed combined oral contraceptives.
COCs contain 50, 35, 30, 25, or 20 µg of estrogenic substance, typically ethinyl estradiol, and as many as 10 progestins have been available in the United States for combined pills. Multiple preparations are available to help select the formulation that satisfies an individual patient, with minimal side effects.

COCs can be packaged as 28-day monophasic pills, which contain the same dose of active pills for 21 or 24 days, followed by 7 or 4 days of placebo pills, respectively. Monophasic formulations are also available for extended cycles of 91 days or 1 yr so that withdrawal bleeding does not occur each month, but at the end of each extended cycle. Extended cycling of monophasic COCs for adolescents has some anticipated benefits associated with increased ovarian activity suppression and may decrease failure rates. Other advantages include
diminished frequency of hormonal withdrawal (premenstrual) effects, including headaches and migraines, mood changes, and heavy monthly bleeding. The most common side effect of extended-cycle OCs is intermenstrual bleeding and/or spotting, with the total days of bleeding over the 1st yr of treatment being similar for extended-cycle users and users following a 28-day cycle regimen. The unscheduled bleeding pattern diminishes over time. Multiphasic pill packs contain various levels of estrogen and progestin for 21 active pills and contains 7 placebo pills. Multiphasic formulations are not available for extended-cycle use. Providers can refer to the U.S. Selected Practice Recommendations for Contraceptive Use to counsel patients on how to manage late or missed COCs.

The short-term adverse effects of COCs, such as nausea and weight gain, often interfere with compliance in adolescent patients. These effects are usually transient and may be overshadowed by the beneficial effects of a shortened menses and the relief of dysmenorrhea. The inhibition of ovulation or the suppressant effect of estrogens on prostaglandin production by the endometrium makes COCs effective in preventing dysmenorrhea (see Chapter 142). Acne may be worsened by some and improved by other oral contraceptive preparations (see Chapter 689). The pills with nonandrogenic progestins are particularly effective in reducing acne and hirsutism. Drospirenone, a progestin with antimineralocorticoid activity, has been shown to reduce premenstrual symptomatology, but the potential for hyperkalemia as a side effect eliminates patients with renal, liver, or adrenal diseases and patients taking certain medications.

As of 2011, the FDA has concluded that drospirenone-containing OCs may be associated with a higher risk of venous thromboembolism (VTE) than other progestin-containing pills. Although no studies have provided consistent estimates of the comparative risk of VTE between OCs that contain drospirenone and those that do not, or accounted for patient characteristics that may affect VTE risk, there has been a 3-fold increased risk of VTE reported for drospirenone compared with products containing levonorgestrel or other progestins. As a result, the FDA is requiring that labeling be revised for the OCs marketed under the Beyaz, Safyral, Yasmin, and Yaz brands. Despite the risk of VTE with all OCs, the absolute risk remains lower than the risk of developing VTE during pregnancy or the postpartum period.

Transdermal Patch
The transdermal patch (Ortho Evra or Xulane) releases 20 µg ethinyl estradiol and 150 µg norelgestromin daily and is applied to the lower abdomen, buttocks, or upper body, excluding the breasts. It is worn continuously for 1 wk and changed weekly for a total of 3 wk, then no patch is worn for the 4th week, at which time bleeding occurs (see Table 143.1). Limited studies in adolescents suggest higher rates of partial or full detachment compared to adults, with high patient satisfaction and 50–83% continuation rates from 3-18 mo of use (Fig. 143.5). As with other combined hormonal methods, the patch is a Tier 2 contraceptive. Providers can refer to the U.S. Selected Practice Recommendations to counsel patients on how to manage delayed application or detachment of the patch.

<table>
<thead>
<tr>
<th>Delayed application or detachment* for &lt;48 hours since a patch should have been applied or reattached.</th>
</tr>
</thead>
</table>
| **•** Apply a new patch as soon as possible. (If detachment occurred <24 hours since the patch was applied, try to reapply the patch or replace with a new patch.)  
**•** Keep the same patch change day.  
**•** No additional contraceptive protection is needed.  
**•** Emergency contraception is not usually needed but can be considered if delayed application or detachment occurred earlier in the cycle or in the last week of the previous cycle. |
| Delayed application or detachment* for ≥48 hours since a patch should have been applied or reattached. |
| **•** Apply a new patch as soon as possible.  
**•** Keep the same patch change day.  
**•** Use back-up contraception (e.g., condoms) or avoid sexual intercourse until a patch has been worn for 7 consecutive days.  
**•** If the delayed application or detachment occurred in the third patch week:  
--- Omit the hormone-free week by finishing the third week of patch use (keeping the same patch change day) and starting a new patch immediately.  
--- If unable to start a new patch immediately, use back-up contraception (e.g., condoms) or avoid sexual intercourse until a new patch has been worn for 7 consecutive days.  
**•** Emergency contraception should be considered if the delayed application or detachment occurred within the first week of patch use and unprotected sexual intercourse occurred in the previous 5 days.  
**•** Emergency contraception may also be considered at other times as appropriate. |

*If detachment takes place but the woman is unsure when the detachment occurred, consider the patch to have been detached for ≥48 hours since a patch should have been applied or reattached.

**FIG. 143.5** Recommended actions after delayed application or detachment with combined hormonal patch. (From Curtis KM, Jatlaoui TC, Tepper NK, et al. U.S. Selected practice recommendations for contraceptive use, 2016, MMWR Recomm Rep 65(RR-4):1–66, 2016, Fig 3, p 28.)
Vaginal Ring

The vaginal contraceptive ring (NuvaRing) is a flexible, transparent, colorless vaginal ring that measures about 2.1 inches in diameter and is inserted into the vagina by the patient. It releases 15 µg ethinyl estradiol and 120 µg etonogestrel per day and remains in place for 3 weeks, during which time these hormones are absorbed. If the ring is accidentally expelled or removed for intercourse, it should be reinserted; however, if it is out of place ≥48 hr, a backup method of contraception should be used (Fig. 143.6). As with other combined hormonal methods, the vaginal ring is a Tier 2 contraceptive. Providers can refer to the U.S. Selected Practice Recommendations to counsel patients on how to manage delayed insertion or reinsertion with the vaginal ring.

If removal takes place but the woman is unsure of how long the ring has been removed, consider the ring to have been removed for ≥48 hours since a ring should have been inserted or reinserted.

![Fig. 143.6 Recommended actions after delayed insertion or reinsertion with combined vaginal ring. (From Curtis KM, Jatlaoui TC, Tepper NK, et al. U.S. selected practice recommendations for contraceptive use, 2016, MMWR Recomm Rep 65(RR-4):1–66, 2016, Fig 4, p 29.)](image-url)
Contraindications

Contraindications to the use of estrogen-containing methods include those conditions for which CHCs pose an unacceptable health risk (category 4) in the U.S. Medical Eligibility Criteria for Contraceptive Use (see Table 143.3): current breast cancer, severe cirrhosis, acute deep venous thrombosis/pulmonary embolism or history of DVT/PE with higher risk for recurrence, major surgery with prolonged immobilization, diabetes with nephropathy, retinopathy or neuropathy, migraines with aura, stage II hypertension, vascular disease, ischemic heart disease, hepatocellular adenoma or malignant liver tumors, multiple risk factors for cardiovascular disease, peripartum cardiomyopathy, postpartum <21 days, complicated solid-organ transplantation, history of cerebrovascular accident, systemic lupus erythematosus with positive antiphospholipid antibodies, thrombogenic mutations, and complicated valvular heart disease. The initial history taken before prescribing CHCs should specifically address these risks. The U.S. Medical Eligibility Criteria provides contraceptive safety guidance with >1,800 recommendations for >120 medical conditions or characteristics.

Keywords

ulipristal
Plan B
levonorgestrel
LNG
EC
Yuzpe

Unprotected intercourse at mid-cycle carries a pregnancy risk of 20–30%. At other times during the cycle, the risk is 2–4%. The risk may be reduced or
eliminated by interventions known collectively as emergency contraception (EC) up to 120 hr after unprotected intercourse or contraceptive failure. Table 143.4 lists the indications for use of EC. EC methods include the Cu IUD and emergency contraceptive pills, which include ulipristal acetate, levonorgestrel (LNG), and COCs following the Yuzpe method. Although the mechanism of action of the Cu IUD as EC is unclear, all emergency contraceptive pills work to delay ovulation and are effective only for intercourse that occurs before administration. Initiation of a regular contraceptive method is necessary to prevent pregnancy for any intercourse that occurs for the remainder of the cycle and for future cycles. If pregnancy has already occurred, emergency contraceptive pills will not cause an abortion or have teratogenic effects on the fetus.

Teens can access EC information through a hotline at 1-888-NOT-2-LATE to obtain EC pills over the counter (OTC). AAP recommends advance provision of EC pills for teens who are or may become sexually active. A follow-up
appointment is also recommended to determine the effectiveness of treatment and to diagnose a possible early pregnancy. The visit also provides an opportunity to counsel the adolescent, explore the situation leading up to the unprotected intercourse or contraceptive failure, test for STIs, offer HIV testing, and initiate continuing contraception when appropriate. Pap smear screening is not initiated until age 21.

Copper IUD

The CuT380A (Paragard) is FDA approved for EC and has been shown to be >99% effective if used within 5 days (120 hr) after unprotected sex. The additional benefit of using the Cu IUD for EC is it also provides long-term reversible contraception.

Ulipristal Acetate

This formulation is available for EC and was FDA approved in 2010 for use up to 120 hr after unprotected sex. Ulipristal acetate is available only by prescription regardless of age. A few studies have shown it to be more effective than LNG at and beyond 72 hr. If starting regular contraception after taking ulipristal acetate, it is recommended to start or resume hormonal contraception no sooner than 5 days after taking ulipristal, to avoid a potential interaction and its decreased effectiveness. If starting a method requires an extra visit (e.g., IUDs, implant, Depo-Provera), starting the method at the time of ulipristal may be considered, weighing the risk of decreasing the effectiveness of ulipristal with the risk of not starting a contraceptive method.

Levonorgestrel

In 2013 the FDA approved the emergency contraceptive drug Plan B One-Step as an OTC option for all women of childbearing potential. Experience in adolescent women demonstrates more effective use of EC with advance provision, and it is not associated with more frequent unprotected intercourse or less condom or pill use. Nausea and vomiting are uncommon side effects, and in a recent comparison, LNG proved more effective at preventing pregnancy than the Yuzpe method.
The **Yuzpe method** has been replaced by the more effective LNG pills but may be useful for women who already have COCs at home and are in need of EC. For EC, pills consist of COCs totaling 200 µg ethinyl estradiol and 2.0 mg norgestrel or 1.0 mg levonorgestrel. This method is effective in reducing the risk of pregnancy by 75%. The most common side effects are nausea (50%) and vomiting (20%), prompting some clinicians to prescribe or recommend antiemetics along with the COCs.

Hatcher RA, Nelson AL, Trussell J, et al. *Contraceptive*
Dual Protection

Keywords

condoms
dual protection
female condom

Dual protection refers to contraceptive use that protects against STIs/HIV as well as pregnancy. Although correct and consistent condom use with every act of sexual intercourse provides dual protection, providers should encourage adolescents to use condoms for STI/HIV protection along with a more effective method for pregnancy protection.

Condoms

This method prevents sperm from being deposited in the vagina. No major side effects are associated with the use of a condom. The risk of HIV may have increased the use of condoms among adolescents, with 46.2% of high school students in 1991 reporting using a condom at last sexual intercourse increasing to 56.9% in 2015. The main advantages of condoms are their low price, availability without prescription, little need for advance planning, and, most important for this age-group, their effectiveness in preventing transmission of STIs, including HIV and human papillomavirus (HPV). The typical-use failure
rate for male condoms is 13%. For the most effective dual protection, **male latex condoms** are recommended as protection against STIs, and should be used with an effective contraceptive method for adolescents, such as a LARC. According to the National Survey of Family Growth, only 21.3% of females used another contraceptive method along with a condom at last sex during the past 12 mo.

A **female condom** is available OTC in single-size disposable units. It is a 2nd choice over the male latex condom because of the complexity of properly using the device, its high typical-use failure rate of 21%, and the lack of human studies demonstrating its effectiveness against STIs. Most adolescents would require intensive education and hands-on practice to use it effectively.

**Bibliography**

Other Barrier Methods

Tara C. Jatlaoui, Yokabed Ermias, Lauren B. Zapata

Keywords

cervical cap
sponge
diaphragm

Diaphragm, Cervical Cap, and Sponge

These methods have few side effects but are much less likely to be used by teenagers. Typical use failure rates exceed 14%. The cervical cap and sponge have lower failure rates in nulliparous women, while the diaphragm has similar rates among nulliparous and parous women. Adolescents tend to object to the messiness of the jelly or the insertion of a diaphragm interrupting the spontaneity of sex (to be inserted before sex and left in for several hours afterward), or they may express discomfort about touching their genitals.
Spermicides

A variety of agents containing the spermicide nonoxynol-9 are available as foams, jellies, creams, films, or effervescent vaginal suppositories. They must be placed in the vaginal cavity shortly before intercourse and reinserted before each subsequent ejaculation to be effective. Rare side effects include contact vaginitis. Some concern surrounds the vaginal and cervical mucosal damage observed with nonoxynol-9, and the overall impact on HIV transmission is unknown. The finding that nonoxynol-9 is gonococcicidal and spirocheticidal has not been substantiated in randomized clinical trials. Spermicides should be used in combination with other barrier methods because their typical-use failure rate alone is 21%.

Withdrawal

The pregnancy risk for use of withdrawal as a contraceptive method is probably underestimated in adolescents, and high typical-use failure rate of 20% should be specifically addressed with young adolescents; especially since 60% of teens have used withdrawal for contraception.

Fertility Awareness–Based Methods

These include the Standard Days method, basal body temperature method, and Billings method and may also include combinations as well. Since fertility awareness methods are based on regular ovulatory cycles, which are less common in teens, these should be used with caution.

Lactational Amenorrhea Method

The lactational amenorrhea method may be a highly effective, temporary contraceptive method if the following criteria are met: (1) no return of menses,
(2) the infant is <6 mo old, and (3) exclusively breastfeeding.

**Bibliography**

Epidemiology

There has been a trend of decreasing teen births and pregnancies since 1991 (Figs. 144.1 and 144.2). Teen birthrates in the United States are at a historic low secondary to increased use of contraception at first intercourse and use of dual methods of condoms and hormonal contraception among sexually active teenagers. Despite these data, the United States continues to lead other industrialized countries in having high rates of adolescent pregnancy, with >700,000 pregnancies per year. Nonetheless, the National Survey of Family Growth (NSFG) 2006–2010 revealed that less than one third of 15-19 yr old females consistently used contraceptive methods at last intercourse.

FIG. 144.1 Birthrates for females age 15-19, by age group: United States, 1991–2015. Rates are plotted on a logarithmic scale. For each age group, differences are significant.

FIG. 144.2 Birthrates (per 1,000) for females ages 15-19, by race and Hispanic origin: Selected years, 1960–2014. Differences in teen childbearing across the race and Hispanic-origin groups have narrowed from 1991 to 2015. In 1991, there was a difference of 77 births per 1,000 teenagers age 15-19 between the lowest rate (27.3 for Asian Pacific Islander [API] females) and the highest rate (104.6 for Hispanic females), compared with a difference of 28 births between the lowest rate (6.9 for API females) and the highest rate (34.9 for Hispanic females) in 2015. From 2014 to 2015, the birthrate for females age 15-19 declined 10% for API (to 6.9), 9% for non-Hispanic black (31.8), 8% for both non-Hispanic white (16.0) and Hispanic (34.9), and 6% for American Indian or Alaska Native (AIAN) (25.7) females. Since 2007, declines in teen birthrates have ranged from 41% for non-Hispanic white females to 54% for Hispanic females. Since 1991, declines have ranged from 63% for non-Hispanic white females to 75% for API females. Data for 2014 are preliminary. (Data for 1960 from National Center for Health Statistics: Health, United States, 2001 with urban and rural health chartbook, Hyattsville, MD, 2001, Table 3; data for 1970–2011 from Martin JA et al: Births: final data for 2011, Natl Vital Stat Rep 62(1), 2013, http://www.cdc.gov/nchs/data/nvsr/nvsr62/nvsr62_01.pdf; data for 2012 from Martin JA et al: Births: final data for 2012, Natl Vital Stat Rep 62(9), 2013, http://www.cdc.gov/nchs/data/nvsr/nvsr62/nvsr62_09.pdf; data for 2013 from Martin JA et al: Births: preliminary data for 2013, Natl Vital Stat Rep 63(2), 2014, http://www.cdc.gov/nchs/data/nvsr/nvsr63/nvsr63_02.pdf.)

The improvement in U.S. female teen birthrates is attributed to 3 factors: more teens are delaying the onset of sexual intercourse, are using some form of contraception when they begin to have sexual intercourse, and are using long-lasting contraceptive agents such as injections, implants, and intrauterine devices (IUDs).

Most pregnancies among U.S. adolescents are unintended (unwanted or mistimed); 88% of births to teenagers 15-17 yr old were the result of unintended pregnancies. Birthrate statistics underestimate actual adolescent pregnancy rates because the birthrate numerator includes the number of actual births per 1000
individuals in that age-group, but the pregnancy rate includes actual births, abortions, and best estimates of fetal loss per 1,000 adolescents in that age-group.

The abortion rate among adolescents 15-19 yr old was 14.3 per 1,000 females and accounted for 16.2% of all abortions in 2008. During the decade 1999–2008, the abortion rate decreased by 20.7% among adolescents 15-19 yr old, with a 5.8% decrease noted from 2004–2008.

**Etiology**

In industrialized countries with policies supporting access to protection against pregnancy and sexually transmitted infections (STIs), older adolescents are more likely to use hormonal contraceptives and condoms, resulting in a lowered risk of unplanned pregnancy. Younger teenagers are likely to be less deliberate and logical about their sexual decisions, and their sexual activity is likely to be sporadic or even coercive, contributing to inconsistent contraceptive use and a greater risk of unplanned pregnancy. Better personal hopes for employment and higher educational goals are associated with lowered probability of childbearing in most groups. In nonindustrialized countries, laws permitting marriage of young and mid-teens, poverty, and limited female education are associated with increased adolescent pregnancy rates.

**Clinical Manifestations**

Adolescents may experience the traditional symptoms of pregnancy: morning sickness (vomiting, nausea that may also occur *any* time of the day), swollen tender breasts, weight gain, and amenorrhea. Often the presentation is less classic; headache, fatigue, abdominal pain, dizziness, and scanty or irregular menses are common presenting complaints.

In the pediatric office, some teens are reluctant to divulge concerns of pregnancy. Denial of sexual activity and menstrual irregularity should not preclude the diagnosis in face of other clinical or historical information. An unanticipated request for a complete checkup or a visit for contraception may uncover a suspected pregnancy. Pregnancy is still the most common diagnosis when adolescents present with secondary amenorrhea.
Diagnosis

Table 144.1 provides classic symptoms, laboratory tests, and physical changes in the diagnosis of pregnancy.

Table 144.1

Diagnosis of Pregnancy Dated from First Day of Last Menstrual Cycle

<table>
<thead>
<tr>
<th>Classic Symptoms</th>
</tr>

</tbody>
</table>

<table>
<thead>
<tr>
<th>Physical Changes</th>
</tr>
</thead>
<tbody>
<tr>
<td>2-3 wk after implantation: cervical softening and cyanosis. 8 wk: uterus size of orange. 12 wk: uterus size of grapefruit and palpable suprapubically. 20 wk: uterus at umbilicus. If physical findings are not consistent with dates, ultrasound will confirm.</td>
</tr>
</tbody>
</table>

On physical examination, the findings of an enlarged uterus, cervical cyanosis (Chadwick sign), a soft uterus (Hegar sign), or a soft cervix (Goodell sign) are highly suggestive of an intrauterine pregnancy. A confirmatory pregnancy test is always recommended, either qualitative or quantitative. Modern qualitative urinary detection methods are efficient at detecting pregnancy,
whether performed at home or in the office. These tests are based on detection of the beta subunit of human chorionic gonadotropin (hCG). Although claims for nonprescription home pregnancy tests may indicate 98% detection on the day of the 1st missed menstrual period, sensitivity and accuracy vary considerably. Office or point-of-care tests have increased standardization and generally have increased sensitivity, with the possibility of detecting a pregnancy within 3-4 days after implantation. However, in any menstrual cycle, ovulation may be delayed, and in any pregnancy, the day of implantation may vary considerably, as may rate of production of hCG. This variability, along with variation of urinary concentration, may affect test sensitivity. Consequently, each negative test should be repeated in 1-4 wk if there is a heightened suspicion of pregnancy. The most sensitive pregnancy detection test is a serum quantitative βhCG radioimmunoassay, with reliable results within 7 days after fertilization. This more expensive test is used primarily during evaluations for ectopic pregnancy, to detect retained placenta after pregnancy termination, or in the management of a molar pregnancy. It is used when serial measurements are necessary in clinical management.

Although not used for primary diagnosis of pregnancy, pelvic or vaginal ultrasound can be helpful in detecting and dating a pregnancy. Pelvic ultrasound will detect a gestational sac at about 5-6 wk (dated from last menstrual period) and vaginal ultrasound at 4.5-5 wk. This tool may also be used to distinguish diagnostically between intrauterine and ectopic pregnancies.

**Pregnancy Counseling and Initial Management**

Once the diagnosis of pregnancy is made, it is important to begin addressing the psychosocial, as well as the medical, aspects of the pregnancy. The patient's response to the pregnancy should be assessed and her emotional issues addressed. It should not be assumed that the pregnancy was unintended. Discussion of the patient's options should be initiated. These options include (a) releasing the child to an adoptive family, (b) electively terminating the pregnancy, and (c) raising the child herself with the help of family, father of the baby, friends, and/or other social resources. Options should be presented in a supportive, informative, nonjudgmental fashion; for some young women, they may need to be discussed over several visits. Physicians who are uncomfortable
in presenting options to their young patients should refer their patients to a provider who can provide this service expeditiously. Pregnancy terminations implemented early in the pregnancy are generally less risky and less expensive than those initiated later.

Other issues that may need discussion are how to inform and involve the patient's parents and the father of the infant; implementing strategies for insuring continuation of the young mother's education; discontinuation of tobacco, alcohol, and illicit drug use; discontinuance and avoidance of any medications that may be considered teratogenic; starting folic acid, calcium, and iron supplements; proper nutrition; and testing for STIs. Especially in younger adolescents, the possibility of coercive sex (see Chapter 145) must be considered and appropriate social work/legal referrals made if abuse has occurred, although most pregnancies are not a result of coercive sex. Patients who elect to continue their pregnancy should be referred as soon as possible to an adolescent-friendly obstetric provider.

Risk factors for teen pregnancy include growing up in poverty, having parents with low levels of education, growing up in a single-parent family, fewer opportunities in their community for positive youth involvement, neighborhood physical disorder, foster care (are more than twice as likely to become pregnant than those not in foster care), and having poor performance in school (see later, Psychosocial Outcomes/Risks for Mother and Child).

The Importance of Prevention

Teen pregnancy and childbearing bring substantial social and economic costs through immediate and long-term impacts on teen parents and their children. In 2010, teen pregnancy and childbirth accounted for at least $9.4 billion in costs to U.S. taxpayers for increased healthcare and foster care, increased incarceration rates among children of teen parents, and lost tax revenue because of lower educational attainment and income among teen mothers.

Adolescent Fathers

Those who become fathers as adolescents also have poorer educational achievement than their age-matched peers. They are more likely than other peers to have been involved with illegal activities and with the use of illegal substances. Adult men who father the children of teen mothers are poorer and
educationally less advanced than their age-matched peers and tend to be 2-3 yr older than the mother; any combination of age differences may exist. Younger teen mothers are more likely to have a greater age difference between themselves and the father of their child, raising the issue of coercive sex or statutory rape (see Chapter 145).

Male partners have a significant influence on the young woman's decision/desire to become pregnant and to parent her child. Sensitively and appropriately including the male partner in discussions of family planning, contraception, and pregnancy options may be a useful strategy in improving outcomes for all. This can only be successful if the young female patient is willing to have her partner involved in such discussions.

Medical Complications of Mothers and Babies

Although pregnant teens are at higher-than-average risk for some complications of pregnancy, most teenagers have pregnancies that are without major medical complications, delivering healthy infants. The miscarriage/stillbirth risk for adolescents is estimated at 15–20%. In the United States, elective pregnancy termination rates peaked from 1985–1988 at 41–46%, decreasing since then to approximately 30% in 2008. Teen mothers have low rates of age-related chronic disease (diabetes or hypertension) that might affect the outcomes of a pregnancy. They also have lower rates of twin pregnancies than older women. They tolerate childbirth well with few operative interventions. However, compared with 20-39 yr old mothers, teens have higher incidences of low birthweight infants, preterm infants, neonatal deaths, passage of moderate to heavy fetal meconium during parturition, and infant deaths within 1 yr after birth. The highest rates of poor outcomes occur in the youngest and most economically disadvantaged mothers. Gastroschisis, although rare, has a much higher incidence in infants of teen mothers, for reasons that are unclear. Teen mothers also have higher rates of anemia, pregnancy-associated hypertension, and eclampsia, with the youngest teens having rates of pregnancy-associated hypertension higher than the rates of women in their 20s and 30s. The youngest teens also have a higher incidence of poor weight gain (<16 lb) during their pregnancy. This correlates with a decrease in the birthweights of their infants. Poor maternal weight gain also has correlated strongly with teens’ late entrance into prenatal care and with inadequate
utilization of prenatal care. Sexually active teens have higher rates of STIs than older sexually active women.

Globally, many young women who become pregnant have been exposed to violence or abuse in some form during their lives. There is some evidence that teenage women have the highest rates of violence during pregnancy of any group. Violence has been associated with injuries and death as well as preterm births, low birthweight, bleeding, substance abuse, and late entrance into prenatal care. An analysis of the Pregnancy Mortality Surveillance System indicates that in the United States 1991–1999, homicide was the 2nd leading cause of injury-related deaths in pregnant and postpartum women. Women age 19 yr and younger had the highest pregnancy-related homicide rate (see Chapter 139).

Ectopic pregnancy occurs in 1–2% of conceptions and is more common in women with a previous history of an ectopic pregnancy, pelvic inflammatory disease, prior appendicitis, infertility, in utero exposure to diethylstilbestrol, and possibly an IUD. Most ectopic pregnancies are in the fallopian tube (tubal pregnancy). Manifestations include vaginal spotting after a missed menstrual period that may progress to more intense vaginal bleeding (suggestive of spontaneous abortion); vaginal bleeding is absent in 10–20%. Abdominal pain is associated with distention of the fallopian tube; tubal rupture results in more intense pain, hemorrhagic shock, and peritonitis. Some women have nonspecific abdominal complaints and are misdiagnosed with gastroenteritis. Cervical motion and adnexal tenderness (and adnexal mass) may be present.

Transvaginal sonography (not transabdominal) is the diagnostic test of choice to detect an ectopic pregnancy and reveals an adnexal mass and no uterine pregnancy. Nonetheless, some women will have pregnancy of unknown location by transvaginal sonography; approximately 20% of these will have an ectopic pregnancy. Measurement of sensitive quantitative serum βhCG levels together with transvaginal sonography has value in diagnosing an ectopic pregnancy. If the initial βhCG is above the discriminatory zone (level at which one expects an intrauterine pregnancy) but on transvaginal sonography there is no intrauterine pregnancy, there may be an ectopic pregnancy or an abnormal uterine pregnancy. In addition, if the βhCG is below the discriminatory level (usually <3000 mIU/mL) with no definitive diagnosis by sonography, serial βhCG testing should be performed every 48 hr. In a normal uterine pregnancy, βhCG levels should increase approximately 50% every 48 hr; declining levels may suggest a miscarriage or an ectopic pregnancy. Some would perform a dilation and
curettage and check for products of conception or follow serial βhCG levels. If there are no products of conception or if βhCG levels plateau or increase, an ectopic pregnancy is present. Treatment of unstable or advanced patients is usually by laparoscopic surgery or by laparotomy. Because of early detection, many patients remain stable (unruptured). Stable patients with an unruptured ectopic pregnancy may be treated with single-dose, or more often multidose, methotrexate to induce abortion. Contraindications to methotrexate in a stable patient include size of the ectopic mass (>3.5 cm) and embryonic cardiac motion.

Prematurity and low birthweight increase the perinatal morbidity and mortality for infants of teen mothers. These infants also have higher-than-average rates of sudden infant death syndrome (see Chapter 402), possibly because of less use of the supine sleep position or cosleeping, and are at higher risk of both intentional and unintentional injury (see Chapter 16). One study showed that risk of homicide is 9-10 times higher if a child born to a teen mother is not the mother's firstborn compared with the risk to a firstborn of a woman age 25 yr or older. The perpetrator is often the father, stepfather, or boyfriend of the mother.

After childbirth, depressive symptoms may occur in as many as 50% of teen mothers. Depression seems to be greater with additional social stressors and with decreased social supports. Support from the infant's father and the teen's mother seems to be especially important in preventing depression. Pediatricians who care for parenting teens should be sensitive to the possibility of depression, as well as to inflicted injury to mother or child; appropriate diagnosis, treatment, and referral to mental health or social agencies should be offered and facilitated.

Psychosocial Outcomes/Risks for Mother and Child

Educational Issues

Pregnancy and birth are significant contributors to high school dropout rates among girls. Only about 50% of teen mothers receive a high school diploma by age 22, whereas approximately 90% of women who do not give birth during adolescence graduate from high school. Mothers who have given birth as teens generally remain 2 yr behind their age-matched peers in formal educational
attainment at least through their 3rd decade. Maternal lack of education limits the income of many of these young families (see Chapter 1).

The children of teenage mothers are more likely to have lower school achievement and to drop out of high school, have more health problems, and face unemployment as a young adult.

**Substance Use**

See also Chapter 140.

Teenagers who abuse drugs, alcohol, and tobacco have higher pregnancy rates than their peers. Most substance-abusing mothers appear to decrease or stop their substance use while pregnant. Use begins to increase again about 6 mo postpartum, complicating the parenting process and the mother's return to school.

**Repeat Pregnancy**

In the United States, approximately 20% of all births to adolescent mothers (age 15-19) are second order or higher. Prenatal care is begun even later with a 2nd pregnancy, and the 2nd infant is at higher risk of poor outcome than the 1st birth. Mothers at risk of early repeat pregnancy (<2 yr) include those who do not initiate long-acting contraceptives after the index birth, those who do not return to school within 6 mo of the index birth, those with mood disorders, those receiving major childcare assistance from the adolescent's mother, those who are married or living with the infant's father, those having peers who were adolescent parents, and those who are no longer involved with the baby's father and who meet a new boyfriend who wants to have a child. To reduce repeat pregnancy rates in these teens, programs must be tailored for this population, preferably offering comprehensive healthcare for both the young mother and her child (Table 144.2). Healthcare providers should remember to provide positive reinforcement for teen parenting successes (i.e., compliment teen parents when they are doing a good job).

**Children Born to Teen Mothers**

Many children born to teen mothers have behavioral problems that may be seen as early as the preschool period. Many drop out of school early (33%), become adolescent parents (25%), or, if male, are incarcerated (16%). Explanations for these poor outcomes include poverty, parental learning difficulties, negative parenting styles of teen parents, maternal depression, parental immaturity, poor parental modeling, social stress, exposure to surrounding violence, and conflicts with grandparents, especially grandmothers. Continued positive paternal involvement throughout the child’s life may be somewhat protective against negative outcomes. Many of these poor outcomes appear to be attributable to the socioeconomic/demographic situation in which the teen pregnancy has occurred, not solely to maternal age. Even when socioeconomic status and demographics are controlled, infants of teen mothers have lower achievement scores, lower high school graduation rates, increased risk of teen births themselves, and, at least in Illinois (where records include age of birth mother), a higher probability of abuse and neglect.

Comprehensive programs focused on supporting adolescent mothers and
infants utilizing life skills training, medical care, and psychosocial support demonstrate higher employment rates, higher income, and less welfare dependency in participating adolescents.

**Prevention of Teen Pregnancies**

Adolescent pregnancy is a multifaceted problem that requires multifactorial solutions. The provision of contraception and education about fertility risk from the primary care physician is important, but insufficient to address the problem fully. Family and community involvement are essential elements for teen pregnancy prevention. Strategies for primary prevention (preventing 1st birth) are different from the strategies needed for secondary prevention (preventing 2nd or more births). Over the last 30 yr, many models of teen pregnancy prevention programs have been implemented and evaluated. Table 144.3 lists the common components of many successful evidence-based programs.

**Table 144.3**

**Common Components of Most Successful Evidence-Based Programs to Prevent Teen Pregnancy**

- Information is provided about the benefits of abstinence.
- Information is provided about contraception for those who are already sexually active.
- Information is provided about the signs and symptoms of STIs and how to prevent STIs.
- Interactive sessions on peer pressure are presented.
- Teenagers are taught communication skills.
- Programs are tailored to meet the needs of specific groups of young people (e.g., young men or young women, cultural groups, younger or older teens).

Abstinence-only sexual education aims to teach adolescents to wait until marriage to initiate sexual activity but, unfortunately, does not mention contraception. Abstinence education is sometimes coupled with “virginity pledges” in which teenagers pledge to remain abstinent until they marry. Other educational programs emphasize HIV and STI prevention and in the process prevent pregnancy, whereas others include both abstinence and contraception in their curricula. Sex education and teaching about contraception do not lead to an increase in sexual activity. Teenagers who participate in programs with comprehensive sex education components generally have lower rates of pregnancy than those exposed solely to abstinence-only programs or no sex education at all.

In many U.S. communities, programs that engage youth in community service and that combine sex education and youth development are also successful in deterring pregnancy. Programs vary in their sites of service from schools to social agencies, health clinics, youth organizations, and churches. Programs must be tailored to the cultural background, ethnicity, age-group, and gender of the group being targeted for the prevention services.

Secondary prevention programs are fewer in number. In the United States, some communities have tried to “pay” young mothers not to become pregnant again, but these efforts have not always been fruitful. Home visiting by nurses has been successful in some areas, and many communities have developed “Teen Tot” Clinics that provide a “one-stop shopping model” for healthcare for both the teen mother and the baby in the same site at the same time. Both programs have reported some successes.

In the practice setting, the identification of the sexually active adolescent through a confidential clinical interview is a first step in pregnancy prevention. The primary care physician should provide the teenager with factual information in a nonjudgmental manner and then guide the teenager in the decision-making process of choosing a contraceptive (see Chapter 143 ). The practice setting is an ideal setting to support the teenager who chooses to remain abstinent. When a teenager does become pregnant and requires prenatal care services, healthcare providers should remember that the pregnant teenager is an adolescent who has become pregnant, not a pregnant woman who happens to be an adolescent.

CHAPTER 145

Adolescent Sexual Assault

Allison M. Jackson, Norrell Atkinson

Sexual assault is an act of violence that may or may not involve rape. Rape, also an act of violence, is not an act of sex. Rape is historically defined as coercive sexual intercourse involving physical force or psychological manipulation of a female or a male. Recognizing that sexual intercourse is not a requirement for the definition, the U.S. Department of Justice (DOJ) defines rape as “the penetration, no matter how slight, of the vagina or anus with any body part or object, or oral penetration by a sex organ of another person, without the consent of the victim.”

Epidemiology

Exact figures on the incidence of rape are unavailable because many rapes are not reported. It is estimated that 1 in 5 women and 1 in 71 men will be raped in their lifetime. Females exceed males as reported rape victims, but male rape may be more underreported than female rape. In 2010 the DOJ National Crime Victimization Survey reported that the annual rates of sexual victimization per 1,000 persons were 4.1 for ages 12-17 yr and 3.7 for 18-34 yr. Between 1995 and 2013 the rate of rape and sexual assault was highest for adolescent females between ages 18 and 24 yr. The National Survey of Children's Exposure to Violence (NatSCEV 2014), revealed that 12.9% of 14-17 yr olds experienced any sexual victimization in the past year, 21.7% had experienced any sexual victimization in their lifetime; and 4.2% experienced sexual assault in the past year and 10.2% in their lifetime. This survey also demonstrated how other experiences with violence compound the risk for sexual victimization. Youth with a history of maltreatment by a caregiver were 4 times more likely to experience sexual victimization and >4 times more likely to experience sexual
victimization if they had any witness to violence. Among older adolescents age 18-24 yr, the rate of rape and sexual assault was 1.2 times higher for those not enrolled in college than those in college. Further, several studies of youth in the juvenile justice system demonstrate a particularly high prevalence of prior sexual victimization of girls in the juvenile justice system.

Rape occurs worldwide and is especially prevalent in war and armed conflicts. The World Health Organization estimates that rape and domestic violence are responsible for 5–16% of healthy years of life lost by females of reproductive age.

Female adolescents and young adults have the highest rates of rape compared to any other age-group. The normal developmental growth tasks of adolescence may contribute to this vulnerability in the following ways: (1) the emergence of independence from parents and the establishment of relationships outside the family may expose adolescents to environments with which they are unfamiliar and situations that they are unprepared to handle; (2) dating and becoming comfortable with one's sexuality may result in activities that are unwanted, but the adolescent is too inexperienced to avoid the unwanted actions; and (3) young adolescents may be naïve and more trusting than they should be (see Chapter 132). Many teens are technologically competent, which gives sexual perpetrators access to unsuspecting vulnerable populations who were previously beyond their reach. Social media, chat rooms, and online dating sites represent a major risk for adolescents, resulting in correspondence with individuals unknown to them or protective family members, while simultaneously providing a false sense of security because of remote electronic communications. A determined perpetrator can obtain specific information to identify the adolescent and arrange for a meeting that is primed for sexual victimization.

Some adolescents are at higher risk of being victims of rape than others (Table 145.1).

**Table 145.1**

**Adolescents at High Risk of Rape Victimization**

- **Male and Female Adolescents**
  - Drug and alcohol users
  - Runaways
Those with intellectual disability or developmental delay
Street youths
Transgender youth
Youths with a parental history of sexual abuse
Sex trafficking

**Primarily Females**
Survivors of prior sexual assault
Newcomers to a town or college

**Primarily Males**
Those in institutionalized settings (detention centers, prison)
Young male homosexuals

**Types of Rape**
Rape and sexual assault can occur in a variety of circumstances (Tables 145.2 and 145.3). A victim can be sexually assaulted or raped by someone they know or a by stranger, though more often the assailant is someone known to the victim. Understanding those circumstances allows for a more trauma-sensitive approach and may impact the medical management and response to the patient. The circumstances and relationship of the assailant to the victim may impact if, when, and how a patient discloses. The gender of the victim may also affect disclosure; transgendered people and males are uniformly less likely to disclose rape/sexual assault than females. The gender of the assailant may be the same or different than the victim's, and there may be one or more than one perpetrator. In any scenario the sexual assault/rape can be facilitated by threats or coercion, physical force, or drugs.

**Table 145.2**
**Types of Nonstranger Rape**

**Acquaintance Rape**
Most common form of rape for adolescents age 16-24 yr.
Assailant may be a neighbor, classmate, or friend of the family.
Victims are more likely to delay seeking medical care, may never report the crime (males > females), and are less likely to proceed with criminal prosecution even after reporting the incident(s).

**Date Rape**

Assailant is in an intimate relationship with the victim.
May be associated with intimate partner violence.
Assailant may engage in more sexual activities than other men his age and often has a history of aggressive behavior toward women.

**Sexual Abuse**

All sexual contact or exposure between an adult and a minor, or when there is a significant age or developmental difference between the youth.
The assailant may be a relative, close family friend, or someone of authority.

**Statutory Rape**

Sexual activity between an adult and an adolescent under the age of legal consent, as defined by individual state law.
Based on the premise that below a certain age or beyond a specific age difference with the assailant, an individual is not legally capable of giving consent to engage in sexual intercourse.
The intent of such laws is to protect youth from being victimized, but they may inadvertently lead a teenager to withhold pertinent sexual information from a clinician for fear that her sexual partner will be reported to the law.

**Male Rape**

Same-sex rape of males.
More prevalent in institutional settings. Males are less likely than females to report rape and less likely to seek professional help.

**Gang Rape**

See Table 145.3.

**Table 145.3**

**Types of Stranger Rape**

**Sex Trafficking and Commercial Sexual Exploitation of Children (CSEC)**

The average age of recruitment into CSEC is between 12 and 13 yr. The assailant(s) can be the pimp (acquaintance) or the john/“date” (stranger). Victims often have a history of child maltreatment. Fear of the pimp results in reluctance to disclose.

**Drug-Facilitated Rape**

Alcohol is the most common drug associated with sexual victimization.

**Gang Rape**

When a group of males rapes a solitary female victim. May be part of a ritualistic activity or rite of passage for some male groups (e.g., gang, college fraternity), or may be displaced rage on the part of the assailants. Victims may fear retaliation or confrontation with assailants. Victims may desire or require relocation.

**Acquaintance rape**, the most common form of rape, is committed by a person known to the victim outside of the family. If the known assailant is a family member, caregiver, or someone in a position of authority, it would be
considered sexual abuse. The victim–assailant relationship may cause conflicting loyalties in families, and the teen's report may be received with disbelief and/or skepticism by the family. Adolescent acquaintance rape differs from adult acquaintance rape because weapons are less often used, and victims are less likely to sustain physical injuries.

**Date rape** is sexual violence perpetrated by a person in an intimate relationship with the victim. These victims may be new to a specific environment (college freshman, newcomer to a town or high school) and lack strong social support. Victims may have difficulty establishing boundaries or limits with their partner and in some cases may be intoxicated when the incident takes place. The assailant may interpret passivity as assent and deny the charge of coercion or force, and he may also be intoxicated at the time of the assault.

**Drug-facilitated rape** may involve illicit and/or legal substances. The opportunity for acquaintance and date rape may be greater with individuals under the influence of alcohol. Even more predatory is the furtive administration of pharmaceuticals to potential victims. In these scenarios, date rape drugs such as γ-hydroxybutyric acid (GHB), flunitrazepam (Rohypnol), and ketamine hydrochloride are the leading agents used for these illegal purposes, but may also include alcohol, benzodiazepines, stimulants, barbiturates, opiates, and other drugs (see Chapter 140). Their pharmacologic properties make these drugs effective for this use because they have simple modes of administration, are easily concealed (colorless, odorless, tasteless), have rapid onset of action with resulting induction of anterograde amnesia, and have rapid elimination because of a short half-life. Detection of these drugs requires a high index of suspicion and medical evaluation within 8-12 hr, prompting specific testing because routine toxicology screening is insufficient.

Acquaintance and date rape victims often experience long-term issues of trust, self-blame, and guilt, resulting in lost confidence in judgment concerning future relationships. Survivors are nearly always ashamed of the incident and are less likely to report the rape. They are also typically reluctant to talk about the rape to family, friends, or a counselor and may never heal from the psychological scars that ensue. For those adolescents who are LGBTQ, the shame and reluctance to disclose the rape may be even greater.

The **commercial sexual exploitation of children (CSEC)**, also known as sex trafficking, is a more complex form of sexual victimization and is considered a form of child abuse (see Chapter 15). Sex trafficking is federally defined as the recruiting, harboring, transporting, providing, obtaining, patronizing, or
soliciting of an individual through the means of force, fraud, or coercion for commercial sex. While a pimp often personally recruits victims, he may use others to recruit. These youth may experience physical and sexual assault by the pimp as well as the “johns.” Many of these youth have a history of child maltreatment, increasing their vulnerability to this form of abuse. Fear of the consequences of disclosure and the survival skills acquired often yield a very guarded presentation in the healthcare setting.

**Male rape** generally refers to same-sex rape of males. Specific subgroups of young men are at high risk of being victims of rape (see Table 145.1 ). Male rape that occurs outside of institutional settings typically involves coercion of the male teen by someone considered an authority figure, either male or female. Male rape victims often experience conflicted sexual identity about whether they are homosexual. Issues of loss of control and powerlessness are particularly bothersome for male rape victims, and these young men usually have symptoms of anxiety, depression, sleep disturbance, and suicidal ideation.

**Stranger rape** occurs less frequently within the adolescent population and is similar to adult rape. There can be a variety of scenarios for stranger rape (see Table 145.3 ). Nevertheless, such rapes frequently occur with abduction, use of weapons, and increased risk of physical injuries. These rapes are more likely to be reported and prosecuted.

**Clinical Manifestations**

The adolescent's acute presentation following a rape may vary considerably, from histrionics to near-mute withdrawal. Even if they do not appear afraid, most victims are extremely fearful and very anxious about the incident, the rape report, examination, and the entire process, including potential repercussions. Because adolescents are between the developmental lines of childhood and adulthood, their responses to rape may have elements of both child and adult behaviors. Many teens, particularly young adolescents, may experience some level of cognitive disorganization.

Adolescents may be reluctant to report rape for a variety of reasons, including self-blame, fear, embarrassment, or in the circumstances of drug-facilitated rape, uncertainty of event details. Adolescent victims, unlike child victims who elicit sympathy and support, often face intense scrutiny regarding their credibility and inappropriately misplaced societal blame for the assault. This view is baseless and should not be used during an evaluation of any teenage victim, including
acquaintance rape. When adolescents do not report a rape, they may present at a future date with concerns for pregnancy, symptoms of or concerns for a sexually transmitted infection (STI), and symptoms of posttraumatic stress disorder (see Chapter 38), such as sleep disturbances, nightmares, mood swings, and flashbacks. Other teens may present with psychosomatic complaints or difficulties with schoolwork; all adolescents should be screened for possible sexual victimization at most health examination visits.

**Interview and Physical Examination**

The purpose of the adolescent medical evaluation following a sexual assault is to provide medical care for the teen and to collect and document evidence of the assault when applicable. Although many teens delay seeking medical care, others present to a medical facility within 72 hr (or up to 96 hr depending on the protocol used) of the rape, at which time forensic evidence collection should be offered to the patient. Experienced clinicians with training and knowledge of forensic evidence collection and medical-legal procedures should complete the rape evaluation or supervise the evaluation when possible.

The clinician's responsibilities are to provide support, obtain the history in a nonjudgmental manner, conduct a complete examination without retraumatizing the victim, and collect forensic evidence. The clinician must complete laboratory testing, administer prophylaxis treatment for STIs and emergency contraception, arrange for counseling services, and file a report to appropriate authorities in accordance with the law. It is not the clinician's responsibility to decide whether a rape has occurred; the legal system will make that determination.

Ideally, a clinician trained in forensic interviewing should obtain the history. In all cases, the history should be obtained by asking only open-ended questions to obtain information about (1) what happened; (2) where it happened; (3) when it happened; and (4) who did it. After obtaining a concise history, including details of the type of physical contact that occurred between the victim and the assailant, the clinician should conduct a thorough and complete physical examination and document all injuries. Clinicians should provide sensitive, nonjudgmental support during the entire evaluation, as the adolescent victim has experienced a major trauma and is susceptible to retraumatization during this process. Each component of the evaluation should be explained in detail to the victim, allowing the adolescent as much control as possible, including refusal to
complete any part or all of the forensic evidence collection process. It is often useful to permit a trusted supportive person, such as a family member, friend or rape crisis advocate, to be present during the evaluation if that is the adolescent's wish.

The examining clinician should be familiar with the forensic evidence collection kit prior to initiating the examination. In the United States, each state's forensic evidence kit is different, but most include some or all of the following components: forensic evidence of semen deposits detected by a fluorescent lamp with a wavelength near 490 nm (many Woods lamps are inadequate); swabs of bite mark impressions to collect genetic markers (DNA, ABO group); swabs of any penetrated orifice or body surface where saliva may be present; and documentation of acute cutaneous injuries using body diagram charts and photographs with visible standard measurements. Areas of restraint should be carefully inspected for injuries; these areas include extremities, neck, and the inner aspect of the oral mucosa, where a dentition impression may be seen.

The genital examination of a female rape victim should be undertaken with the patient in the lithotomy position. The prone knee-chest position may be used as an exam-clarifying technique, specifically to evaluate the posterior rim of the hymen. The genital exam of a male rape victim should be undertaken with the patient in supine position. The clinician's exam should include careful inspection of the entire pelvic, genital, and perianal areas. The clinician should document any acute injuries such as edema, erythema, petechiae, bruising, hemorrhage, or tearing. Aqueous solution of toluidine blue (1%), which adheres to nucleated cells, may be used during the acute examination to improve visualization of microtrauma in the perianal area. Any disruption to the superficial epidermis will allow for dye uptake and thus cannot differentiate between disruption of the skin from trauma, irritation, or infection. Additionally, a colposcope may be used to provide magnification and photo documentation of injuries.

Laboratory Data

When adolescents present for medical care within 72-96 hr of a sexual assault, a forensic evidence collection kit should be offered to the patient. Regardless of an adolescent's decision to have evidence collection completed, medical care, including physical examination, laboratory testing (Table 145.4), and prophylactic therapies, should be offered to the patient. Follow-up evaluations should be scheduled to repeat these laboratory studies.
<table>
<thead>
<tr>
<th><strong>Table 145.4</strong></th>
<th><strong>Laboratory Evaluation of Sexual Assault</strong></th>
</tr>
</thead>
</table>

**Within 8-12 hr (if Indicated by History)**

- Urine and blood for date rape drugs (GHB, Rohypnol, ketamine)

**Within 24 hr (if Indicated by History)**

- Blood for comprehensive toxicology screen (for other classes of drugs)

**Within 72 hr (or Up to 96 hr Depending on the Protocol Used)**

- Forensic evidence kit
- Pregnancy test
- Hepatitis B screen (hepatitis B surface antigen, surface antibody, and core antibody)
- Syphilis (rapid plasma reagin [RPR], Venereal Disease Research Laboratories [VDRL])
- HIV infection
- Bacterial vaginosis (BV) and candidiasis: point-of-care testing and/or wet mouth with measurement of vaginal pH and KOH application for whiff test
- *Trichomonas vaginalis*: nucleic acid amplification tests (NAATs) by urine or vaginal specimen or point-of-care testing (DNA probes) from vaginal specimen
- *Chlamydia* and *Neisseria gonorrhoeae*: nucleic acid amplification testing (NAATs) at sites of penetration or possible penetration:
  - 1. *N. gonorrhoeae*: oropharynx, rectum, urine*
  - 2. *Chlamydia*: urine,* rectum

* Dirty urine sample may be used as alternate for genital swab.

From Centers for Disease Control and Prevention: Sexually transmitted diseases:

Treatment

Treatment includes prophylactic antimicrobials for STIs (see Chapter 146) and emergency contraception (see Chapter 143). The Centers for Disease Control and Prevention (CDC) reports that trichomoniasis, bacterial vaginosis, gonorrhea, and chlamydial infection are the most frequently diagnosed infections among women who have been sexually assaulted. Antimicrobial prophylaxis is recommended for adolescent rape victims because of the risk of acquiring an STI and the risk of pelvic inflammatory disease (Table 145.5). A two- or three-drug antiretroviral regimen for HIV postexposure prophylaxis (PEP) must be considered and an infectious disease specialist consulted if higher transmission risk factors are identified (e.g., knowing that the perpetrator is HIV-positive, significant mucosal injury of the victim) to prescribe a triple-antiretroviral regimen (Fig. 145.1). Similar considerations should be made for possible exposure to the hepatitis B virus in vaccinated/unvaccinated individuals. Clinicians should review the importance for patient's compliance with medical and psychological treatment and follow-up care.

Table 145.5

Postexposure Prophylaxis (PEP) for Acute Sexual Assault Victims

Routine

Recommended Regimen for STI Prophylaxis

- Ceftriaxone 250 mg intramuscularly
  plus
- Azithromycin 1g orally in a single dose
  plus
- Metronidazole 2 g orally in a single dose or
- Tinidazole 2 g orally in a single dose
**Pregnancy Prophylaxis***

Levonorgestrel (Plan B) 1.5 mg orally in a single dose  
OR  
Ulipristal acetate (Ella) 30 mg is effective for up to 120 hr.

**Human Papillomavirus (HPV)**

Assess HPV vaccine history; to unimmunized, administer initial vaccine at initial exam, with 2 follow-up doses at 1-2 mo and at 6 mo if >15 yr old  
*or* a single follow-up dose at 6-12 mo if ≤15 yr old

**As Indicated**

All persons offered PEP should be prescribed a 28-day course of a two- or three-drug antiretroviral regimen.

**Human Immunodeficiency Virus (HIV) †**

Preferred regimen:  
Tenofovir 300 mg and fixed-dose combination emtricitabine, 200 mg (Truvada) once daily  
*plus*  
Raltegravir 400 mg twice daily *or*  
Dolutegravir 50 mg daily ‡  
Alternative regimens available (The National Clinicians Consultation Center is a resource for providers prescribing PEP, reachable at 1-888-448-4911.)

**Hepatitis B virus (HBV)**

Specific indications for vaccine, immunoglobulin and/or booster dependent upon assailant's status
* Provided for patients with negative urine pregnancy screen. In addition, antiemetic (Compazine, Zofran) can be prescribed for patients receiving emergency contraception.

† HIV PEP is provided for patients with penetration and when the assailant is known to be HIV-positive or at high risk because of a history of incarceration, intravenous drug use, or multiple sexual partners. If provided, laboratory studies must be drawn before administration of medication (HIV, CBC, LFTs, BUN/Cr, amylase, lipase), and follow-up must be arranged.

‡ Dolutegravir has been associated with neural tube defects if the exposure occurs within the first trimester of pregnancy. Therefore it should be avoided in pregnant patients or those at risk for becoming pregnant. U.S. Department of Health and Human Services, U.S. Food & Drug Administration. Julica, Tivicay, Triumeq (dolutegravir): FDA to evaluate potential risk of neural tube birth defects. May 18, 2018. https://www.fda.gov/safety/medwatch/safetyinformation/safetyalertsforhumanmedicines.

At the time of presentation, the clinician should address the need for follow-up care, including psychological counseling. Adolescent victims are at increased risk of posttraumatic stress disorder, depression, self-abusive behaviors, suicidal ideation, delinquency, substance abuse, eating disorders, and sexual revictimization. It is important for the adolescent victim and parents to understand the value of timely counseling services to decrease these potential long-term sequelae. Counseling services should be arranged during the initial evaluation, with follow-up arranged with the primary care physician to improve compliance. Counseling services for family members of the victim may improve their ability to provide appropriate support to the adolescent victim. Caution parents not to use the assault as a validation of their parental guidance, as it will only serve to place blame inappropriately on the adolescent victim.
Prevention

**Primary prevention** may be accomplished through education of preadolescents and adolescents on the issues of rape, healthy relationships, internet dangers, and drug- and alcohol-facilitated rape. Prevention messages should be targeted to both males and females at high schools and colleges. Particular emphasis on prevention efforts during college orientation is highly recommended. High-risk situations that may increase the likelihood of a sexual assault (use of drugs or alcohol) should be discouraged. **Secondary prevention** includes informing adolescents of the benefits of timely medical evaluations when rape has occurred. Individual clinicians should ask adolescents about past experiences of forced and unwanted sexual behaviors and offer help in dealing with those experiences. The importance of prevention cannot be overstated because adolescents are disproportionately affected by rape, and they are particularly vulnerable to long-term consequences.

Bibliography

Centers for Disease Control and Prevention. Sexually

Jimenez M, Jackson AM, Deye K. Aspects of abuse:

Age-specific rates of many sexually transmitted infections (STIs) are highest among sexually experienced adolescents and young adults, after controlling for sexual activity. Although some STI pathogens present as STI syndromes with a specific constellation of symptoms, most are asymptomatic and only detected by a laboratory test. The approach to prevention and control of these infections lies in education, screening, and early diagnosis and treatment.

**Etiology**

Any adolescent who has had oral, vaginal, or anal sexual intercourse is at risk for acquiring an STI. Not all adolescents are at equal risk; physical, behavioral, and social factors contribute to the adolescent's higher risk (Table 146.1). Adolescents who initiate sex at a younger age, youth residing in detention facilities, youth attending sexually transmitted disease (STD) clinics, young men having sex with men, and youth who are injection drug users are at higher risk for STIs. Risky behaviors, such as sex with multiple concurrent partners or multiple sequential partners of limited duration, failure to use barrier protection consistently and correctly, and increased biologic susceptibility to infection, also contribute to risk. Although all 50 states and the District of Columbia explicitly allow minors to consent for their own sexual health services, many adolescents encounter multiple obstacles to accessing this care. Adolescents who are victims of sexual assault may not consider themselves “sexually active,” given the context of the encounter, and need reassurance, protection, and appropriate intervention when these circumstances are uncovered (see Chapter 145).
Circumstances Contributing to Adolescents' Susceptibility to Sexually Transmitted Infections

Physical

Younger age at puberty
Cervical ectopy
Smaller introitus leading to traumatic sex
Asymptomatic nature of sexually transmitted infection
Uncircumcised penis

Behavior Limited by Cognitive Stage of Development

Early adolescence: have not developed ability to think abstractly
Middle adolescence: develop belief of uniqueness and invulnerability

Social Factors

Poverty
Limited access to “adolescent-friendly” healthcare services
Adolescent health-seeking behaviors (forgoing care because of confidentiality concerns or denial of health problem)
Sexual abuse, trafficking, and violence
Homelessness
Drug use
Young adolescent females with older male partners
Young men having sex with men

STI prevalence varies by age, gender, and race/ethnicity. In the United States, although adolescents and young adults ages 15-24 yr represent 25% of the sexually experienced population, this age-group accounts for almost 50% of all incident STIs each year. Adolescents and young adults <25 yr of age have the highest reported prevalence of gonorrhea (see Chapter 219) and chlamydia (see Chapter 253); among females and males, rates are highest in the 15-24 yr old age-groups (Fig. 146.1). In 2015, females age 20-24 yr had the highest reported chlamydia rate (3,730 per 100,000 population), followed by females 15-19 yr of age (2,994/100,000). The reported 2015 chlamydia rate for 15-19 yr old females was almost 4 times higher than for 15-19 yr old males. Chlamydia is common among all races and ethnic groups; Blacks, Native American/Alaska Native, and Hispanic females are disproportionately affected. In 2015, non-Hispanic black females 20-24 yr of age had the highest chlamydia rate of any group (6,783), followed by black females 15-19 yr of age (6,340). Data from the 2007–2012 National Health and Nutrition Examination Survey (NHANES) estimated the prevalence of chlamydia among the U.S. population was highest among African Americans (Fig. 146.2).

![FIG. 146.1 Proportion of reported gonorrhea and chlamydia cases by age, United States, 2015. (Adapted from Centers for Disease Control and Prevention: Reported STDs in the United States.](https://www.cdc.gov/nchhstp/newsroom/docs/factsheets/STD-Trends-508.pdf.)
Reported rates of other bacterial STIs are also high among adolescents and young adults. In 2015, 20-24 yr old females had the highest (547/100,000) and 20-24 yr old males had the second highest gonorrhea rates (539/100,000) compared to any other age/sex group (see Chapter 219). Gonorrhea rates among 15-24 yr old males and females increased between 2014 and 2015. Syphilis rates are increasing at an alarming rate, especially among males, accounting for >90% of all primary and secondary syphilis cases. Of those male cases, men who have sex with men (MSM) account for 82% of male cases when the gender of the sex partner is known. Males age 20-24 yr have the 2nd highest rate of primary and secondary syphilis among males of any age-group (36/100,000); whereas rates among males 15-19 yr old (8/100,000) are much lower. Female primary and secondary syphilis rates are much lower than male rates (5/100,000 among 20-24 yr olds; 3/100,000 among 15-19 yr olds) (see Chapter 245). Pelvic inflammatory disease (PID) rates are highest among females age 15-24 compared with older women.

Adolescents also carry a large burden of viral STIs. U.S. youth are at persistent risk for HIV infection (see Chapter 302). In 2015, youth age 13-24 yr accounted for 22% (8,807) of all new HIV diagnoses in the United States, with most (81%) occurring among gay and bisexual males. Of those new infections, 55% (4,881) were among blacks, 22% (1,957) among Hispanic/Latinos, and 17% (1,506) among whites. Only 10% of high school students have been tested
for HIV. Among male students who had sexual contact with other males, only 21% have ever been tested for HIV.

**Human papillomavirus (HPV)** is the most frequently acquired STI in the United States. According to NHANES, prevalence of HPV vaccine types 6, 11, 16, and 18 (4vHPV) declined between the prevaccine (2003–2006) and vaccine (2009–2012) eras: from 11.5% to 4.3% among females age 14-19 yr and from 18.5% to 12.1% among females age 20-24 (see Chapter 293).

**Herpes simplex virus type 2 (HSV-2)** is the most prevalent viral STI (see Chapter 279). NHANES data show that among 14-19 yr olds, HSV-2 seroprevalence has remained low (<2%, in 1999–2010 surveys). In addition, according to NHANES, HSV-1 seroprevalence among 14-19 yr olds has significantly decreased, from 39% in 1999–2004 to 30% in 2005–2010, indicating less orolabial infection in this age-group. Studies have also found that genital HSV-1 infections are increasing among young adults. Youth who lack HSV-1 antibodies at sexual debut are more susceptible to acquiring a genital HSV-1 infection and developing symptomatic disease from primary genital HSV-2 infection. Increasing oral sex among adolescents and young adults also has been suggested as a contributing factor in the rise in genital HSV-1 infections.

**Pathogenesis**

During puberty, increasing levels of estrogen cause the vaginal epithelium to thicken and cornify and the cellular glycogen content to rise, the latter causing the vaginal pH to fall. These changes increase the resistance of the vaginal epithelium to penetration by certain organisms (including *Neisseria gonorrhoeae*) and increase the susceptibility to others (*Candida albicans* and *Trichomonas*; see Chapter 310). The transformation of the vaginal cells leaves columnar cells on the ectocervix, forming a border of the 2 cell types on the ectocervix, known as the squamocolumnar junction. The appearance is referred to as **ectopy** (Fig. 146.3). With maturation, this tissue involutes. Prior to involution, it represents a unique vulnerability to infection for adolescent females. The association of early sexual debut and younger gynecologic age with increased risk of STIs supports this explanation of the pathogenesis of infection in young adolescents.
Screening

Early detection and treatment are primary STI control strategies. Some of the most common STIs in adolescents, including HPV, HSV, chlamydia, and gonorrhea, are usually asymptomatic and if undetected can be spread inadvertently by the infected host. Screening initiatives for chlamydial infections have demonstrated reductions in PID cases by up to 40%. Although federal and professional medical organizations recommend annual chlamydia screening for sexually active females <25 yr old, according to the National Center for Quality Assurance, in 2015 among sexually active 16-20 yr old females, approximately 42% of commercial health maintenance organization (HMO) members and 52% Medicaid HMO members were tested for chlamydia during the previous year. The lack of a dialog about STIs or the provision of STI services at annual preventive service visits to sexually experienced adolescents are missed opportunities for screening and education. Comprehensive, confidential, reproductive health services, including STI screening, should be offered to all sexually experienced adolescents (Table 146.2).

Table 146.2

| Routine Laboratory Screening Recommendations for Sexually Transmitted Infections in Sexually Active Adolescents and |
**Young Adults**

*Chlamydia Trachomatis and Neisseria Gonorrhoeae*

- Routine screening for *C. trachomatis* and *N. gonorrhoeae* of all sexually active females aged <25 yr is recommended annually.
- Routinely screen sexually active adolescent and young adult MSM at sites of contact for chlamydia (urethra, rectum) and gonorrhea (urethra, rectum, pharynx) at least annually regardless of condom use. More frequent screening (i.e., at 3-6 mo intervals) is indicated for MSM who have multiple or anonymous partners or who have sex with illicit drug use.
- Consider screening for *C. trachomatis* of sexually active adolescent and young adult males annually who have a history of multiple partners in clinical settings with high prevalence rates, such as jails or juvenile corrections facilities, national job training programs, STD clinics, high school clinics, or adolescent clinics.

*Human Immunodeficiency Virus (HIV)*

- HIV screening should be discussed and offered to all adolescents at least once by age 16-18 yr and throughout young adulthood in healthcare settings. HIV risk should be assessed annually for >13 yr and offered if HIV risk factors identified.
- Routinely screen sexually active adolescent and young adult MSM at least annually regardless of condom use. More frequent screening (i.e., at 3-6 mo intervals) is indicated for MSM who have multiple or anonymous partners or who have sex with illicit drug use.

*Syphilis*

- Syphilis screening should be offered to sexually active adolescents reporting risk factors, including MSM.
- Routinely screen sexually active adolescent and young adult MSM at least annually regardless of condom use. More frequent screening (i.e., at 3-6 mo intervals) is indicated for MSM who have multiple or anonymous partners
or who have sex with illicit drug use.

• Providers should consult with their local health department regarding local syphilis prevalence and associated risk factors that are associated with syphilis acquisition.

Hepatitis C Virus (HCV)

• Screening adolescents for HCV who report risk factors, i.e., injection drug use, receipt of an unregulated tattoo, received blood products or organ donation before 1992, received clotting factor concentrates before 1987, long-term hemodialysis.
• Given the high HCV prevalence among young injection drug users, screening should be strongly considered.

MSM, Men who have sex with men; STD, sexually transmitted disease.

From Centers for Disease Control and Prevention.

Common Infections and Clinical Manifestations

STI syndromes are generally characterized by the location of the manifestation (vaginitis) or the type of lesion (genital ulcer). Certain constellations of presenting symptoms suggest the inclusion of a possible STI in the differential diagnosis.

Urethritis

Urethritis is an STI syndrome characterized by inflammation of the urethra, usually caused by an infectious etiology. Urethritis may present with urethral discharge, dysuria, urethral irritation, or meatal pruritus. Urgency, frequency of urination, erythema of the urethral meatus, and urethral pain or burning are less common clinical presentations. Approximately 30–50% of males are asymptomatic but may have signs of discharge on diagnosis. On examination,
the classic finding is mucoid or purulent discharge from the urethral meatus (Fig. 146.4). If no discharge is evident on exam, providers may attempt to express discharge by applying gentle pressure to the urethra from the base distally to the meatus 3-4 times. *Chlamydia trachomatis* and *N. gonorrhoeae* are the most commonly identified pathogens. *Mycoplasma genitalium* has been associated with urethritis, but data supporting *Ureaplasma urealyticum* have been inconsistent. *Trichomonas vaginalis* can cause nongonococcal urethritis (NGU), but the prevalence varies. HSV-1, HSV-2, and Epstein-Barr virus (EBV) are also potential urethritis pathogens in some cases. Sensitive diagnostic *C. trachomatis* and *N. gonorrhoeae* tests are available for the evaluation of urethritis. However, other pathogens can be considered when NGU is not responsive to treatment, although commercial diagnostic tests are not available for males. Noninfectious causes of urethritis include urethral trauma or foreign body. Unlike in females, urinary tract infections (UTIs) are rare in males who have no genitourinary medical history. In the typical sexually active adolescent male, dysuria and urethral discharge suggest the presence of an STI unless proven otherwise.

![FIG. 146.4 Gonococcal urethral discharge. (From Seattle STD/HIV Prevention Training Center, University of Washington, Connie Celum and Walter Stamm.)](image-url)
**Epididymitis**

The inflammation of the epididymis in adolescent males is most often associated with an STI, most frequently *C. trachomatis* or *N. gonorrhoeae*. The presentation of unilateral scrotal swelling and tenderness, often accompanied by a hydrocele and palpable swelling of the epididymis, associated with the history of urethral discharge, constitute the presumptive diagnosis of epididymitis. Males who practice insertive anal intercourse are also vulnerable to *Escherichia coli* infection. **Testicular torsion**, a surgical emergency usually presenting with sudden onset of severe testicular pain, should be considered in the differential diagnosis (see Chapter 560). The evaluation for epididymitis should include obtaining evidence of urethral inflammation by physical exam, Gram stain of urethral secretions, urine leukocyte esterase test, or urine microscopy. A *C. trachomatis* and *N. gonorrhoeae* nucleic acid amplification test (NAAT) should be performed.

**Vaginitis**

Vaginitis is a superficial infection of the vaginal mucosa frequently presenting as a vaginal discharge, with or without vulvar involvement (see Chapter 564). **Bacterial vaginosis**, **vulvovaginal candidiasis**, and **trichomoniasis** are the predominant infections associated with vaginal discharge. Bacterial vaginosis is replacement of the normal hydrogen peroxide (H\(_2\)O\(_2\))–producing *Lactobacillus* species vaginal flora by an overgrowth of anaerobic microorganisms, as well as *Gardnerella vaginalis*, *Ureaplasma*, and *Mycoplasma*. Although bacterial vaginosis is not categorized as an STI, sexual activity is associated with increased frequency of vaginosis. Vulvovaginal candidiasis, usually caused by *C. albicans*, can trigger vulvar pruritus, pain, swelling, and redness and dysuria. Findings on vaginal examination include vulvar edema, fissures, excoriations, or thick curdy vaginal discharge. Trichomoniasis is caused by the protozoan *T. vaginalis*. Infected females may present with symptoms characterized by a diffuse, malodorous, yellow-green vaginal discharge with vulvar irritation or may be diagnosed by screening an asymptomatic patient. Cervicitis can sometimes cause a vaginal discharge. Laboratory confirmation is recommended because clinical presentations may vary and patients may be infected with >1 pathogen.
Cervicitis

The inflammatory process in cervicitis involves the deeper structures in the mucous membrane of the cervix uteri. Vaginal discharge can be a manifestation, but cervicitis frequently is asymptomatic. Patients also present with complaints of irregular or postcoital bleeding. Two major diagnostic signs characterize cervicitis: (1) a purulent or mucopurulent endocervical exudate visible in the endocervical canal or on an endocervical swab specimen (e.g., swab sign; Fig. 146.5), called **mucopurulent cervicitis** or cervicitis, and (2) sustained endocervical bleeding easily induced by gentle passage of a cotton swab through the cervical os, signifying friability. Cervical changes associated with cervicitis must be distinguished from cervical ectopy in the younger adolescent to avoid the overdiagnosis of inflammation (Fig. 146.6; see Fig. 146.3). The pathogens identified most frequently with cervicitis are *C. trachomatis* and *N. gonorrhoeae*, although no pathogen is identified in most cases. HSV is a less common pathogen associated with ulcerative and necrotic lesions on the cervix.

![Mucopurulent cervical discharge positive swab test.](http://www2a.cdc.gov/stdtraining/ready-to-use/pid.htm)
Pelvic Inflammatory Disease

PID encompasses a spectrum of inflammatory disorders of the female upper genital tract, including endometritis, salpingitis, tuboovarian abscess, and pelvic peritonitis, usually in combination rather than as separate entities. N. gonorrhoeae and C. trachomatis predominate as the involved pathogenic organisms in younger adolescents (see Chapters 219 and 253), although PID should be approached as multiorganism etiology, including pathogens such as anaerobes, G. vaginalis, Haemophilus influenzae, enteric gram-negative rods, and Streptococcus agalactiae. In addition, cytomegalovirus, Mycoplasma hominis, Ureaplasma urealyticum, and M. genitalium may be associated with PID. PID (tuboovarian abscess) has rarely been reported in virgins and is usually caused by E. coli and associated in some patients with obesity and possible pooling of urine in the vagina.

PID is difficult to diagnose because of the wide variation in the symptoms and signs. Many females with PID have subtle or mild symptoms, resulting in many unrecognized cases. Healthcare providers should consider the possibility of PID in young, sexually active females presenting with vaginal discharge or abdominal pain.

The clinical diagnosis of PID is based on the presence of at least 1 of the minimal criteria, either cervical motion tenderness, uterine tenderness, or adnexal tenderness, to increase the diagnostic sensitivity and reduce the likelihood of missed or delayed diagnosis. Providers should also consider that
adolescents are the population in whom PID is typically diagnosed and thus should have a low threshold for initiating empirical treatment. In addition, the majority of females with PID have either mucopurulent cervical discharge or evidence of white blood cells (WBCs) on a microscopic evaluation of a vaginal fluid–saline preparation. If the cervical discharge appears normal and no WBCs are observed on the wet prep of vaginal fluid, the diagnosis of PID is unlikely, and alternative causes of pain should be investigated. Specific, but not always practical, criteria for PID include evidence of endometritis on biopsy, transvaginal sonography or MRI evidence of thickened, fluid-filled tubes, or Doppler evidence of tubal hyperemia or laparoscopic evidence of PID.

Genital Ulcer Syndromes

An ulcerative lesion in a mucosal area exposed to sexual contact is the unifying characteristic of infections associated with these syndromes. These lesions are most frequently seen on the penis and vulva but also occur on oral and rectal mucosa, depending on the adolescent's sexual practices. HSV and Treponema pallidum (syphilis) are the most common organisms associated with genital ulcer syndromes.

Genital herpes, the most common ulcerative STI among adolescents, is a chronic, lifelong viral infection. Two sexually transmitted HSV types have been identified, HSV-1 and HSV-2. The majority of cases of recurrent genital herpes are caused by HSV-2. However, among young women and MSM, an increasing proportion of anogenital herpes has been HSV-1. Most HSV-2–infected persons are unaware of their diagnosis because they experience mild or unrecognized infections but continue to shed virus intermittently in the genital tract. Therefore, most genital herpes infections are transmitted by asymptomatic persons who are unaware of their infection.

Although the initial herpetic lesion is a vesicle, by the time the patient presents clinically, the vesicle most often has ruptured spontaneously, leaving a shallow, painful ulcer (Fig. 146.7A), although recurrences are generally less intense and painful (Fig. 146.7B). Up to 50% of first genital herpes episodes are caused by HSV-1, but recurrences and subclinical shedding are much more frequent for genital HSV-2 infection.
FIG. 146.7  A, Initial herpes infection showing multiple erosions with polycyclic outlines surrounded by an erythematous halo and associated with intense pain. B, Erosions surrounded by an erythematous halo. Clinical signs and symptoms of recurrences are usually less intense than those of initial infection. (From Martín JM, Villalón G, Jordá E: Update on treatment of genital herpes, Actas Dermosifiliogr 100:22–32, 2009, Figs 1 and 2.)

Syphilis is a less common cause of genital ulcers in adolescents than in adults. Lymphogranuloma venereum caused by C. trachomatis serovars L1-L3 is uncommon, although outbreaks do occur in MSM. In these circumstances, proctitis or proctocolitis is the usual manifestation. HIV is often present in affected men. Unusual infectious causes of genital, anal, or perianal ulcers in the United States and other industrialized countries include chancroid and donovanosis.

Table 146.3 presents the clinical characteristics differentiating the lesions of the most common infections associated with genital ulcers, along with the required laboratory diagnosis to identify the causative agent accurately. The differential diagnosis includes Behçet disease (see Chapter 186), Crohn disease (Chapter 362), aphthous ulceration, and acute genital ulcers caused by cytomegalovirus (Chapter 282) or Epstein-Barr virus (Chapter 281). Acute genital ulcers often follow a flu or mononucleosis-like illness in an immunocompetent female and is unrelated to sexual activity. The lesions are 0.5-2.5 cm in size, bilateral, symmetric, multiple, painful, and necrotic, and are associated with inguinal lymphadenopathy. This primary infection is also
associated with fever and malaise. The diagnosis may require Epstein-Barr virus titers, or polymerase chain reaction (PCR) testing. Treatment is supportive care including pain management.

Genital Lesions and Ectoparasites

Lesions that present as outgrowths on the surface of the epithelium and other limited epidermal lesions are included under this categorization of syndromes. HPV can cause genital warts and genital-cervical abnormalities that can lead to cancer (see Chapter 293). Genital HPV types are classified according to their association with cervical cancer. Infections with low-risk types, such as HPV types 6 and 11, can cause benign or low-grade changes in cells of the cervix, genital warts, and recurrent respiratory papillomatosis. High-risk HPV types can cause cervical, anal, vulvar, vaginal, and head and neck cancers. High-risk HPV types 16 and 18 are detected in approximately 70% of cervical cancers. Persistent infection increases the risk of cervical cancer. Molluscum contagiosum and condyloma latum associated with secondary syphilis complete the classification of genital lesion syndromes.

As a result of the close physical contact during sexual contact, common ectoparasitic infestations of the pubic area occur as pediculosis pubis or the papular lesions of scabies (see Chapter 688).

HIV Disease and Hepatitis B

HIV and hepatitis B virus (HBV) present as asymptomatic, unexpected occurrences in most infected adolescents. High vaccination coverage rates among infants and adolescents have resulted in substantial declines in acute HBV incidence among U.S.-born adolescents. Risk factors identified in the history or routine screening during prenatal care are much more likely to result in suspicion of infection, leading to the appropriate laboratory screening, than are clinical manifestations in this age-group (see Chapters 302 and 385).

Diagnosis

Most often, adolescents infected with viral and bacterial STI pathogens do not report symptoms suggestive of infection. With the use of very sensitive, noninvasive chlamydia and gonorrhea NAAT, providers are finding that most genital infections in females as well as many males are asymptomatic. A thorough sexual history is key to identifying adolescents who should be screened for STIs and for identifying those who require a laboratory diagnostic evaluation for an STI syndrome.
When eliciting a sexual health history, discussions should be appropriate for the patient's developmental level. In addition to questions regarding vaginal or urethral discharge, genital lesions, and lower abdominal pain among females, one should ask about prior treatment of any STI symptoms, including self-treatment using nonprescription medications. **Dyspareunia** is a consistent symptom in adolescents with **PID**. Providers must ask about oral or anal sexual activity to determine sites for specimen collection.

**Urethritis** should be objectively documented by evidence of inflammation or infectious etiology. Patient complaint without objective clinical or laboratory evidence does not fulfill diagnostic criteria. Inflammation can be documented by (a) observing urethral mucopurulent discharge, (b) ≥2 WBCs per high-power field on microscopic examination of Gram stain urethral secretions, (c) urine microscopic findings of ≥10 WBCs per high-power field of first-void urine specimen, or (d) a positive urine leukocyte esterase test of a first-void specimen. Laboratory evaluation is essential to identify the involved pathogens to determine treatment, partner notification, and disease control. **C. trachomatis** and **N. gonorrhoeae** NAATs of a urine specimen are recommended. The presence of gram-negative intracellular diplococci on microscopy obtained from a male urethral specimen confirms the diagnosis of gonococcal urethritis.

An essential component of the diagnostic evaluation of vaginal, cervical, or urethral discharge is a chlamydia and gonorrhea NAAT. NAATs are the most sensitive chlamydia and gonorrhea tests available and are licensed for use with urine, urethral, vaginal, and cervical specimens. Many of the chlamydia NAATs are approved by the U.S. Food and Drug Administration (FDA) to test patient-collected vaginal swabs in the clinical setting and liquid cytology specimens. Female vaginal swab specimens and male first-void urine are considered the optimal specimen types. Female urine remains an acceptable chlamydia and gonorrhea NAAT specimen, but may have slightly reduced performance when compared with cervical or vaginal swab specimens. Urine is the recommended specimen for male urethral infection. Gonorrhea and chlamydia NAATs perform well on rectal and oropharyngeal specimens and can be performed by clinical laboratories that have completed the appropriate verification studies to obtain Clinical Laboratory Improvement Amendments (CLIA) approval, which includes most clinical laboratories.

Evaluation of adolescent females with **vaginitis** includes laboratory data. Traditionally, the cause of vaginal symptoms was determined by pH and microscopic examination of the discharge. However, CLIA-waived point-of-care
vaginitis tests are available. Using pH paper, an elevated pH (i.e., >4.5) is common with bacterial vaginosis or trichomoniasis. Because pH testing is not highly specific, discharge should be further examined. For microscopic exam, a slide can be made with the discharge diluted in 1-2 drops of 0.9% normal saline solution and another slide with discharge diluted in 10% potassium hydroxide (KOH) solution. Examining the saline specimen slide under a microscope may reveal motile or dead T. vaginalis or clue cells (epithelial cells with borders obscured by small bacteria), which are characteristic of bacterial vaginosis. WBCs without evidence of trichomonads or yeast are usually suggestive of cervicitis. The yeast or pseudohyphae of Candida species are more easily identified in the KOH specimen (Fig. 146.8). The sensitivity of microscopy is approximately 50% and requires immediate evaluation of the slide for optimal results. Therefore, lack of findings does not eliminate the possibility of infection. More sensitive point-of-care vaginitis tests include the OSOM Trichomonas Rapid Test (Sekisui Diagnostics, Lexington, MA), an immunochromatographic capillary flow dipstick technology with reported 83% sensitivity. The OSOM BVBLUE Test (Sekisui) detects elevated vaginal fluid sialidase activity, an enzyme produced by bacterial pathogens associated with bacterial vaginosis, including Gardnerella, Bacteroides, Prevotella, and Mobiluncus, and has a reported 90% sensitivity. Both tests are CLIA waived, with results available in 10 min.
Clinical laboratory–based vaginitis tests are also available. The Affirm VPIII (Becton Dickenson, San Jose, CA) is a moderate-complexity nucleic acid probe test that evaluates for *T. vaginalis*, *G. vaginalis*, and *C. albicans* and has a sensitivity of 63% and specificity >99.9%, with results available in 45 min. Some gonorrhea and chlamydia NAATs also offer an assay for *T. vaginalis* testing of female specimens tested for *N. gonorrhoeae* and *C. trachomatis*, considered the gold standard for *Trichomonas* testing.

Objective signs of vulvar inflammation in the absence of vaginal pathogens, along with a minimal amount of discharge, suggest the possibility of mechanical, chemical, allergic, or other noninfectious irritation of the vulva (Table 146.4).

- Cervicitis

The definitive diagnosis of PID is difficult based on clinical findings alone. Clinical diagnosis is imprecise, and no single historical, physical, or laboratory finding is both sensitive and specific for the diagnosis of acute PID. Clinical criteria have a positive predictive value of only 65–90% compared with laparoscopy. Although healthcare providers should maintain a low threshold for the diagnosis of PID, additional criteria to enhance specificity of diagnosis, such as transvaginal ultrasonography, can be considered (Table 146.5).

**Table 146.5**

Evaluation for Pelvic Inflammatory Disease (PID)

**2015 CDC Diagnostic Criteria**

**Minimal Criteria**

- Cervical motion tenderness
  - or
- Uterine tenderness
  - or
- Adnexal tenderness

**Additional Criteria to Enhance Specificity of the Minimal Criteria**
• Oral temperature >38.3°C (101°F)
• Abnormal cervical or vaginal mucopurulent discharge*
• Presence of abundant numbers of WBCs on saline microscopy of vaginal secretions*
• Elevated ESR or C-reactive protein
• Laboratory documentation of cervical *Neisseria gonorrhoeae* or *Chlamydia trachomatis* infection

**Most Specific Criteria to Enhance the Specificity of the Minimal Criteria**

• Transvaginal sonography or MRI techniques showing thickened, fluid-filled tubes, with or without free pelvic fluid or tuboovarian complex, or Doppler studies suggesting pelvic infection (e.g., tubal hyperemia)
• Endometrial biopsy with histopathologic evidence of endometritis
• Laparoscopic abnormalities consistent with PID

**Differential Diagnosis (Partial List)**

• Gastrointestinal: appendicitis, constipation, diverticulitis, gastroenteritis, inflammatory bowel disease, irritable bowel syndrome
• Gynecologic: ovarian cyst (intact, ruptured, or torsed), endometriosis, dysmenorrhea, ectopic pregnancy, mittelschmerz, ruptured follicle, septic or threatened abortion, tuboovarian abscess
• Urinary tract: cystitis, pyelonephritis, urethritis, nephrolithiasis

ESR, Erythrocyte sedimentation rate; WBCs, white blood cells.

* If the cervical discharge appears normal and no WBCs are observed on the wet prep of vaginal fluid, the diagnosis of PID is unlikely, and alternative causes of pain should be investigated.

Adapted from Centers for Disease Control and Prevention (CDC).
Cell culture and polymerase chain reaction (PCR) are the preferred HSV tests. Viral culture sensitivity is low, and intermittent viral shedding causes false-negative results. NAATs, including PCR assays for HSV DNA, are more sensitive and increasingly available for diagnosing genital HSV. The Tzanck test is insensitive and nonspecific and should not be considered reliable.

Accurate type-specific HSV serologic assays are based on the HSV-specific glycoproteins G2 (HSV-2) and G1 (HSV-1). Both laboratory-based point-of-care tests are available. Because almost all HSV-2 infections are sexually acquired, the presence of type-specific HSV-2 antibody implies anogenital infection. The presence of HSV-1 antibody alone is more difficult to interpret because of the frequency of oral HSV infection acquired during childhood. Type-specific HSV serologic assays might be useful in the following scenarios: (1) recurrent genital symptoms or atypical symptoms with negative HSV cultures; (2) a clinical diagnosis of genital herpes without laboratory confirmation; and (3) a patient with a partner with genital herpes, especially if considering suppressive antiviral therapy to prevent transmission.

For syphilis testing, nontreponemal tests, such as the rapid plasma reagin (RPR) or Venereal Disease Research Laboratories (VDRL), and treponemal testing, such as fluorescent treponemal antibody absorbed tests, the T. pallidum passive particle agglutination (TP-PA) assay, and various enzyme and chemiluminescence immunoassays (EIA/CIA), are recommended. However, many clinical laboratories have adopted a reverse sequence of screening in which a treponemal EIA/CIA is performed first, followed by testing of reactive sera with a nontreponemal test (e.g., RPR). A positive treponemal EIA or CIA test can identify both previously treated and untreated or incompletely treated syphilis. False-positive results can occur, particularly among populations with low syphilis prevalence. Persons with a positive treponemal screening test should have a standard nontreponemal test with titer (RPR or VDRL) to guide patient management decisions. If EIA/CIA and RPR/VDRL results are discordant, the laboratory should perform a different treponemal test to confirm the results of the initial test. Patients with discordant serologic results by EIA/CIA and RPR/VDRL testing whose sera are reactive by TP-PA testing are considered to have past or present syphilis; if sera is TP-PA nonreactive, syphilis is unlikely (Fig. 146.9).
Centers for Disease Control and Prevention (CDC) recommended algorithm for reverse-sequence syphilis screening: treponemal test screening followed by nontreponemal test confirmation. (From Association of Public Health Laboratories: Suggested reporting language for syphilis serology testing, 2015.)

Rapid HIV testing with results available in 10-20 min can be useful when the likelihood of adolescents returning for their results is low. Point-of-care CLIA-waived tests for whole blood fingerstick and oral fluid specimen testing are available. Clinical studies have demonstrated that the rapid HIV test performance is comparable to those of EIAs. Because some reactive test results may be false positive, every reactive rapid test must be confirmed.

Treatment

See Part XVI for chapters on the treatment of specific microorganisms and Tables 146.6 to 146.8. Treatment regimens using nonprescription products for candidal vaginitis and pediculosis reduce financial and access barriers to rapid treatment for adolescents, but potential risks for inappropriate self-treatment and
Complications from untreated more serious infections must be considered before using this approach. Minimizing noncompliance with treatment, notifying and treating the sexual partners, addressing prevention and contraceptive issues, offering available vaccines to prevent STIs, and making every effort to preserve fertility are additional physician responsibilities.

</table>
| *Chlamydia trachomatis*         | Azithromycin 1 g orally once or Doxycycline 100 mg orally twice daily for 7 days | For pregnancy: Azithromycin 1 g orally once  
**Alternative regimens:**  
Erythromycin base 500 mg orally 4 times daily for 7 days  
or  
Erythromycin ethylsuccinate 800 mg orally 4 times daily for 7 days  
or  
Levofoxacin 500 mg orally once daily for 7 days  
or  
Ofloxacin 300 mg orally twice daily for 7 days |
| *Neisseria gonorrhoeae* (cervix, urethra, and rectum) | Ceftriaxone 250 mg IM in a single dose plus Azithromycin 1 g orally once | Single-dose injectable cephalosporin regimens (other than ceftriaxone 250 mg IM) that are safe and effective against uncomplicated urogenital and anorectal gonococcal infections include cefitzoxime 500 mg IM, cefoxitin 2 g IM with probenecid 1 g orally, and cefotaxime 500 mg IM plus Azithromycin 1 g orally once  
**Alternative if unable to offer IM:**  
Cefixime 400 mg orally in a single dose plus  
Azithromycin 1 g orally in a single dose  
**If patient is allergic to azithromycin:**  
Doxycycline 100 mg orally twice daily for 7 days may be substituted for azithromycin as the 2nd antimicrobial.  
**Severe cephalosporin allergy:**  
Gemifloxacin 320 mg orally plus azithromycin 2 g orally in a single dose  
or  
Gentamicin 240 mg IM plus oral azithromycin 2 g orally in a single dose |
| *N. gonorrhoeae* (pharynx)      | Ceftriaxone 250 mg IM in a single dose plus Azithromycin 1 g orally once | No recommended alternative therapy  
Possibly gemifloxacin plus azithromycin as above for cervix, urethra, rectum  
Patients treated with an alternative regimen should return 14 days after treatment for a test of cure using either culture or NAAT. |
| *Treponema pallidum* (primary and secondary) | Benzathine penicillin G 2.4 million units IM in a single dose | **Penicillin allergy:** Doxycycline 100 mg orally twice daily for 14 days, or tetracycline 500 mg orally 4 times daily for 7 days |
secondary syphilis or early latent syphilis, i.e., infection <12 mo) | single dose | 14 days. Limited data suggest ceftriaxone 1-2 g daily either IM or IV for 10-14 days. or Azithromycin 2 g orally in a single dose has been effective, but treatment failures have been documented.

*T. pallidum* (late latent syphilis or syphilis of unknown duration) | Benzathine penicillin G 7.2 million units total, administered as 3 doses of 2.4 million units IM each at 1 wk intervals | Penicillin allergy: Doxycycline 100 mg orally twice daily for 28 days, or tetracycline 500 mg orally 4 times daily for 28 days, with close serologic and clinical follow-up

*Haemophilus ducreyi* (chancroid: genital ulcers, lymphadenopathy) | Azithromycin 1 g orally in a single dose or Ceftriaxone 250 mg IM in a single dose or Ciprofloxacin 500 mg orally twice daily for 3 days or Erythromycin base 500 mg orally 3 times daily for 7 days |

*C. trachomatis* serovars L1, L2, or L3 (lymphogranuloma venereum) | Doxycycline 100 mg orally twice daily for 21 days | Alternative: Erythromycin base 500 mg orally 4 times daily for 21 days or Azithromycin 1 g orally once weekly for 3 wk

IM, Intramuscularly; IV, intravenously; NAAT, nucleic acid amplification test.

</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>Consider extending treatment if healing is incomplete after 10 days of therapy</td>
</tr>
</tbody>
</table>
| **Episodic therapy for recurrences** | **Treat with 1 of the following:**  
Acyclovir 400 mg orally 3 times daily for 5 days  
Acyclovir 800 mg orally twice daily for 5 days  
Acyclovir 800 mg orally 3 times daily for 2 days  
Valacyclovir 500 mg orally twice daily for 3 days  
Valacyclovir 1,000 mg orally once daily for 5 days  
Famciclovir 125 mg orally twice daily for 5 days  
Famciclovir 1,000 mg orally twice daily for 1 day  
Famciclovir 500 mg orally once, then 250 mg twice daily for 2 days | Effective episodic treatment of recurrences requires initiation of therapy within 1 day of lesion onset or during the prodrome that precedes some outbreaks. The patient should be provided with a supply or a prescription for the medication with instructions to initiate treatment immediately when symptoms begin. |

| **Suppressive therapy to reduce frequency of recurrences** | **Treat with 1 of the following:**  
Acyclovir 400 mg orally twice daily  
Valacyclovir 500 mg orally once daily* or 1 g orally once daily  
Famciclovir 250 mg orally twice daily | All patients should be counseled regarding suppressive therapy availability, regardless of number of outbreaks per year. Since the frequency of recurrent outbreaks diminishes over time in many patients, providers should periodically discuss the need to continue therapy. |

* Valacyclovir 500 mg once daily might be less effective than other valacyclovir or acyclovir dosing regimens in patients who have very frequent recurrences (i.e., ≥10 episodes per year).  

Chlamydia- and gonorrhea-infected males and females should be retested approximately 3 mo after treatment, regardless of whether they believe that their sex partners were treated, or whenever persons next present for medical care in the 12 mo following initial treatment. Once an infection is diagnosed, partner evaluation, testing, and treatment are recommended for sexual contacts within 60 days of symptoms or diagnosis, or the most recent partner if sexual contact was >60 days, even if the partner is asymptomatic. Abstinence is recommended for at least 7 days after both patient and partner are treated. A test for pregnancy should be performed for all females with suspected PID because the test outcome will affect management. Repeat testing 3 mo after treatment is also recommended for *Trichomonas* infection.
Diagnosis and therapy are often carried out within the context of a confidential relationship between the physician and the patient. Therefore, the need to report certain STIs to health department authorities should be clarified at the outset. Health departments are Health Insurance Portability and Affordability Act (HIPAA) exempt and will not violate confidentiality. The health department's role is to ensure that treatment and case finding have been accomplished and that sexual partners have been notified of their STI exposure. **Expedited partner therapy (EPT)**, the clinical practice of treating sex partners of patients diagnosed with chlamydia or gonorrhea, by providing prescriptions or medications to the patient to take to the partner without the healthcare provider first examining the partner, is a strategy to reduce further transmission of infection. In randomized trials, EPT has reduced the rates of persistent or recurrent gonorrhea and chlamydia infection. Serious adverse reactions are rare with recommended chlamydia and gonorrhea treatment regimens, such as doxycycline, azithromycin, and cefixime. Transient gastrointestinal side effects are more common but rarely result in severe morbidity. Most states expressly permit EPT or may allow its practice. Resources for information regarding EPT and state laws are available at the Centers for Disease Control and Prevention website ([http://www.cdc.gov/std/ept/](http://www.cdc.gov/std/ept/)).

**Prevention**

Healthcare providers should integrate sexuality education into clinical practice with children from early childhood through adolescence. Providers should counsel adolescents regarding sexual behaviors associated with risk of STI acquisition and should educate using evidence-based prevention strategies, which include a discussion of abstinence and other risk reduction strategies, such as consistent and correct condom use. The U.S. Preventive Services Task Force recommends **high-intensity behavioral counseling** to prevent STIs for all sexually active adolescents. The HPV vaccine (Gardasil 9) is recommended for 11 and 12 yr old males and females as routine immunization. Catch-up vaccination is recommended for females age 13-26 and for males age 13-21 who have not yet received or completed the vaccine series; males age 22 through 26 may be vaccinated.

In chronic overlapping pain conditions (COPCs), several painful symptoms affecting different body systems coexist without clear underlying pathophysiology. Other terms for COPCs include medically unexplained symptoms, functional somatic syndromes (FSS), and central sensitivity syndromes. These disorders are probably highly prevalent; for example, 2 COPCs, irritable bowel syndrome (IBS) and migraine, each affect 10–20% of the population. Pediatric COPC studies usually focus on populations with 1 painful condition (headaches) and their psychiatric comorbidities, rather than somatic comorbidities. The overlap of these disorders with psychiatric conditions has led both the public and the medical specialists to dichotomize these disorders artificially into “physical,” by implication, “real” disorders; and “psychological,” by implication, “not real” disorders. This classification ignores the unity of brain and body and hinders progress in understanding these disorders. COPC connotes a nonassumptive neutral position, appropriately attributing no assumed pathophysiology to the disorder, in contrast to other terms, such as “medically unexplained syndrome,” subtly suggesting a psychological process, more strongly implied in the term “functional.”

**Prevalence**

The prevalence of COPCs is unknown, ranging from 20% to >50% depending on which symptom is being assessed and how much overlap exists across disorders. A large study from 28 countries (about 400,000 participants) found a prevalence of headache of 54%, stomachache 50%, and backache 37%,
occurring at least once a month for at least 6 mo. Females had a higher prevalence of having all 3 complaints when compared to males; the prevalence increased with age. These three pain syndromes, headache, stomach-ache and backache, frequently coexist.

IBS and chronic abdominal pain affect 6–20% of children and adolescents. Idiopathic musculoskeletal pain affects about 16% of schoolchildren age 5-16 yr and is often associated with sleep disturbances, headache, abdominal pain, daytime tiredness, and feeling sad (see Chapter 193). Migraines present >6 mo occur in about 8% of the population (children and adolescents <20 yr) (see Chapter 613.1). Fibromyalgia is present in 1.2–6% (see Chapter 193.3). The prevalence of chronic disabling fatigue increases during adolescence from about 1.9% at age 13 to 3% at 18 yr (see Chapter 147.1). As with most COPCs, fibromyalgia has many comorbid disorders, such as sleep disturbance, fatigue, headache, sore throat, joint pain, and abdominal pain. The American College of Rheumatology definition of fibromyalgia incorporates some of these comorbid conditions.

**Symptom/Disorder Overlap**

Diagnostic criteria of many of these disorders overlap with one another, making differentiation between two disorders more of a semantic issue rather than a clinical differentiation. **Chronic fatigue syndrome (CFS)**, clinically the most concerning symptom, shares many of the diagnostic criteria with fibromyalgia. Patients with a single pain condition, such as fibromyalgia, CFS, IBS, multiple chemical sensitivity (MCS), headaches, or temporomandibular joint disorder (TMJD), will typically have another disorder. This overlap of symptoms may reflect a shared pathophysiology, possibly a central nervous system (CNS) dysfunction, as was implied in the prior term “central sensitization syndrome”. A CNS pathophysiology would also explain the “invisibility” of these disorders to usual screening tools that most often target an end organ.

COPCs also harbor many symptoms that are not strictly “pain,” although they may be equally or more disabling. Adolescents seen in a tertiary referral center with a **functional gastrointestinal disorder (FGID)** also manifest dizziness, chronic nausea, chronic fatigue and sleep disturbance, as well as migraines. Up to 50% of adolescents complain of weekly fatigue, and 15%, daily fatigue.

Migraine headaches are frequently associated with anxiety and depression. **Anxiety** also predicts the persistence of migraine headaches. Sleep disturbance
and migraine also interact closely. Poor sleep can trigger a migraine or a migraine cluster; migraine headache itself disturbs sleep. Juvenile fibromyalgia is associated with sleep disturbances such as prolonged sleep latency, frequent awakening, less total sleep time, and periodic limb movements. Adult patients with IBS also have sleep disturbances, correlating with anxiety, depression, and stress.

The comorbidities of hypermobility Ehlers-Danlos (hEDS) and postural orthostatic tachycardia syndrome (POTS) have been significant. Patients with hEDS may complain of widespread and sometimes debilitating pain with or after activity, severe fatigue, handwriting difficulties, “cracking” of joints, joint swelling, joint dislocation, subluxation, or back pain. The chronic pain reduces exercise tolerance, with poorer quality of life and an ever-worsening cycle because exercise is a key piece of management. Patients with FGID may also have hEDS, fibromyalgia, chronic pains, and higher somatizations scores than those with organic gastrointestinal (GI) disorders.

Diagnosis of pediatric POTS requires an increase in heart rate >40 beats/min in the 1st 10 min of upright tilt test associated with orthostatic symptoms. POTS is also associated with multiple comorbidities, including sleep disruption, chronic pain, Raynaud-like symptoms, GI abnormalities, and less frequently headaches, syncope, and urinary complaints. Patients with both POTS and hEDS usually have more migraines and syncope than those with POTS alone. The prevalence of comorbid disorders in children with COPC is identical whether they have POTS or hEDS.

Psychiatric Comorbidities

Many of these disorders have significant psychiatric comorbidities. Juvenile fibromyalgia is associated with anxiety disorders and major mood disorders. Children with medically unexplained symptoms generally have more anxiety and depression than children with other chronic disorders. Other associations include disruptive behaviors, symptom internalization, fearfulness, greater dependency, hyperactivity, and concern about sickness.

Predisposing Factors

Female gender and older age (adolescence) increase the risk of COPCs. Certain
conditions (e.g., headache) are more common in males or have similar prevalence across genders during childhood, but the prevalence in females increases after puberty. Trauma or posttraumatic stress disorder increases psychological comorbidities in juvenile fibromyalgia. Some studies suggest that anxiety predisposes to chronic pain. A population-based study following children from 18 mo to 14 yr of age suggested that maternal psychological distress in early childhood and depressive and pain complaints in preadolescence increase the risk of recurrent abdominal pain at age 14. Postinfectious IBS is an identifiable risk factor for new-onset anxiety, depression, and sleep disruption in adults. Children with recurrent abdominal pain often have parents with abdominal pain. It is unclear if this association is caused by a common environmental/genetic factor or a learned behavior of the child imitating the parent.

Natural History

The natural history of COPC is not well known. Chronic disabling fatigue in the general adolescent population persists 2-3 yr in about 25% of patients, but only 8% of youth affected at age 13 still had the complaints at ages 16 and 18. A meta-analysis suggests that the prognosis of CFS in children is usually good, with a small minority having persistent disabling symptoms. The patient's belief in an underlying physical disorder and the presence of psychiatric comorbidities predicts a poorer outcome.

In a study of children with FGID, the outcome depended on specific variables. Those who perceived their abdominal pain as more threatening, with high levels of pain catastrophization and little capacity to cope with pain because of reduced activity levels, had a poorer outcome. This “high pain dysfunctional profile” subgroup was predominately female (70%) with a mean age of 12.2 yr. Two thirds of this subgroup still complained of FGID at follow-up, vs about one third of those in the other groups. These groups included a “high pain adaptive profile” group with similar pain levels but better adaptive skills and less catastrophization, predominantly slightly younger (11.8 yr) females, and a “low pain adaptive profile” group, slightly younger (11.1 yr), with equal males and females but less abdominal pain, better coping mechanisms, and less impairment of daily activities. In the high pain dysfunctional profile group, 41% had both FGID and nonabdominal chronic pain at follow-up, vs 11% in the high pain adaptive and 17% in the low pain adaptive group. Another study following
children age 4-16.6 yr with IBS demonstrated resolution of symptoms in 58%, usually without medication. The differences between these studies may result from the age of the groups, with better outcome in the younger patients, as well as the number of comorbidities and psychological profile.

**Proposed Pathophysiology**

There may be dysfunction in the hypothalamic-hypophyseal-adrenal axis, circadian patterns, autonomic responses, some aspects of CNS processing, the inflammatory immune response, and the musculoskeletal system. Vagal tone measured by heart rate variability is decreased in some children with FGID symptoms and in children with COPCs. Alterations in the autonomic nervous system may affect the immune system, as well as circadian patterns. The stress response may increase muscle tone, which in turn leads to body aches and tension headaches. In fibromyalgia the cortisol response is altered, with lower cortisol levels on awakening and throughout the day. Orthostatic intolerance from autonomic abnormalities may also contribute to poor concentration from brain hypoperfusion and blood pooling in the lower extremities.

The pathophysiology has been better studied in myalgic encephalomyelitis (ME)/CFS (Chapter 147.1). ME/CFS has been associated with joint hypermobility, orthostatic intolerance, decreased range of motion, and reduced activity. These patients demonstrate excessive glial activation resulting in neuroexcitation, neuroinflammation, and possibly neurodegeneration. These features may contribute to the cognitive issues and fatigue present in this disorder.

Neuroinflammation and other changes in processing may lead to abnormal descending inhibitory pain pathways, resulting in distal pain and “central sensitization.” The malfunction of descending antinociceptive pathways allows pain to spread in the body, associated with increased activity of the nociceptive facilitator pathways. These facilitator pathways are further activated by psychological factors, such as catastrophization, depression, lack of acceptance, and hypervigilance. Other signals such as pressure, sound, heat, and cold are also aberrantly processed, with activation of areas of the brain that are typically activated only by acute pain stimuli, such as the insula, prefrontal cortex, and anterior cingulate cortex, as well as some regions usually not involved in pain processing.
Treatment

As general rules, chronic pain should never be treated with opioids, and cognitive-behavioral therapy (CBT) and a gradually progressive exercise program constitute the cornerstones of treatment. The complex comorbid nature of COPCs typically requires a multidisciplinary approach. Since neither CBT nor exercise will have any effect in the absence of full patient engagement and understanding, the team must include the family and the patient, a pain psychologist with experience in CBT, a physical therapist, and the primary care physician. Depending on comorbid conditions, rheumatology, neurology, or gastroenterology may have important roles for symptom management and possible alternative diagnosis. Depending on the initial symptomatology, the differential diagnosis should include inflammatory bowel disease, celiac disease, juvenile idiopathic arthritis, systemic lupus erythematosus, dermatomyositis, autoinflammatory disorders, Fabry disease, porphyrias, hereditary sensory-autonomic neuropathies, and Ehlers-Danlos syndrome.

When a thorough evaluation for a structural cause of symptoms is unrevealing, an important next step is patient and family education. This should include the common presentation, the expectation that “markers” for these types of disorders would typically be absent, and the presence of solid management tools with high probability of improvement. Families and patients need to receive encouragement to stop seeking a “magic diagnosis and cure” and to begin the path to full recovery. Without this step, critical patient engagement in the treatment will not occur. In our practice, we sometimes call functional disorders a problem of “software,” in contrast to structural issues that would involve “hardware.” We explain that successful management must change the software, not just mask symptoms. Approaches that accomplish such a goal include CBT, and a rehabilitative program that may require physical therapy, vigorous exercise program with interval training, meditation, and/or yoga. Patients are often deconditioned and may need to start with a very low level of physical activity. In addition, their exercise tolerance may be significantly hampered by an orthostatic intolerance syndrome (e.g., POTS). For these reasons, we frequently recommend starting with a water aerobics program, which provides several benefits: (1) very low gravitational force, so the patient can be set up for success, working only on conditioning and not simultaneously fighting an orthostatic challenge; (2) builds both limb and core strength; and (3) gentle on joints for those with arthralgias or a hypermobility syndrome. When
water is unavailable, we recommend starting with a recumbent exercise program such as a recumbent stationary bike. In both circumstances, we then slowly introduce upright aerobic activities on land over 2-3 mo. Strength exercises are also useful. A Cochrane Review in adults with painful disorders showed exercise to have minimal side effects, to improve functionality, reduce pain, and improve quality of life. Patients with fibromyalgia who undergo a 3 mo multidisciplinary program with twice-weekly physical therapy and CBT benefited in function and physical activity level, and most importantly continued to exercise regularly at 1 yr follow-up. Pharmacologic interventions have less impact than nonmedical treatments.

When children are missing school or are homebound, it is important to work closely with the school to encourage reentry to school. This may require modifying the school schedule initially, starting with fewer hours at school, and providing extra time for homework on days that the children are not feeling well. Although medications such as tricyclic antidepressants are often added to the treatment, the improvement with these medications for chronic pain is minimal, and the side effects need to be considered. Nonetheless, amitriptyline is often used because it helps in treating headaches and abdominal pain and improves sleep quality, a critical element to manage any chronic pain condition.

147.1

Chronic Fatigue Syndrome

cognitive-behavioral therapy
orthostatic intolerance

Chronic fatigue syndrome (CFS), also known as myalgic encephalomyelitis (ME), is a complex, diverse, and debilitating illness characterized by chronic or intermittent fatigue accompanied by select symptoms and occurring in children, adolescents, and adults. The combination of fatigue and other symptoms interferes significantly with daily activities and has no identified medical explanation (Fig. 147.1). The fatigue does not require exertion by the patient, nor does rest relieve it. Some consider postexertion malaise, or worsening of the fatigue with additional symptoms after mental or physical exertion and lasting >24 hr, to be characteristic of CFS. A definitive causal agent or process has not been identified, although the differential diagnosis includes infectious, inflammatory, metabolic, genetic, and autoimmune diseases. Our understanding of this condition is largely from studies of adults and adolescents, with limited descriptions of chronic fatiguing illnesses in younger children.
The illness was formally defined in 1988 as *chronic fatigue syndrome* because persistent unexplained fatigue was considered the principal and invariable physical symptom. A variety of other names have been used to describe the illness, including chronic mononucleosis, chronic Epstein-Barr virus (EBV) infection, postinfection syndrome, and immune dysfunction syndrome. Several case definitions have been developed and are in use in both clinical care and
research (Table 147.1).

CFS, Chronic fatigue syndrome; ME, myalgic encephalomyelitis.

The Institute of Medicine (IOM) 2015 recommendations apply to all ages and include a special focus on pediatrics. The IOM suggested new diagnostic criteria and a new name, **systemic exertion intolerance disease (SEID)**, to emphasize the postexertion malaise criterion and better understand the illness (Table 147.2). The most recent expert consensus report (June 2017) from the International Writing Group for Pediatric ME/CFS provides a primer for diagnosis and management.

**Table 147.2**
Criteria for Diagnosis of Myalgic Encephalomyelitis/Chronic Fatigue Syndrome (ME/CFS)
Patient has each of the following 3 symptoms at least half the time, to at least a moderately severe degree:

- A substantial reduction or impairment in the ability to engage in preillness levels of occupational, educational, social, or personal activities that persists for >6 mo and is accompanied by fatigue, which is often profound, is of new or definite onset (not lifelong), is not the result of ongoing excessive exertion, and is not substantially alleviated by rest.
- Postexertional malaise*
- Unrefreshing sleep*

Plus at least 1 of the 2 following manifestations (chronic, severe):

- Cognitive impairment*
- Orthostatic intolerance

* Frequency and severity of symptoms should be assessed. The diagnosis of ME/CFS should be questioned if patients do not have these symptoms at least half of the time with moderate, substantial, or severe intensity.

**Epidemiology**

Based on worldwide studies, 0.2–2.3% of adolescents or children have CFS. Most epidemiology studies use the 1994 definition. CFS is more prevalent in adolescents than in younger children. The variation in CFS prevalence estimates may result from variations in case definition, study methodology and application, study population composition (specialty vs general practice or general population), and data collection (parent, self-reporting vs clinician evaluation). Gender distribution in children differs from that in adults, with a more equal distribution in children <15 yr old, while remaining 2-3–fold higher in females 15-18 yr old. Few studies have reported the incidence of CFS among children <10 yr old, leading to uncertainty in this group. In adolescents in The Netherlands, the pediatrician-diagnosed incidence of CFS/ME was 0.01%, and in
the United Kingdom, 0.5%.

**Pathogenesis**

Although etiology and pathophysiology of CFS are unknown, some patients and clinicians correlate the onset with a recent episode of a viral illness such as infectious mononucleosis (10–12%) (EBV; see Chapter 281). A pathophysiologic relationship of CFS to infection is suggested because the symptoms and biologic markers elicited by the nonspecific innate host responses to infections in general are present in CFS. CFS-like illness after infectious mononucleosis is not predicted by viremia or altered host response to EBV infection but is associated with the severity of the primary infection. A wide variety of other candidate viral infections have been associated with postinfectious fatigue syndromes, particularly in adolescents and adults. There are ongoing efforts to determine if infections with these or other agents may produce the illness.

Similarities between CFS symptoms and those experienced by patients with autoimmune and other inflammatory disorders suggests primary perturbation of immune function in the pathogenesis of CFS. Hypo- and hypergammaglobulinemia, immunoglobulin subclass deficiencies, elevated levels of circulating immune complexes, altered helper/suppressor lymphocyte ratios, natural killer cell dysfunction, elevated cytokines, and monocyte dysfunction have been reported in adult patients with CFS. These findings have not been consistent among studies. CFS patients as a group differ from healthy controls, but most laboratory values of the immune parameters are not outside the normal range.

Autonomic nervous system (ANS) changes are suggested by the orthostatic intolerance (OI) experienced by some patients with CFS. OI syndromes with circulatory dysfunction include neutrally mediated hypotension and postural orthostatic tachycardia syndrome (POTS) (see Chapter 147) have been observed in some patients with CFS and could contribute to the syndrome. The pathophysiology of these manifestations among adolescents with CFS is unclear, but in postinfectious states could be associated with unreplenished fluid and electrolyte losses associated with acute infection or immune-mediated injury (autoantibodies directed against ANS).

Because the widespread musculoskeletal pain in CFS is similar to fibromyalgia (see Chapter 193.3), and because some consider these to be
overlapping syndromes, fibromyalgia and CFS may share similarities in pathogenesis. Other hypotheses under investigation for the biologic basis of CFS involve alterations in energy metabolism (e.g., mitochondrion, particularly as related to exercise intolerance and postexertion malaise), alterations in sleep, the stress response, hypothalamic-pituitary axis. Understanding CFS has proved so challenging because it likely represents more than 1 underlying pathophysiology. Current studies and guidelines are attempting to stratify or subgroup patients to address this possibility.

**Clinical Manifestations**

The dominant symptom expressed by adolescents and adults is a substantial reduction or impairment in the ability to engage in preillness levels of activity, accompanied by fatigue (see Fig. 147.1). In younger children, who often do not spontaneously report symptoms, exertion induces behavioral changes, manifested by a lack of their usual energy and reduced participation in activities. In adolescents, fatigue and postexertion malaise may lead to decreased participation in school, family activities, and social exchange.

**Cognitive impairment** includes reported difficulties in concentrating, which are common and indicated by reduced participation in school, difficulty keeping up with homework, and drop in grades. Sleep may be impaired, and nonrestorative sleep is common. Other sleep complaints include difficulty falling asleep and staying asleep, whereas diagnosed sleep disorders, including restless legs syndrome, parasomnias, and sleep apnea, are less common. Myalgia and arthralgia may accompany fatigue and altered sleep. Sore throat and cervical lymph node tenderness can occur but may be part of an inciting illness. Adolescents also have increased reports of headache, abdominal pain, nausea, and sensitivity to light and sound with amplified pain.

Patients diagnosed with CFS in primary care practices are more likely to report abrupt onset of their symptoms, often as part of an initial virus-like illness, whereas gradual onset is more common in those identified in population-based studies. School absenteeism is a major social issue. In one study, two thirds of adolescents missed >2 wk over a 6 wk observation period, and one third required home tutoring. Unlike school phobia, inactivity due to CFS persists on the weekends and during holidays the same as it does during the school week.

Although fatigue and accompanying symptoms are subjective, the magnitude of impairment of each component can be measured by questionnaires addressing
pain and function or, in the case of suspected orthostatic instability, by recording routine supine and standing heart rate and blood pressure measurement's. Fatigue cannot be dismissed as a minor ailment. It generally manifests as lassitude, profound tiredness, intolerance of exertion with easy fatigability, and general malaise.

Abnormal physical examination findings are conspicuously absent, providing both reassurance and consternation for the patient, family, and physician. The presence of “alarm symptoms” such as weight loss, chest pain with exertion, paresthesia, dry mouth and eyes, fevers, diarrhea, cough, night sweats, and rash is uncommon and warrants consideration of a diagnosis other than CFS.

**Diagnosis**

There are no pathognomonic signs or diagnostic tests for CFS. The diagnosis is clinically defined based on inclusion and exclusion criteria ([Fig. 147.2](#)). The diagnostic criteria are applicable to adults and adolescents >11 yr old because of the current requirement for a self-generated history. Whereas duration of symptoms is 3-6 mo, depending on age, symptom management should not wait until this criterion is met.
CFS is difficult to diagnose in children, who may have difficulty describing their symptoms and articulating their concerns. Sole reliance on parental history...
can be fraught with confusion because parents may also struggle to interpret their children's symptoms and feelings in providing accurate historical information. A combination of child and parent reporting is most effective. It is important to document the child's activity levels and worsening of symptoms after physical or mental endeavors. Changes in participation in hobbies and family or other social activities can help identify the impact of CFS on function.

The diagnosis of CFS can be established only after other medical and psychiatric causes of fatigue and other symptoms, many of which are treatable, have been excluded. These include medical conditions presenting with chronic symptoms, such as hypothyroidism, adrenal insufficiency, respiratory and food allergies, sleep apnea, narcolepsy, substance abuse, posttraumatic stress disorder, adverse drug reactions, and obesity. A previously diagnosed medical condition with incomplete or uncertain resolution that may explain fatigue needs be considered.

Certain illnesses (e.g., fibromyalgia), amplified pain, and depression share similar symptoms with CFS but are not exclusionary diagnoses. These should be considered in the differential diagnosis in select cases. There is concern that CFS might be mistaken for readily identifiable psychiatric disorders such as anxiety and mood disorders, but evidence supports differences in their clinical presentation from CFS. CFS should not be diagnosed in persons with prior diagnosis of major depressive disorder with psychotic or melancholic features, bipolar affective disorders, schizophrenia of any subtype, delusional disorders of any subtype, dementia of any subtype, eating disorder of any type, or alcohol or other substance abuse within 2 yr before the onset of the chronic fatigue or any time thereafter.

Although evaluation of each patient should be individualized, initial laboratory evaluation should be limited to screening laboratory testing sufficient to provide reassurance of the lack of significant medical illness. Further evaluation should be directed primarily toward excluding treatable illnesses that may be suggested by the history, symptoms, signs, or physical exam findings present in specific patients.

**Management**

Management of CFS is based on relief of the core and most disruptive symptoms in the individual patient. The diagnostic criterion of 6 mo duration of illness should not delay evaluation and symptom management, since these may be
initiated as soon as the child or adolescent presents with a CFS-like picture. Problems with sleep can be addressed by encouraging patients to adopt good sleep habits using standard sleep hygiene techniques. It may be beneficial to refer the patient to a sleep medicine specialist for the identification and treatment of sleep disorders and disturbances. Once pain is found not to be related to other specific disease of illness, nonpharmacologic treatment is indicated.

One of the nonpharmacologic approaches to pain management, **cognitive-behavioral therapy** (CBT), may also assist patient in managing and coping with CFS. Through explanation and changes in perception of the illness, CBT may help patients and their families develop coping skills and provide emotional support. Improved methods of coping may allow some improved function while living with the illness. Comorbid psychiatric conditions such as anxiety require appropriate evaluation and intervention. Guided graded-exercise therapy may be beneficial and added to CBT.

While the overall goal is to help patients with CFS tolerate activity, children and adolescents with CFS should limit physical or mental efforts that result in aggravated symptoms. Return to school should be initiated gradually and systematically with the goal return to full-time attendance. Home tutoring, cyberschool, and partial attendance can be interim steps. Parents and clinicians can work with teachers and school administrators to define appropriate expectations for attendance and performance for children with CFS. Because of the crucial importance of learning socialization skills, even brief attendance in school or participation in school activities should be encouraged, remembering that too rapid remobilization usually exacerbates symptoms and should be avoided.

Continued **empathy and support** by the treating physician are crucial in maintaining a physician–parent–patient relationship that is conducive to managing this illness. Careful attention must be directed to family dynamics to identify and resolve family problems or psychopathology that may be contributing to children's perception of their symptoms.

**Prognosis**

The natural history of CFS is highly variable, and patients and families understand that the symptoms will wax and wane. Children and adolescents with CFS appear to have a more optimistic outcome than adults, typically with an undulating course of gradual improvement over several years. Overall, a good
functional outcome has been reported in up to 80% of patients. Poor prognostic factors include gradual onset, increased school absenteeism, lower socioeconomic status, chronic maternal health problems, and untreated comorbid individual and family psychiatric disorders. Favorable prognostic factors include patient control of the rehabilitation program, with continuing support from health professionals and family members, and improvement in orthostatic intolerance.

Chapter 148 Evaluation of Suspected Immunodeficiency
Primary care physicians must have a high index of suspicion to diagnose immune system defects early enough to institute appropriate treatment before irreversible damage develops. Diagnosis can be difficult because most affected patients do not have abnormal physical features. The most typical manifestation of immunodeficiency in children is recurrent sinopulmonary infections. Although infections are common in children in general, an infection exceeding the expected frequency and usually involving multiple sites can suggest immunodeficiency. A single, severe, opportunistic, or unusual infection can also be the presentation of an immunodeficiency (Table 148.1). Increasingly recognized is the co-occurrence of autoimmune disease or inflammatory conditions and recurrent infections. Newborn screening for T-cell lymphopenia has been instituted in most states; this has led to the identification of some infants with immunodeficiency before any clear manifestations but is limited to T-cell deficiencies. Additional clues to immunodeficiency include failure to thrive with or without chronic diarrhea, persistent infections after receiving live vaccines, and chronic oral or cutaneous candidiasis (Tables 148.2 and 148.3).

**Table 148.3**

**Clinical Aids to the Diagnosis of Immunodeficiency**

**Suggestive of B-Cell Defect (Humoral Immunodeficiency)**

- Recurrent bacterial infections of the upper and lower respiratory tracts
- Recurrent skin infections, meningitis, osteomyelitis secondary to encapsulated bacteria (*Streptococcus pneumoniae, Haemophilus influenzae, Staphylococcus aureus, Neisseria meningitidis*)
- Paralysis after vaccination with live-attenuated poliovirus
- Reduced levels of immunoglobulins

**Suggestive of T-Cell Defect (Combined Immunodeficiency)**

- Systemic illness after vaccination with any live virus or bacille Calmette-Guérin (BCG)
- Unusual life-threatening complication after infection with benign viruses (giant cell pneumonia with measles; varicella pneumonia)
- Chronic oral candidiasis after age 6 mo
- Chronic mucocutaneous candidiasis
- Graft-versus-host disease after blood transfusion
- Reduced lymphocyte counts for age
- Low levels of immunoglobulins
- Absence of lymph nodes and tonsils
- Small thymus
- Chronic diarrhea
- Failure to thrive
- Recurrent infections with opportunistic organisms

**Suggestive of Macrophage Dysfunction**
Disseminated atypical mycobacterial infection, recurrent Salmonella infection
Fatal infection after BCG vaccination

**Congenital Syndromes With Immunodeficiency**

Ataxia-telangiectasia: ataxia, telangiectasia
Autoimmune polyglandular syndrome: hypofunction of 1 or more endocrine organs, chronic mucocutaneous candidiasis
Cartilage-hair hypoplasia: short-limbed dwarfism, sparse hair, neutropenia
Wiskott-Aldrich syndrome: thrombocytopenia, male gender, eczema
Chédiak–Higashi syndrome: oculocutaneous albinism, nystagmus, recurrent bacterial infections, peripheral neuropathies
DiGeorge syndrome (22q deletion syndrome): unusual facies, heart defect, hypocalcemia

**Suggestive of Asplenia**

Heterotaxia, complex congenital heart disease, Howell-Jolly bodies on blood smear, sickle cell anemia

With >300 distinct primary immunodeficiencies, in order to focus the diagnostic approach and appropriate testing, it is often useful to consider 5 categories: T-cell disorders, B-cell and antibody disorders, complement disorders, phagocytic disorders, and natural killer cell disorders (Table 148.4 and Fig. 148.1).

* X-linked (Bruton) agammaglobulinemia.
The initial evaluation of immunologic function includes a thorough history, physical examination, and family history (Table 148.5). Over 10 immunodeficiencies are X-linked, and a growing number are autosomal dominant with variable expressivity and/or incomplete penetrance. Close attention to physical signs of autoimmune disease or end-organ effects from recurrent infections should be noted. The history of infections should include the age of onset, severity, involved locations, and assessment of the underlying microbial cause. Viral, bacterial, fungal, and mycobacterial infections all require distinct arms of the immune system for eradication; therefore identification of microbiologic causes of infection can be extremely helpful in defining the deficiency states in people with primary immunodeficiencies.

Most immunologic defects can be excluded at minimal cost with the proper choice of screening tests, which should be broadly informative, reliable, and cost-effective (Table 148.6 and Figs. 148.2 and 148.3). A complete blood count
(CBC) with differential is the initial study if neutropenia is a consideration but is
less recognized as a screening test for T-cell defects. Lymphopenia is seen the
majority of T-cell defects. If an infant's neutrophil count is persistently elevated
in the absence of any signs of infection, a leukocyte adhesion deficiency should
be suspected. Normal lymphocyte counts are higher in infancy and early
childhood than later in life (Fig. 148.4 ). Knowledge of normal values for
absolute lymphocyte counts at various ages in infancy and childhood is crucial in
the detection of T-cell defects. Additional clues from the CBC include absence
of Howell-Jolly bodies, which argues against congenital asplenia. Normal
platelet size or count excludes Wiskott-Aldrich syndrome. When
immunodeficiency is suspected, obtaining IgG, IgA, IgM, and IgE levels can be
a useful strategy, since antibody defects are the most common type of
immunodeficiency. Immunoglobulin levels must be interpreted within the
context of age-specific normative data.

Screening Tests for B-Cell Defects

- IgG, IgA, IgM (low in most antibody defects)
- Isohemagglutinins (low in agammaglobulinemia)
- Antibody titers tetanus, diphtheria, Haemophilus influenzae, and
pneumococcus (low in most antibody defects)

**Screening Tests for T-Cell Defects**

Absolute lymphocyte count (normal result indicates T-cell defect unlikely)
Flow cytometry to examine for the presence of naïve T cells (CD3⁺ CD45RA⁺ cells)

**Screening Tests for Phagocytic Cell Defects**

Microscopy (abnormal in some neutropenias)
Respiratory burst assay (abnormal in chronic granulomatous disease)

**Screening Test for Complement Deficiency**

CH₅₀ (nearly absent in classical pathway and terminal component deficiencies)
AH₅₀ (nearly absent in alternative pathway and terminal component deficiencies)
FIG. 148.2  Initial workup and follow-up studies of patients with suspected immunodeficiency. Consultation with a clinical immunologist is recommended to guide advanced testing and interpret results. CBC, Complete blood count; CGD, chronic granulomatous disease; LAD, leukocyte adhesion defect; NK, natural killer cell; IL, interleukin; IFN, interferon. (From Kliegman RM, Lye PS, Bordini BJ, et al, editors: Nelson pediatric symptom-based diagnosis, Philadelphia, 2018, Elsevier, p 753.)
Advanced Testing

Additional testing should be focused based on the phenotype and suspected category of immune deficiency (Table 148.7; see Figs. 148.2 and 148.3). For patients with recurrent sinopulmonary infections in whom an antibody defect is suspected, further attention to antibody testing may be revealing. In addition to Ig levels, responses to vaccines should also be pursued in this setting. A small but significant subset of patients with antibody deficiencies will have normal Ig levels but abnormal function, as detected by poor responses to vaccines. When hypogammaglobulinemia is identified, it is important to determine whether it is primary or secondary. Patients receiving corticosteroids or who have protein-losing states (nephrosis, protein-losing enteropathy) often have low serum IgG concentrations but produce normal responses to vaccines. Thus, if Ig levels are low, it is crucial before starting immune globulin replacement therapy that antibody titers to vaccines are measured. Antibody titers are not interpretable after the patient has received a blood transfusion, fresh-frozen plasma, or immune globulin therapy.

One useful test for B-cell function is to determine the presence and titer of **isohemagglutinins**, or natural antibodies to type A and B red blood cell polysaccharide antigens. This test measures predominantly IgM antibodies. Isohemagglutinins may be absent normally in the first 2 yr of life and are always absent if the patient is blood type AB.

Because most infants and children are immunized with diphtheria-tetanus-pertussis (dTP), conjugated *Haemophilus influenzae* type b, and pneumococcal conjugate vaccine, it is often informative to test for specific antibodies to diphtheria, tetanus, *H. influenzae* polyribose phosphate, and pneumococcal antigens. If the titers are low, measurement of antibodies to diphtheria or tetanus toxoids before and 2-8 wk after a pediatric dTP or dT booster is helpful in assessing the capacity to form IgG antibodies to protein antigens. To evaluate a
patient's ability to respond to polysaccharide antigens, antipneumococcal antibodies can be measured before and 4-8 wk after immunization with 23-valent unconjugated pneumococcal polysaccharide vaccine in patients ≥2 yr old. Antibodies detected in these tests are of the IgG isotype. These antibody studies can be performed in several different laboratories, but it is important to choose a reliable laboratory and to use the same laboratory for pre- and postimmunization titers.

Patients with defective B-cell maturation due to a class-switching defects produce neither IgA nor IgG antibodies normally. IgM is normal or elevated. Vaccine responses are uniformly low. If antibody responses to vaccines are normal and the IgG level is low, studies should be performed to evaluate the possible loss of immunoglobulins through the urinary or gastrointestinal tract (nephrotic syndrome, protein-losing enteropathies, intestinal lymphangiectasia). Another common confounder is the use of rituximab or corticosteroids, leading to hypogammaglobulinemia. Very high serum concentrations of 1 or more Ig classes suggest HIV infection, chronic granulomatous disease, chronic inflammation, or autoimmune lymphoproliferative syndrome.

IgG subclass measurements are seldom helpful in assessing immune function in young children with recurrent infections. They are strongly developmentally regulated with highly variable production in early childhood. It is difficult to know the biologic significance of the various mild to moderate deficiencies of IgG subclasses, particularly when completely asymptomatic individuals have been described as totally lacking IgG1, IgG2, IgG4, and/or IgA1 because of IgG heavy-chain gene deletions. Many healthy children have been described as having low levels of IgG2 but normal responses to polysaccharide antigens when immunized. In older children and adults, a low IgG2 maybe an antecedent finding before evolving into common variable immunodeficiency (CVID). Specific vaccine responses are usually much more useful than IgG subclass determinations.

Patients found to be agammaglobulinemic should have their blood B cells enumerated by flow cytometry using dye-conjugated monoclonal antibodies to B-cell–specific CD antigens (usually CD19 or CD20). Normally, approximately 5–10% of circulating lymphocytes are B cells. B cells are absent in X-linked agammaglobulinemia (XLA) and in several very rare autosomal recessive conditions, but they are usually present in CVID, IgA deficiency, and hyper-IgM syndromes. This distinction is important, because children with hypogammaglobulinemia from XLA and CVID can have different clinical
problems, and the 2 conditions clearly have different inheritance patterns. Patients with CVID have more problems with autoimmune diseases and lymphoid hyperplasia. Molecular testing for XLA and other B-cell defects (see Chapter 150.1) is indicated in cases without a family history to aid genetic counseling.

**T cells and T cell subpopulations** can be enumerated by flow cytometry using dye-conjugated monoclonal antibodies recognizing CD antigens present on T cells (i.e., CD2, CD3, CD4, and CD8). This is a particularly important test to perform on any infant who is lymphopenic, because CD3⁺ T cells usually constitute 70% of peripheral lymphocytes. Regardless of molecular type, infants with SCID are unable to produce T cells, so are lymphopenic at birth. The flow cytometry for infants suspected of having SCID should also include monoclonal antibodies to naïve (CD45RA) and memory (CD45RO) T cells. In normal infants, >95% of the T cells are CD45RA⁺ (naïve) T cells. If the infant has SCID, there could be transplacentally transferred maternal T cells detected by flow cytometry, but they would be predominantly CD45RO⁺ T cells. SCID is a pediatric emergency that can be successfully treated by hematopoietic stem cell transplantation in more than 90% of cases if diagnosed before serious, untreatable infections develop. Normally, there are about twice as many CD4⁺ (helper) T cells as there are CD8⁺ (cytotoxic) T cells. Because some severe immunodeficiencies have phenotypically normal T cells, tests of T-cell function can be helpful. T cells can be stimulated directly with **mitogens** such as phytohemagglutinin, concanavalin A, or pokeweed mitogen. After 3-5 days of incubation with the mitogen, the proliferation of T cells is measured. Other stimulants that can be used to assess T-cell function in the same type of assay include antigens (*Candida*, tetanus toxoid) and allogeneic cells.

**Natural killer (NK)** cells can be enumerated by flow cytometry using monoclonal antibodies to NK-specific CD antigens, CD16 and CD56. NK function is assessed by killing of target cells and flow cytometry for CD107a, a marker of degranulation.

**Chronic granulomatous disease** should be suspected if a patient has recurrent staphylococcal abscesses or fungal infections. It can be evaluated by screening tests measuring the neutrophil respiratory burst after phorbol ester stimulation. **Leukocyte adhesion defects** (LAD) can be easily diagnosed by flow cytometric assays of blood lymphocytes or neutrophils, using monoclonal antibodies to CD18 or CD11 (LAD1) or to CD15 (LAD2). **Neutrophil defects** are most often associated with neutropenia or morphologic abnormalities visible
by microscopy. Therefore, a combination of a CBC with differential, microscopic evaluation, and the flow cytometric approaches previously described often yields a diagnosis. The same is not true for macrophage defects, which are usually associated with susceptibility to mycobacteria, and testing requires advanced functional analyses or sequencing.

When invasive infection with encapsulated organisms or Neisseria leads to a suspicion of a complement defect, a CH$_{50}$ test should be obtained. This bioassay measures the intactness of the entire complement pathway and yields abnormal results if classical pathway or terminal components are missing. Genetic deficiencies in the complement system often have a CH$_{50}$ that is almost absent, although the most frequent cause of a slightly low CH50 is improper transport of the specimen. Complement proteins are highly labile and must be transported on ice. Specific factor assays are available at reference laboratories. Rare causes of neisserial susceptibility include alternative pathway defects, and the test for these deficiencies is the AH$_{50}$ test. Identifying the specific component deficiency in the mode of inheritance is important for genetic counseling. Properdin deficiency is X-linked, and other deficiencies are autosomal recessive or autosomal dominant.

OUTLINE

Chapter 149 Lymphocyte Development and Function
Chapter 150 Primary Defects of Antibody Production
Chapter 151 Primary Defects of Cellular Immunity
Chapter 152 Immunodeficiencies Affecting Multiple Cell Types
Defense against infectious agents is secured through a combination of anatomic physical barriers, including the skin, mucous membranes, mucous blanket, and ciliated epithelial cells, and the components of the immune system. The immune system of vertebrates integrates 2 fundamental response mechanisms. Innate (natural) immunity is rapid and utilizes receptors encoded in the germline. The innate defenses comprise cell-intrinsic responses to viral infections, leukocyte responses to pathogens, and soluble mediators such as complement proteins. Acquired (adaptive) immunity is specific to T and B cells. These cells undergo DNA recombination to generate receptors and require an education process to minimize autoreactive cells. In addition, there are lymphocyte subsets that are innate in nature and either do not require DNA recombination or utilize a single recombination event to generate a monospecific receptor.

Lymphopoiesis in the Fetus

Pluripotent hematopoietic stem cells first appear in the yolk sac at 2.5-3 wk of gestational age, migrate to the fetal liver at 5 wk gestation, and later reside in the bone marrow, where they remain throughout life (Fig. 149.1). Lymphoid stem cells develop and differentiate into T, B, or natural killer (NK) cells, depending on the organs or tissues to which the stem cells traffic. Development of the primary lymphoid organs—thymus and bone marrow—begins during the middle of the 1st trimester of gestation and proceeds rapidly. Development of the secondary lymphoid organs—spleen, lymph nodes, tonsils, Peyer patches, and lamina propria—soon follows. These organs serve as sites of differentiation of T,
B, and NK lymphocytes from stem cells throughout life. Both the initial organogenesis and the continued cell differentiation result from the interaction of a vast array of lymphocytic and microenvironmental cell surface molecules and proteins secreted by the involved cells. Clusters of differentiation (CD) refer to cellular protein (Table 149.1), whereas cytokines and chemokines refer to soluble mediators of immune function (Table 149.2).

### T-Cell Development and Differentiation

The primitive thymic rudiment is formed from the ectoderm of the 3rd branchial cleft and endoderm of the 3rd branchial pouch at 4 wk gestation. Beginning at 7-8 wk, the right and left rudiments fuse in the midline. Bloodborne T-cell precursors from the fetal liver then begin to colonize the perithymic mesenchyme at 8 wk gestation and move into the thymus at 8.0-8.5 wk. The earliest cells to enter the thymus are found in the subcapsular region and do not express CD3, CD4, CD8, or either type of T-cell receptor (TCR). These lymphoid cell precursors are triggered to proliferate and become thymocytes through interactions with the thymic stroma. The cells are arrested at this stage until they productively rearrange the β-chain locus of the TCR. The β chain then pairs with the surrogate pre-T α chain. This tests the function of the β chain, and if signaling occurs, β-chain rearrangement ceases. CD4 and CD8 are then expressed simultaneously (i.e., they are double-positive thymocytes). Fetal cortical thymocytes are among the most rapidly dividing cells in the body and increase in number by 100,000-fold within 2 wk after stem cells enter the thymus. As these cells proliferate and mature, they migrate deeper into the thymic cortex. The double-positive thymocytes begin efficient rearrangement of the α-chain locus. TCR gene rearrangement occurs by a process in which large,
noncontiguous blocks of DNA are spliced together. **V (variable)**, **D (diversity)**, and **J (joining)** blocks exist in families of minimally different segments. Random combinations of the segments account for much of the enormous diversity of TCRs that enables humans to recognize millions of different antigens. TCR gene rearrangement requires the presence of recombinase-activating genes, **RAG1** and **RAG2**, as well as other recombinase components.

As immature cortical thymocytes begin to express TCRs, the processes of positive and negative selection take place. **Positive selection** occurs in immature thymocytes, recognizing major histocompatibility complex (MHC) antigens present on cortical thymic epithelial cells. Some cells are selected to mature into CD4 or CD8 single-positive cells. **Negative selection** occurs next in the thymic medulla on medullary thymic epithelial cells. Autoreactive T cells undergo apoptosis and die. T cells begin to emigrate from the thymus to the spleen, lymph nodes, and appendix at 11-12 wk of embryonic life and to the tonsils by 14-15 wk. They leave the thymus via the bloodstream and are distributed throughout the body, with the heaviest concentrations in the paracortical areas of lymph nodes, the periarteriolar areas of the spleen, and the thoracic lymph duct. Recent thymic emigrants co-express the CD45RA isoforms and CD62L (L-selectin).

Rearrangement of the TCR locus during intrathymic T-cell development results in the excision of DNA and the excised elements form circular episomes as a by-product. These **TCR recombination excision circles** can be detected in T cells that are recent thymic emigrants. TCR recombination excision circles detected in dried-blood spots collected from infants shortly after birth is the test used for newborn screening for severe combined immunodeficiency (SCID). By 12 wk gestation, T cells can proliferate in response to plant lectins, such as phytohemagglutinin and concanavalin A. Antigen-specific T cells have been found by 20 wk gestation. **Hassall corpuscles (bodies)**, which are swirls of terminally differentiated medullary epithelial cells, are first seen in the thymic medulla at 16-18 wk of embryonic life.

### B-Cell Development and Differentiation

B-cell development begins in the fetal liver by 7 wk gestation. Fetal liver CD34 stem cells are seeded to the bone marrow of the clavicles by 8 wk of embryonic life and to that of the long bones by 10 wk (see Fig. 149.1). As B cells differentiate from primitive stem cells, they proceed through stages that are
marked by the sequential rearrangement of immunoglobulin gene segments to generate a diverse repertoire of antigen receptors. The early pro-B cell is the first descendent of the pluripotential stem cell committed to B-lineage development, and in this stage the heavy chain locus rearranges first. In the early pro-B cell, D-J rearrangements are made on both chromosomes. In the late pro-B cell, the V segment rearranges to a D-J gene segment. The next stage is the pre-B cell, during which immunoglobulin (Ig) light-chain genes are rearranged. The pre-B cell is distinguished by the expression of cytoplasmic µ heavy chains but no surface IgM (sIgM), because Ig light chains are not yet produced. Next is the immature B-cell stage, during which the light-chain genes have already been rearranged, and sIgM but not sIgD is expressed. Immature B cells leave the bone marrow for secondary lymphoid organs. The last stage of antigen-independent B-cell development is the mature naïve B cell, which co-expresses both sIgM and sIgD. Pre-B cells can be found in fetal liver at 7 wk gestation, sIgM+ and sIgG+ B cells at 7-11 wk, and sIgD+ and sIgA+ B cells by 12-13 wk. By 14 wk of embryonic life, the percentage of circulating lymphocytes bearing sIgM and sIgD is the same as in cord blood and slightly higher than in the blood of adults.

Antigen-dependent stages of B-cell development are those that develop after the mature B cell is stimulated by antigen in secondary lymphoid organs. Once antigen stimulation has occurred, the mature B cells can become memory B cells or plasmablasts. Both outcomes require the presence of T-cell help.

There are 5 immunoglobulin isotypes, which are defined by unique heavy chains: IgM, IgG, IgA, IgD, and IgE. IgG and IgM, the only complement-fixing isotypes, are the most important immunoglobulins in the blood and other internal body fluids for protection against infectious agents. IgM is confined primarily to the intravascular compartment because of its large size, whereas IgG is present in all internal body fluids. IgA is the major protective immunoglobulin of external secretions—in the gastrointestinal, respiratory, and urogenital tracts—but it is also present in the circulation. IgE, present in both internal and external body fluids, has a major role in host defense against parasites. Because of high-affinity IgE receptors on basophils and mast cells, however, IgE is the principal mediator of allergic reactions of the immediate type. The significance of IgD is still not clear. There are also immunoglobulin subclasses, including 4 subclasses of IgG (IgG1, IgG2, IgG3, and IgG4) and 2 subclasses of IgA (IgA1 and IgA2). These subclasses each have different biologic roles. Secreted IgM and IgE have been found in as young as 10 wk gestation, and IgG as early as 11-12 wk.
Even though these B-cell developmental stages have been described in the context of B-cell ontogeny in utero, it is important to recognize that the process of B-cell development from pluripotential stem cells goes on throughout postnatal life. Plasma cells are not usually found in lymphoid tissues of a fetus until about 20 wk gestation, and then only rarely, because of the sterile environment of the uterus. Intestinal lymphoid development occurs relatively late. Peyer patches have been found in significant numbers by the 5th intrauterine mo, and plasma cells have been seen in the lamina propria by 25 wk gestation. Before birth there may be primary follicles in lymph nodes, but secondary follicles are usually not present.

A human fetus begins to receive significant quantities of maternal IgG transplacentally at around 12 wk gestation, and the quantity steadily increases until, at birth, cord-blood serum contains a concentration of IgG comparable to or greater than that of maternal serum. IgG is the only class to cross the placenta to any significant degree. All 4 IgG subclasses cross the placenta, but IgG2 does so least well. A small amount of IgM (10% of adult levels) and a few nanograms of IgA, IgD, and IgE are normally found in cord blood serum. Because none of these proteins crosses the placenta, they are presumed to be of fetal origin. These observations suggest that certain antigenic stimuli normally cross the placenta to provoke responses, even in uninfected fetuses. Some atopic infants occasionally have IgE antibodies to antigens, such as egg white, to which they have had no known exposure during postnatal life, suggesting that synthesis of these antibodies could have been induced in the fetus by antigens ingested by the mother.

**Natural Killer–Cell Development**

NK cell activity is found in human fetal liver cells at 8-11 wk of gestation. NK lymphocytes are also derived from bone marrow precursors. Thymic processing is not necessary for NK-cell development, although NK cells have been found in the thymus. After release from bone marrow, NK cells enter the circulation or migrate to the spleen, with very few NK cells in lymph nodes. In normal individuals, NK cells represent 8–10% of lymphocytes. Certain tissues harbor large numbers of NK cells.

Unlike T and B cells, NK cells do not rearrange antigen receptor genes during their development but are defined by their functional capacity to mediate non–antigen-specific cytotoxicity. NK cells have killer inhibitory receptors that
recognize certain MHC antigens and inhibit the killing of self tissues. NK-activating receptors recognize stress protein, and the balance of activating and inhibitory receptor engagement determines the action of the NK cells. If a viral infection drives down MHC class I expression, the loss of inhibitory function drives cytotoxicity. High levels of stress proteins, typically seen in viral infections, can also activate cytotoxicity.

**Lymphocyte Choreography**

The main functions of T cells are to signal B cells to make antibody, to kill virally infected cells or tumor cells, and to activate macrophages for intracellular killing. The subset of regulatory T cells (Tregs), is critical in the prevention of autoimmune responses. T cells are activated by antigen presented by antigen-presenting cells (APCs). These are usually dendritic cells, macrophages, or B cells. For high-affinity binding of T cells to APCs, several molecules on T cells, in addition to TCRs, bind to molecules on APCs or target cells. The CD4 molecule binds directly to MHC class II molecules on APCs. CD8 on cytotoxic T cells binds the MHC class I molecule on the target cell. Lymphocyte function–associated antigen 1 (LFA-1) on the T cell binds a protein called ICAM-1 (intracellular adhesion molecule 1), designated CD54, on APCs. CD2 on T cells binds LFA-3 (CD58) on the APCs. With the adhesion of T cells to APCs (the immunologic synapse), T-helper (Th) cells are stimulated to make interleukins and upregulate cell surface molecules, such as the CD40 ligand (CD154), that provide help for B cells, and cytotoxic T cells are stimulated to kill their targets. A key safety net to ensure appropriate activation of T cells in the setting of a true threat is the requirement for co-stimulation of the T cells. APCs that have encountered a pathogen express CD80 and CD86. Engagement of these molecules provides the 2nd, co-stimulatory, signal. Without co-stimulation, the T cell will be rendered anergic, or nonfunctional.

In the primary antibody response, native antigen is carried to a lymph node draining the site, captured by complement, taken up by specialized cells called follicular dendritic cells (FDCs), and expressed on their surfaces. Mature B cells bearing sIgM specific for that antigen then bind to the antigen on the surfaces of the FDCs. If the affinity of the B-cell sIgM antibody for the antigen present on the FDCs is sufficient, and if other signals are provided by activated T cells, the B cell develops into a memory B cells or antibody-producing plasma cell. The signals from activated T cells include several cytokines (IL-4, IL-5, IL-
6, IL-10, IL-13, and IL-21) that they secrete (see Table 149.2) and a surface T-cell molecule, the CD40 ligand or CD154, which, on contact of the activated CD4+ T cell with the B cell, binds to CD40 on the B-cell surface. Binding of CD40 on B cells by CD154 on T cells in the presence of certain cytokines causes the B cells to undergo proliferation and to initiate immunoglobulin synthesis. In the primary immune response, only IgM antibody is usually made, and most of it is of relatively low affinity. Some B cells become memory B cells during the primary immune response. The secondary antibody response occurs when these memory B cells again encounter that antigen. Developing memory B cells switch their Ig genes so that IgG, IgA, and/or IgE antibodies of higher affinity are formed on a secondary exposure to the same antigen. Plasma cells form, just as in the primary response; however, many more cells are rapidly generated, and IgG, IgA, and IgE antibodies are made. In addition, genetic changes in Ig genes (somatic hypermutation) lead to increased affinity of those antibodies.

The exact pattern of isotype response to antigen in normal individuals varies, depending on the type of antigen and the cytokines present in the microenvironment. Both class switching and somatic hypermutation are completely dependent on T-cell help. Thus, T cells represent a kind of gatekeeper for specific antibody production.

**Postnatal Lymphocyte Behavior**

Virtually all T cells in cord blood bear the CD45RA (naïve) isoform, and a dominance of CD45RA over CD45RO T cells persists during childhood. After mid-adulthood, the CD45RO (memory) T cells predominate. CD4 T cells can be further subdivided according to the cytokines they produce when activated. **Th1 cells** produce interleukin (IL)-2 and interferon (IFN)-γ, which promote cytotoxic T-cell or delayed hypersensitivity types of responses, whereas **Th2 cells** produce IL-4, IL-5, IL-6, IL-13, and IL-21 (see Table 149.2), which promote B-cell responses and allergic sensitization, **Th17 cells** produce IL-17, and **Tregs** produce IL-10 (Fig. 149.2). Differentiation into these memory subsets is dictated by the cytokine milieu regulating specific transcription factors and epigenetic changes. In vivo, these subsets are largely stable but in some circumstances can change to a different subset. The importance of these subsets is that memory cells respond to antigen more quickly and are primed to produce the cytokines most likely to drive pathogen clearance.
Newborn infants have increased susceptibility to infections with gram-negative organisms because IgM antibodies, powerful opsonins that enhance phagocytosis, do not cross the placenta. The other major opsonin, C3b, is also lower in newborn serum than in adults. These factors probably account for impaired phagocytosis of some organisms by newborn polymorphonuclear cells. Maternally transmitted IgG antibodies serve quite adequately for most gram-positive bacteria, and IgG antibodies to viruses offer protection against those agents. Because there is a relative deficiency of the IgG2 subclass in infancy, antibodies to capsular polysaccharide antigens may be deficient. Because premature infants have received less maternal IgG by the time of birth than full-term infants, their serum opsonic activity is low for all types of organisms.

Neonates begin to synthesize antibodies of the IgM class at an increased rate very soon after birth in response to the immense antigenic stimulation of their new environment. Premature infants appear to be as capable of doing this as are full-term infants. At about 6 days after birth, the serum concentration of IgM rises sharply. This rise continues until adult levels are achieved by approximately 1 yr of age. Cord serum from noninfected normal newborns does not contain detectable IgA. Serum IgA is normally first detected at around the 13th day of postnatal life but remains low throughout infancy. Cord serum contains an IgG concentration comparable to or greater than that of maternal serum. Maternal...
IgG gradually disappears during the 1st 6-8 mo of life, while the rate of infant IgG synthesis increases (IgG1 and IgG3 faster than IgG2 and IgG4 during the 1st yr) until adult concentrations of total IgG are reached and maintained by 7-8 yr. IgG1 and IgG4 reach adult levels first, followed by IgG3 at 10 yr and IgG2 at 12 yr. The serum IgG level in infants usually reaches a low point at about 3-4 mo of postnatal life. The rate of development of IgE generally follows that of IgA.

After adult concentrations of each of the 3 major immunoglobulins are reached, these levels remain remarkably constant for a normal individual. The capacity to produce specific antibodies to protein antigens is intact at birth, but infants cannot usually produce antibodies to polysaccharide antigens until after 2 yr of age unless the polysaccharide is conjugated to a protein carrier, as is the case for the conjugate *Haemophilus influenzae* type b and *Streptococcus pneumoniae* vaccines.

The percentage of NK cells in cord blood is usually lower than in the blood of children and adults, but the absolute number of NK cells is approximately the same because of the higher lymphocyte count. The capacity of cord blood NK cells to mediate target lysis in either NK-cell assays or antibody-dependent cellular cytotoxicity assays is about two-thirds that of adults.

**Lymphoid Organ Development**

Lymphoid tissue is proportionally small but rather well developed at birth and matures rapidly in the postnatal period. The thymus is largest relative to body size during fetal life and at birth is ordinarily two-thirds its mature weight, which it attains during the 1st yr of life. It reaches its peak mass, however, just before puberty, then gradually involutes thereafter. By 1 yr of age, all lymphoid structures are mature histologically. Absolute lymphocyte counts in the peripheral blood also reach a peak during the 1st yr of life (see Fig. 149.2 ). The spleen, however, gradually accrues its mass during maturation and does not reach full weight until adulthood. The mean number of Peyer patches at birth is one-half the adult number, and gradually increases until the adult mean number is exceeded during adolescent years.

**Inheritance of Abnormalities in T-, B-, and NK-Cell Development**
More than 300 immunodeficiency syndromes have been described. Specific molecular defects have been identified for most diseases. Most are recessive traits with X-linked, autosomal dominant loss of function, and autosomal dominant gain of function also is seen. Defects include those associated with absence of a cell type, either a lineage (e.g., absence of T cells in SCID), absence of a subset of cells (e.g., absence of Tregs in immune dysregulation, polyendocrinopathy, X-linked syndrome), or dysfunction of a cell (e.g., the hemophagocytic lymphohistiocytosis disorders). In some cases, multiple cell types are affected, and in some syndromes, excess of a certain cell type or function disrupts the critical balance needed for immune homeostasis.

**Bibliography**

Of the primary immunodeficiency diseases, those affecting antibody production are the most prevalent. Selective absence of IgA is the most common defect, with rates ranging from 1 in 333 to 1 in 18,000 persons among different races and ethnicities. Patients with antibody deficiency are usually recognized because they have recurrent infections with encapsulated bacteria, predominantly in the upper and lower respiratory tracts. Some individuals with selective IgA deficiency or infants with transient hypogammaglobulinemia may have few or no infections. These conditions have a complex and likely polygenic inheritance, as do the common variable immunodeficiency (CVID) syndromes. The gene defects for many primary antibody deficiency disorders have been identified (Table 150.1) and localized (Fig. 150.1). Sometimes the defect is not in the B cell itself but in T cells, which are required for complete B-cell function. Some disorders are caused by unknown factors or are secondary to an underlying disease or its treatment (Table 150.2).

CVID, Common variable immunodeficiency; EBV, Epstein-Barr virus.
The pre-B cell receives proliferation and differentiation signals through the pre-B-cell receptor (BCR) and the co-receptors Igα and Igβ. Signaling from the pre-BCR involves the immunoreceptor tyrosine-based activation motifs (ITAMs) of the co-receptors Igα and Igβ, which scaffold and activate the tyrosine kinase SYK. SYK either activates the extracellular signal–regulated kinase (ERK) pathway or phosphorylates (P) (together with LYN) the adaptor protein B-cell linker (BLNK) and Bruton tyrosine kinase (BTK), leading to the activation of phospholipase Cy2 (PLCy2) and the phosphoinositide-3 kinase (PI3K) pathway. Defects in this pathway affect the pre-BCR (in Cµ or pseudo light-chain ε5), the pre-BCR signal transduction molecules Igα and Igβ, the downstream molecules BTK, BLNK, and PI3K, components of the co-stimulatory CD19 complex (CD19, CD21, and CD81), and the B-cell marker CD20. The BCR triggers the canonical nuclear factor-κB (NF-κB) pathway through the scaffolding protein CARD11 and activation of the IκB kinase (IKK) complex (comprising IKKα, IKKβ, and NEMO [NF-κB essential modulator]). IKK activation leads to the phosphorylation and degradation of NF-κB inhibitor-α (IκBα) and the subsequent release of the p50-p65 NF-κB heterodimer, which then translocates to the nucleus to regulate gene transcription (not shown).

Following antigen binding to antigen receptors (e.g., BCR), endoplasmic reticulum Ca^{2+} stores are depleted, STIM1 is activated, and ORAI1 Ca^{2+} release-activated Ca^{2+} channels open, resulting in store-operated Ca^{2+} entry. This influx results in activation of the transcription factor NFAT (nuclear factor of activated T cell). The dashed arrows indicate downstream signaling events. ER, Endoplasmic reticulum; PAD, primary antibody deficiency; PtdIns(4,5)P_2 , phosphatidylinositol-4,5-bisphosphate; PtdIns(3,4,5)P_3 , phosphatidylinositol-3,4,5-trisphosphate. **X-Linked Agammaglobulinemia**

Patients with X-linked agammaglobulinemia (XLA), or Bruton agammaglobulinemia, have a profound defect in B-lymphocyte development resulting in severe hypogammaglobulinemia, an absence of circulating B cells, small to absent tonsils, and no palpable lymph nodes.

**Genetics and Pathogenesis**

The abnormal gene in XLA maps to q22 on the long arm of the X chromosome and encodes the B-cell protein tyrosine kinase Btk (Bruton tyrosine kinase). Btk is a member of the Tec family of cytoplasmic protein tyrosine kinases and is
expressed at high levels in all B-lineage cells, including pre-B cells. Some pre-B cells are found in the bone marrow, but the percentage of peripheral blood B lymphocytes is $<1\%$. The percentage of T cells is increased, ratios of T-cell subsets are normal, and T-cell function is intact. The thymus is normal.

Seven **autosomal recessive defects** have also been shown to result in **agammaglobulinemia with an absence of circulating B cell**s (see Table 150.1), including mutations in the genes encoding (1) the $\mu$ heavy chain gene; (2) the Ig$\alpha$ and (3) Ig$\beta$ signaling molecules; (4) B-cell linker adaptor protein (BLNK); (5) the surrogate light chain, $\lambda5/14.1$; (6) leucine-rich repeat-containing 8 (LRRC8); and (7) the p85$\alpha$ subunit of phosphatidylinositol-3 kinase. These are rare but are clinically indistinguishable from the X-linked form.

### Clinical Manifestations

Most boys afflicted with XLA remain well during the first 6-9 mo of life by virtue of maternally transmitted IgG antibodies. Thereafter, they acquire infections with extracellular pyogenic organisms, such as *Streptococcus pneumoniae* and *Haemophilus influenzae*, unless they are given prophylactic antibiotics or immunoglobulin therapy. Infections include sinusitis, otitis media, pneumonia, or, less often, sepsis or meningitis. Infections with *Mycoplasma* are also particularly problematic. Chronic fungal infections are seen; *Pneumocystis jiroveci* pneumonia rarely occurs. Viral infections are usually handled normally, with the exceptions of hepatitis viruses and enteroviruses. There were several examples of **paralysis** when live polio vaccine was administered to these patients, and chronic, eventually fatal, central nervous system (CNS) infections with various echoviruses and coxsackieviruses have occurred in a significant number of patients. An enterovirus-associated **myositis** resembling dermatomyositis has also been observed. **Neutropenia**, typically seen at diagnosis when infected, can be associated with *Pseudomonas* or staphylococcal infections.

### Diagnosis

The diagnosis of XLA should be suspected if **lymphoid hypoplasia** is found on physical examination (minimal or no tonsillar tissue and no palpable lymph nodes), and serum concentrations of IgG, IgA, IgM, and IgE are far below the 95% confidence limits for appropriate age- and race-matched controls; total
immunoglobulins are usually <100 mg/dL. Levels of natural antibodies to type A and B red blood cell polysaccharide antigens (isohemagglutinins) and antibodies to antigens given during routine immunizations are abnormally low in XLA, whereas they are typically normal in transient hypogammaglobulinemia of infancy. Flow cytometry is an important test to demonstrate the absence of circulating B cells, which will distinguish XLA from most types of CVID, the hyper-IgM syndrome, and transient hypogammaglobulinemia of infancy.

Common Variable Immunodeficiency

CVID is a syndrome characterized by hypogammaglobulinemia. Serum IgG must be <2 standard deviations below the age-adjusted norms, with low IgA and or IgM levels. CVID patients may appear similar clinically to those with XLA in the types of infections experienced and bacterial etiologic agents involved, except that enterovirus meningoencephalitis is rare in patients with CVID (Table 150.3). In contrast to XLA, the sex distribution in CVID is almost equal, the age at onset is later, and infections may be less severe. CVID is the most common of the antibody defects.

Genetics and Pathogenesis

CVID is a phenotypic diagnosis with a polygenic inheritance in most cases.
Genes known to produce the CVID phenotype when mutated include *ICOS* (inducible co-stimulator) deficiency, *SH2DIA* (responsible for X-linked lymphoproliferative disease [XLP]), *CD19, CD20, CD21, CD81, BAFF-R* (B-cell–activating factor of the tumor necrosis factor family of receptors), *TACI* (transmembrane activator, calcium modulator, and cyclophilin ligand interactor). These mutations in aggregate account for <10% of all cases of CVID. With rare exceptions, management of CVID does not depend on a genetic diagnosis. In the setting of atypical infections or autoimmunity, pursuing a genetic diagnosis can be useful because some genetic etiologies can have a poor prognosis and transplantation should be considered.

Despite normal numbers of circulating B cells in many patients and the presence of lymphoid cortical follicles, blood B cells from CVID patients do not differentiate normally into immunoglobulin-producing cells. They may have a deficiency of switched memory B cells.

**Clinical Manifestations**

The serum immunoglobulin and antibody deficiencies in CVID are associated with recurrent sinopulmonary infections. Repeated pulmonary infections may produce bronchiectasis. Sepsis and meningitis with encapsulated bacteria occur more frequently than in the general population. Patients with recurrent infections as their only manifestation typically have a normal life expectancy and do well with immunoglobulin replacement. The presence of autoimmune disease or lymphoproliferation confers a poor prognosis. Patients with CVID often have autoantibody formation and normal-sized or enlarged tonsils and lymph nodes; about 25% of patients have splenomegaly. CVID has also been associated with a sprue-like enteropathy with or without nodular lymphoid hyperplasia of the intestine. Other autoimmune diseases include alopecia areata, hemolytic anemia, thrombocytopenia, gastric atrophy, achlorhydria, and pernicious anemia. Lymphoid interstitial pneumonia, intestinal lung disease, pseudolymphoma, B-cell lymphomas, amyloidosis, and noncaseating sarcoid-like granulomas of the lungs, spleen, skin, and liver also occur. There is an increased risk of lymphomas.

**Selective IgA Deficiency**

An isolated absence or near absence (<5 mg/dL) of serum and secretory IgA is
the most common well-defined immunodeficiency disorder, with a disease frequency as high as 0.33% in some populations. Patients may be asymptomatic or may develop sinopulmonary or gastrointestinal (GI) infections (especially *Giardia*). IgA deficiency is also associated with celiac disease and autoimmune disorders. The diagnosis cannot be made until about 4 yr of age, when IgA levels should be matured to adult levels.

The basic defect resulting in IgA deficiency is unknown. Phenotypically normal blood B cells are present. This defect also often occurs in pedigrees containing individuals with CVID. Indeed, IgA deficiency may evolve into CVID. IgA deficiency is noted in patients treated with the same drugs associated with producing CVID (phenytoin, L-penicillamine, gold, and sulfasalazine), suggesting that environmental factors may trigger this disease in a genetically susceptible person.

**Clinical Manifestations**

Infections occur predominantly in the respiratory, GI, and urogenital tracts. Bacterial agents responsible are the same as in other antibody deficiency syndromes. Intestinal giardiasis is common. Serum concentrations of other immunoglobulins are usually normal in patients with selective IgA deficiency, although IgG2 (and other) subclass deficiency has been reported.

Serum antibodies to IgA are reported in as many as 44% of patients with selective IgA deficiency. These antibodies can cause nonhemolytic transfusion reactions. Washed erythrocytes (frozen blood would have this done routinely) or blood products from other IgA-deficient individuals should be administered to patients with IgA deficiency. Many intravenous immune globulin (IVIG) preparations contain sufficient IgA to cause reactions. However, administration of IVIG, which is >99% IgG, is not indicated because most IgA-deficient patients make IgG antibodies normally.

**IgG Subclass Deficiencies**

Some patients have deficiencies of 1 or more of the 4 subclasses of IgG despite normal or elevated total IgG serum concentration. Some patients with absent or very low concentrations of IgG2 also have IgA deficiency. Other patients with IgG subclass deficiency have gone on to develop CVID, suggesting that the presence of IgG subclass deficiency may be a marker for more generalized
immune dysfunction. The biologic significance of the numerous moderate deficiencies of IgG subclasses that have been reported is difficult to assess. IgG subclass measurement is not cost-effective in evaluating immune function in the child with recurrent infection. The more relevant issue is a patient's capacity to make specific antibodies to protein and polysaccharide antigens, because profound deficiencies of antipolysaccharide antibodies have been noted even in the presence of normal concentrations of IgG2. IVIG should not be administered to patients with IgG subclass deficiency unless they are shown to have a deficiency of antibodies to a broad array of antigens.

**Immunoglobulin Heavy- and Light-Chain Deletions**

Some completely asymptomatic individuals have been documented to have a total absence of IgG1, IgG2, IgG4, and/or IgA1 as a result of gene deletions. These patients illustrate the importance of assessing specific antibody formation before deciding to initiate IVIG therapy in IgG subclass–deficient patients.

**Transient Hypogammaglobulinemia of Infancy**

A common laboratory finding in infants, transient hypogammaglobulinemia represents developmental delay in the production of immunoglobulin. It is thought to occur in as many as 1:1000 children. Most infants begin to produce IgG in the 1st 3 mo of life, and the quantity produced increases throughout infancy. For reasons incompletely understood, a small number of infants either begin late or do not increases their production as expected. This condition will resolve with no intervention but represents a source of diagnostic confusion. A key distinction is that responses to vaccines are usually preserved in this condition, whereas in the others, responses will be low to absent.

**Class Switch Defects**

The *hyper-IgM syndrome* is genetically heterogeneous and characterized by normal or elevated serum IgM levels associated with low or absent IgG, IgA,
and IgE serum levels, indicating a defect in the class switch recombination (CSR) process. Causative mutations have been identified in the CD40 ligand gene on the X chromosome and 3 genes on autosomal chromosomes: the activation-induced cytidine deaminase (AID) gene, the uracil DNA glycosylase gene (UNG), and the CD40 gene on chromosome 20. Distinctive clinical features permit presumptive recognition of the type of mutation in these patients, thereby aiding proper choice of therapy. All such patients should undergo molecular analysis to ascertain the affected gene for purposes of genetic counseling, carrier detection, and decisions regarding definitive therapy.

**X-Linked Hyper-IgM Caused by Mutations in CD40 Ligand Gene**

X-linked hyper IgM is caused by mutations in the gene that encodes the CD40 ligand (CD154, CD40L), which is expressed on activated T-helper (Th) cells. Boys with this syndrome have very low serum concentrations of IgG and IgA, with a usually normal or sometimes elevated concentration of polyclonal IgM; may or may not have small tonsils; usually have no palpable lymph nodes; and often have profound neutropenia.

**Genetics and Pathogenesis**

The B cells are actually normal in this condition; the defect is in the T cells. CD40L is the ligand for CD40, which is present on B cells and monocytes. CD40L is upregulated on activated T cells. Mutations result in an inability to signal B cells to undergo isotype switching, and thus the B cells produce only IgM. The failure of T cells to interact with B cells through this receptor-ligand pair also causes a failure of upregulation of the B-cell and monocyte surface molecules CD80 and CD86 that interact with CD28/CTLA4 on T cells, resulting in failure of “crosstalk” between immune system cells.

**Clinical Manifestations**

Similar to patients with XLA, boys with the CD40 ligand defect become symptomatic during the 1st or 2nd yr of life with recurrent pyogenic infections, including otitis media, sinusitis, pneumonia, and tonsillitis. They have marked susceptibility to *P. jiroveci* pneumonia and can be neutropenic. Lymph node histology shows only abortive germinal center formation with severe depletion
and phenotypic abnormalities of follicular dendritic cells. These patients have normal numbers of circulating B lymphocytes, but a decreased frequency of CD27+ memory B cells. Circulating T cells are also present in normal number and in vitro responses to mitogens are normal, but there is decreased antigen-specific T-cell function. In addition to opportunistic infections such as P. jiroveci pneumonia, there is an increased incidence of extensive verruca vulgaris lesions, Cryptosporidium enteritis, subsequent liver disease, and an increased risk of malignancy.

**Treatment**

Because of the poor prognosis, the treatment of choice is an HLA-identical hematopoietic stem cell transplant at an early age. Alternative treatment for this condition is monthly infusion of IVIG. In patients with severe neutropenia, the use of granulocyte colony-stimulating factor has been beneficial.

**Autosomal Recessive Hyper-IgM**

**Genetics and Pathogenesis**

In contrast to patients with the CD40L defect, B cells from these patients are not able to switch from IgM-secreting to IgG-, IgA-, or IgE-secreting cells, even when co-cultured with normal T cells. The defects are all B cell intrinsic. The most common autosomal recessive defect in a gene that encodes AID. AID deaminates cytosine into uracil in targeted DNA, which is followed by uracil removal by UNG. Severely impaired CSR was found in 3 hyper-IgM patients reported to have UNG deficiency. Their clinical characteristics were similar to those with AID deficiency, with increased susceptibility to bacterial infections and lymphoid hyperplasia. Histologic examination of the enlarged lymph nodes reveals the presence of giant germinal centers (5-10 times > normal) filled with highly proliferating B cells. Autosomal recessive hyper-IgM can be caused by defects in CD40. Clinical manifestations included recurrent sinopulmonary infections, P. jiroveci pneumonia, and Cryptosporidium parvum infections, very similar to the manifestations seen in X-linked hyper IgM syndrome.

**Clinical Manifestations**

Concentrations of serum IgG, IgA, and IgE are very low in AID, UNG, and CD40 deficiencies. In contrast to the CD40 ligand defect, however, the serum
IgM concentration in patients with AID deficiency is usually markedly elevated and polyclonal. Patients with AID and UNG mutations have lymphoid hyperplasia, are generally older at age at onset, do not have susceptibility to *P. jiroveci* pneumonia, often do have isohemagglutinins, and are much less likely to have neutropenia unless it occurs on an autoimmune basis. They have a tendency, however, to develop autoimmune and inflammatory disorders, including diabetes mellitus, polyarthritis, autoimmune hepatitis, hemolytic anemia, immune thrombocytopenia, Crohn disease, and chronic uveitis.

**Treatment and Prognosis**
With early diagnosis and monthly infusions of IVIG, as well as good management of infections with antibiotics, patients with AID and UNG mutations generally have a more benign course than do boys with the CD40L or CD40 defects. CD40 deficiency is rare but appears to mimic the manifestations of CD40L quite closely.

**X-Linked Lymphoproliferative Disease**
There are two types of X-linked lymphoproliferative disease ([Table 150.4](#)). They have distinct clinical features but share a susceptibility to *Epstein-Barr virus* (*EBV*) and the development of *hemophagocytic lymphohistiocytosis* (*HLH*).

### Genetics and Pathogenesis

The defective gene in **XLP type I** was localized to Xq25, cloned, and the gene product was initially named SAP (SLAM-associated protein), but is now known officially as SH2D1A. SLAM (signaling lymphocyte activation molecule) is an adhesion molecule that is upregulated on both T and B cells with infection and other stimulation. The absence of SH2D1A can lead to an uncontrolled cytotoxic T-cell immune response to EBV. The SH2D1A protein associates permissively with 2B4 on natural killer (NK) cells; thus selective impairment of 2B4-mediated NK-cell activation also contributes to the immunopathology of XLP.

**XLP type 2** is caused by a mutation in **XIAP** (X-linked inhibitor of apoptosis protein). Disease manifestations are similar to XLP. The precise role of this protein in the susceptibility to EBV has not been elucidated.

### Clinical Manifestations

Affected males are usually healthy until they acquire EBV infection. The mean age of presentation is <5 yr. There are 3 major clinical phenotypes: (1) fulminant, often fatal, infectious mononucleosis (50% of cases); (2) lymphomas, predominantly involving B-lineage cells (25%); and (3) acquired hypogammaglobulinemia (25%). A less common manifestation is CNS vasculitis. There is a marked impairment in production of antibodies to the EBV
nuclear antigen, whereas titers of antibodies to the viral capsid antigen have ranged from absent to greatly elevated. XLP has an unfavorable prognosis. Unless there is a family history of XLP, diagnosis before the onset of complications is difficult because affected individuals are asymptomatic initially.

In 2 pedigrees reported, boys in one arm of each pedigree were diagnosed with CVID, whereas those in the other arms had fulminant infectious mononucleosis. The family members with CVID never gave a history of infectious mononucleosis. All affected members of each pedigree had the same distinct SH2D1A mutation, however, despite the different clinical phenotypes. Because the SH2D1A mutation was the same but the phenotype varied in these families, XLP should be considered in all males with a diagnosis of CVID, particularly if there is more than 1 male family member with this phenotype.

150.1
Treatment of B-Cell Defects

Kathleen E. Sullivan, Rebecca H. Buckley

Except for the CD40 ligand defect and XLP, for which stem cell transplantation is recommended, judicious use of antibiotics to treat documented infections and regular administration of immunoglobulin are the only effective treatments for primary B-cell disorders. The most common forms of replacement therapy are either intravenous or subcutaneous immune globulin (IVIG or SCIG). Broad antibody deficiency should be carefully documented before such therapy is initiated. The rationale for the use of IVIG or SCIG is to provide missing antibodies, not to raise the serum IgG or IgG subclass level. The development of safe and effective immunoglobulin preparations is a major advance in the treatment of patients with severe antibody deficiencies, although it is expensive and there have been national shortages. Almost all commercial preparations are isolated from normal plasma by the Cohn alcohol fractionation method or a modification of it. Cohn fraction II is then further treated to remove aggregated IgG. Additional stabilizing agents such as sugars, glycine, and albumin are
added to prevent reaggregation and protect the IgG molecule during lyophilization. The ethanol used in preparation of immunoglobulin inactivates HIV, and an organic solvent/detergent step inactivates hepatitis B and C viruses. Some preparations are also nanofiltered to remove infectious agents. Most commercial lots are produced from plasma pooled from 10,000 to 60,000 donors and therefore contain a broad spectrum of antibodies. Each pool must contain adequate levels of antibody to antigens in various vaccines, such as tetanus and measles. However, there is no standardization based on titers of antibodies to more clinically relevant organisms, such as S. pnemoniae and H. influenzae type b.

The IVIG and SCIG preparations available in the United States have similar efficacy and safety. Rare transmission of hepatitis C virus has occurred in the past, but this has been resolved by the additional treatment step. There has been no documented transmission of HIV by any of these preparations. **IVIG or SCIG at a dose of 400 mg/kg per month** achieves trough IgG levels close to the normal range. Higher doses are indicated in patients with chronic or severe respiratory infections. Systemic reactions may occur, but rarely are these true anaphylactic reactions. Neutropenia associated with B-cell defects has responded to granulocyte colony-stimulating factor.

**Bibliography**

Resnick ES, Moshier EL, Godbold JH, et al. Morbidity and mortality in common variable immune deficiency over 4
Defects in cellular immunity, historically referred to *T-cell defects*, comprise a large number of distinct immune deficiencies. The manifestations usually include prolonged viral infections, opportunistic fungal or mycobacterial infections, and a predisposition to autoimmunity. To facilitate conceptualization of this large and complex category, this chapter describes immunodeficiencies where the defect primarily affects T cells and those where the defect alters function of many cell types. Chapter 152.1 describes severe combined immunodeficiency (SCID). These disorders are further approached clinically by considering whether or not nonhematologic features are present.

**Chromosome 22Q11.2 Deletion Syndrome**

Chromosome 22q11.2 deletion syndrome is the most common of the T-cell disorders, occurring in about 1 in 3,000 births in the United States. Chromosome 22q11.2 deletion disrupts development of the 3rd and 4th pharyngeal pouches during early embryogenesis, leading to hypoplasia or aplasia of the thymus and parathyroid glands. Other structures forming at the same age are also frequently affected, resulting in anomalies of the great vessels (right-sided aortic arch), esophageal atresia, bifid uvula, congenital heart disease (conotruncal, atrial, and ventricular septal defects), a short philtrum of the upper lip, hypertelorism, an antimongoloid slant to the eyes, mandibular hypoplasia, and posteriorly rotated ears (see Chapters 98 and 128). The diagnosis is often first suggested by hypocalcemic seizures during the neonatal period.
Genetics and Pathogenesis

Chromosome 22q11.2 deletions occur with high frequency because complex repeat sequences that flank the region represent a challenge for DNA polymerase. This condition is inherited in an autosomal dominant fashion and occurs with comparable frequency in all populations. Within the deleted region, haplosufficiency for the TBX1 transcription factor appears to underlie the majority of the phenotype. The phenotype is highly variable; a subset of patients has a phenotype that has also been called DiGeorge syndrome, velocardiofacial syndrome, or conotruncal anomaly face syndrome.

Variable hypoplasia of the thymus occurs in 75% of the patients with the deletion, which is more frequent than total aplasia; aplasia is present in <1% of patients with 22q11.2 deletion syndrome. Slightly less than half of patients with complete thymic aplasia are hemizygous at chromosome 22q11.2. Approximately 15% are born to diabetic mothers. Another 15% of infants have no identified risk factors. Approximately one third of infants with complete DiGeorge syndrome have CHARGE association (c oloboma, h eart defect, choanal a tresia, growth or developmental r etardation, g enital hypoplasia, and e ar anomalies including deafness). Mutations in the chromodomain helicase DNA-binding protein 7 (CHD7) gene on chromosome 8q12.2 are found in approximately 60–65% of individuals with CHARGE syndrome; a minority have mutations in SEMA3E.

Absolute lymphocyte counts are usually only moderately low for age. The CD3 T-cell counts are variably decreased in number, corresponding to the degree of thymic hypoplasia. Lymphocyte responses to mitogen stimulation are absent, reduced, or normal, depending on the degree of thymic deficiency. Immunoglobulin levels are often normal, but there is an increased frequency of IgA deficiency, low IgM levels, and some patients develop progressive hypogammaglobulinemia.

Clinical Manifestations

Children with partial thymic hypoplasia may have little trouble with infections and grow normally. Patients with thymic aplasia resemble patients with SCID in their susceptibility to infections with low-grade or opportunistic pathogens, including fungi, viruses, and Pneumocystis jiroveci, and to graft-versus-host disease from nonirradiated blood transfusions. Patients with complete DiGeorge
syndrome can develop an atypical phenotype in which oligoclonal T-cell populations appear in the blood associated with rash and lymphadenopathy. These atypical patients appear phenotypically similar to patients with Omenn syndrome or maternal T-lymphocyte engraftment.

It is critical to ascertain in a timely manner whether an infant has thymic aplasia, because this disease is fatal without treatment. A T-cell count should be obtained on all infants born with primary hypoparathyroidism, CHARGE syndrome, and conotruncal cardiac anomalies with syndromic features. Some infants are being identified by newborn screening for SCID and when 22q11.2 deletion is suspected, a calcium level should be obtained at the time of T-cell evaluation. The 3 manifestations with the highest morbidity in early infancy are profound immunodeficiency, severe cardiac anomaly, and seizures from hypocalcemia. Thus an early focus on these concerns is warranted even before the diagnosis is confirmed. Affected patients may develop autoimmune cytopenias, juvenile idiopathic arthritis, atopy, and malignancies (lymphomas).

**Treatment**

The immunodeficiency in thymic aplasia is correctable by cultured unrelated thymic tissue transplants. Some infants with thymic aplasia have been given nonirradiated unfractionated bone marrow or peripheral blood transplants from a human leukocyte antigen–identical sibling, with subsequent improved immune function because of adoptively transferred T cells. Infants and children with low T-cell counts but not low enough to consider transplantation should be monitored for evolution of immunoglobulin defects. Infections in these patients are multifactorial. Their anatomy may not favor drainage of secretions; they have a higher rate of atopy, which may complicate infections; and their host defense may allow persistence of infections. Interventions range from hand hygiene, probiotics, prophylactic antibiotics, and risk management to immunoglobulin replacement for those who have demonstrated defective humoral immunity.

**T-Cell Activation Defects**

T-cell activation defects are characterized by the presence of normal or elevated numbers of blood T cells that appear phenotypically normal but fail to proliferate or produce cytokines normally in response to stimulation with mitogens, antigens, or other signals delivered to the TCR, owing to defective signal
transduction from the TCR to intracellular metabolic pathways (Fig. 151.1).

These patients have problems similar to those of other T-cell–deficient individuals, and some with severe T-cell activation defects may clinically resemble SCID patients (Table 151.1). In some cases, susceptibility to a single pathogen or a limited number of pathogens dominates the clinical phenotype. Susceptibility to Epstein-Barr virus, cytomegalovirus, and papillomavirus is common in this set of T-cell defects. Most individuals with significant T-cell activation defects will require a hematopoietic stem cell transplant. Although each infection may be manageable early in life, the long-term prognosis is not favorable in many of these conditions.

**Chronic Mucocutaneous Candidiasis**

Chronic mucocutaneous candidiasis (CMC) is a syndrome characterized by impaired immune responsiveness to Candida. Some of the known gene defects with CMC have autoimmune polyendocrinopathy syndrome type 1 (APS1, or autoimmune polyendocrinopathy-candidiasis–ectodermal dystrophy [APECED]). One of the other genetic types of CMC is associated with autoimmunity and predisposition to other infections (STAT1 gain-of-function mutations). However, most of the specific genetic types of CMC have isolated susceptibility to Candida. These types of CMC relate to defects in the Th17 cell pathway. Autosomal recessive deficiency in the interleukin-17 receptor A (IL-17RA) chain, and an autosomal dominant deficiency of the cytokine IL-17F are both associated with predisposition to Candida. Other immunodeficiencies in which Candida occurs in the context of other infections also affect the Th17 cells. Another CMC genetic type, caused by mutations in CARD9, has a strong predisposition to Candida but also to other fungi.
Although the underlying gene defects are varied, the clinical presentation of CMC is usually similar. Symptoms can begin in the 1st mo of life or as late as the 2nd decade. The disorder is characterized by chronic and severe Candida skin and mucous membrane infections. Patients rarely develop systemic Candida disease, except as noted below. Topical antifungal therapy can provide limited improvement early in the course of the disease, but systemic courses of azoles are usually necessary; antifungal resistance often develops later in life. The infection usually responds temporarily to treatment, but it is not eradicated and recurs. Patients with CARD9 gene mutations have a more severe fungal susceptibility than typical CMC patients. Two described patients with CARD9 mutations had fungal sepsis in addition to CMC; deep tissue dermatophyte infections were also present.

**Autoimmune Polyendocrinopathy-Candidiasis-Ectodermal Dysplasia**

Patients with this syndrome present with CMC and autoimmune polyendocrinopathy, usually developing hypoparathyroidism and Addison disease before adulthood. Additional features include male and female hypogonadism, chronic active hepatitis, alopecia, vitiligo, pernicious anemia, enamel hypoplasia, type 1 diabetes, asplenia, malabsorption, interstitial nephritis, hypothyroidism, hypopituitarism, and Sjögren syndrome. APECED, or APS1, is caused by a mutation in the autoimmune regulator (AIRE) gene (see Table 151.1 ). The gene product, AIRE, is expressed at high levels in purified human thymic medullary stromal cells and is thought to regulate the cell surface expression of tissue-specific proteins such as insulin and thyroglobulin. Expression of these self proteins allows for the negative selection of autoreactive T cells during their development. Failure of negative selection results in organ-specific autoimmune destruction.

Reichenbach J, Schubert R, Horvath R, et al. Fatal neonatal-
The manifestations of immune deficiencies that affect multiple cell types range from profound to mild; these conditions can present with severe infection, recurrent infections, unusual infections, or autoimmunity. The most profound disorder is severe combined immunodeficiency. Other combined immunodeficiencies include defects of innate immunity and defects leading to immune dysregulation; the latter category is typically associated with profound autoimmunity. Combined immunodeficiencies are characterized by a predisposition to viral infections, and the innate immunodeficiencies are susceptible to a range of bacteria.

152.1

Severe Combined Immunodeficiency

Kathleen E. Sullivan, Rebecca H. Buckley

Keywords

SCID
newborn screening
lymphoid development

Severe combined immunodeficiency (SCID) is caused by diverse genetic mutations that lead to absence of T- and B-cell function. Patients with this group of disorders have the most severe immunodeficiency.

**Pathogenesis**

SCID is caused by mutations in genes crucial for lymphoid cell development (Table 152.1 and Fig. 152.1). All patients with SCID have very small thymuses that contain no thymocytes and lack corticomedullary distinction or Hassall corpuscles. The thymic epithelium appears histologically normal. Both the follicular and the paracortical areas of the spleen are depleted of lymphocytes. Lymph nodes, tonsils, adenoids, and Peyer patches are absent or extremely underdeveloped.

Clinical Manifestations

SCID is included in the newborn screening program in many states. Thus, infants are identified prior to symptoms, which has dramatically improved the survival of infants with SCID. A few genetic types of SCID are not detected by newborn screening, and there are a few states where newborn screening for SCID is not yet performed.

When infants with SCID are not detected through newborn screening, they most often present with infection. Diarrhea, pneumonia, otitis media, sepsis, and cutaneous infections are common presentations. Infections with a variety of opportunistic organisms, either through direct exposure or immunization, can lead to death. Potential threats include Candida albicans, Pneumocystis jiroveci, parainfluenza 3 virus, adenovirus, respiratory syncytial virus (RSV), rotavirus vaccine, cytomegalovirus (CMV), Epstein-Barr virus (EBV), varicella-zoster virus, measles virus, MMRV (measles, mumps, rubella, varicella) vaccine, or bacille Calmette-Guérin (BCG) vaccine. Affected infants also lack the ability to reject foreign tissue and are therefore at risk for severe or fatal graft-versus-host disease (GVHD) from T lymphocytes in nonirradiated blood products or maternal immunocompetent T cells that crossed the placenta while the infant was in utero. This devastating presentation is characterized by expansion of the allogeneic cells, rash, hepatosplenomegaly and diarrhea. A 3rd presentation is often called Omenn syndrome, in which a few cells generated in the infant expand and cause a clinical picture similar to GVHD (Fig. 152.2). The difference in this case is that the cells are the infant's own cells.
A key feature of SCID is that almost all patients will have a low lymphocyte count. A combination of opportunistic infections and a persistently low lymphocyte count is an indication to test for SCID. The diagnostic strategy both for symptomatic infants and those detected by newborn screening is to perform flow cytometry to quantitate the T, B, and natural killer (NK) cells in the infant. The CD45RA and CD45RO markers can be helpful to distinguish maternal engraftment and Omenn syndrome. T-cell function is also often assessed by measuring proliferative responses to stimulation.

All genetic types of SCID are associated with profound immunodeficiency. A small number have other associated features or atypical features that are important to recognize. Adenosine deaminase (ADA) deficiency can be associated with pulmonary alveolar proteinosis and chondroosseous dysplasia. Adenylate kinase 2 (AK2) deficiency causes a picture referred to as **reticular dysgenesis** where neutrophils, myeloid cells, and lymphocytes are all low. This condition is also often associated with deafness.
Treatment

SCID is a true pediatric immunologic emergency. Unless immunologic reconstitution is achieved through hematopoietic stem cell transplantation (HSCT) or gene therapy, death usually occurs during the 1st yr of life and almost invariably before 2 yr of age. HSCT in an infant prior to infection is associated with a 95% survival rate. ADA-deficient SCID and X-linked SCID have been treated successfully with gene therapy. Early trials of gene therapy were associated with a risk of malignancy, but this has not been seen in trials with new vectors. ADA-deficient SCID can also be treated with repeated injections of polyethylene glycol–modified bovine ADA (PEG-ADA), although the immune reconstitution achieved is not as effective as with stem cell or gene therapy.

Genetics

The 4 most common types of SCID are the X-linked form, caused by mutations in CD132; autosomal recessive RAG1 and RAG2 deficiencies; and ADA deficiency. Additional forms are listed in Table 152.1. For X-linked SCID and ADA deficiency, gene therapy exists, but genetic counseling is the most compelling reason for genetic sequencing to identify the gene defect. Several specific gene defects are associated with increased sensitivity to radiation and chemotherapy, and their early identification can lead to a better transplant experience.

Sequencing is often done by requesting a SCID gene panel. There are certain laboratory features that predict specific gene defects. When both T cells and B cells are low, often a gene encoding a protein involved in V(D)J recombination is the cause. Similarly, certain cytokine receptor defects are associated with specific lymphocyte phenotypes.

Hypomorphic mutations in genes most often associated with SCID can lead to varied phenotypes. This condition is often referred to as leaky SCID, referring to the mutation being “leaky” for some lymphocyte development. Leaky phenotypes range from the dramatic Omenn syndrome phenotype to later-onset immunodeficiency, granulomas, and autoimmunity.

Bibliography

152.2

**Combined Immunodeficiency**

*Kathleen E. Sullivan, Rebecca H. Buckley*

**Keywords**

cartilage-hair hypoplasia
Wiskott-Aldrich syndrome
lymphopenia

Combined immunodeficiency (CID) is distinguished from SCID by the presence of low but not absent T-cell function. CID is a syndrome of diverse genetic causes. Patients with CID have recurrent or chronic pulmonary infections, failure to thrive, oral or cutaneous candidiasis, chronic diarrhea, recurrent skin infections, gram-negative bacterial sepsis, urinary tract infections, and severe varicella in infancy. Although they usually survive longer than infants with SCID, they fail to thrive and often die before adulthood. Neutropenia and eosinophilia are common. Serum immunoglobulins may be normal or elevated for all classes, but selective IgA deficiency, marked elevation of IgE, and elevated IgD levels occur in some cases. Although antibody-forming capacity is impaired in most patients, it is not absent.

Studies of cellular immune function show lymphopenia, deficiencies of T
cells, and extremely low but not absent lymphocyte proliferative responses to mitogens, antigens, and allogeneic cells in vitro. Peripheral lymphoid tissues demonstrate paracortical lymphocyte depletion. The thymus is usually small, with a paucity of thymocytes and usually no Hassall corpuscles.

**Cartilage-Hair Hypoplasia**

Cartilage-hair hypoplasia (CHH) is an unusual form of short-limbed dwarfism with frequent and severe infections. It occurs with a high frequency among the Amish and Finnish people.

**Genetics and Pathogenesis**

CHH is an autosomal recessive condition. Numerous mutations that cosegregate with the CHH phenotype have been identified in the untranslated RNase MRP (RMRP) gene. The RMRP endoribonuclease consists of an RNA molecule bound to several proteins and has at least 2 functions: cleavage of RNA in mitochondrial DNA synthesis and nucleolar cleaving of pre-RNA. Mutations in RMRP cause CHH by disrupting a function of RMRP RNA that affects multiple organ systems. In vitro studies show decreased numbers of T cells and defective T-cell proliferation because of an intrinsic defect related to the G1 phase, resulting in a longer cell cycle for individual cells. NK cells are increased in number and function.

**Clinical Manifestations**

Clinical features include short, pudgy hands; redundant skin; hyperextensible joints of hands and feet but an inability to extend the elbows completely; and fine, sparse, light hair and eyebrows. Infections range from mild to severe. Associated conditions include deficient erythrogenesis, Hirschsprung disease, and an increased risk of malignancies. The bones radiographically show scalloping and sclerotic or cystic changes in the metaphyses and flaring of the costochondral junctions of the ribs. Some patients have been treated with HSCT.

**Wiskott-Aldrich Syndrome**

Wiskott-Aldrich syndrome is an X-linked recessive disorder characterized by
atopic dermatitis, thrombocytopenic purpura with normal-appearing megakaryocytes but small defective platelets, and susceptibility to infection.

**Genetics and Pathogenesis**

The Wiskott-Aldrich syndrome protein (WASP) binds CDC42H2 and Rac, members of the Rho family of guanosine triphosphatases. WASP controls the assembly of actin filaments required for cell migration and cell-cell interactions.

**Clinical Manifestations**

Patients often have prolonged bleeding from the circumcision site or bloody diarrhea during infancy. The thrombocytopenia is not initially caused by antiplatelet antibodies. **Atopic dermatitis** and **recurrent infections** usually develop during the 1st yr of life. *Streptococcus pneumoniae* and other bacteria having polysaccharide capsules cause otitis media, pneumonia, meningitis, and sepsis. Later, infections with agents such as *P. jiroveci* and the herpesviruses become more frequent. Infections, bleeding, and EBV-associated malignancies are major causes of death.

Patients with this defect uniformly have an impaired humoral immune response to polysaccharide antigens, as evidenced by absent or greatly diminished isohemagglutinins, and poor or absent antibody responses after immunization with polysaccharide vaccines. The predominant immunoglobulin pattern is a low serum level of IgM, elevated IgA and IgE, and a normal or slightly low IgG concentration. Because of their profound antibody deficiencies, these patients should be given immunoglobulin replacement regardless of their serum levels of the different immunoglobulin isotypes. Percentages of T cells are moderately reduced, and lymphocyte responses to mitogens are variably depressed.

**Treatment**

Good supportive care includes appropriate nutrition, immunoglobulin replacement, use of killed vaccines, and aggressive management of eczema and associated cutaneous infections. HSCT is the treatment of choice when a high-quality matched donor is available and is usually curative. Gene-corrected autologous HSCT has resulted in sustained benefits in 6 patients.
Ataxia-Telangiectasia

Ataxia-telangiectasia is a complex syndrome with immunologic, neurologic, endocrinologic, hepatic, and cutaneous abnormalities.

Genetics and Pathogenesis

The ataxia-telangiectasia mutation (ATM) gene encodes a protein critical for responses to DNA damage. Cells from patients, as well as from heterozygous carriers, have increased sensitivity to ionizing radiation, defective DNA repair, and frequent chromosomal abnormalities.

In vitro tests of lymphocyte function have generally shown moderately depressed proliferative responses to T- and B-cell mitogens. Percentages of CD3 and CD4 T cells are moderately reduced, with normal or increased percentages of CD8 and elevated numbers of γ/δ T cells. The thymus is very hypoplastic, exhibits poor organization, and lacks Hassall corpuscles.

Clinical Manifestations

The most prominent clinical features are progressive cerebellar ataxia, oculocutaneous telangiectasias, chronic sinopulmonary disease, a high incidence of malignancy, and variable humoral and cellular immunodeficiency. Ataxia typically becomes evident soon after these children begin to walk and progresses until they are confined to a wheelchair, usually by age 10-12 yr. The telangiectasias begin to develop at 3-6 yr. The most frequent humoral immunologic abnormality is the selective absence of IgA, which occurs in 50–80% of these patients. IgG2 or total IgG levels may be decreased, and specific antibody titers may be decreased or normal. Recurrent sinopulmonary infections occur in approximately 80% of these patients. Although common viral infections have not usually resulted in untoward sequelae, fatal varicella has occurred. The malignancies associated with ataxia-telangiectasia are usually of the lymphoreticular type, but adenocarcinomas also occur. Unaffected carriers of mutations have an increased incidence of malignancy.

Therapy in ataxia-telangiectasia is supportive.

Autosomal Dominant Hyper-IgE
**Syndrome**

This syndrome is associated with early-onset atopy and recurrent skin and lung infections.

**Genetics and Pathogenesis**

The autosomal dominant hyper-IgE syndrome is caused by heterozygous mutations in the gene encoding signal transducer and activator of transcription 3 (STAT-3). These mutations result in a dominant negative effect. The many clinical features are caused by compromised signaling downstream of the interleukin (IL)-6, type I interferon, IL-22, IL-10 and epidermal growth factor (EGF) receptors.

**Clinical Manifestations**

The characteristic clinical features are staphylococcal abscesses, pneumatoceles, osteopenia, and unusual facial features. There is a history from infancy of recurrent staphylococcal abscesses involving the skin, lungs, joints, viscera, and other sites. Persistent pneumatoceles develop as a result of recurrent pneumonia. Patients often have a history of sinusitis and mastoiditis. *Candida albicans* is the 2nd most common pathogen. Allergic respiratory symptoms are usually absent. The pruritic dermatitis that occurs is not typical atopic eczema and does not always persist. There can be a prominent forehead, deep-set wide-spaced eyes, a broad nasal bridge, a wide fleshy nasal tip, mild prognathism, facial asymmetry, and hemihypertrrophy, although these are most evident in adulthood. In older children, delay in shedding primary teeth, recurrent fractures, and scoliosis occur.

These patients demonstrate an **exceptionally high serum IgE concentration**; an elevated serum IgD concentration; usually normal concentrations of IgG, IgA, and IgM; pronounced blood and sputum eosinophilia; and poor antibody and cell-mediated responses to neoantigens. Traditionally, IgE levels >2000 IU/mL confirm the diagnosis. However, IgE levels may fluctuate and even decrease in adults. In neonates and infants with the pruritic pustular dermatosis, IgE levels will be elevated for age and are usually in the 100s. In vitro studies show normal percentages of blood T, B, and NK lymphocytes, except for a decreased percentage of T cells with the memory (CD45RO) phenotype and an absence or
deficiency of T-helper type 17 (Th17) cells. Most patients have normal T-lymphocyte proliferative responses to mitogens but very low or absent responses to antigens or allogeneic cells from family members. Blood, sputum, and histologic sections of lymph nodes, spleen, and lung cysts show striking eosinophilia. Hassall corpuscles and thymic architecture are normal. Therapy is generally directed at prevention of infection using antimicrobials and immunoglobulin replacement.

**DOCK8 Deficiency**

Deficiency of DOCK8 (dedicator of cytokinesis 8) is an autosomal recessive condition that most often presents with impressively severe eczema in infancy and toddlerhood. Cutaneous viral infections and susceptibility to CMV, EBV, and cryptosporidia are common (Fig. 152.3). The infectious susceptibility tends to worsen over time, as do the laboratory features of immune dysfunction, most often low T-cell counts and poor proliferative function. Although these patients can survive to adulthood without transplantation, they suffer many complications and their quality of life is often poor. For this reason, most patients are now transplanted early in life to avoid the later complications.

152.3 Defects of Innate Immunity

*Jennifer R. Heimall, Kathleen E. Sullivan*

**Keywords**

TLR
NK cells
mycobacteria

The innate immune system is the earliest responding feature of host defense in vertebrates. Components include the physical barrier function of the skin and mucosal surfaces, complement, neutrophils, macrophages, dendritic cells (DCs), NK cells, and their associated cytokines. The activation of innate immunity is critically reliant on a group of **pattern recognition receptors (PRRs)** that respond to host infections or tissue damage within minutes. These receptors are all germline encoded and are therefore able to be expressed in all cells, where they serve as critical monitors for the presence of **pathogen-associated molecular patterns (PAMPs)**.
Interferon-γ Receptors 1 and 2, IL-12 Receptor $\beta_1$, and IL-12P40 Defects

Among the best-described defects of innate immunity are those associated with susceptibility to nontuberculous mycobacteria. These defects are associated with abnormalities in the interferon-gamma (IFN-γ)–IL-12 signaling axis.

Pathogenesis
Interleukin-12 is a cytokine secreted by macrophages, neutrophils, and DCs in response to infection with mycobacterial and other microbes. IL-12 then binds to receptors on NK cells and T cells to stimulate secretion of IFN-γ. IFN-γ is critical in the activation of phagocyte secretion of tumor necrosis factor alpha (TNF-α) and destruction of the phagocytosed microbe. IFN-γ activates phagocytes via binding of IFN-γ receptor 1 (IFN-γR1) which is found in a homodimerized form associated with Janus-associated kinase-1 (Jak1) that recruits and binds IFN-γ receptor 2 (IFN-γR2) which is associated with Janus-associated kinase-2 (Jak2). Jak1 and Jak2 are then transphosphorylated, which leads to phosphorylation of IFN-γR1 and subsequent docking of signal transducer and activator of transcription 1 (STAT1). Phosphorylated STAT1 then homodimerizes and translocates to the cell nucleus to induce gene transcription. Deficiency of any of these components has a significant impact on phagocyte activation.

Clinical Manifestations
IFN-γR1 deficiency leads to impaired IFN-γ binding and signaling and inability to form mature granulomas and indicates a risk of susceptibility to *Mycobacteria* species and *Salmonella*. There are both autosomal recessive (AR) and autosomal dominant (AD) forms of this defect. In the AR form are both partial and complete defects. In the complete AR form, patients present with early onset of disseminated *Mycobacteria*, and some have been reported to present with nontyphoid *Salmonella* or *Listeria monocytogenes*. Treatment should be directed at the presenting infection, with multiple antimicrobial agents used without interruption. HSCT has been used once mycobacterial disease is controlled but requires conditioning to permit the myeloid engraftment necessary to correct the underlying disease. In the partial AR form, IFN-γR1 deficiency
remains associated with disseminated *Mycobacteria* and *Salmonella* infections but is managed with symptomatic treatment of infections and consideration of IFN-γ therapy to induce higher serum IFN-γ levels. The AD form is also a partial defect in IFN-γ signaling and most often presents with *Mycobacteria* osteomyelitis, although *Salmonella* and *Histoplasma* infections have also been described. Similar to the partial AR defect, these patients are able to be managed with antimicrobial therapy of infections and supplemental IFN-γ injections. Deficiency of IFN-γR2 is an AR defect that also has partial and complete forms. The complete form is a phenocopy to complete IFN-γR1, presenting with early-onset, severe, and disseminated mycobacterial infections. Treatment involves uninterrupted multidrug therapy for the infections and consideration for HSCT. A partial form of IFN-γR2 also presents with mild but potentially disseminated *Mycobacteria* or *Salmonella* infections, which can be controlled with antibiotic therapy that can be stopped once the infection is resolved.

Deficiencies of the IL-12 receptor (IL-12R) components have also been described as inherited in an AR fashion, with defects in both the IL-12p40 chain as well as the shared IL-12/IL-23Rβ1, causing impaired IFN-γ secretion and resultant susceptibility to *Mycobacteria* and *Salmonella*. Both forms of IL-12R defects are characterized by relatively mild disease, with some ability to form granulomatous lesions in response to *Mycobacteria* infections. These defects can usually be managed with antimicrobials and supplemental IFN-γ. Partial defects in STAT1, inherited in an AD fashion, are associated with *Mycobacteria* susceptibility, whereas complete AR defects in STAT1 are associated with mycobacterial susceptibility as well as defects in responses to IFN-α and IFN-β, leading to fulminant herpesvirus infections. Other defects associated with poor production of IFN-γ leading to increased *Mycobacteria* susceptibility include AR inherited defects in *ISG-15*, which is associated with *Mycobacteria*-induced brain calcifications, and RORγC deficiency, which leads to a lack of IL-17-producing T cells, in addition to lack of IFN-γ production. RORγC defects are associated with an increased risk of candidiasis in addition to *Mycobacteria* infections. Defects in Tyk2, inherited in an AR fashion, generally present with susceptibility to intracellular bacteria, fungi, and viruses. AD mutations in interferon regulatory factor 8 (*IRF8*) are also associated with impaired IL-12 production by the CD1-DCs, leading to increased risk of recurrent mycobacterial infection, which can be treated with antimicrobial therapy.
IL-1R–Associated Kinase 4 Deficiency and Myeloid Differentiation Factor 88

Toll-like receptors (TLRs) are the best described of the PRRs in humans, and deficiencies almost uniformly cause infection susceptibility.

Pathogenesis

Among those expressed on the cell surface, TLRs 1, 2, and 6 bind lipoproteins and are important in defense to bacteria and fungi. TLR4 binds lipopolysaccharides and has an important role in defense from gram-negative bacteria as well as the fusion protein of RSV. TLR5 binds flagellin, found in many bacterial organisms. The remaining TLRs (3, 7, 8, and 9) are expressed intracellularly, respond to nucleic acids and are initiators for the host response for viral defense. When bound to their PAMP, TLRs activate an intracellular signaling cascade that in most cases utilizes myeloid differentiation primary response gene 88 (MyD88) and IL-1R–associated kinase 4 (IRAK4). TLR4 also signals using the Toll/IL-1R domain-containing adaptor-inducing interferon-B (TRIF). Both MyD88 and TRIF can lead to activation of the nuclear factor (NF)-κB pathway via the IKK complex to induce proinflammatory cytokine production. The IKK complex is composed of IKKα and IKKβ, and IKKγ (NF-κB essential modulator, or NEMO).

Clinical Manifestations

IRAK4 and MYD88 deficiencies have identical features and are associated with deep infections such as pneumonia, meningitis, or sepsis with encapsulated organisms early in life. The main organisms recovered from patients are *Staphylococcus aureus*, *Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Pseudomonas aeruginosa*. This is one of the few types of immunodeficiency where clostridial infections are also seen with increased frequency. Most patients have an improved infection risk after adolescence. Therapy has generally focused on education of parents and clinicians to the life-threatening nature of the infections with encouragement of timely cultures and empirical antibiotic use. These patients may have a blunted febrile response, and clinical features of infection may be subtle.

Among the first-described defects of TLR signaling were X-linked mutations
in NEMO, which causes a broad range of clinical manifestations, with most demonstrating a poor inflammatory response. NEMO is typically considered in the category of combined immunodeficiency because of its impact on both innate and adaptive immune responses. Severely affected patients may present with disseminated Mycobacteria infections, severe infections from encapsulated organisms such as S. pneumoniae or other opportunistic infections. In addition to the infectious phenotype, these patients characteristically have conical or peg-shaped teeth, hypohydrosis, and hypotrichosis from anhidrotic ectodermal dysplasia (EDA). Patients should be treated with immunoglobulin replacement, antibiotic prophylaxis with trimethoprim/sulfamethoxazole, azithromycin, and/or penicillin VK. HSCT is a treatment consideration, but myeloid lineage engraftment is needed to fully correct the underlying immunodeficiency.

**Natural Killer Cell Deficiency**

NK cells are the major lymphocytes of the innate immune system. NK cells recognize virally infected and malignant cells and mediate their elimination. Individuals with absence or functional deficiencies of NK cells are rare, and they typically have susceptibility to the herpesviruses (including varicella-zoster virus, herpes simplex virus (HSV), CMV, and EBV) as well as papillomaviruses. A number of gene defects are associated with these isolated abnormalities in NK cells. Autosomal recessive CD16 gene mutations were described in 3 separate families and altered the first immunoglobulin-like domain of this important NK cell activation receptor. Patients with these mutations have NK cells that are functionally impaired and have clinical susceptibility to herpesviruses. AD deficiency of NK cells occurs in individuals with mutations in the GATA2 transcription factor. These patients also have cytopenias and very low numbers of monocytes. They have extreme susceptibility to human papillomavirus (HPV) as well as mycobacteria, the latter presumably from the monocytic defect. They are at risk for alveolar proteinosis, myelodysplasia, and leukemia. AR mutations in the MCM4 gene have been identified in a cohort of patients who had growth failure and susceptibility to herpesviruses. Therapeutically, patients should be maintained on antiviral prophylaxis, and HSCT has been successful in certain cases.

**Defects in Innate Responses to Viral**
Infection

Defects in both the JAK-STAT signaling pathways and the TLR signaling pathways have been implicated in patients with increased susceptibility to severe viral infections. AR defects in STAT1 cause a complete lack of response to INF-γ and IFN-α/β, affecting the function of T and NK cells as well as monocytes, leading to disseminated mycobacterial infections as well as severe herpesvirus infections, including recurrent HSV encephalitis and EBV-driven lymphoproliferative disease. In these patients, lifelong antibiotic therapy to protect from Mycobacteria and antiviral therapy for herpesviruses is recommended, and HSCT should be considered. Defects in STAT2, inherited in an AR fashion, lead to poor T- and NK-cell responses to IFN-α and IFN-β, leading to increased viral susceptibility, in particular development of disseminated vaccine strain measles with central nervous system (CNS) involvement despite development of normal vaccine titers. The interferon response factor 7 (IRF7) is important in induction of IFN-α/β via the both the MyD88-dependent and independent pathways of TLR signaling. AR defects in IRF7 have been associated with severe respiratory distress with influenza A infection in a patient with otherwise normal vaccine responses and T- and B-cell populations.

HSV-1 encephalitis has been associated with a group of defects in TLR signaling that lead to decreased production of IFN-α/β/λ causing impaired immunity to HSV-1 but not other viral infections. The first described was deficiency of UNC93B1, a protein involved in trafficking of the TLRs 7 and 9 and inherited in an AR fashion. Subsequently, defects in TLR3 and TRIF as well as the other TLR pathway signaling molecules tumor necrosis factor (TNF), receptor–associated factor 3 (TRAF3), and tank-binding kinase 1 (TBK1) were described to lead to decreased production of IFN-α/β/λ and an associated risk of sporadic HSV-1 encephalitis that can be recurrent. The symptoms were controlled with acyclovir prophylaxis.

Defects in Innate Responses to Fungi

Although chronic mucocutaneous candidiasis (CMC) can be seen in association with CID, T-cell disorders, and hyper-IgE syndromes, there are also innate defects known to cause CMC (see Chapter 151). The most common include AD gain-of-function mutations in STAT1, where an increased response
to IFN-α/β/γ leads to decreased Th17 differentiation. In addition to CMC, these patients also have increased susceptibility to bacterial, fungal, and HSV viral infections; autoimmunity; and enteropathy. Patients with CMC are managed with antifungal, antibacterial, and acyclovir prophylaxis, and HSCT should be considered as a treatment option. Mutations in the IL-17RA and IL-17F have also been described to increase risk of CMC; IL-17RA and IL-17F deficiencies are also associated with S. aureus folliculitis, likely from impaired skin β-defensin production. Treatment includes fluconazole and sulfamethoxazole/trimethoprim prophylaxis. TRAF3-interacting protein 2 (TRAF3IP2) interacts with IL-17RA on binding of IL-17; AR mutations in TRAF3IP2 have been described in patients with CMC, blepharitis, folliculitis, and macroGLOSSia. CMC is also seen in 25% of patients with IL-12RB1 and IL12p40 defects. Invasive fungal infections, including invasive dermatophyte infections and Candida brain abscesses, have been seen in addition to CMC in patients with AR inherited defects in CARD9. CARD9 leads to NF-κB–induced cytokine production in response to fungal PAMPS that bind to C-type lectin receptors, including Dectin 1, Dectin 2, and MINCLE. Both granulocyte-macrophage colony-stimulating factor (GM-CSF) and G-CSF have been successfully used to control refractory brain lesions, and once identified, these patients should be maintained on fluconazole prophylaxis.

**IVIG, Intravenous immune globulin.**

Transplantation of major histocompatibility complex (MHC)–compatible sibling or rigorously T-cell–depleted haploidentical (half-matched) parental hematopoietic stem cells is the treatment of choice for patients with fatal T-cell or combined T- and B-cell defects. The major risk to the recipient from transplants of bone marrow or peripheral blood stem cells is GVHD from donor T cells. Patients with less severe forms of cellular immunodeficiency, including some forms of CID, Wiskott-Aldrich syndrome, cytokine deficiency, and MHC antigen deficiency, reject even HLA-identical marrow grafts unless chemoablative treatment is given before transplantation. Several patients with
these conditions have been treated successfully with hematopoietic stem cell transplantation after conditioning.

More than 90% of patients with primary immunodeficiency transplanted with HLA-identical related marrow will survive with immune reconstitution. T-cell–depleted haploidentical-related marrow transplants in patients with primary immunodeficiency have had their greatest success in patients with SCID, who do not require pretransplant conditioning or GVHD prophylaxis. Of patients with SCID, 92% have survived after T-cell–depleted parental marrow is given soon after birth when the infant is healthy, without pretransplant chemotherapy or posttransplant GVHD prophylaxis. Bone marrow transplantation remains the most important and effective therapy for SCID. In ADA-deficient and X-linked SCID, there has been success in correcting the immune defects with ex vivo gene transfer to autologous hematopoietic stem cells. Gene therapy has also been successful in the Wiskott-Aldrich syndrome. Initial protocols of gene therapy for X-linked SCID resulted in insertional mutagenesis with the development of leukemic-like clonal T cells or lymphoma in some patients. Modification of the gene therapy protocol has greatly reduced the risk of insertional mutagenesis.

152.5

Immune Dysregulation With Autoimmunity or Lymphoproliferation

Jennifer W. Leiding, Kathleen E. Sullivan, Rebecca H. Buckley

Keywords

ALPS
cytopenias
Primary immunodeficiency diseases characterized by immune dysregulation, autoimmunity, and autoinflammation are monogenic defects of the immune system. These complex multisystem diseases often have a progressive phenotype with organ-specific autoimmunity, specific infectious susceptibility, and lymphoproliferation.

**Autoimmune Lymphoproliferative Syndrome**

Autoimmune lymphoproliferative syndrome (ALPS), also known as Canale-Smith syndrome, is a disorder of abnormal lymphocyte apoptosis leading to polyclonal populations of T cells (double-negative T cells), which express CD3 and α/β antigen receptors but do not have CD4 or CD8 co-receptors (CD3$^+$ T-cell receptor α/β$^+$, CD4$^-$ CD8$^-$). These T cells respond poorly to antigens or mitogens and do not produce growth or survival factors (IL-2). The genetic deficit in most patients is a germline or somatic mutation in the FAS gene, which produces a cell surface receptor of the TNF receptor superfamily (TNFRSF6), which, when stimulated by its ligand, will produce programmed cell death (Table 152.3). Persistent survival of these lymphocytes leads to immune dysregulation and autoimmunity. ALPS is also caused by other genes in the Fas pathway (FASLG and CASP10). In addition, ALPS-like disorders are associated with other mutations: RAS-associated autoimmune lymphoproliferative disorder (RALD), caspase-8 deficiency, Fas-associated protein with death domain deficiency (FADD), and protein kinase C delta deficiency (PRKCD). These disorders have varying degrees of immunodeficiency, autoimmunity, and lymphoproliferation.

* A *definitive* diagnosis is based on the presence of both required criteria plus one primary accessory criterion. A *probable* diagnosis is based on the presence of both required criteria plus one secondary accessory criterion.

**Clinical Manifestations**

ALPS is characterized by **autoimmunity, chronic persistent or recurrent lymphadenopathy**, splenomegaly, hepatomegaly (in 50%), and hypergammaglobulinemia (IgG, IgA). Many patients present in the 1st yr of life, and most are symptomatic by age 5 yr. Lymphadenopathy can be striking (Fig. 152.4). Splenomegaly may produce hypersplenism. Autoimmunity also produces anemia (Coombs-positive hemolytic anemia) or thrombocytopenia or a mild neutropenia. The lymphoproliferative process (lymphadenopathy, splenomegaly) may regress over time, but autoimmunity does not regress and is characterized by frequent exacerbations and recurrences. Other autoimmune features include urticaria, uveitis, glomerulonephritis, hepatitis, vasculitis, panniculitis, arthritis, and CNS involvement (seizures, headaches, encephalopathy).
FIG. 152.4  Clinical, radiographic, immunologic, and histologic characteristics of the autoimmune lymphoproliferative syndrome. A, Front view of the National Institutes of Health patient. B, Top middle, a CT scan of the neck is shown demonstrating enlarged preauricular, cervical, and occipital lymph nodes. Arrowheads denote the most prominent lymph nodes. The top right panels show the flow-cytometric analysis of peripheral blood T cells from a patient with autoimmune lymphoproliferative syndrome (ALPS), with CD8 expression on the vertical axis and CD4 on the horizontal axis. The lower left quadrant contains CD4−CD8− (double-negative) T cells, which are usually present at <1% of T cells expressing the αβ T-cell receptor. The bottom panels show CD3, CD4, and CD8 staining on serial sections of a lymph node biopsy specimen from a patient with ALPS, and also show that large numbers of DNCD3+CD4−CD8− (double-negative) T cells are present in the interfollicular areas of the lymph node. (Adapted from Siegel RM, Fleisher TA: The role of Fas and related death receptors in autoimmune and other disease states, J Allergy Clin Immunol 103:729–738, 1999.)

Malignancies are also more common in patients with ALPS and include Hodgkin and non-Hodgkin lymphomas and solid-tissue tumors of thyroid, skin, heart, or lung. ALPS is one cause of Evan syndrome (immune thrombocytopenia and immune hemolytic anemia).

**Diagnosis**

Laboratory abnormalities depend on the lymphoproliferative organ response (hypersplenism) or the degree of autoimmunity (anemia, thrombocytopenia). There may be lymphocytosis or lymphopenia. Table 152.3 lists the criteria for the diagnosis. Flow cytometry helps identify the lymphocyte type (see Fig. 152.4). Functional genetic analysis for the TNFRSF6 gene often reveals a heterozygous mutation.
Treatment

Rapamycin (sirolimus) will often control the adenopathy and autoimmune cytopenias. Malignancies can be treated with the usual protocols used in patients unaffected by ALPS. Stem cell transplantation is another possible option in treating the autoimmune manifestations of ALPS.

Immune Dysregulation, Polyendocrinopathy, Enteropathy, X-Linked Syndrome

This immune dysregulation syndrome is characterized by onset within the 1st few wk or mo of life with watery diarrhea (autoimmune enteropathy), an eczematous rash (erythroderma in neonates), insulin-dependent diabetes mellitus, hyperthyroidism or more often hypothyroidism, severe allergies, and other autoimmune disorders (Coombs-positive hemolytic anemia, thrombocytopenia, neutropenia). Psoriasiform or ichthyosiform rashes and alopecia have also been reported.

Immune dysregulation, polyendocrinopathy, enteropathy, X-linked (IPEX) syndrome is caused by a mutation in the FOXP3 gene, which encodes a forkhead-winged helix transcription factor (scurfin) involved in the function and development of CD4$^+$ CD25$^+$ regulatory T cells (Tregs). The absence of Tregs may predispose to abnormal activation of effector T cells. Dominant gain-of-function mutations in STAT1 and other gene mutations (Table 152.4) produce an IPEX-like syndrome, also associated with compromised Tregs.

Clinical Manifestations

Watery diarrhea with intestinal **villous atrophy** leads to failure to thrive in most patients. Cutaneous lesions (usually eczema) and insulin-dependent diabetes begin in infancy. Lymphadenopathy and splenomegaly are also present. Serious bacterial infections (meningitis, sepsis, pneumonia, osteomyelitis) may be related to neutropenia, malnutrition, or immune dysregulation. Laboratory features reflect the associated autoimmune diseases, dehydration, and malnutrition. In addition, serum IgE levels are elevated, with normal levels of IgM, IgG, and IgA. The diagnosis is made clinically and by mutational analysis of the **FOXP3** gene.

Treatment

Inhibition of T-cell activation by cyclosporine, tacrolimus, or sirolimus with corticosteroids is the treatment of choice, along with the specific care of the endocrinopathy and other manifestations of autoimmunity. These agents are
typically used as a bridge to transplant. HSCT is the only possibility for curing IPEX.

Cytotoxic T-Lymphocyte Antigen 4 (CTLA4) Deficiency

Patients with CTLA4 deficiency have lost the ability to maintain immune tolerance, leading to a disease characterized by autoimmunity and multiorgan lymphocytic infiltration of lymphoid and nonlymphoid organs. CTLA4, also known as CD152, is a protein receptor that is expressed on activated T cells. It acts as an immune checkpoint, downregulating immune responses, on T-cell activation. CTLA4 deficiency is inherited in a haploinsufficient manner.

Autoimmune cytopenias, lymphoid infiltration of lymphoid and nonlymphoid organs, granulomatous disease, hypogammaglobulinemia, and recurrent respiratory infections are key features. Nonlymphoid organs most often affected with lymphoid infiltration are the brain and gastrointestinal (GI) tract. The immune phenotype of CTLA4-deficient patients includes reduced naïve T cells (CD4+ CD45RA+ CD62L+), loss of circulating B cells, and reduced Treg expression. Treatment is symptom specific, although use of abatacept, a CTLA4-Ig fusion protein, has alleviated disease-specific symptoms in several patients. When refractory to therapy, HSCT has led to remission of symptoms and cure of disease.

Lipopolysaccharide (Lps)-Responsive Beige-Like Anchor Protein (LRBA) Deficiency

Homozygous mutations in LRBA cause a syndrome of early-onset hypogammaglobulinemia, autoimmunity, lymphoproliferation, and inflammatory bowel disease.

LRBA is a member of the pleckstrin homology-beige and Chédiak-Higashi–tryptophan–aspartic acid dipeptide (PH-BEACH-WD40) protein family. Much is unknown about the function of LRBA. However, in normal T cells, LRBA co-localizes with CTLA4 within recycling endosomes, suggesting that LRBA may
play a specific role in the regulation of recycling endosomes. Homozygous mutations in *LRBA* abrogate LRBA protein expression.

Immune dysregulation consisting of enteropathy, autoimmune cytopenias, granulomatous-lymphocytic *interstitial lung disease*, *lymphadenopathy*, and hepatomegaly or splenomegaly are the most common manifestations. Other, less common symptoms of immune dysregulation include cerebral granulomas, type 1 diabetes mellitus, alopecia, uveitis, myasthenia gravis, and eczema. Growth failure occurs in many patients, complicated especially by enteropathy. Bacterial, fungal, and viral infections have been reported in about 50% of patients. The immune phenotype is variable but can consist of reduced T-cell quantities (CD3\(^+\)), elevated double-negative T cells (CD3\(^+\) CD4\(^-\) CD8\(^-\)), normal T-cell proliferation to mitogens and antigens, reduced Treg numbers (CD4\(^+\) CD25\(^+\) FoxP3\(^+\)), reduced NK cells (CD56\(^+\)), and reduced B cells (CD19\(^+\)). Immunoglobulin quantities are also variable, with hypogammaglobulinemia occurring most frequently.

The focus of therapy is treatment of the immunodysregulatory features with immunosuppression. Corticosteroids, immunoglobulin replacement, mycophenolate mofetil, tacrolimus, rapamycin, budesonide, cyclosporine, azathioprine, rituximab, infliximab, and hydroxychloroquine have all been used with mixed success. Abatacept has been successful in treating the immunodysregulatory features. HSCT has been successfully performed in LRBA-deficient patients as well.

**Activated Phosphoinositide 3-Kinase (PI3K) \(\delta\) Syndromes**

These syndromes are primary immunodeficiencies that cause a spectrum of immunodeficiency, lymphadenopathy, and senescent T cells. PI3K molecules are composed of a p110 catalytic subunit (p110\(\alpha\), p110\(\beta\), or p110\(\delta\)) and a regulatory subunit (p85\(\alpha\), p55\(\alpha\), p50\(\alpha\), p85\(\beta\), or p55\(\gamma\)). PI3Ks convert phosphatidylinositol 4,5-bisphosphate to phosphatidylinositol 3,4,5-triphosphate (PIP\(_3\)), an important second messenger.

Autosomal dominant gain-of-function mutations in *PIK3CD*, the gene that encodes for the catalytic unit, p110\(\delta\), leads to hyperactivated PI3K\(\delta\) signaling. AD mutations in *PI3KR*, the gene that encodes the regulatory subunit (p85\(\alpha\), p55\(\alpha\), and p50\(\alpha\)) of PI3Ks are associated with the same phenotype. Defects in
this pathway lead to a syndrome of chronic lymphoproliferation and T-cell senescence.

Early-onset respiratory tract infections, noninfectious lymphadenopathy, and hepatosplenomegaly are the most common features. A large proportion of patients develop early-onset bronchiectasis as a result of recurrent pneumonia. Persistent, severe, or recurrent herpesvirus infections are also common. Lymphadenopathy often starts in childhood and localizes to sites of infection. However, lymphadenopathy may be diffuse and is usually associated with chronic CMV or EBV viremia. Mucosal lymphoid hyperplasia of the respiratory and GI tracts is also frequent. Histologically, lymph nodes show atypical follicular hyperplasia. Autoimmune cytopenias are the most frequent autoimmune manifestation, but others include glomerulopathies, autoantibody-mediated thyroid disease, and sclerosing cholangitis. Early-onset lymphoma, as early as the 2nd yr of life, have been reported as well and are a major cause of mortality. Growth impairment affecting weight and height and developmental delay with mild cognitive impairment also may occur.

The immunophenotype consists of reduced naïve T cell (CD3\(^+\) CD4\(^+\)) and B-cell counts (CD19\(^+\)) and normal NK cell counts (CD56\(^+\)). More specifically, reduced numbers of recent thymic emigrants (CD3\(^+\) CD4\(^+\) CD45RA\(^+\) CD31\(^+\)) with increased effector memory cytotoxic T-cell counts (CD3\(^+\) CD8\(^+\) CCR7\(^-\) CD45RA\(^+/−\)), increased transitional B cells (CD19\(^+\) IgM\(^+\) CD38\(^+\)), and reduced nonswitched memory B cells (CD19\(^+\) IgD\(^+\) CD27\(^+\)) and class-switched memory B cells (CD19\(^+\) IgD\(^+\) CD27\(^+\)) are hallmark. Immunoglobulin levels are variable, but typically there are increased serum quantities of IgM, reduced or normal IgG, and reduced or normal IgA.

Treatment is symptom specific but can include antimicrobial prophylaxis and immunoglobulin replacement. Various immunosuppressive agents (e.g., rituximab, rapamycin) have been used to treat the lymphoproliferative disease and autoimmune cytopenias that are often present. HSCT has also been successfully performed in those refractory to medical therapy.

**Signal Transducer and Activator of Transcription (STAT) Pathway Defects**

The Janus kinase (JAK)-STAT signal transduction pathway is used for signal
transduction by type 1 and type 2 cytokine receptors within most hematopoietic cells. Cytokines bind to their cognate receptor, triggering JAK-STAT pathways, ultimately leading to the upregulation of genes involved in the immune response against many pathogens. There are 4 JAK proteins (Jak1, Jak2, Jak3, Tyk2) and 6 STATs (1-6). Mutations in several JAKs and STATs cause immunodeficiency. Table 152.5 includes diseases affecting STAT proteins characterized by immune dysregulation. Chronic immunosuppression is necessary for control of STAT defects. Ruxolitinib, a JAK-STAT inhibitor, has been used with some success. With the advent of JAK-STAT immunomodulating therapies, more treatment options will be available to patients.

### Nuclear Factor-κB Pathway Defects

The NF-κB pathways consists of canonical (NF-κB1) and noncanonical (NF-
κB2) pathways. On cellular activation, both pathways lead to activation and translocation of NF-κB proteins into the nucleus, where they initiate downstream inflammatory responses. Defects in many proteins in both pathways have been described. Table 152.6 describes immune defects of the NF-κB pathways that cause symptoms of immune dysregulation or autoimmunity. Treatment of NF-κB defects includes prevention of infections and replacement of immunoglobulin and has included HSCT.

### Tetratricopeptide Repeat Domain 7A (TTC7A) Deficiency

Combined immunodeficiency with T-cell and B-cell defects had long accompanied hereditary **multiple intestinal atresia**. Mutations in **TTC7A** are causative of the combined intestinal and immunologic defects. TTC7A is involved in cell cycle control, cytoskeletal organization, cell shape and polarity, and cell adhesion. Deficiency of TTC7A is inherited in an autosomal recessive manner. Multiple intestinal atresia with disruption of intestinal architecture is a universal feature. Often, early-onset severe enterocolitis occurs concurrently. Immunodeficiency with severe T-cell lymphopenia has been described; B- and NK-cell defects are variable. T-cell proliferative responses are also abnormal. Severe hypogammaglobulinemia is common. Treatment includes removal of atretic areas of the intestine and antimicrobial prophylaxis in immunodeficient patients. Bowel transplant has also been performed with some success.

### Deficiency of Adenosine Deaminase 2 (DADA2)

Deficiency in ADA2 is a cause of early **vasculopathy, stroke**, and immunodeficiency. DADA2 is secondary to autosomal recessive mutations in cat-eye syndrome chromosome region 1 (**CECR1**), mapped to chromosome 22q11.1. ADA2 is important in purine metabolism converting adenosine to inosine and 2′-deoxyadenosine to 2′-deoxyinosine. The pathogenesis is not exactly known, but ADA2 is mostly secreted by myeloid cells, and deficiency leads to upregulation of proinflammatory genes and increased secretion of proinflammatory cytokines. DADA2 is characterized by chronic or recurrent inflammation with elevated acute-phase reactants and fever. Skin manifestations include livedo reticularis, maculopapular rash, nodules, purpura, erythema nodosum, Raynaud phenomenon, ulcerative lesions, and digital necrosis. CNS
involvement is variable but can include transient ischemic attacks and ischemic or hemorrhagic stroke. Peripheral neuropathy is also common. GI manifestations include hepatosplenomegaly, gastritis, bowel perforation, and portal hypertension. Nephrogenic hypertension is common and can be associated with glomerulosclerosis or amyloidosis. Immunodeficiency consists of hypogammaglobulinemia and variable decreases in IgM.

Treatment with chronic long-term corticosteroids and anti-TNF-α agents have shown modest control of disease manifestations. HSCT has been successful in 2 patients as well.

Neutrophils

The Phagocytic Inflammatory Response

The phagocyte system includes both granulocytes (neutrophils, eosinophils, and basophils) and mononuclear phagocytes (monocytes and tissue macrophages). Neutrophils and mononuclear phagocytes share primary functions, including the defining properties of large-particle ingestion and microbial killing. Phagocytes participate primarily in the innate immune response but also help initiate acquired immunity. Mononuclear phagocytes, including tissue macrophages and circulating monocytes, are discussed in Chapter 154.

Neutrophils provide the rapid effector arm of the innate immune system. They circulate in the bloodstream for only about 6 hr (Table 153.1), but on encountering specific chemotactic signals, they adhere to the vascular endothelium and transmigrate into tissues. There they ingest and kill microbes and release chemotactic signals to recruit more neutrophils and to attract dendritic cells and other initiators of the acquired immune response.

**Hematopoiesis**

The hematopoietic progenitor system can be viewed as a continuum of functional compartments, with the most primitive compartment composed of very rare **pluripotential stem cells**, which have high self-renewal capacity and give rise to more mature stem cells, including cells that are committed to either lymphoid or myeloid development (Fig. 153.1). Common lymphoid progenitor cells give rise to T- and B-cell precursors and their mature progeny (see Chapter 149). Common myeloid progenitor cells eventually give rise to committed single-lineage progenitors of the recognizable precursors through a random process of lineage restriction in a stepwise process (see Chapter 473). The capacity of lineage-specific committed progenitors to proliferate and differentiate in response to demand provides the hematopoietic system with a remarkable range of response to changing requirements for mature blood cell production.
FIG. 153.1 Major cytokine sources and actions and transcription factor requirements for hematopoietic cells. Cells of the bone marrow microenvironment, such as macrophages, endothelial cells, and reticular fibroblastoid cells, produce macrophage, granulocyte-macrophage, and granulocyte colony-stimulating factors (M-CSF, GM-CSF, G-CSF), interleukin-6 (IL-6), and probably stem cell factor (SCF) (cellular sources not precisely determined) after induction with endotoxin (macrophage) or IL-1/tumor necrosis factor (TNF) (endothelial cells and fibroblasts). T cells produce IL-3, GM-CSF, and IL-5 in response to antigenic and IL-1 stimulation. These cytokines have overlapping actions during hematopoietic differentiation, as indicated, and for all lineages, optimal development requires a combination of early-acting and late-acting factors. Transcription factors important for survival or self-renewal of stem cells are shown in red at the top, whereas stages of hematopoiesis blocked after the depletion of indicated transcription factors are shown in red for multipotent and committed progenitors. (From Nathan & Oski's hematology and oncology of infancy and childhood, ed 8, vol 2, Philadelphia, 2015, Elsevier, p 10.)

The proliferation, differentiation, and survival of immature hematopoietic progenitor cells are governed by hematopoietic growth factors, a family of
glycoproteins (see Chapter 473). Besides regulating proliferation and differentiation of progenitors, these factors influence the survival and function of mature blood cells. During granulopoiesis and monopoiesis, multiple cytokines regulate the cells at each stage of differentiation from pluripotent stem cells to nondividing, terminally differentiated cells (monocytes, neutrophils, eosinophils, and basophils). As cells mature, they lose receptors for most cytokines, especially those that influence early cell development; however, they retain receptors for cytokines that affect their mobilization and function, such as granulocyte and macrophage colony-stimulating factors. Mature phagocytes also express receptors for chemokines, which help direct the cells to sites of inflammation. Chemokine receptors such as CXCR4 and its ligand SDF-1 play a key role in retention of developing myeloid cells within bone marrow.

**Neutrophil Maturation and Kinetics**

The process of intramedullary granulocyte maturation involves changes in nuclear configuration and accumulation of specific intracytoplasmic granules. The bone marrow microenvironment supports the normal steady-state renewal of peripheral blood neutrophils through the generation of growth and differentiation factors by stromal cells. Growth factors such as granulocyte colony-stimulating factor (G-CSF) and granulocyte-macrophage colony-stimulating factor (GM-CSF) not only stimulate cell division, but also induce the expression of transcription factors that regulate the biosynthesis of functional components of the neutrophil, such as granule proteins. The transcription factor PU.1 is essential for myelopoiesis, both as a positive regulatory element and as a suppressor of GATA1, a transcription factor that directs nonmyeloid differentiation. Other transcription factors, such as Runx1 (AML1), c-myb, CDP, C/EBPα, C/EBPγ, and MEF, are expressed in the myeloblast and promyelocyte, and some of these are required for azurophil granule protein expression. As cells enter the myelocyte stage, Runx1 and myb are downregulated, whereas PU.1 and C/EBPε expression rises to initiate terminal differentiation.

Granulocytes survive for only 6-12 hr in the circulation, and therefore daily production of $2 \times 10^4$ granulocytes/µL of blood is required to maintain a level of circulating granulocytes of $5 \times 10^3$ /µL (see Table 153.1). The relatively small peripheral blood pool includes the rapidly interchanging circulating and marginating pools; the latter provides entrance into the tissue phase, where
neutrophils may survive for hours or days. The circulating pool is fed and buffered by a much larger marrow population of mature neutrophils and myeloid precursors, representing the marrow reserve and proliferating pools, respectively. Proliferation of myeloid cells, encompassing approximately 5 mitotic divisions, takes place only during the first 3 stages of neutrophil development, in myeloblasts, promyelocytes, and myelocytes. After the myelocyte stage, the cells terminally differentiate into nongrowing, maturing metamyelocytes, bands, and neutrophils.

Neutrophil maturation is associated with nuclear condensation and lobulation and the sequential production of characteristic granule populations. A **myeloblast** is a relatively undifferentiated cell with a large oval nucleus, a sizable nucleolus, and a deficiency of granules. **Promyelocytes** acquire peroxidase-positive azurophilic (primary) granules, and then **myelocytes** and **metamyelocytes** acquire specific (secondary) granules; tertiary granules and secretory vesicles develop in the final stage of neutrophil maturation.

**Neutrophil Function**

Neutrophil responses are initiated as circulating neutrophils flowing through the postcapillary venules detect low levels of chemokines and other chemotactic substances released from a site of infection. The sequence of events as the neutrophil moves from circulating in the blood to the encounter and destruction of bacteria is carefully orchestrated by a series of biochemical events, defects of which are associated with genetic disorders of neutrophil function (Fig. 153.2). In fact, these disorders of neutrophil function lead to our understanding of the cell biology of phagocyte function. A subset of circulating neutrophils loosely adheres to the endothelium through low-affinity receptors called **selectins** and rolls along the endothelium, forming the marginated pool. Soluble effectors of inflammation trigger subtle changes in surface adhesion molecules on endothelial cells at the site of infection. The rolling of neutrophils allows more intense exposure of neutrophils to activating factors such as tumor necrosis factor or interleukin-1 (Fig. 153.2). Exposure of neutrophils to these same activating factors induces qualitative and quantitative changes in the family of β2-integrin adhesion receptors (the CD11/CD18 group of surface molecules), leading to tight adhesion between neutrophils and endothelial cells at the site of inflammation and ultimately to transmigration of the neutrophil into the tissue.
The neutrophil-mediated inflammatory response and associated neutrophil dysfunction syndromes. Circulating neutrophils loosely attach to endothelium via selectins and roll along the vessel wall until they arrive at the site of infection. Inflammatory monokines, interleukin-1 (IL-1), and tumor necrosis factor (TNF) activate endothelial cells to express E- and P-selectins. E- and P-selectins serve as counter-receptors for neutrophils sialyl Lewis X and Lewis X to cause low-avidity neutrophil rolling. Activated endothelial cells express ICAM-1, which serves as a counter-receptor for neutrophil β₂-integrin molecules, leading to high-avidity leukocyte spreading and the start of transendothelial migration at the infection site. Neutrophils invade through the vascular basement membrane with the release of proteases and reactive oxidative intermediates, causing local destruction of surrounding tissue at sites of high concentrations of chemotactic factors, and migrate to the site of infection, where they ingest and kill the bacteria. (Modified from Kyono W, Coates TD: A practical approach to neutrophil disorders, Pediatr Clin North Am 49:929, 2002.)

Once through the endothelium, the neutrophil senses the gradient of chemokines or other chemoattractants and migrates to sites of infection. Neutrophil migration is a complex process involving rounds of receptor
engagement, signal transduction, and remodeling of the actin microfilaments composing in part the cytoskeleton. Actin polymerization-depolymerization occurs in approximately 8 sec cycles and drives cyclic extension and retraction of the actin-rich lamella at the front of the neutrophil. Receptors at the leading edge of the lamella detect the gradient of attractant and follow microorganisms, then ingest and destroy them. When the neutrophil reaches the site of infection, it recognizes pathogens by means of Fc immunoglobulin and complement receptors, Toll-like receptors, fibronectin receptors, and other adhesion molecules.

The neutrophil ingests microbes that are coated by opsonins, serum proteins such as immunoglobulin and complement component C3. The pathogens are engulfed into a closed vacuole, the phagosome (Fig. 153.3), where 2 cellular responses essential for optimal microbicidal activity occur concomitantly: degranulation and activation of nicotinamide-adenine dinucleotide phosphate (NADPH)–dependent oxidase. Fusion of neutrophil granule membranes with the phagosome membrane delivers potent antimicrobial proteins and small peptides into the phagosome.
FIG. 153.3  Nicotinamide adenine dinucleotide phosphate (NADPH) oxidase components and activation. On activation of phagocytic cells, the 3 cytosolic components (red) of the NADPH oxidase (p67phox, p47phox, and p40phox), plus the small guanosine triphosphatase (GTPase) protein Rac2, are translocated to the membrane of the phagocytic vacuole. The p47phox subunit binds to the flavocytochrome b558 membrane component (blue-green) of the NADPH oxidase (gp91phox plus p22phox). The NADPH oxidase catalyzes the formation of superoxide by transferring an electron from NADPH to molecular oxygen (O2), thereby forming the superoxide free radical. The unstable superoxide anion is converted to hydrogen peroxide, either spontaneously or by superoxide dismutase (SOD). H2O2 can follow different metabolic pathways into more potent reactive oxidants, such as OH* or HOCl) or degradation to H2O + O2. (Adapted from Stiehm ER, Ochs HD, Winkelstein JA: Immunologic disorders in infants and children, ed 5, Philadelphia, 2004, Saunders, p 622.)

Assembly and activation of NADPH oxidase occur at the phagosome membrane as well (see Fig. 153.3), generating large amounts of superoxide (O2⁻) from molecular oxygen, which in turn decomposes to produce hydrogen peroxide (H2O2) and singlet oxygen. Myeloperoxidase, a major azurophil granule component, catalyzes the reaction of H2O2 with ubiquitously present
chloride ions to create hypochlorous acid (HOCl) in the phagosome. H$_2$O$_2$ and HOCl are potent microbicidal agents that break down and clear pathogens from sites of infection.

In addition, neutrophils secrete a wide variety of cytokines and chemokines that recruit more neutrophils to fight the infection, attract monocytes and macrophages that possess both microbicidal and scavenger functions, and promote antigen presentation to help initiate the adaptive immune response. Also, the reactive oxidants can inactivate chemotactic factors and may serve to terminate the process of neutrophil influx, thereby attenuating the inflammatory process. Finally, the release of reactive oxygen species, granule proteins, and cytokines can also damage local tissues, leading to the classic signs of inflammation or to more permanent impairment of tissue integrity and function.

**Bibliography**

Dinauer MC, Coates TD. Disorders of phagocyte function.

Timár CI, Lőrincz AM, Ligeti E. Changing world of
Mononuclear phagocytes (monocytes, macrophages) are distributed across all body tissues and play a central role in maintaining immunologic and metabolic homeostasis. They are essential for innate host defense against infection, tissue repair and remodeling, and the antigen-specific adaptive immune response. No human has been identified as having congenital absence of this cell line, probably because macrophages are required to remove primitive tissues during fetal development as new tissues develop to replace them. Monocytes and tissue macrophages in their several forms have variable morphology, surface markers, and transcriptional profiles but common functions, particularly phagocytosis (Table 154.1). Dendritic cells (DCs) are specialized derivatives of this mononuclear phagocyte system that develop from myeloid cell precursors or monocytes themselves.

### Table 154.1

**Principal Sites of Macrophages in Tissues**

- Serosal cavities (pleural and peritoneal macrophages)
- Synovial membrane (type A synoviocytes)
- Bone (osteoclasts)
- Brain and retina (microglial cells)
- Spleen, lymph nodes, bone marrow
Development

Monocytes develop more rapidly during bone marrow hematopoiesis and remain longer in the circulation than do neutrophils (see Table 153.1). The monoblast is the first recognizable monocyte precursor, followed by the promonocyte, with cytoplasmic granules and an indented nucleus, and finally the fully developed monocyte with cytoplasmic granules filled with hydrolytic enzymes. The transition from monoblast to mature circulating monocyte requires about 6 days.

Three major subsets of human monocytes can be identified on the basis of surface antigens: CD14++ CD16− classical monocytes that constitute the majority of total monocytes in the resting state; the more mature CD14++ CD16+ proinflammatory (intermediate) monocytes, which produce proinflammatory hormone-like factors termed cytokines, such as tumor necrosis factor-α (TNF-α), in response to microbial stimuli; and nonclassical (regulatory) monocytes (CD14+ CD16++ ) that promote wound healing. Monocytes from these subsets migrate into tissues in response to localized inflammation or injury and provide proinflammatory host defense or antiinflammatory responses and wound healing.

Tissue (organ)-specific macrophages arise from macrophage progenitors that develop in the yolk sac and fetal liver before hematopoiesis occurs in the bone marrow. These cells maintain their population through self-renewal. Tissue macrophages can also be populated to some extent by circulating monocytes. Monocytes or macrophages at sites of active inflammation mature into proinflammatory (M1) macrophages or proresolving (M2) macrophages. In ongoing tissue injury or inflammation, many (perhaps most) of the macrophages will express a mix of the properties of the classic types.

Whether embryonic or blood derived, tissue macrophages are directed by organ-specific factors to differentiate into macrophages characteristic of that organ. Embryonic progenitors or monocytes in the liver become Kupffer cells that bridge the sinusoids separating adjacent plates of hepatocytes. Those at the
lung airway surface become large ellipsoid alveolar macrophages, those in the bone become osteoclasts, and those in brain or retina become microglia. All macrophages, however, have at least 3 major functions in common: phagocytosis, presentation of antigens to lymphocytes, and enhancement or suppression of the immune response through release of a variety of potent cytokines. At sites of inflammation, monocytes and macrophages can fuse to form multinucleated giant cells; these cells maintain the antimicrobial functions of macrophages.

**Activation**

The most important step in the maturation of tissue macrophages is the conversion from a resting to a more functionally active cell, a process driven primarily by certain cytokines and microbial products. *Macrophage activation* is a generic term, with the functional characteristics of an activated macrophage population varying with the cytokine or other stimulus (microbial, chemical) to which the population has been exposed.

**Classical activation** refers to a response to infection that is driven by specifically activated T-helper (Th) type 1 (Th1-type) lymphocytes and natural killer (NK) cells through their release of interferon-γ (IFN-γ). TNF-α secreted by activated macrophages amplifies their activation, as does bacterial cell wall protein or endotoxin through Toll-like receptors (TLRs). **Alternative activation** is driven by Th2-type lymphocytes through release of interleukin-4 (IL-4) and IL-13, cytokines that regulate antibody responses, allergy, and resistance to parasites. Alternatively activated macrophages may have particular functional advantages, such as in wound healing and immunoregulation. In the traditional context of host defense, the term *activated macrophage* indicates that the “classically activated” cell has an enhanced capacity to kill microorganisms or tumor cells. These macrophages are larger, with more pseudopods and pronounced ruffling of the plasma membrane, and they exhibit accelerated activity of many functions (Table 154.2). Considering the variety of macrophage activities essential to the maintenance of homeostasis, it seems likely that so-called classically activated, M1-type, and alternatively activated, M2-type, macrophages are extremes of a continuum of physiologic functions expressed by these long-lived cells in response to the specific task at hand.

| **Table 154.2** |
Upregulated Functions in Macrophages Activated in Response to Infection

- Microbicidal and tumoricidal activity
- Phagocytosis (of most particles) and pinocytosis
- Phagocytosis-associated respiratory burst ($O_2^−$, $H_2O_2$)
- Generation of nitric oxide
- Chemotaxis
- Glucose transport and metabolism
- Membrane expression of MHC, CD40, TNF receptor
- Antigen presentation

**Secretion:**
- Complement components
- Lysozyme, acid hydrolases, and cytolytic proteinases
- Collagenase
- Plasminogen activator
- Interleukins, including IL-1, IL-12, and IL-15
- TNF-α
- Interferons, including IFN-α and IFN-β
- Antimicrobial peptides (cathelicidin, defensins)
- Angiogenic factors

$H_2O_2$, Hydrogen peroxide; IFN, interferon; IL, interleukin; MHC, major histocompatibility complex; $O_2^−$, superoxide anion; TNF, tumor necrosis factor.

Classical macrophage activation is accomplished during infection with intracellular pathogens (e.g., mycobacteria, *Listeria*) through crosstalk between Th1 lymphocytes and antigen-presenting macrophages mediated by the engagement of a series of ligands and receptors on the 2 cell types, including class II major histocompatibility complex (MHC) molecules and CD40 on macrophages and CD40 ligand on Th1 cells, and through secretion of cytokines. Macrophages encountering microorganisms release IL-12, which stimulates T cells to release IFN-γ. These interactions constitute the basis of cell-mediated immunity. IFN-γ is an especially important macrophage-activating cytokine; it is currently used as a therapeutic agent.
**Functional Activities**

Numerous functions are upregulated when the macrophage is activated in response to infection (see Table 154.2). Of importance are the ingestion and killing of *intracellular* pathogens such as mycobacteria, *Listeria, Leishmania, Toxoplasma*, and some fungi. Killing of the ingested organisms of any kind depends heavily on products of the *respiratory burst* (e.g., hydrogen peroxide) and on nitric oxide, and release of these metabolites is enhanced in activated macrophages. Whether activated or not, splenic and hepatic macrophages are essential for clearing the bloodstream of *extracellular* pathogens such as pneumococci.

The capacity to undergo diapedesis across the endothelial wall of blood vessels and to migrate to sites of microbial invasion is essential to monocyte function. Chemotactic factors for monocytes include complement products and chemotactic peptides (*chemokines*) derived from neutrophils, lymphocytes, and other cell types. Phagocytosis of the invading organisms can then occur, influenced by the presence of opsonins for the invader (antibody, complement, mannose-binding and surfactant proteins), the inherent surface properties of the microorganism, and the state of activation of the macrophage.

Monocytes migrating to intestinal mucosa are modified by stromal factors so that they lose innate receptors for microbial products such as endotoxin, and they do not effectively produce proinflammatory cytokines. They retain, however, the capacity to ingest and kill microbes. They have been modified during evolution to allow the absence of inflammation typical of normal intestinal mucosa despite its constant exposure to huge numbers of microbes and their inflammatory by-products.

Macrophages play an essential role in the disposal of damaged and dying cells, helping resolve the inflammatory response and heal wounds. Brain microglia demonstrate these functions particularly well. In conditions such as stroke, neurodegenerative disease, and tumor invasion, these cells can become activated, surround damaged and dead cells, and clear cellular debris. Macrophages lining the sinusoids of the spleen are especially important in ingesting aged or autoantibody-coated erythrocytes or platelets; splenectomy is used to manage autoimmune cytopenias. In the process of *efferocytosis*, macrophages in inflammatory sites can recognize changes in phosphatidylserine on the membrane of neutrophils undergoing apoptosis, and these can be removed before they spill their toxic contents into the tissue. Macrophages also remove
the extracellular traps exuded by inflammatory neutrophils, thus reducing the risk of autoimmunity. Macrophages can be identified early in fetal development, where they function to remove debris as one maturing embryonic tissue replaces another; in the brain, microglia prune synapses opsonized with C1q. Macrophages are also important in removing inorganic particles, such as elements of cigarette smoke, that enter the alveoli.

Macrophages are involved in the induction and expression of adaptive immune responses, including antibody formation and cell-mediated immunity. This depends on their capacity to break down foreign material, then present individual antigens on their surface as peptides or polysaccharides bound to MHC class II molecules. Monocytes, B lymphocytes, and most effectively, DCs, also present antigens to T cells for the specific immune response. Activated macrophages express increased MHC class II molecules, and antigen presentation is more effective.

The heightened capacity of activated macrophages to synthesize and release various hydrolytic enzymes and microbicidal materials contributes to their increased killing capacity (see Table 154.2). The macrophage is an extraordinarily active secretory cell shown to secrete >100 distinct substances, including cytokines, growth factors, and sterol hormones, placing it in a class with the hepatocyte. Because of the profound effect of some of these secretory products on other cells and the large number and widespread distribution of macrophages, this network of cells can be viewed as an important endocrine organ. IL-1 illustrates this point. Microbes and microbial products, burns, ischemia–reperfusion, and other causes of inflammation or tissue damage stimulate the release of IL-1, mainly by monocytes, macrophages, and epithelial cells. In turn, IL-1 elicits fever, sleep, and release of IL-6, which induces production of acute-phase proteins.

The complex relationship between mononuclear phagocytes and cancer is becoming more clear. Macrophages have been demonstrated to kill tumor cells by ingestion and by means of secreted products, including lysosomal enzymes, nitric oxide, oxygen metabolites, and TNF-α. In contrast, M2-type tumor-associated macrophages (TAMs) can stimulate growth of tumors through secretion of growth and angiogenic factors such as vascular endothelial growth factor (VEGF), promote metastasis, and inhibit T-cell antitumor immune responses. TAMs are currently targets of clinical trials studying attempts to reprogram them to antitumor macrophages or otherwise blunt their tumor-supportive capacity.
As traumatic damage and infection subside, the macrophage population shifts toward playing an essential role in tissue repair and healing through removal of apoptotic cells and secretion of IL-10, transforming growth factor-β, lipoxins, and the “specialized proresolving mediators,” omega-3 fatty acid–derived resolvins, protectins, and maresins.

**Dendritic Cells**

Dendritic cells are a type of mononuclear phagocyte found in blood, lymphoid organs, and all tissues. DCs are specialized to capture, process, and present antigens to T cells to generate adaptive immunity or tolerance to self-antigens. Human monocytes can be induced to differentiate into DCs in some circumstances, particularly inflammation. DCs express retractable dendritic (branched) extensions and potent endocytic capacity but are a heterogeneous population from the standpoint of location, surface markers, level of antigen-presenting activity, and function. Single-cell RNA sequencing has defined 6 human DC subtypes; but 2 major functional types of DCs can be identified: conventional DCs, which include Langerhans cells in the epithelial surfaces of skin and mucosa, dermal or interstitial DCs in subepithelial skin, and interstitial DCs in solid organs; and plasmacytoid DCs, sentinels for viral infection and principal source of antiviral IFN-α and IFN-β.

DCs migrating from the bloodstream enter skin, epithelial surfaces, and lymphoid organs where, as immature cells, they internalize self and foreign antigens. Microbial products, cytokines, or molecules exposed in damaged tissue (“danger signals” or “alarmins”) induce DC maturation, with upregulation of cytokine receptors and MHC class II and co-stimulatory molecules that expedite cell-cell binding. Stimulated DCs in the periphery migrate to lymphoid organs, where they continue to mature. They function there as the most potent cells that present antigens to T lymphocytes and induce their proliferation, activities that are central to the antigen-specific adaptive immune response. Macrophage IL-10 acts to suppress DC maturation during resolution of inflammation.

DCs from cancer patients have been used in an attempt to control their cancer. The patient's DCs are amplified and matured from blood monocytes or marrow progenitor cells by cytokines, exposed to antigens from the patient's tumor, then injected into the patient as a “vaccine” against the cancer.
Abnormalities of Monocyte-Macrophage or Dendritic Cell Function

Mononuclear phagocytes and neutrophils from patients with chronic granulomatous disease (CGD) exhibit a profound defect of phagocytic killing (see Chapter 156). The inability of affected macrophages to kill ingested organisms leads to abscess formation and characteristic granulomas at sites of macrophage accumulation beneath the skin and in the liver, lungs, spleen, and lymph nodes. IFN-γ is used to prevent infection in CGD patients and to treat the decreased bone resorption of congenital osteopetrosis, which is caused by decreased function of osteoclasts. Genetic deficiency of the CD11/CD18 complex of membrane adherence glycoproteins (leukocyte adhesion defect 1), which includes a receptor for opsonic complement component 3, results in impaired phagocytosis by monocytes (see Chapter 156).

The monocyte-macrophage system is prominently involved in lipid storage diseases called sphingolipidoses (see Chapter 104). In these conditions, macrophages express a systemic enzymatic defect that permits accumulation of cell debris that they normally clear. Resistance to infection can be impaired, at least partly because of impairment in macrophage function. In Gaucher disease, the prototype for these disorders, the enzyme glucocerebrosidase functions abnormally, allowing accumulation of glucocerebroside from cell membranes in Gaucher cells throughout the body. In all locations the Gaucher cell is an altered macrophage. These patients can be treated with infusions of the normal enzyme modified to expose mannose residues, which bind to mannose receptors on macrophages.

The cytokine IL-12 is a powerful inducer of IFN-γ production by T cells and NK cells. Individuals with inherited deficiency in macrophage receptors for IFN-γ or lymphocyte receptors for IL-12, or in IL-12 itself, undergo a severe, selective susceptibility to infection by nontuberculous mycobacteria such as Mycobacterium avium complex or bacille Calmette-Guérin (see Chapter 152). About half these patients have had disseminated Salmonella infection. These abnormalities are grouped as defects in the IFN-γ–IL-12 axis.

Monocyte-macrophage function has been shown to be partially abnormal in various clinical conditions. Cultured mononuclear phagocytes of newborns are more readily infected than adult cells by HIV-1 and measles virus. Macrophages from newborns release less granulocyte colony-stimulating factor (G-CSF) and
IL-6 in culture, and this deficiency is accentuated in cells from preterm infants. This finding supports the observations that G-CSF levels are significantly decreased in blood from newborns, and that the marrow granulocyte storage pool is diminished in infants, particularly preterm infants. Mononuclear cells from newborns produce less IFN-γ and IL-12 than do adult cells, and macrophages cultured from cord blood are not activated normally by IFN-γ. This combination of deficiencies would be expected to blunt the newborn’s response to infection by viruses, fungi, and intracellular bacteria.

More than 100 different subtypes of the histiocytoses have been organized into 5 major groups based on clinical, pathologic, genetic, and other features. These rare disorders are characterized by accumulation of macrophages or DCs in tissues or organs. “Histiocyte” is a histologic term and not cell specific, but it has been retained because of its long usage to identify the classic members of this family. Familial and secondary hemophagocytic lymphohistiocytosis is characterized by uncontrolled activation of T cells and macrophages, with resultant fever, hepatosplenomegaly, lymphadenopathy, pancytopenia, marked elevation of serum proinflammatory cytokines, and macrophage hemophagocytosis (see Chapter 534). The familial form usually presents in the 1st yr of life. Up to 5% of children with systemic-onset juvenile rheumatoid arthritis develop an acute severe complication termed macrophage activation syndrome, with persistent fever (rather than typical febrile spikes), hepatosplenomegaly, pancytopenia, macrophage hemophagocytosis, and coagulopathy, which can progress to disseminated intravascular coagulation and death if not recognized (see Chapter 180).

Two genetic autoinflammatory diseases result from dysregulation of the mononuclear phagocyte–produced proinflammatory cytokine IL-1. In neonatal-onset multisystem inflammatory disorder, monocytes overproduce IL-1. In deficiency of the IL-1 receptor antagonist, normal activity levels of IL-1 go unopposed. In both conditions, patients present in the 1st few days or weeks of life with pustular or urticarial rash, bony overgrowth, sterile osteomyelitis, elevated erythrocyte sedimentation rate, and other evidence of systemic inflammation. The recombinant IL-1 receptor antagonist anakinra is effective treatment for both these disorders (Chapter 188).

Emile J-F, Oussama A, Fraitag S, et al. Revised classification of

Eosinophils are distinguished from other leukocytes by their morphology, constituent products, and association with specific diseases. Eosinophils are nondividing, fully differentiated cells with a diameter of approximately 8 µm and a bilobed nucleus. They differentiate from stem cell precursors in the bone marrow under the control of T-cell–derived interleukin-3 (IL-3), granulocyte-macrophage colony-stimulating factor (GM-CSF), and especially IL-5. Their characteristic membrane-bound specific granules stain bright pink with eosin and consist of a crystalline core made up of major basic protein (MBP) surrounded by a matrix containing the eosinophil cationic protein (ECP), eosinophil peroxidase (EPX), and eosinophil-derived neurotoxin (EDN). These basic proteins are cytotoxic for the larval stages of helminthic parasites and are also thought to contribute to much of the inflammation associated with chronic allergic diseases such as asthma (see Chapter 169).

Eosinophil MBP, ECP, and EPX are also present in large quantities in the airways of patients who have died of asthma and are thought to inflict epithelial cell damage leading to airway hyperresponsiveness, although recent studies indicate the role of these granule proteins may be more nuanced and not purely destructive. Eosinophil granule contents also contribute to eosinophilic endomyocardial disease associated with the hypereosinophilic syndrome. MBP has the potential to activate other proinflammatory cells, including mast cells, basophils, neutrophils, and platelets. Eosinophils have the capacity to generate large amounts of the lipid mediators platelet-activating factor and leukotriene C₄, both of which can cause vasoconstriction, smooth muscle contraction, and mucus hypersecretion (Fig. 155.1). Eosinophils are a source of a number of proinflammatory cytokines, including IL-1, IL-3, IL-4, IL-5, IL-9, IL-13, and GM-CSF. They have also been shown to influence T-cell recruitment and
immune polarization in inflammatory settings. Thus, eosinophils have considerable potential to initiate and sustain the inflammatory response of the innate and acquired immune systems.

**FIG. 155.1** Schematic diagram of an eosinophil and its diverse properties. Eosinophils are bilobed granulocytes that respond to diverse stimuli, including allergens, helminths, viral infections, allografts, and nonspecific tissue injury. Eosinophils express the receptor for IL-5, a critical eosinophil growth and differentiation factor, as well as the receptor for eotaxin and related chemokines (CCR3). The secondary granules contain four primary cationic proteins designated eosinophil peroxidase (EPO), major basic protein (MBP), eosinophil cationic protein (ECP) and eosinophil-derived neurotoxin (EDN). All 4 proteins are cytotoxic molecules; also, ECP and EDN are ribonucleases. In addition to releasing their preformed cationic proteins, eosinophils can release a variety of cytokines, chemokines and neuromediators and generate large amounts of LTC4. Lastly, eosinophils can be induced to express MHC class II and co-stimulatory molecules and may be involved in propagating immune responses by presenting antigen to T cells. (From Leung YM, Szeffler SJ, Bomilla FA, Akdis CA, Sampson HA: Pediatric allergy principles and practice, ed 3, Philadelphia, 2016, Elsevier, p 42.)

Eosinophil migration from the vasculature into the extracellular tissue is mediated by the binding of leukocyte adhesion receptors to their ligands or counterstructures on the postcapillary endothelium. Similar to neutrophils (see **Fig. 153.2**), transmigration begins as the eosinophil selectin receptor binds to the endothelial carbohydrate ligand in loose association, which promotes eosinophils rolling along the endothelial surface until they encounter a priming stimulus such as a chemotactic mediator. Eosinophils then establish a high-
affinity bond between integrin receptors and their corresponding immunoglobulin-like ligand. Unlike neutrophils, which become flattened before transmigrating between the tight junctions of the endothelial cells, eosinophils can use unique integrins, known as very late antigens (VLA-4), to bind to vascular cell adhesion molecule (VCAM)-1, which enhances eosinophil adhesion and transmigration through endothelium. Eosinophils are recruited to tissues in inflammatory states by a group of chemokines known as eotaxins (eotaxin 1, 2, and 3). These unique pathways account for selective accumulation of eosinophils in allergic and inflammatory disorders. Eosinophils normally dwell primarily in tissues, especially tissues with an epithelial interface with the environment, including the respiratory, gastrointestinal (GI), and lower genitourinary tracts. The life span of eosinophils may extend for weeks within tissues.

IL-5 selectively enhances eosinophil production, adhesion to endothelial cells, and function. Considerable evidence shows that IL-5 has a pivotal role in promoting eosinophil poeisis. It is the predominant cytokine in allergen-induced pulmonary late-phase reaction, and antibodies against IL-5 (mepolizumab, reslizumab, benralizumab), decrease sputum eosinophils and reduce exacerbations in a subset of patients with asthma. Eosinophils also bear unique receptors for several chemokines, including RANTES (regulated on activation, normal T-cell expressed and secreted), eotaxin, and monocyte chemotactic proteins 3 and 4. These chemokines appear to be key mediators in the induction of tissue eosinophilia.

Diseases Associated With Eosinophilia

The absolute eosinophil count (AEC) is used to quantify peripheral blood eosinophilia. Calculated as the white blood cell (WBC) count/µL × percent of eosinophils, it is usually <450 cells/µL and varies diurnally, with eosinophil numbers higher in the early morning and diminishing as endogenous glucocorticoid levels rise.

Many diseases with allergic, infectious, hematologic, autoimmune, or idiopathic origins are associated with moderate (AEC 1,500-5,000 cells/µL) or severe (AEC >5,000 cells/µL) eosinophilia in peripheral blood (Table 155.1). These disorders may range from mild and transient to chronic and life threatening. Importantly, blood eosinophil numbers do not always reflect the extent of eosinophil involvement in tissues and degranulation products may
more accurately reflect disease activity. Because prolonged eosinophilia is associated with end-organ damage, especially involving the heart, patients with persistently elevated AECs should undergo a thorough evaluation to search for an underlying cause.

Immunodeficiency/Immune Dysregulation Disease
Allergic Diseases

Allergy is the most common cause of eosinophilia in children in the United States. Patients with allergic asthma typically have eosinophils in the blood, sputum, and/or lung tissue. Hypersensitivity drug reactions can elicit eosinophilia, and when associated with organ dysfunction (e.g., DRESS [drug rash with eosinophilia and systemic symptoms]), these reactions can be serious (see Chapter 177). If a drug is suspected of triggering eosinophilia, biochemical evidence of organ dysfunction should be sought, and if found, the drug should be discontinued. Various skin diseases have also been associated with eosinophilia, including atopic dermatitis/eczema, pemphigus, urticaria, and toxic epidermal necrolysis.

Eosinophilic gastrointestinal diseases are important emerging allergic causes of eosinophilia in tissue and, in some cases, peripheral blood (see Chapter 363). In these conditions, eosinophils are recruited to esophagus, stomach, and/or intestine, where they cause tissue inflammation and clinical symptoms such as dysphagia, food aversion, abdominal pain, vomiting, and diarrhea. Treatment
options include allergen elimination diets and swallowed or inhaled corticosteroids.

**Infectious Diseases**

Eosinophilia is often associated with invasive infection with multicellular helminthic parasites, which are the most common cause in developing countries. Table 155.1 includes examples of specific organisms. The level of eosinophilia tends to parallel the magnitude and extent of tissue invasion, especially by larvae such as *visceral larva migrans* (see Chapter 324 ). Eosinophilia often *does not* occur in established parasitic infections that are well contained within tissues or are solely intraluminal in the gastrointestinal tract, such as *Giardia lamblia* and *Enterobius vermicularis* infection.

In evaluating patients with unexplained eosinophilia, the dietary history and geographic or travel history may indicate potential exposures to helminthic parasites. It is frequently necessary to examine the stool for ova and larvae at least 3 times. Additionally, the diagnostic parasite stages of many of the helminthic parasites that cause eosinophilia never appear in feces. Thus, normal results of stool examinations do not absolutely preclude a helminthic cause of eosinophilia; diagnostic blood tests or tissue biopsy may be needed. *Toxocara* causes visceral larva migrans usually in toddlers with pica (see Chapter 324 ). Most young children are asymptomatic, but some develop fever, pneumonitis, hepatomegaly, and hypergammaglobulinemia accompanied by severe eosinophilia. Isohemagglutinins are frequently elevated, and serology can establish the diagnosis.

Two fungal diseases may be associated with eosinophilia: aspergillosis in the form of *allergic bronchopulmonary aspergillosis* (see Chapter 264.1 ) and *coccidioidomycosis* (see Chapter 267 ) following primary infection, especially in conjunction with erythema nodosum. HIV infection can also be associated with peripheral eosinophilia.

**Hypereosinophilic Syndrome**

The idiopathic hypereosinophilic syndrome is a heterogeneous group of disorders characterized by sustained overproduction of eosinophils. The 3 diagnostic criteria for this disorder are (1) AEC >1,500 cells/µL persisting for 6 mo or longer or at least on 2 occasions or with evidence of tissue eosinophilia;
(2) absence of another diagnosis to explain the eosinophilia; and (3) signs and symptoms of hypereosinophilic syndrome can be heterogeneous because of the diversity of potential organ (pulmonary, cutaneous, neurologic, serosal, GI) involvement. Eosinophilic endomyocardial disease, one of the most serious and life-threatening complications, can cause heart failure from endomyocardial thrombosis and fibrosis. Eosinophilic leukemia, a clonal myeloproliferative variant, may be distinguished from idiopathic hypereosinophilic syndrome by demonstrating a clonal interstitial deletion on chromosome 4q12 that fuses the platelet-derived growth factor receptor-α (PDGFRA) and FIP1-like-1 (FIP1L1) genes; this disorder is treated with imatinib mesylate, a tyrosine kinase inhibitor, which helps target the fusion oncoprotein (Fig. 155.2).

![Fig. 155.2](image)

**FIG. 155.2 Revised classification of hypereosinophilic syndromes.** Changes from the previous classification are indicated in red. Dashed arrows identify hypereosinophilic syndrome (HES) forms for which at least some patients have T-cell–driven disease. Classification of myeloproliferative forms has been simplified, and patients with HES and eosinophil hematopoietin–producing T cells in the absence of a T-cell clone are included in the lymphocytic forms of HES. CEL, Chronic eosinophilic leukemia; CSS, Churg-Strauss syndrome; IBD, inflammatory bowel disease. (From Simon HU, Rothenberg ME, Bocher BS, et al: Refining the definition of hypereosinophilic syndrome, J Allergy Clin Immunol 126:47, 2010.)

Therapy is aimed at suppressing eosinophilia and is initiated with corticosteroids. Imatinib mesylate may be effective in FIP1L1-PDGFRα–negative patients. Hydroxyurea or interferon-alfa may be beneficial in patients...
unresponsive to corticosteroids. Specific anti–IL-5 monoclonal antibodies (mepolizumab) target this cytokine, which has a central role in eosinophil differentiation, mobilization, and activity. With therapy, the eosinophil count declines and corticosteroid doses may be reduced. For patients with prominent organ involvement who fail to respond to therapy, the mortality is about 75% after 3 yr.

**Miscellaneous Diseases**

Eosinophilia is observed in many patients with primary immunodeficiency syndromes, especially hyper-IgE syndrome, Wiskott-Aldrich syndrome, and Omenn syndrome (see Chapters 148 and 152). Eosinophilia is also frequently present in the syndrome of thrombocytopenia with absent radii and in familial reticuloendotheliosis with eosinophilia. Eosinophilia can be found in patients with Hodgkin disease, as well as in acute lymphoid and myeloid leukemia. Other considerations include GI disorders such as ulcerative colitis, Crohn disease during symptomatic phases, chronic hepatitis, eosinophilic granulomatosis with polyangiitis (Churg-Strauss vasculitis), and adrenal insufficiency.

**Bibliography**

Neutrophils are the first line of defense against microbial invasion. They arrive at the site of inflammation during the critical 2-4 hr after microbial invasion to contain the infection and prevent hematogenous dissemination. This well-orchestrated process is one of the most interesting stories in modern cell biology. In fact, much of our knowledge about neutrophil function derives from studies done in patients with genetic errors in neutrophil function. These critical functions and their associated disorders are depicted in Fig. 153.2. Children with phagocytic dysfunction present at a young age with recurrent infections that often involve unusual organisms and are poorly responsive to treatment.

Primary defects of phagocytic function comprise <20% of immunodeficiencies, and there is significant overlap in the presenting signs and symptoms between phagocytic disorders and lymphocyte and humoral disorders. Children with phagocytic defects present with deep tissue infection, pneumonia, adenitis, or osteomyelitis rather than bloodstream infections (Tables 156.1 and 156.2 and Fig. 156.1). A few clinical features point to phagocyte defects rather than other immunodeficiencies, but correct diagnosis relies on highly specialized laboratory tests.

AMP, Adenosine monophosphate; AR, autosomal recessive; C, complement; CD, cluster of differentiation; ELAM, endothelial-leukocyte adhesion molecule; FMF, familial Mediterranean fever; G6PD, glucose-6-phosphate dehydrogenase; GDP, guanosine diphosphate; ICAM, intracellular adhesion molecule; IL-1, interleukin-1; NADPH, nicotinamide adenine dinucleotide phosphate; NK, natural killer.

Chemotaxis, the direct migration of cells into sites of infection, involves a complex series of events (see Chapter 153). Disorders of adhesion or granule abnormalities can have intermediate or profound motility defects, and the propensity to infections is related to a combination of these functional deficits. One family with recessively inherited neutrophil actin dysfunction demonstrated that a pure severe chemotactic defect can result in fatal recurrent infection. Defective in vitro chemotaxis of neutrophils can be detected in children with various clinical conditions. However, unless chemotaxis is essentially absent, it is difficult to establish whether frequent infections arise from a primary chemotactic abnormality or occur as secondary medical complications of the underlying disorder. Dental infection with *Capnocytophaga* is associated with a clear neutrophil motility defect that resolves when the infection is eliminated.

Motility defects present with significant skin and mucosal infections. Tender cutaneous nodular lesions may also be present and characteristically do not contain neutrophils. In fact, presence of a true abscess makes the diagnosis of a significant chemotactic defect less likely.

Laboratory tests of chemotaxis are biologic assays and have high variability.
except in the most experienced hands. The assays must be done on freshly obtained blood and are affected by many factors related to blood sampling itself. It is best to assay other features of the suspected disorder, such as surface marker expression, to establish a specific diagnosis.

**Leukocyte Adhesion Deficiency**

Leukocyte adhesion deficiency types 1 (LAD-1), 2 (LAD-2), and 3 (LAD-3) are rare autosomal recessive disorders of leukocyte function. LAD-1 affects about 1 per 10 million individuals and is characterized by recurrent bacterial and fungal infections and depressed inflammatory responses despite striking blood neutrophilia (Table 156.3 ). The neutrophils have significant defects in adhesion, motility, and ability to phagocytose bacteria.

CDG-IIc, Congenital disorder of glycosylation IIc, OMIM, Online Mendelian Inheritance in Man.

**Genetics and Pathogenesis**
**LAD-1** results from mutations of the gene on chromosome 21q22.3 encoding CD18, the 95-kDa β₂-leukocyte transmembrane integrin subunit. Normal neutrophils express 4 heterodimeric adhesion molecules: LFA-1 (CD11a/CD18), Mac-1 (CD11b/CD18, also known as CR3 or iC3b receptor), p150,95 (CD11c/CD18), and α₁β₂ (CD11d/CD18). These 4 transmembrane adhesion molecules are composed of unique extracellular α₁ encoded on chromosome 16, and they share a common β₂ subunit (CD18) that links them to the membrane and connects them to intracellular signal transduction machinery. This group of leukocyte integrins is responsible for the tight adhesion of neutrophils to the endothelial cell surface, egress from the circulation, and adhesion to iC3b-coated microorganisms, which promotes phagocytosis and particulate activation of the phagocyte nicotinamide adenine dinucleotide phosphate (NADPH) oxidase. Some mutations of CD11/CD18 allow a low level of assembly and activity of integrin molecules, resulting in retention of some neutrophil integrin adhesion function and a moderate phenotype.

Because of their inability to adhere firmly to intercellular adhesion molecules 1 (ICAM-1) and 2 (ICAM-2) expressed on inflamed endothelial cells (see Chapter 153), neutrophils cannot transmigrate through the vessel wall and move to the site infection. Furthermore, neutrophils that do arrive at inflammatory sites fail to recognize microorganisms opsonized with complement fragment iC3b, an important stable opsonin formed by the cleavage of C3b. Therefore, other neutrophil functions such as degranulation and oxidative metabolism normally triggered by iC3b binding are also greatly compromised in LAD-1 neutrophils, resulting in impaired phagocytic function and high risk for serious and recurrent bacterial infections.

Monocyte function is also impaired, with poor fibrinogen-binding function, an activity that is promoted by the CD11/CD18 complex. Consequently, such cells are unable to participate effectively in wound healing.

Children with **LAD-2** share the clinical features of LAD-1 but have normal CD11/CD18 integrins. Features unique to LAD-2 include neurologic defects, cranial facial dysmorphism, and absence of the erythrocyte ABO blood group antigen (Bombay phenotype). LAD-2 (also known as congenital disorder of glycosylation IIc (CDG-IIc)) derives from mutations in the gene encoding a specific guanosine diphosphate (GDP)-L-fucose transporter of the Golgi apparatus. This abnormality prevents the incorporation of fucose into various cell surface glycoproteins, including the carbohydrate structure sialyl Lewis X.
that is critical for low-affinity rolling adhesion of neutrophils to vascular endothelium. This is an important initial step necessary for subsequent integrin-mediated activation, spreading, and transendothelial migration. Infections in LAD-2 are milder than that in LAD-1.

LAD-3 is characterized by a Glanzmann thrombasthenia–like bleeding disorder, delayed separation of the umbilical cord, and serious skin and soft tissue infections similar to those seen in LAD-1, and failure of leukocytes to undergo β₂ - and β₁ -integrin–mediated adhesion and migration. Mutations in KINDLIN3 affect integrin activation.

Clinical Manifestations

Patients with the severe clinical form of LAD-1 express <0.3% of the normal amount of the β₂ -integrin molecules, whereas patients with the moderate phenotype may express 2–7% of the normal amount. Children with severe forms of LAD present in infancy with recurrent, indolent bacterial infections of the skin, mouth, respiratory tract, lower intestinal tract, and genital mucosa. Significant neutrophilic leukocytosis, often >25,000/mm³, is a prominent feature. They may have a history of delayed separation of the umbilical cord, usually with associated infection of the cord stump. The presence of significant omphalitis is an important feature that distinguishes these rare patients from the 10% of healthy infants who can have cord separation at age 3 wk or later. Skin infection may progress to large chronic ulcers with polymicrobial infection, including anaerobic organisms (Fig. 156.2). The ulcers heal slowly, need months of antibiotic treatment, and often require plastic surgery grafting. Severe gingivitis can lead to early loss of primary and secondary teeth (Fig. 156.3). Infected areas characteristically have very little neutrophilic infiltration.
FIG. 156.2 Skin infection of a patient with leukocyte adhesion deficiency type 1. Failure to form pus, inability to demarcate the fibrotic skin debris, and limited inflammation. *Enterococcus gallinarium* was cultured from the wound. (From Rich RR: Clinical immunology principles and practices, ed 4, Philadelphia, 2013, Saunders, p 273.)

FIG. 156.3 Oral pathology in a patient with leukocyte adhesion deficiency type 1. Gingivitis and severe periodontitis are hallmarks of LAD-1. (From Rich RR: Clinical immunology principles and practices, ed 4, Philadelphia, 2013, Saunders, p 273.)

The pathogens infecting patients with LAD-1 are similar to those affecting patients with severe neutropenia (see Chapter 157) and include *Staphylococcus aureus* and enteric gram-negative organisms such as *Escherichia coli*. These patients are also susceptible to opportunistic infection by fungi such as *Candida* and *Aspergillus*. Typical signs of inflammation, such as swelling, erythema, and
warmth, may be absent. Pus does not form, and few neutrophils are identified microscopically in biopsy specimens of infected tissues. Despite the paucity of neutrophils within the affected tissue, the circulating neutrophil count during infection typically exceeds 30,000/µL and can surpass 100,000/µL. During intervals between infections, the peripheral blood neutrophil count may chronically exceed 12,000/µL. LAD-1 genotypes with only moderate, rather than absent, amounts of functional integrins at the surface of the neutrophil have significantly reduced severity and frequency of infections compared to children with the severe form, although gingival disease is still a prominent feature.

**Laboratory Findings**

The diagnosis of LAD-1 is established most readily by flow cytometric measurements of surface CD11b/CD18 in stimulated and unstimulated neutrophils. Neutrophil and monocyte adherence, aggregation, chemotaxis, and iC3b-mediated phagocytosis demonstrate striking abnormalities. However, these assays are not clinically available. Delayed-type hypersensitivity reactions are normal, and most individuals have normal specific antibody synthesis, although some patients have impaired T-lymphocyte–dependent antibody responses. The diagnosis of LAD-2 is established by flow cytometric measurement of sialyl Lewis X (CD15) on neutrophils. It is important to note that the flow cytometric assays are not done the same as the more common lymphocyte subset analysis and require specialized approaches to detect levels of surface expression, especially to detect milder phenotypes.

**Treatment**

Treatment of LAD-1 depends on the phenotype, as determined by the level of expression of functional CD11/CD18 integrins. Early allogeneic hematopoietic stem cell transplantation (HSCT) is the treatment of choice for severe LAD-1 (and LAD-3). One patient was successfully treated with ustekinumab, an inhibitor of interleukins 12 and 23. Other treatment is largely supportive. Patients can be maintained on prophylactic trimethoprim/sulfamethoxazole (TMP/SMX) and should have close surveillance for early identification of infections and initiation of empirical treatment with broad-spectrum antibiotics. Specific determination of the etiologic agent by culture or biopsy is important because of the prolonged antibiotic treatment required in the absence of
neutrophil function. Some LAD-2 patients have responded to fucose supplementation, which induced a rapid reduction in the circulating leukocyte count and appearance of the sialyl Lewis X molecules, accompanied by marked improvement in leukocyte adhesion.

**Prognosis**

The severity of infectious complications correlates with the degree of $\beta_2$-integrin deficiency. Patients with severe deficiency may die in infancy, and those surviving infancy have a susceptibility to severe life-threatening systemic infections. Patients with moderate deficiency have infrequent life-threatening infections and relatively long survival.

**Chédiak-Higashi Syndrome**

Chédiak-Higashi syndrome (CHS) is a rare autosomal recessive disorder characterized by increased susceptibility to infection caused by defective degranulation of neutrophils, a mild bleeding diathesis, partial oculocutaneous albinism, progressive peripheral neuropathy, and a tendency to develop a life-threatening form of hemophagocytic lymphohistiocytosis (see Chapter 534.2). CHS is caused by a fundamental defect in granule morphogenesis that results in abnormally large granules in multiple tissues. Pigmentary dilution involving the hair, skin, and ocular fundi results from pathologic aggregation of melanosomes. Neurologic deficits are associated with a failure of decussation of the optic and auditory nerves. Patients exhibit an increased susceptibility to infection that can be explained only in part by defects in neutrophil function. The patients have progressive neutropenia as well as abnormalities in natural killer (NK) function, again related to granule dysfunction.

**Genetics and Pathogenesis**

LYST (for lysosomal traffic regulator), the gene mutated in CHS, is located at chromosome 1q2-q44. The LYST/CHS protein is thought to regulate vesicle transport by mediating protein-protein interaction and protein-membrane associations. Loss of function may lead to indiscriminate interactions with
lysosomal surface proteins, yielding giant granules through uncontrolled fusion of lysosomes with each other.

Almost all cells of patients with CHS show some oversized and dysmorphic lysosomes, storage granules, or related vesicular structures. Melanosomes are oversized, and delivery to the keratinocytes and hair follicles is compromised, resulting in hair shafts devoid of pigment granules. This abnormality in melanosomes leads to the macroscopic impression of hair and skin that is lighter than expected from parental coloration. The same abnormality in melanocytes leads to the partial ocular albinism associated with light sensitivity.

Beginning early in neutrophil development, spontaneous fusion of giant primary granules with each other or with cytoplasmic membrane components results in huge secondary lysosomes with reduced contents of hydrolytic enzymes, including proteinases, elastase, and cathepsin G. This deficiency of proteolytic enzymes may be responsible for the impaired killing of microorganisms by CHS neutrophils.

Clinical Manifestations

Patients with CHS have light skin and silvery hair and frequently complain of solar sensitivity and photophobia that is associated with rotary nystagmus. Other signs and symptoms vary considerably, but frequent infections and neuropathy are common. The infections involve mucous membranes, skin, and respiratory tract. Affected children are susceptible to gram-positive bacteria, gram-negative bacteria, and fungi, with Staphylococcus aureus being the most common offending organism. The neuropathy may be sensory or motor in type, and ataxia may be a prominent feature. Neuropathy often begins in the teenage years and becomes the most prominent problem.

Patients with CHS have prolonged bleeding times with normal platelet counts, resulting from impaired platelet aggregation associated with a deficiency of the dense granules containing adenosine diphosphate and serotonin.

The most life-threatening complication of CHS is the development of an accelerated phase characterized by pancytopenia, high fever, and lymphohistiocytic infiltration of liver, spleen, and lymph nodes. The onset of the accelerated phase, which can occur at any age, is now recognized to be a genetic form of hemophagocytic lymphohistiocytosis. This occurs in 85% of patients and usually results in death.
**Laboratory Findings**

The diagnosis of CHS is established by finding large inclusions in all nucleated blood cells. These can be seen on Wright-stained blood films and are accentuated by a peroxidase stain. Because of impaired egress from the bone marrow, cells containing the large inclusions may be missed on peripheral blood smear but readily identified on bone marrow examination. The patients have progressive neutropenia and abnormal platelet, neutrophil, and NK function.

**Treatment**

High-dose ascorbic acid (200 mg/day for infants; 2,000 mg/day for adults) may improve the clinical status of some children in the stable phase. Although controversy surrounds the efficacy of ascorbic acid, given the safety of the vitamin, it is reasonable to administer ascorbic acid to all patients.

The only curative therapy to prevent the accelerated phase is HSCT. Normal stem cells reconstitute hematopoietic and immunologic function, correct the NK cell deficiency, and prevent conversion to the accelerated phase, but cannot correct or prevent the neuropathy. If the patient is in the accelerated phase with active hemophagocytic lymphohistiocytosis, HSCT often fails to prevent death.

**Myeloperoxidase Deficiency**

Myeloperoxidase (MPO) deficiency is an autosomal recessive disorder of oxidative metabolism and is one of the most common inherited disorders of phagocytes, occurring at a frequency approaching 1 per 2,000 individuals. MPO is a green heme protein located in the azurophilic lysosomes of neutrophils and monocytes and is the basis for the greenish tinge to pus accumulated at a site of infection.

**Clinical Manifestations**

MPO deficiency is usually clinically silent. Rarely, patients may have disseminated candidiasis, usually in conjunction with diabetes mellitus. Acquired partial MPO deficiency can develop in acute myelogenous leukemia and in myelodysplastic syndromes.
Laboratory Findings

Deficiency of neutrophil and monocyte MPO can be identified by histochemical analysis. Severe MPO deficiency can cause the dihydrorhodamine (DHR) flow cytometric assay for chronic granulomatous disease (CGD) to be falsely positive. Unlike CGD, eosinophils in severe MPO deficiency will still reduce DHR and yield a normal reaction.

Treatment

There is no specific therapy for MPO deficiency. Aggressive treatment with antifungal agents should be provided for candidal infections. The prognosis is usually excellent.

Chronic Granulomatous Disease

Chronic granulomatous disease is characterized by neutrophils and monocytes capable of normal chemotaxis, ingestion, and degranulation, but unable to kill catalase-positive microorganisms because of a defect in the generation of microbicidal oxygen metabolites. CGD is a rare disease, affecting 4-5 per 1 million individuals; it is caused by 4 genes: 1 X-linked and 3 autosomal recessive in inheritance (Table 156.4).

**Genetics and Pathogenesis**

Activation of the phagocyte NADPH oxidase requires stimulation of the neutrophils and involves assembly from cytoplasmic and integral membrane subunits (see Fig. 153.3). Oxidase activation initiates with phosphorylation of a cationic cytoplasmic protein, p47\(^{phox}\) (47-kDa phagocyte oxidase protein). Phosphorylated p47\(^{phox}\), together with 2 other cytoplasmic components of the oxidase, p67\(^{phox}\) and the low-molecular-weight guanosine triphosphatase Rac2, translocates to the membrane, where they combine with the cytoplasmic domains of the transmembrane flavocytochrome b\(_{558}\) to form the active oxidase complex. The flavocytochrome is a heterodimer composed of p22\(^{phox}\) and highly glycosylated gp91\(^{phox}\). The gp91\(^{phox}\) glycoprotein catalyzes electron transport through its NADPH-binding, flavin-binding, and heme-binding domains. Defects in any of these NADPH oxidase components can lead to CGD.

Approximately 65% of patients with CGD are males who inherit their disorder as a result of mutations in CYBB, an X-chromosome gene encoding gp91\(^{phox}\). Approximately 35% of patients inherit CGD in an autosomal recessive fashion resulting from mutations in the NCF1 gene on chromosome 7, encoding p47\(^{phox}\). Defects in the genes encoding p67\(^{phox}\) (NCF2 on chromosome 1) and p22\(^{phox}\) (CYBA on chromosome 16) are inherited in an autosomal recessive manner and account for approximately 5% of cases of CGD.

The CGD phagocytic vacuoles lack microbicidal reactive oxygen species and remain acidic, so bacteria are not killed or digested properly (Fig. 156.4). Hematoxylin-eosin–stained sections from patients’ tissues show multiple granulomas that give CGD its descriptive name.
Clinical Manifestations

Although the clinical presentation is variable, several features suggest the diagnosis of CGD. Any patient with recurrent pneumonia, lymphadenitis, hepatic, subcutaneous, or other abscesses, osteomyelitis at multiple sites, a family history of recurrent infections, or any infection with an unusual catalase-positive organism requires evaluation. Other clinical features include chronic colitis or enteritis, gastric outlet or ureteral obstruction from granulomas, or bloodstream infection caused by *Salmonella*, *Burkholderia cepacia*, or *Candida*.

The onset of clinical signs and symptoms usually occurs in early infancy, although a few patients with very rare CGD subtypes have presented later in life. The attack rate and severity of infections are exceedingly variable; however, the infection incidence decreases in the 2nd decade, coincident with maturation of
the lymphocyte and humoral immunity. The most common pathogen is *S. aureus*, but any catalase-positive microorganism may be involved. Other organisms frequently causing infections include *Serratia marcescens*, *B. cepacia*, *Aspergillus*, *Candida albicans*, *Nocardia*, and *Salmonella*. There may also be increased susceptibility to mycobacteria, including the bacille Calmette-Guérin vaccine. Pneumonia, lymphadenitis, osteomyelitis, and skin infections are the most common illnesses encountered. Bacteremia or fungemia occurs but is much less common than focal infections and usually only occurs when local infections have been inappropriately treated for long periods. Patients may have sequelae of chronic infection, including anemia of chronic disease, poor growth, lymphadenopathy, hepatosplenomegaly, chronic purulent dermatitis, restrictive lung disease, gingivitis, hydronephrosis, esophageal dysmotility, and pyloric outlet narrowing. Perirectal abscesses and recurrent skin infections, including folliculitis, cutaneous granulomas, and discoid lupus erythematosus, also suggest CGD.

**Granuloma formation** and inflammatory processes are a hallmark of CGD and may be the presenting symptoms that prompt testing for CGD if they cause pyloric outlet obstruction, bladder outlet or ureter obstruction, or rectal fistulas and granulomatous colitis simulating Crohn disease. More than 80% of CGD patients have positive serology for Crohn disease. Persistent fever, especially with splenomegaly and cytopenia warrants an evaluation for secondary macrophage activation syndrome. This has been seen in CGD and may require treatment with corticosteroids and discontinuation of interferon-γ treatment.

**Laboratory Findings**

The diagnosis is most often made by performing flow cytometry using DHR to measure oxidant production through its increased fluorescence when oxidized by hydrogen peroxide (H₂O₂). The nitroblue tetrazolium dye test is frequently cited in the literature but is now only rarely used clinically. The X-linked carrier state is usually easily diagnosed in the mother by DHR fluorescence through a bimodal response to stimulation. It is important to test the mother as some extremely lyonized carriers with <5% positive cells may have chronic clinical problems as well. Ideally, at least the first patient in a kindred should have DNA analysis to facilitate prenatal diagnosis and for genetic counseling purposes.

A few individuals have been described with apparent CGD caused by severe glucose-6-phosphate dehydrogenase deficiency, leading to insufficient NADPH
substrate for the phagocyte oxidase. The erythrocytes of these patients also lack the enzyme, leading to chronic hemolysis.

**Treatment**

HSCT is the only known cure for CGD, although gene therapy has been transiently successful in a few patients and is the topic of active research. HSCT transplant for all patients with CGD is strongly recommended if a suitable sibling or unrelated donor can be identified. The long-term outcome for survival late into adulthood is not good, even in the hands of experienced CGD physicians.

Patients with CGD should be given daily oral TMP/SMX because it reduces the number of bacterial infections. A placebo-controlled study found that interferon-γ 50 µg/m² 3 times/wk significantly reduces the number of hospitalizations and serious infections, although the mechanism of action is unclear. Itraconazole (200 mg/day for patients weighing >50 kg and 100 mg/day for patients <50 kg and ≤5 yr old) administered prophylactically reduces the frequency of fungal infections.

Management of infection is dramatically different than in normal children. CGD patients are always at risk for deep-seated, indolent bacterial infections that can become widespread if not treated properly. They also develop the same kinds of infections that occur in normal children, so determination of the appropriate treatment can be difficult. The erythrocyte sedimentation rate (ESR) can be quite helpful. If the child does not have a deep-seated infection, the ESR will be normal or will normalize within several days with standard management. If it does not, however, a search for deep tissues is warranted, as is consideration of empirical antibiotics. Cultures should be obtained, but are usually negative. Because all neutrophil functions in CGD except killing are normal, there is often an exuberant inflammatory reaction to a very small number of organisms. Thus, blood cultures and direct cultures of biopsy samples are usually negative unless there are many organisms. Most abscesses require surgical drainage for therapeutic and diagnostic purposes. Prolonged use of antibiotics is required even for common bacterial infections. A simple pneumonia may require 6-8 wk or more of parenteral antibiotics. Infections should be treated for at least 1 wk past normalization of ESR to prevent recurrence. Severe pneumonias can be cleared completely but may require many months of parenteral antibiotics. Especially because cultures are often not helpful, many support an “antibiotic
sensitivity by sedimentation rate response” approach to treatment. The ESRs are often 40-80 mm/hr or more with severe infection and will drop monotonically over a week or so after starting antibacterial drugs. It is important to check the ESR daily or every other day because of moderate variability in this test, and changes in treatment need to be based on trends rather than individual values. If there is a clear downward trend over 3-10 days, continue with antibacterials alone. If this is not the case, parenteral voriconazole should be added to cover Aspergillus. Failure of the ESR to drop suggests another antimicrobial approach needs to be tried. This sequential addition of antimicrobials offers some insight into the nature of the infection. If both antibacterials and antifungal are started at the same time, one cannot know what caused a response.

Because of the rarity of this disorder, it is critical to seek counsel from someone with significant direct experience with management of several CGD patients. Granulocyte transfusions have been used, but their benefit is unclear. The ESR should be regularly monitored in well patients and whenever they appear ill. A high ESR itself is usually not enough to trigger treatment. However, in the presence of symptoms, one should search for sources at least by contrast CT of the sinus, chest, and abdomen. If the patient is unstable or has very high fevers, B. cepacia should be considered and empirically covered. This organism can cause septic shock quickly, unlike the usual smoldering infections seen in CGD. The patient can be treated with antibiotics until the ESR is normal and radiographic evidence of infection has been cleared, if possible. The overall incidence of infection decreases in the 2nd decade of life as nonneutrophil immunity matures, but increased risk of infection is lifelong.

Corticosteroids may be useful for the treatment of children with antral and urethral obstruction or severe granulomatous colitis. Corticosteroids can also be helpful in pneumonia to shrink granulomas in the lung and promote drainage. Short (4-6 days) pulses of 1-2 mg/kg of prednisone are recommended, with rapid taper to avoid long-term side effects and risk of fungus. Pulses can be repeated if clinical effect has not been achieved.

**Genetic Counseling**

Identifying a patient's specific genetic subgroup by DNA analysis is useful primarily for genetic counseling and prenatal diagnosis. In X-linked CGD, all possibly affected females should be tested by DHR to exclude carrier state. Diagnosis by DNA is strongly recommended in suspected carriers with normal
DHR who are related to a known proband, because rarely DHR testing is normal in obligate carriers. Counseling is best done by a physician who has direct knowledge of the clinical manifestations of CGD.

Prognosis

The overall mortality rate for CGD is about 2 patient deaths per year per 100 cases, with the highest mortality among young children. The development of effective infection prophylaxis regimens, close surveillance for signs of infections, and aggressive surgical and medical interventions have improved the prognosis.

Leukopenia refers to an abnormally low number of white blood cells (WBCs) in the circulating blood secondary to a paucity of lymphocytes, granulocytes, or both. Because there are marked developmental changes in normal values for WBC counts during childhood (see Chapter 748), normal ranges must be considered in the context of age. For newborns, the mean WBC count at birth is high, followed by a rapid fall beginning at 12 hr through the 1st wk of life. Thereafter, values are stable until 1 yr of age, after which a slow, steady decline in the WBC count continues throughout childhood until adult values are reached during adolescence. Evaluation of patients with leukopenia begins with a thorough history, physical examination, and at least 1 confirmatory complete blood count with differential. Further evaluation then depends on whether the leukopenia represents a decreased number of neutrophils, lymphocytes, or both cell populations (Table 157.1). Treatment depends on the etiology and clinical manifestations of the leukopenia.

Neutropenia

Neutropenia is defined as a decrease in the absolute number of circulating segmented neutrophils and bands in the peripheral blood. The **absolute neutrophil count (ANC)** is determined by multiplying the total WBC count by the percentage of segmented neutrophils plus bands. Normal neutrophil counts must be stratified for age and race. Neutrophils predominate at birth but rapidly decrease in the 1st few days of life. During infancy, neutrophils constitute 20–30% of circulating leukocyte populations. Near-equal numbers of neutrophils and lymphocytes are found in the peripheral circulation at 5 yr of age, and the characteristic 70% predominance of neutrophils that occurs in adulthood is usually attained during puberty. For white children >12 mo old, the lower limit of normal for the ANC is 1,500/µL; for black children >12 mo old, the lower limit of normal is 1,200/µL. The relatively lower limit of normal in blacks likely reflects the prevalence of the Duffy negative (Fy−/−) blood group, which is enriched in populations in the malarial belt of Africa and is associated with ANCs 200-600/µL less than those who are Duffy positive.

Neutropenia may be characterized as **mild** (ANC 1,000-1,500/µL), **moderate** (ANC 500-1,000/µL), or **severe** (ANC <500/µL). ANC <200 is also termed **agranulocytosis**. This stratification aids in predicting the risk of pyogenic infection in patients who have neutropenia resulting from disorders of bone marrow production, because only patients with severe neutropenia have a significantly increased susceptibility to life-threatening infections. Neutropenia associated with monocytopenia, lymphocytopenia, or hypogammaglobulinemia increases the risk for infection compared to isolated neutropenia. *Patients with neutropenia caused by increased destruction (e.g., autoimmune) may tolerate very low ANCs without increased frequency of infection*, because of their often robust ability to generate additional neutrophils from their functioning marrow when needed.

**Acute neutropenia** evolves over a few days and is often a result of rapid neutrophil use and compromised neutrophil production. **Chronic neutropenia** by definition lasts longer than 3 mo and arises from reduced production, increased destruction, or excessive splenic sequestration of neutrophils. The etiology of neutropenia can be classified as either an acquired disorder or extrinsic insult (**Table 157.2**) or more rarely an inherited, intrinsic defect (**Table 157.3**).

### Clinical Manifestations of Neutropenia

Individuals with neutrophil counts <500/µL are at substantial risk for developing
infections, primarily from their endogenous flora as well as from nosocomial organisms. However, some patients with isolated chronic neutropenia may not experience many serious infections, probably because the remainder of the immune system remains intact or because neutrophil delivery to tissues is preserved, as in autoimmune neutropenias. In contrast, children whose neutropenia is secondary to acquired disorders of production, as occurs with cytotoxic therapy, immunosuppressive drugs, or radiation therapy, are likely to develop serious bacterial infections because many arms of the immune system are markedly compromised and the ability of the marrow to robustly generate new phagocytes is impaired. Neutropenia associated with additional monocytopenia or lymphocytopenia is more highly associated with serious infection than neutropenia alone. The integrity of skin and mucous membranes, the vascular supply to tissues, and nutritional status also influence the risk of infection.

The most common clinical presentation of profound neutropenia includes fever, aphthous stomatitis, and gingivitis. Infections frequently associated with neutropenia include cellulitis, furunculosis, perirectal inflammation, colitis, sinusitis, warts, and otitis media, as well as more serious infections such as pneumonia, deep tissue abscess, and sepsis. The most common pathogens causing infections in neutropenic patients are Staphylococcus aureus and gram-negative bacteria. Isolated neutropenia does not heighten a patient's susceptibility to parasitic or viral infections or to bacterial meningitis but does increase the risk of fungal pathogens causing disease. The usual signs and symptoms of local infection and inflammation (e.g., exudate, fluctuance, regional lymphadenopathy) may be diminished in the absence of neutrophils because of the inability to form pus, but patients with agranulocytosis still experience fever and feel pain at sites of inflammation.

Laboratory Findings

Isolated absolute neutropenia has a limited number of causes (see Tables 157.2 to 157.5). The duration and severity of the neutropenia greatly influence the extent of laboratory evaluation. Patients with chronic neutropenia since infancy and a history of recurrent fevers and chronic gingivitis should have WBC counts and differential counts determined 3 times/wk for 6-8 wk to evaluate for periodicity suggestive of cyclic neutropenia. Bone marrow aspiration and biopsy should be performed on select patients to assess cellularity and myeloid...
maturation. Additional marrow studies, such as cytogenetic analysis and special stains for detecting leukemia and other malignant disorders, should be obtained for patients with suspected intrinsic defects in the myeloid progenitors and for patients with suspected malignancy. Selection of further laboratory tests is determined by the duration and severity of the neutropenia and the associated findings on physical examination (see Table 157.1).

### Acquired Neutropenia

#### Infection-Related Neutropenia

Transient neutropenia often accompanies or follows viral infections and is the most frequent cause of neutropenia in childhood (Table 157.4). Viruses causing
acute neutropenia include influenzas A and B, adenovirus, respiratory syncytial
virus, enteroviruses, human herpesvirus 6, measles, rubella, and varicella.
Parvovirus B19 and hepatitis A or B may also cause neutropenia, but are more
often associated with pure red cell aplasia or multiple cytopenias, respectively.
Viral-associated acute neutropenia often occurs during the 1st 24-48 hr of illness
and usually persists for 3-8 days, which generally corresponds to the period of
viremia. The neutropenia is related to virus-induced redistribution of neutrophils
from the circulating to the marginating pool. In addition, neutrophil
sequestration may occur after virus-induced tissue damage or splenomegaly.

Significant neutropenia also may be associated with severe bacterial,
protozoal, rickettsial, or fungal infections (see Table 157.4). Bacterial sepsis is
a particularly serious cause of neutropenia, especially among younger infants
and children. Premature neonates are especially prone to exhausting their
marrow reserve and rapidly succumbing to bacterial sepsis.

Chronic neutropenia often accompanies infection with Epstein-Barr virus,
cytomegalovirus, or HIV and certain immunodeficiencies such as X-linked
agammaglobulinemia, hyper IgM syndrome and HIV. The neutropenia
associated with AIDS probably arises from a combination of viral bone marrow
suppression, antibody-mediated destruction of neutrophils, and effects of
antiretroviral or other drugs.

**Drug-Induced Neutropenia**

Drugs constitute a common cause of neutropenia (Table 157.5). The incidence
of drug-induced neutropenia increases dramatically with age; only 10% of cases
occur among children and young adults. The majority of cases occur among
adults >65 yr, likely reflecting the more frequent use of multiple medications in
that age-group. Almost any drug can cause neutropenia. The most common
offending drug classes are antimicrobial agents, antithyroid drugs,
antipsychotics, antipyretics, and antirheumatics. Drug-induced neutropenia has
several underlying mechanisms—immune-mediated, toxic, idiosyncratic,
hypersensitivity, idiopathic—that are distinct from the severe neutropenia that
predictably occurs after administration of antineoplastic drugs or radiotherapy.

Drug-induced neutropenia from immune mechanisms usually develops
abruptly, is accompanied by fever, and lasts for about 1 wk after the
discontinuation of the drug. The process likely arises from effects of drugs such as
propylthiouracil or penicillin that act as haptns to stimulate antibody
formation, or drugs such as quinine that induce immune complex formation.
Other drugs, including the antipsychotic drugs such as the phenothiazines, can cause neutropenia when given in toxic amounts, but some individuals, such as those with preexisting neutropenia, may be susceptible to levels at the high end of the usual therapeutic range. Late-onset neutropenia can occur after rituximab therapy. Idiosyncratic reactions, for example to chloramphenicol, are unpredictable with regard to dose or duration of use. Hypersensitivity reactions are rare and may involve arene oxide metabolites of aromatic anticonvulsants. Fever, rash, lymphadenopathy, hepatitis, nephritis, pneumonitis, and aplastic anemia are often associated with hypersensitivity-induced neutropenia. Acute hypersensitivity reactions such as those caused by phenytoin or phenobarbital may last for only a few days if the offending drug is discontinued. Chronic hypersensitivity may last for months to years.

Once neutropenia occurs, the most effective therapeutic measure is withdrawal of nonessential drugs, particularly drugs most commonly associated with neutropenia. Usually the neutropenia will resolve soon after withdrawal of the offending drug. If the neutropenia fails to improve with drug withdrawal and the patient is symptomatic with infection or stomatitis, subcutaneous administration of recombinant human granulocyte colony-stimulating factor (filgrastim, 5 µg/kg/day) should be considered. Drug-induced neutropenia may be asymptomatic and noted only as an incidental finding or because of regular monitoring of WBC counts during drug therapy. For patients who are asymptomatic, continuation of the suspected offending drug depends on the relative risks of neutropenia vs discontinuation of a possibly essential drug. If the drug is continued, blood counts should be monitored for possible progression to agranulocytosis.

Neutropenia usually and predictably follows the use of anticancer drugs or radiation therapy, especially radiation directed at the pelvis or vertebrae, secondary to cytotoxic effects on rapidly replicating myeloid precursors. A decline in the WBC count typically occurs 7-10 days after administration of the anticancer drug and may persist for 1-2 wk. The neutropenia accompanying malignancy or following cancer chemotherapy is frequently associated with compromised cellular immunity and barrier compromise secondary to central venous lines and mucositis, thereby predisposing patients to a much greater risk of infection (see Chapter 205) than found in disorders associated with isolated neutropenia. Patients with chemotherapy/radiation-related neutropenia and fever must be treated aggressively with broad-spectrum antibiotics.
Nutrition-Related Neutropenia

Poor nutrition can contribute to neutropenia. Ineffective myelopoiesis may result in neutropenia caused by acquired dietary copper, vitamin B<sub>12</sub>, or folic acid deficiency. In addition, megaloblastic pancytopenia also can result from extended use of antibiotics such as trimethoprim/sulfamethoxazole that inhibit folic acid metabolism and from the use of phenytoin, which may impair folate absorption in the small intestine, or from surgical resection of the small intestine. Neutropenia also occurs with starvation and marasmus in infants, with anorexia nervosa, and occasionally among patients receiving prolonged parenteral nutrition without vitamin supplementation.

Immune-Mediated Neutropenia

Immune-mediated neutropenia is usually associated with the presence of circulating antineutrophil antibodies, which may mediate neutrophil destruction by complement-mediated lysis or splenic phagocytosis of opsonized neutrophils, or by accelerated apoptosis of mature neutrophils or myeloid precursors. **Alloimmune neonatal neutropenia** occurs after transplacental transfer of maternal alloantibodies directed against antigens on the infant's neutrophils, analogous to Rh-hemolytic disease. Prenatal sensitization induces maternal IgG antibodies to neutrophil antigens on fetal cells. The neutropenia is often severe and infants may present within the 1st 2 wk of life with skin or umbilical infections, fever, and pneumonia caused by the usual microbes that cause neonatal disease. By 7 wk of age, the neutrophil count usually returns to normal, reflecting the decay of maternal antibodies in the infant's circulation. Treatment consists of supportive care and appropriate antibiotics for clinical infections, plus granulocyte colony-stimulating factor (G-CSF) for severe infections without neutrophil recovery.

Mothers with autoimmune disease may give birth to infants who develop transient neutropenia, known as **neonatal passive autoimmune neutropenia**. The duration of the neutropenia depends on the time required for the infant to clear the maternally transferred circulating IgG antibody. It persists in most cases for a few weeks to a few months. Neonates almost always remain asymptomatic.

**Autoimmune neutropenia (AIN) of infancy** is a benign condition with an annual incidence of approximately 1 per 100,000 among children between infancy and 10 yr of age. Patients usually have severe neutropenia on presentation, with ANC <500/µL, but the total WBC count is generally within
normal limits. Monocytosis or eosinophilia may occur but does not impact the low rate of infection. The median age of presentation is 8-11 mo, with a range of 2-54 mo. The diagnosis is often evident when a blood count incidentally reveals neutropenia in a child with a minor infection or when a routine complete blood count is obtained at the 12 mo well-child visit. Occasionally, children may present with more severe infections, including abscesses, pneumonia, or sepsis. The diagnosis may be supported by the presence of antineutrophil antibodies in serum; however, the test has frequent false-negative and false-positive results, so the absence of detectable antineutrophil antibodies does not exclude the diagnosis, and a positive result does not exclude other conditions. Therefore the diagnosis is best made clinically based on a benign course and, if obtained, a normal or hyperplastic myeloid maturation in the bone marrow. There is considerable overlap between AIN of infancy and “chronic benign neutropenia.”

Treatment is not generally necessary because the disease is only rarely associated with severe infection and usually remits spontaneously. Low-dose G-CSF may be useful for severe infections, to promote wound healing following surgery, or to avert emergency room visits or hospitalizations for febrile illnesses. Longitudinal studies of infants with AIN demonstrate median duration of disease ranging from 7-30 mo. Affected children generally have no evidence or risk of other autoimmune diseases.

**AIN in older children** can occur as an isolated process, as a manifestation of other autoimmune diseases, or as a secondary complication of infection, drugs, or malignancy. In primary AIN, low circulating neutrophil counts are the only hematologic finding, and associated diseases or other factors that cause neutropenia are absent. Secondary AIN associated with immune dysregulation or other factors is more often identified in older children and is less likely to remit spontaneously. AIN is distinguished from other forms of neutropenia by the demonstration of antineutrophil antibodies (with caveats previously discussed) and myeloid hyperplasia on bone marrow examination. The most common antineutrophil antibody targets are human neutrophil antigens 1a, 1b, and 2.

Treatment of AIN relies on management of any underlying disorders. In addition, judicious use of appropriate antibiotics for bacterial infections and regular dental hygiene are generally beneficial, as is family and primary care provider education. Infections tend to be less frequent in AIN than with the corresponding degree of neutropenia from other causes, probably because tissue delivery of neutrophils is greater than that in conditions resulting from impaired production. Prophylactic antibiotics may be helpful for the management of
recurrent minor infections. For patients with serious or recurrent infections, G-CSF is generally effective at raising the ANC and preventing infection. Very low doses (<1-2 µg/kg/day) are usually effective, and administration of standard doses can lead to severe bone pain from marrow expansion.

**Neutropenia Secondary to Bone Marrow Replacement**

Various acquired bone marrow disorders lead to neutropenia, usually accompanied by anemia and thrombocytopenia. Hematologic malignancies, including leukemia, lymphoma, and metastatic solid tumors, suppress myelopoiesis by infiltrating the bone marrow with tumor cells. Neutropenia may also accompany aplastic anemia, myelodysplastic disorders, or preleukemic syndromes, which are characterized by multiple cytopenias and often macrocytosis. Treatment requires management of the underlying disease.

**Neutropenia Secondary to Reticuloendothelial Sequestration**

Splenic enlargement resulting from intrinsic splenic disease (storage disease), portal hypertension, or systemic causes of splenic hyperplasia (inflammation or neoplasia) can lead to neutropenia. Most often the neutropenia is mild to moderate and is accompanied by corresponding degrees of thrombocytopenia and anemia. The reduced neutrophil survival corresponds to the size of the spleen, and the extent of the neutropenia is inversely proportional to bone marrow compensatory mechanisms. Usually the neutropenia can be corrected by successfully treating the underlying disease. In select cases, splenectomy may be necessary to restore the neutrophil count to normal, but results in increased risk of infections by encapsulated bacterial organisms. Patients undergoing splenectomy should receive appropriate preoperative immunizations and may benefit from antibiotic prophylaxis after splenectomy to help mitigate the risk of sepsis. Splenectomy should be avoided in patients with common variable immunodeficiency (CVID), autoimmune lymphoproliferative disease, and other immunodeficiency syndromes because of the higher risk of sepsis.

**Inherited Neutropenia**

Intrinsic disorders of proliferation or maturation of myeloid precursor cells are rare. Table 157.6 presents a classification based on genetics and molecular
mechanisms; select disorders are discussed next.

Primary Disorders of Granulocytopenias

Cyclic neutropenia is an autosomal dominant congenital granulopoietic disorder occurring with an estimated incidence of 0.5-1 cases per 1 million population. The disorder is characterized by regular, periodic oscillations, with the ANC ranging from normal to <200/µL, mirrored by reciprocal cycling of monocytes. Cyclic neutropenia is sometimes termed cyclic hematopoiesis because of the secondary cycling of other blood cells, such as platelets and reticulocytes. The mean oscillatory period of the cycle is 21 days (±4 days). During the neutropenic nadir, many patients develop malaise, fever, oral and genital ulcers, gingivitis, periodontitis, or pharyngitis, and occasionally lymph node enlargement. More serious infections occasionally occur, including pneumonia, mastoiditis, and intestinal perforation with peritonitis leading to life-threatening clostridial sepsis. Before the availability of G-CSF, approximately 10% of patients developed fatal clostridial or gram-negative infections. Cyclic neutropenia arises from a regulatory abnormality involving early hematopoietic precursor cells and is almost invariably associated with mutations in the neutrophil elastase gene, ELANE, that lead to accelerated apoptosis as a result of abnormal protein folding. Many patients experience abatement of symptoms with age. The cycles tend to become less noticeable in older patients, and the hematologic picture often begins to resemble that of chronic idiopathic neutropenia.

Cyclic neutropenia is diagnosed by obtaining blood counts 3 times/wk for 6-8 wk. The requirement for repeated blood counts is necessary because some of the elastase mutations overlap with those in patients who have severe congenital neutropenia. Demonstrating oscillation or a lack thereof in the blood counts...
helps to identify the patients' risk for progression to myelodysplastic syndrome (MDS)/acute myelogenous leukemia (AML), a risk that is only associated with severe congenital neutropenia. The diagnosis can be confirmed with genetic studies demonstrating a mutation in ELANE. Affected patients with neutrophil nadirs <200/µL are treated with G-CSF, and their cycle of profound neutropenia changes from a 21-day period with at least 3-5 days of profound neutropenia to 9-11 days with 1 day of less profound neutropenia. The dose needed to maintain nadirs >500/µL is usually 2-4 µg/kg/day administered daily or every other day.

Severe congenital neutropenia (SCN) is a rare, genetically heterogeneous, congenital granulopoietic disorder with an estimated incidence of 1-2 cases per 1 million population. The disorder is characterized by an arrest in myeloid maturation at the promyelocyte stage in the bone marrow, resulting in ANCs consistently <200/µL and may occur sporadically, with autosomal dominant or recessive inheritance. The dominant form is caused most often by mutations in ELANE, which accounts for 60–80% of SCN cases, whereas recessive forms arise from mutations in HAX1 (the form also known as Kostmann disease) or G6PC3 (encoding a myeloid-specific isoform of glucose-6-phosphatase). HAX1 mutations may be associated with neurologic deficits, and G6PC3 with heart defects, urogenital abnormalities, and venous angiectasia. In addition to severe neutropenia, peripheral blood counts generally show monocytosis and many also exhibit eosinophilia; chronic inflammation may lead to secondary anemia and thrombocytosis. Patients who have SCN experience frequent episodes of fever, skin infections (including omphalitis), oral ulcers, gingivitis, pneumonia, and perirectal abscesses, typically appearing in the 1st few mo of life. Infections often disseminate to the blood, meninges, and peritoneum and are usually caused by S. aureus, Escherichia coli, and Pseudomonas species. Without filgrastim therapy, most patients die of infectious complications within the first 1-2 yr of life despite prophylactic antibiotics.

More than 95% of SCN patients respond to filgrastim treatment with an increase in the ANC and a decrease in infections. Doses required to achieve an ANC >1000/uL vary greatly. A starting dose of filgrastim at 5 µg/kg/day is recommended; the dose should be gradually increased, if necessary, as high as 100 µg/kg/day to attain an ANC of 1,000-2,000/µL. The 5% of patients who do not respond to filgrastim or who require high doses (>8 µg/kg/day) should be considered for hematopoietic stem cell transplantation (HSCT). Besides infections, patients with SCN are at risk for developing MDS associated with monosomy 7 and AML. For this reason, regular monitoring with blood counts...
and yearly bone marrow surveillance, including karyotyping and fluorescence in situ hybridization, should be performed on all SCN patients. Although clonal cytogenetic abnormalities may spontaneously remit, their appearance should be considered a strong indication for HSCT, which is much more likely to be successful before progression to MDS/AML.

**Disorders of Molecular Processing**

**Shwachman-Diamond syndrome (SDS)** is an autosomal recessive disorder classically characterized by neutropenia, pancreatic insufficiency, and short stature with skeletal abnormalities. SDS is most commonly caused by proapoptotic mutations of the *SBDS* gene, which encodes a protein that plays a role in ribosome biogenesis and RNA processing. The initial symptoms are usually steatorrhea and failure to thrive because of malabsorption, which usually develops by 4 mo of age, although the gastrointestinal symptoms may be subtle in some patients and go unrecognized. Patients have also been reported to have respiratory problems with frequent otitis media, pneumonia, and eczema. Virtually all patients with SDS have neutropenia, with the ANC periodically <1000/µL. Some children have defects in chemotaxis or in the number or function of B, T, and natural killer (NK) cells that may contribute to the increased susceptibility to pyogenic infection. The diagnosis of SDS is based on clinical phenotype; approximately 90% of patients have mutations identified in *SBDS* with additional mutations now recently discovered in *DNAJC21, EFL1*, and *SRP54*. SDS may progress to bone marrow hypoplasia or MDS/AML; cytogenetic abnormalities, particularly isochromosome i(7q) and del(20q), often precede conversion to MDS, so bone marrow monitoring is warranted. Treatment includes pancreatic enzyme replacement, plus G-CSF in patients with severe neutropenia.

**Dyskeratosis congenita**, a disorder of telomerase activity, most often presents as bone marrow failure rather than isolated neutropenia. The classic phenotype also includes nail dystrophy, leukoplakia, malformed teeth, and reticulated hyperpigmentation of the skin, although many patients, particularly young ones, do not exhibit these clinical features.

**Vesicular Trafficking Disorders**

This group of rare primary immunodeficiency syndromes (see Table 157.6) derives from autosomal recessive defects in the biogenesis or trafficking of
lysosomes and related endosomal organelles. As a result, the syndromes share phenotypic characteristics, including defects in melanosomes contributing to partial albinism, abnormal platelet function, and immunologic defects involving not only neutrophil number, but also the function of neutrophils, B lymphocytes, NK cells, and cytotoxic T lymphocytes. The syndromes share a high risk of hemophagocytic lymphohistiocytosis (HLH) as a result of defects in T and NK cells.

**Chédiak-Higashi syndrome**, best known for the characteristic giant cytoplasmic granules in neutrophils, monocytes, and lymphocytes, is a disorder of subcellular vesicular dysfunction caused by mutations in the *LYST* gene, with resultant giant granules in all granule-bearing cells. Patients have increased susceptibility to infections, mild bleeding diathesis, progressive peripheral neuropathy, and predisposition to life-threatening HLH. The only curative treatment is HSCT, but transplant does not treat all aspects of the disorder.

**Griscelli syndrome type II** also features neutropenia, partial albinism, and a high risk of HLH, but peripheral blood granulocytes do not show giant granules. Patients often have hypogammaglobulinemia. The disorder is caused by mutations in *RAB27a*, which encodes a small guanosine triphosphatase that regulates granule secretory pathways. The only curative treatment is HSCT.

**Disorders of Metabolism**

Recurrent infections with neutropenia are a distinctive feature of **glycogen storage disease (GSD) type Ib**. As in classic **von Gierke disease** (GSDIa), glycogen storage in GSDIb causes massive hepatomegaly and severe growth retardation. Mutations in glucose-6-phosphate transporter 1, *G6PT1*, inhibit glucose transport in GSDIb, resulting in both defective neutrophil motility and increased apoptosis associated with neutropenia and recurrent bacterial infections. Treatment with G-CSF can correct the neutropenia but does not correct the underlying functional neutrophil defects.

**Neutropenia in Disorders of Immune Dysfunction**

Congenital immunologic disorders that have severe neutropenia as a clinical feature include X-linked agammaglobulinemia (XLA), CVID, the severe combined immunodeficiencies, autoimmune lymphoproliferative syndrome, hyperimmunoglobulin M syndrome, WHIM (warts, hypogammaglobulinemia, infections, myelokathexis) syndrome, GATA2 haploinsufficiency, and a number
of even rarer immunodeficiency disorders (see Table 157.6).

**Unclassified Neutropenic Disorders**

**Chronic benign neutropenia** of childhood represents a common group of disorders characterized by mild to moderate neutropenia that does not lead to an increased risk of pyogenic infections. Spontaneous remissions are often reported, although these may represent misdiagnosis of AIN of infancy, in which remissions often occur during childhood. Chronic benign neutropenia may be sporadic or inherited in either dominant or recessive form. Because of the relatively low risk of serious infection, patients usually do not require any therapy.

**Idiopathic chronic neutropenia** is characterized by the onset of neutropenia after 2 yr of age, with no identifiable etiology. Patients with an ANC persistently <500/µL may have recurrent pyogenic infections involving the skin, mucous membranes, lungs, and lymph nodes. Bone marrow examination reveals variable patterns of myeloid formation with arrest generally occurring between the myelocyte and band forms. The diagnosis overlaps with chronic benign and AINs.

**Treatment**

The management of acquired transient neutropenia associated with malignancies, myelosuppressive chemotherapy, or immunosuppressive chemotherapy differs from that of congenital or chronic forms of neutropenia. In the former situation, infections sometimes are heralded only by fever, and sepsis is a major cause of death. Early recognition and treatment of infections may be lifesaving (see Chapter 205). Therapy of severe chronic neutropenia is dictated by the clinical manifestations. Patients with benign neutropenia and no evidence of repeated bacterial infections or chronic gingivitis require no specific therapy. Superficial infections in children with mild to moderate neutropenia may be treated with appropriate oral antibiotics. In patients who have invasive or life-threatening infections, broad-spectrum intravenous antibiotics should be started promptly.

Subcutaneously administered G-CSF can provide effective treatment of severe chronic neutropenia, including SCN, cyclic neutropenia, and chronic symptomatic idiopathic neutropenias. Treatment leads to dramatic increases in
neutrophil counts, resulting in marked attenuation of infection and inflammation. Doses range from 2-5 µg/kg/day for cyclic, idiopathic, and autoimmune neutropenias, to 5-100 µg/kg/day for SCN. The long-term effects of G-CSF therapy include a propensity for the development of moderate splenomegaly, thrombocytopenia, and rarely vasculitis; only patients with SCN are at risk for MDS/AML.

Patients with SCN or SDS who develop MDS or AML respond only to HSCT; chemotherapy is ineffective. HSCT is also the treatment of choice for aplastic anemia or familial HLH.

**Lymphopenia**

The definition of lymphopenia, as with neutropenia, is age dependent and can have acquired or inherited causes. The absolute lymphocyte count (ALC) is determined by multiplying the total WBC count by the percentage of total lymphocytes. For children <12 mo old, lymphopenia is defined as an ALC <3,000 cells/µL. For older children and adults, an ALC <1,000 cells/µL is considered lymphopenia. In isolation, mild to moderate lymphopenia is generally a benign condition often detected only in the evaluation of other illnesses. However, severe lymphopenia can result in serious, life-threatening illness. Lymphocyte subpopulations can be measured by flow cytometry, which uses the pattern of lymphocyte antigen expression to quantitate and classify T, B, and NK cells.

**Acquired Lymphopenia**

Acute lymphopenia is most often a result of infection and/or is iatrogenic from lymphocyte-toxic medications and treatments (Table 157.7). Microbial causes include viruses (e.g., respiratory syncytial virus, cytomegalovirus, influenza, measles, hepatitis), bacterial infections (e.g., tuberculosis, typhoid fever, histoplasmosis, brucellosis), and malaria. The mechanisms behind infection-associated lymphopenia are not fully elucidated but probably include lymphocyte redistribution and accelerated apoptosis. Corticosteroids are a common cause of medication-induced lymphopenia, as are lymphocyte-specific immunosuppressive agents (e.g., antilymphocyte globulin, alemtuzumab, rituximab), chemotherapy drugs, and radiation. In most cases, infectious and iatrogenic causes of acute lymphopenia are reversible, although full lymphocyte
recovery from chemotherapy and lymphocyte-specific immunosuppressive agents may take several months to years. Prolonged lymphopenia (Table 157.7) may be caused by recurrent infection; persistent infections, mostly notably HIV; malnutrition; mechanical loss of lymphocytes through protein-losing enteropathy or thoracic duct leaks; or systemic diseases such as lupus erythematosus, rheumatoid arthritis, sarcoidosis, renal failure, lymphoma, and aplastic anemia.

Inherited Lymphopenia

Primary immunodeficiencies and bone marrow failure syndromes are the main cause of inherited lymphopenia in children (see Table 157.7). Primary immunodeficiency may result in a severe quantitative defect, as in XLA and severe combined immunodeficiency (SCID), or a qualitative or progressive defect, as in Wiskott-Aldrich syndrome and CVID. XLA is characterized by a near-absence of mature B cells because of a mutation in BTK that results in a dysfunctional tyrosine kinase. SCIDs are a genetically heterogeneous group of disorders characterized by abnormalities of thymopoiesis and T-cell maturation. Newborn screening for severe T-cell deficiency, by analysis of T-cell receptor excision circles from dried blood spot Guthrie cards, aids in the rapid identification and treatment of infants with SCID and other T-cell disorders. Quantitative defects in lymphocytes can also be appreciated in select forms of inherited bone marrow failure such as reticular dysgenesis, SCN secondary to GFI1 mutation, and dyskeratosis congenita.

Makaryan V, Zeidler C, Bolyard AA, et al. The diversity of

Leukocytosis is an elevation in the total leukocyte or white blood cell (WBC) count that is 2 SD above the mean for age (see Chapter 748). It is most often caused by elevated numbers of neutrophils (i.e., neutrophilia), although marked increases in monocytes, eosinophils, basophils, and lymphocytes can be seen. Before extensive evaluation, it is important to assess for spurious elevations in the WBC count caused by platelet clumping (secondary to insufficient sample anticoagulation or the presence of EDTA-dependent agglutinins), high numbers of circulating nucleated red blood cells (RBCs), and the presence of cryoglobulins by review of the peripheral smear.

Malignancy, namely leukemia and lymphoma, is a primary concern for patients with leukocytosis. For discussion of WBC elevation caused by immature leukocytes in acute and chronic leukemias, see Chapter 522. Nonmalignant WBC counts exceeding 50,000/µL have historically been termed a leukemoid reaction. Unlike leukemia, leukemoid reactions show relatively small proportions of immature myeloid cells, consisting largely of band forms, occasional metamyelocytes, and progressively rarer myelocytes, promyelocytes, and blasts. Leukemoid reactions are most often neutrophilic and are frequently associated with severe bacterial infections, including shigellosis, salmonellosis, and meningococcemia; physiologic stressors; and certain medications.

The presence of a left shift, defined as having >5% immature neutrophils in the peripheral blood, is consistent with marrow stress. Higher degrees of left shift with more immature neutrophil precursors are indicative of serious bacterial infections and may be a dire sign of depletion of the bone marrow reserve pool of neutrophils. Marked left shift may occasionally be encountered with trauma, burns, surgery, acute hemolysis, or hemorrhage.
Neutrophilia

Neutrophilia is an increase in the total number of blood neutrophils that is 2 SD above the mean count for age (see Chapter 748). Elevated absolute neutrophil counts represent disturbances of the normal equilibrium involving bone marrow neutrophil production, migration out of the marrow compartments into the circulation, and neutrophil destruction. Neutrophilia may arise either alone or in combination with enhanced mobilization into the circulating pool from either the bone marrow storage compartment or the peripheral blood marginating pool, by impaired neutrophil egress into tissues, or by expansion of the circulating neutrophil pool secondary to increased granulocytopenesis. Myelocytes are not released to the blood except under extreme circumstances.

Acute Acquired Neutrophilia

Neutrophilia is usually an acquired, secondary finding associated with inflammation, infection, injury, or an acute physical or emotional stressor (Table 158.1). Bacterial infections, trauma (especially with hemorrhage), and surgery are among the most common causes encountered in clinical practice. Neutrophilia may also be associated with heat stroke, burns, diabetic ketoacidosis, pregnancy, or cigarette use.

Drugs commonly associated with neutrophilia include epinephrine, corticosteroids, and recombinant growth factors such as recombinant human granulocyte colony-stimulating factor (G-CSF) and recombinant human granulocyte-macrophage colony-stimulating factor (GM-CSF). Epinephrine causes release into the circulation of a sequestered pool of neutrophils that normally marginate along the vascular endothelium. Corticosteroids accelerate the release of neutrophils and bands from a large storage pool within the bone marrow and impair the migration of neutrophils from the circulation into tissues. G-CSF and GM-CSF cause acute and chronic neutrophilia by mobilizing cells from the marrow reserves and stimulating neutrophil production.

Acute neutrophilia in response to inflammation and infections occurs because of release of neutrophils from the marrow storage pool. The postmitotic marrow neutrophil pools are approximately 10 times the size of the blood neutrophil pool, and about half of these cells are bands and segmented neutrophils. Exposure of blood to foreign substances such as hemodialysis membrane activates the complement system and causes transient neutropenia, followed by neutrophilia secondary to release of bone marrow neutrophils. Reactive neutrophils often have toxic granulation and Döhle bodies present.

**Chronic Acquired Neutrophilia**

Chronic acquired neutrophilia is usually associated with continued stimulation of neutrophil production resulting from persistent inflammatory reactions or chronic infections (e.g., tuberculosis), vasculitis, postsplenectomy states, Hodgkin disease, chronic myelogenous leukemia, chronic blood loss, sickle cell disease, some chronic hemolytic anemias, and prolonged administration of corticosteroids (see Table 158.1 ). Chronic neutrophilia can arise after expansion of cell production secondary to stimulation of cell divisions within the mitotic precursor pool, which consists of promyelocytes and myelocytes. Subsequently, the size of the postmitotic pool increases. These changes lead to an increase in the marrow reserve pool, which can be readily mobilized for release of neutrophils into the circulation. The neutrophil production rate can increase greatly in response to exogenously administered hematopoietic growth factors, such as G-CSF, with a maximum response taking at least 1 wk to develop.

**Lifelong Neutrophilia**
Congenital or acquired asplenia is associated with lifelong neutrophilia. Some patients with trisomy-21 also have neutrophilia. Uncommon genetic disorders that present with neutrophilia include leukocyte function disorders such as leukocyte adhesion deficiency and Rac2 deficiency (see Chapter 156) and systemic disorders such as familial cold urticaria, periodic fever syndromes, and familial myeloproliferative disease (see Table 158.1). Rare patients with an autosomal dominant hereditary neutrophilia have been reported.

Evaluation of persistent neutrophilia requires a careful history, physical examination, and laboratory studies to search for infectious, inflammatory, and neoplastic conditions. The leukocyte alkaline phosphatase score of circulating neutrophils can differentiate chronic myelogenous leukemia, in which the level is uniformly almost zero, from reactive or secondary neutrophilia, which features normal to elevated levels.

**Additional Forms of Leukocytosis**

**Monocytosis**

The average absolute blood monocyte count varies with age, which must be considered in the assessment of monocytosis. Given the role of monocytes in antigen presentation and cytokine secretion and as effectors of ingestion of invading organisms, it is not surprising that many clinical disorders give rise to monocytosis (Table 158.2). Typically, monocytosis occurs in patients recovering from myelosuppressive chemotherapy and is a harbinger of the return of the neutrophil count to normal. Monocytosis is occasionally a sign of an acute bacterial, viral, protozoal, or rickettsial infection and may also occur in some forms of chronic neutropenia and postsplenectomy states. Chronic inflammatory conditions can stimulate sustained monocytosis, as can preleukemia, chronic myelogenous leukemia, and lymphomas.

**Eosinophilia**

**Eosinophilia** is defined as an absolute eosinophil count >1500 cells/µL. The majority of eosinophilic conditions are reactive, including infections (especially parasitic diseases), connective tissue disorders, allergic and hyperinflammatory diseases, pulmonary disorders, and dermatologic conditions. Hypereosinophilic syndrome and systemic mastocytosis are additional important causes of an elevated eosinophil count. However, persistent eosinophilia can also herald a malignancy such as leukemia, lymphoma, or carcinoma.

**Basophilia**

**Basophilia** is defined as an absolute basophil count >120 cells/µL. Basophilia is a nonspecific sign of a wide variety of disorders and is usually of limited diagnostic importance. Basophilia is most often present in hypersensitivity reactions and frequently accompanies the leukocytosis of chronic myeloid leukemia.

**Lymphocytosis**

The most common cause of lymphocytosis is an acute viral illness, as part of the normal T-cell response to the infection. In infectious mononucleosis, the B cells are infected with the Epstein-Barr virus, and the T cells react to the viral antigens present in the B cells, resulting in atypical lymphocytes with characteristic large, vacuolated morphology. Other viral infections classically associated with lymphocytosis are cytomegalovirus and viral hepatitis. Chronic bacterial infections such as tuberculosis and brucellosis may lead to a sustained lymphocytosis. Pertussis is accompanied by marked lymphocytosis in approximately 25% of infants infected before 6 mo of age. Thyrotoxicosis and Addison disease are endocrine disorders associated with lymphocytosis.
Persistent or pronounced lymphocytosis suggests acute lymphocytic leukemia.

SECTION 4
The Complement System

OUTLINE

Chapter 159 Complement Components and Pathways
Chapter 160 Disorders of the Complement System
Complement is an exquisitely balanced, highly influential system that is fundamental to the clinical expression of host defense and inflammation. The complement system also has the capacity to perform functions beyond host defense, such as promoting phagocytic removal of dying cells, molecular debris, and weak or superfluous synapses during brain formation. Complement components and receptors function within individual cells and can stabilize intracellular homeostasis. However, complement activation can also cause harm and has been implicated in many illnesses.

The complement system, an essential component of innate and adaptive immunity, is broadly conceptualized as (1) the classical, lectin, and alternative pathways, which interact and depend on each other for their full activity; (2) the membrane attack complex (C5b6789), formed from activity of any pathway; (3) cell membrane receptors that bind complement components or fragments to mediate complement activity; and (4) a large array of serum and membrane regulatory proteins (Table 159.1 and Fig. 159.1). The circulating components and regulators together comprise approximately 15% of the globulin fraction and 4% of the total proteins in serum. The normal concentrations of serum complement components vary by age (see Chapter 748); newborn infants have mild to moderate deficiencies of all components.

**Table 159.1**

**Constituents of the Complement System**

<table>
<thead>
<tr>
<th>Serum Components That Are the Core of the Complement System</th>
</tr>
</thead>
</table>
Classical pathway: C1q, C1r, C1s, C4, C2, C3
Alternative pathway: factor B, factor D
Lectin pathway: Mannose-binding lectin (MBL), ficolins 1/2/3, MBL-associated serine proteases (MASPs) 1/2/3
Membrane attack complex: C5, C6, C7, C8, C9
Regulatory protein, enhancing: properdin
Regulatory proteins, downregulating: C1 inhibitor (C1 INH), C4-binding protein (C4-bp), factor H, factor I, vitronectin, clusterin, carboxypeptidase N (anaphylatoxin inactivator)

Membrane Regulatory Proteins

CR1 (CD35), membrane cofactor protein (MCP; CD46), decay-accelerating factor (DAF, CD55), CD59 (membrane inhibitor of reactive lysis)

Membrane Receptors

CR1 (CD35), CR2 (CD21), CR3 (CD11b/CD18), CR4 (CD11c/CD18), C3a receptor, C5a receptor, C1q receptors, complement receptor of the immunoglobulin superfamily (CR1g)
Activation of the complement cascade. The classical pathway is activated primarily by antibody, whereas the mannose-binding lectin and alternative pathways are activated directly by pathogens. In each case, the activation arm leads to cleavage of C3. (From Leung DYM, editor: Pediatric allergy principles and practice, ed 2, Philadelphia, 2010, Saunders, p 121.)

After C1423, complement nomenclature is logical and consists of only a few rules. Fragments of components resulting from cleavage by other components acting as enzymes are assigned lowercase letters (a, b, c, d, e); with the exception of C2 fragments, the smaller piece that is released into surrounding fluids is assigned the lowercase letter a, and the major part of the molecule, bound to other components or to some part of the immune complex, is assigned letter b, such as C3a and C3b. Components of the alternative pathway, B and D, have been assigned uppercase letters, as have the control proteins I and H, which downregulate both pathways. C3, and especially its major fragment C3b, is a component of both classical and alternative pathways.

Complement is a system of interacting proteins. The biologic functions of the system depend on the interactions of individual components, which occur in sequential, cascade fashion. Activation of each component, except the 1st, depends on activation of the prior component or components in the sequence. Interaction occurs along the 3 pathways (Fig. 159.2): the classical pathway, in the order antigen–antibody–C142356789; the lectin (carbohydrate-binding) pathway, in the order microbial carbohydrate–lectin (mannose-binding lectin
[MBL] or ficolin)–MBL-associated serine protease–C42356789; and the alternative pathway, in the order activator–C3bBD–C356789. Antibody accelerates the rate of activation of the alternative pathway, but activation can occur on appropriate surfaces in the absence of antibody. The classical and the alternative pathways interact with each other through the ability of both to activate C3.

FIG. 159.2 Sequence of activation of the components of the classical and lectin pathways of complement and interaction with the alternative pathway. MBL, Mannose-binding lectin; MASP, MBL-associated serine protease. Activation of C3 is the essential target. Functional activities generated during activation are enclosed in boxes. The multiple sites at which inhibitory regulator proteins (not shown) act are indicated by asterisks, emphasizing the delicate balance between action and control in this system that is essential for host defense yet capable of profound damage to host tissues. Ab, Antibody (immunoglobulin G or M class); Ag, antigen (bacterium, virus, tumor or tissue cell); B, D, I, P, factors B, D, I, and properdin; C-CRP, carbohydrate–carbohydrate-reactive protein; C4-bp, C4-binding protein; MBL, mannose-binding lectin; MASP, MBL-associated serine protease.

Activation of the early-acting components of complement (C1423) results in the generation of a series of active enzymes, C1, C42, and C423, on the surface of the immune complex or underlying cell. These enzymes cleave and activate the next component in the sequence. In contrast, the interaction among C5b, C6,
C7, C8, and C9 is nonenzymatic and depends on changes in molecular configuration.

**Classical and Lectin Pathways**

The classical pathway sequence begins with fixation of C1, by way of C1q, to the Fc, non–antigen-binding part of the antibody molecule after antigen-antibody interaction. The C1 tricomplex changes configuration, and the C1s subcomponent becomes an active enzyme, “C1 esterase.” Certain bacteria, RNA viruses, and the lipid A component of bacterial endotoxin can activate C1q directly and trigger the full complement cascade.

As part of the *innate immune response*, broadly reactive “natural” antibodies and C-reactive protein, which reacts with carbohydrate from microorganisms and with dying cells, can substitute for specific antibody in the fixation of C1q and initiate reaction of the entire sequence. Endogenous agents, including uric acid crystals, amyloid deposits, DNA, and components of damaged cells such as apoptotic blebs and mitochondrial membranes, can activate C1q directly. In this case, however, the ligand-C1q complex interacts strongly with the inhibitors C4-binding protein and factor H, allowing some C3-mediated opsonization and phagocytosis but limiting the full inflammatory response typically triggered by microbes. C1q synthesized in the brain and retina fixes to superfluous synapses, which then can be cleared through C1q receptors on microglia, clearing the way for fresh synapses to populate the developing nervous system.

There are 4 recognition molecules in the lectin pathway: ***mannose-binding lectin (MBL)*** and ***ficolins*** 1, 2, and 3. MBL is the prototype of the collectin family of carbohydrate-binding proteins (lectins) that are believed to play an important part in innate, nonspecific immunity; its structure is homologous to that of C1q. These lectins, in association with ***MBL-associated serine proteases*** 1, 2, and 3 (MASPs 1, 2, 3), can bind to mannose, lipoteichoic acid, and other carbohydrates on the surface of bacteria, fungi, parasites, and viruses. There, MASP1s then function like C1s to cleave C4 and C2 and activate the complement cascade. The peptide C4a has weak “anaphylatoxin” activity and reacts with mast cells to release the chemical mediators of immediate hypersensitivity, including histamine. C3a and C5a, released later in the sequence, are potent anaphylatoxins, and C5a is also an important chemotactic factor. Fixation of C4b to the complex permits it to adhere to neutrophils, macrophages, B cells,
dendritic cells, and erythrocytes. MASP-2 can activate clotting by generating thrombin from prothrombin, which could prevent microbial spread.

Cleavage of C3 and generation of C3b is the next step in the sequence. The serum concentration of C3 is the highest of any component, and its activation is the most crucial step in terms of biologic activity. Cleavage of C3 can be achieved through the C3 convertase of the classical pathway, C142, or of the alternative pathway, C3bBb. Once C3b is fixed to a complex or dead or dying host cell, it can bind to cells with receptors for C3b (complement receptor 1 [CR1]), including B lymphocytes, erythrocytes, and phagocytic cells (neutrophils, monocytes, and macrophages). Efficient phagocytosis of most microorganisms, especially by neutrophils, requires binding of C3 to the microbe. The severe pyogenic infections that frequently occur in C3-deficient patients illustrate this point. The biologic activity of C3b is controlled by cleavage by factor I to iC3b, which promotes phagocytosis on binding to the iC3b receptor (CR3) on phagocytes. Further degradation of iC3b by factor I and proteases yields C3dg, then C3d; C3d binds to CR2 on B lymphocytes and thereby serves as a co-stimulator of antigen-induced B-cell activation.

**Alternative Pathway**

The alternative pathway can be activated by C3b generated through classical pathway activity or proteases from neutrophils or the clotting system. It can also be activated by a form of C3 created by low-grade, spontaneous reaction of native C3 with a molecule of water, a “tickover” that occurs constantly in plasma. Once formed, C3b or the hydrolyzed C3 can bind to any nearby cell or to factor B. Factor B attached to C3b in the plasma or on a surface can be cleaved to Bb by the circulating protease factor D. The complex C3bBb becomes an efficient C3 convertase, which generates more C3b through an amplification loop. Properdin can bind to C3bBb, increasing stability of the enzyme and protecting it from inactivation by factors I and H, which modulate the loop and the pathway.

Certain “activating surfaces” promote alternative pathway activation if C3b is fixed to them, including bacterial teichoic acid and endotoxin, virally infected cells, antigen–immunoglobulin A complexes, and cardiopulmonary bypass and renal dialysis membranes. These surfaces act by protecting the C3bBb enzyme from the control otherwise exercised by factors I and H. Rabbit red blood cell membrane is such a surface, which serves as the basis for an assay of serum
alternative pathway activity. Conversely, sialic acid on the surface of microorganisms or cells prevents formation of an effective alternative pathway C3 convertase by promoting activity of factors I and H. In any event, significant activation of C3 can occur through the alternative pathway, and the resultant biologic activities are qualitatively the same as those achieved through activation by C142 (see Fig. 159.2).

Membrane Attack Complex

The sequence leading to cytolysis begins with the attachment of C5b to the C5-activating enzyme from the classical pathway, C4b2a3b, or from the alternative pathway, C3bBb3b. C6 is bound to C5b without being cleaved, stabilizing the activated C5b fragment. The C5b6 complex then dissociates from C423 and reacts with C7. C5b67 complexes must attach promptly to the membrane of the parent or a bystander cell, or they lose their activity. Next, C8 binds, and the C5b678 complex then promotes the addition of multiple C9 molecules. The C9 polymer of at least 3-6 molecules forms a transmembrane channel, and lysis ensues.

Control Mechanisms

Without control mechanisms acting at multiple points, there would be no effective complement system, and unbridled consumption of components would generate severe, potentially lethal damage to the host. At the 1st step, C1 inhibitor (C1 INH) inhibits C1r and C1s enzymatic activity, and thus the cleavage of C4 and C2. C1 INH also inhibits MASP-2, factors XIa and XIIa of the clotting system, and kallikrein of the contact system. Activated C2 has a short half-life, and this relative instability limits the effective life of C42 and C423. The alternative pathway enzyme that activates C3, C3bBb, also has a short half-life, although it can be prolonged by the binding of properdin (P) to the enzyme complex. P can also bind directly to microbes and promote assembly of the alternative pathway C3 convertase.

Serum contains the enzyme carboxypeptidase N, which cleaves the N-terminus arginine from C4a, C3a, and C5a, thereby limiting their biologic activity. Factor I inactivates C4b and C3b; factor H accelerates inactivation of C3b by factor I; and an analogous factor, C4-binding protein (C4-bp),
accelerates C4b cleavage by factor I, thus limiting assembly of the C3 convertase. Three protein constituents of cell membranes—CR1, membrane cofactor protein (MCP), and decay-accelerating factor (DAF)—promote the disruption of C3 and C5 convertases assembled on those membranes. Another cell membrane–associated protein, CD59, can bind C8 or both C8 and C9 and thereby interfere with insertion of the membrane attack complex (C5b6789). The serum proteins vitronectin and clusterin can inhibit attachment of the C5b67 complex to cell membranes, bind C8 or C9 in a full membrane attack complex, or otherwise interfere with the formation or insertion of this complex. Vitronectin also promotes macrophage uptake of dying neutrophils. The genes for the regulatory proteins factor H, C4-bp, MCP, DAF, CR1, and CR2 are clustered on chromosome 1.

**Participation in Host Defense**

Neutralization of virus by antibody can be enhanced with C1 and C4 and further enhanced by the additional fixation of C3b through the classical or alternative pathway. Complement may therefore be particularly important in the early phases of a viral infection when antibody is limited. Antibody and the full complement sequence can also eliminate infectivity of at least some viruses by the production of typical complement “holes,” as seen by electron microscopy. Fixation of C1q can opsonize (promote phagocytosis) through binding to the phagocyte C1q receptor.

C4a, C3a, and C5a can bind to mast cells and thereby trigger release of histamine and other mediators, leading to vasodilation and the swelling and redness of inflammation. C5a can enhance macrophage phagocytosis of C3b-opsonized particles and induce macrophages to release the cytokines tumor necrosis factor and interleukin-1. C5a is a major chemotactic factor for neutrophils, monocytes, and eosinophils, which can efficiently phagocytize microorganisms opsonized with C3b or cleaved C3b (iC3b). Further inactivation of cell-bound C3b by cleavage to C3d and C3dg removes its opsonizing activity, but it can still bind to B cells. Fixation of C3b to a target cell can enhance its lysis by natural killer cells or macrophages.

Insoluble immune complexes can be solubilized if they bind C3b, apparently because C3b disrupts the orderly antigen-antibody lattice. Binding C3b to a complex also allows it to adhere to C3 receptors (CR1) on red blood cells, which then transport the complexes to hepatic and splenic macrophages for removal.
This phenomenon may at least partially explain the immune complex disease found in patients who lack C1, C4, C2, or C3.

The complement system serves to link the innate and adaptive immune systems. C4b or C3b coupled to immune complexes promotes their binding to antigen-presenting macrophages, dendritic cells, and B cells. Coupling of antigen to C3d allows binding to CR2 on B cells, which greatly reduces the amount of antigen needed to trigger an antibody response.

Neutralization of endotoxin in vitro and protection from its lethal effects in experimental animals require C1 INH and later-acting components of complement, at least through C6. Finally, activation of the entire complement sequence can result in lysis of virus-infected cells, tumor cells, and most types of microorganisms. Bactericidal activity of complement has not appeared to be important to host defense, except for the occurrence of *Neisseria* infections in patients lacking later-acting components of complement (see Chapter 160).

160.1
Evaluation of the Complement System

Richard B. Johnston Jr.

Keywords

hereditary angioedema
total hemolytic complement activity
$\text{CH}_{50}$
alternative pathway activity
$\text{AP}_{50}$

Testing for total hemolytic complement activity ($\text{CH}_{50}$) effectively screens for most of the common diseases of the complement system. A normal result in this assay depends on the ability of all 11 components of the classical pathway and membrane attack complex to interact and lyse antibody-coated sheep erythrocytes. The dilution of serum that lyses 50% of the cells determines the end-point. In congenital deficiencies of C1 through C8, the $\text{CH}_{50}$ value is 0 or close to 0; in C9 deficiency the value is approximately half-normal. Values in the acquired deficiencies vary with the type and severity of the underlying disorder.
This assay does not detect deficiency of mannose-binding lectin (MBL), factor D or B of the alternative pathway, or properdin (Fig. 160.1). Deficiency of factor I or H permits persistence of the classical and alternative pathway convertase and thus consumption of C3, with reduction in the CH$_{50}$ value. When clotted blood or serum sits at room temperature or warms, CH$_{50}$ activity begins to decline, leading to values that are falsely low but not zero. It is important to separate the serum and freeze it at −70°C (−94°F) by no more than 1 hr after blood draw.

![Flow chart for the evaluation of inherited complement deficiencies using hemolytic screening assays for the classical (CH50) and alternative pathways (AH50).](image)

For each assay, the entire activation pathway, including the membrane attack complex, is required for lysis. MASP, MBL-associated serine protease; MBL, mannose-binding lectin. *Gonococcal and meningococcal. † C9 deficiency may have up to 30% normal CH50 with low AH50. (Adapted from Rich RR, Fleisher TA, Shearer WT, et al, editors: Clinical immunology: principles and practice, ed 4, Philadelphia, 2012, Saunders, p 262.)

In *hereditary angioedema*, depression of C4 and C2 during an attack significantly reduces the CH$_{50}$. Typically, C4 is low and C3 normal or slightly decreased. Concentrations of C1 inhibitor protein will be normal in 15% of cases; but C1 acts as an esterase, and the diagnosis can be established by showing increased capacity of the patient's sera to hydrolyze synthetic esters.

A decrease in serum concentration of both C4 and C3 suggests activation of
the classical pathway by immune complexes. Decreased C3 and normal C4 levels suggest activation of the alternative pathway. This difference is particularly useful in distinguishing nephritis secondary to immune complex deposition from that caused by NeF (nephritic factor). In the latter condition and in deficiency of factor I or H, factor B is consumed and C3 serum concentration is low. Alternative pathway activity can be measured with a relatively simple and reproducible hemolytic assay that depends on the capacity of rabbit erythrocytes to serve as both an activating (permissive) surface and a target of alternative pathway activity. This assay, \( \text{AP}_{50} \), detects deficiency of properdin, factor D, and factor B. Immunochemical methods can be used to quantify individual components and split products of all 3 pathways, guided by results of the screening hemolytic assays.

A defect of complement function should be considered in any patient with recurrent angioedema, autoimmune disease (especially SLE), chronic nephritis, hemolytic-uremic syndrome, or partial lipodystrophy, or with recurrent pyogenic infections, disseminated meningococcal or gonococcal infection, or a 2nd episode of bacteremia at any age. A previously well adolescent or young adult with meningococcal meningitis caused by an uncommon serotype (not A, B, or C) should undergo screening for a late-component or alternative pathway deficiency with \( \text{CH}_{50} \) and \( \text{AP}_{50} \) assays.

160.2
Genetic Deficiencies of Complement Components

Richard B. Johnston Jr.

Keywords

- complement component deficiencies
- C1q deficiency
- C3 deficiency
- MBL deficiency
- complement deficiency and meningitis

Congenital deficiencies of all 11 components of the classical–membrane attack pathway and of factors D and B and properdin of the alternative pathway are described in Table 160.1. All components of the classical and alternative pathways except properdin and factor B are inherited as autosomal recessive co-dominant traits. Each parent transmits a gene that codes for synthesis of half the serum level of the component. Deficiency results from inheritance of 1 null gene from each parent; the hemizygous parents typically have low normal CH₅₀ levels and no consequences of the partial deficiency. Properdin deficiency is transmitted as an X-linked trait. Factor B is an autosomal recessive non-co-dominant trait.

AD, Autosomal dominant; aHUS, atypical hemolytic-uremic syndrome; AR, autosomal recessive; SLE, systemic lupus erythematosus; XL, X-linked; 3MC, previously Carnevale, Mingarelli, Malpuech, and Michels syndromes.

Most patients with primary **C1q deficiency** have systemic lupus erythematosus (SLE); some have an SLE-like syndrome without typical SLE serology, a chronic rash with underlying vasculitis, or membranoproliferative glomerulonephritis (MPGN). Some C1q-deficient children have serious infections, including septicemia and meningitis. Individuals with **C1r, C1s, combined C1r/C1s, C4, C2, or C3 deficiency** also have a high incidence of autoimmune syndromes (see **Table 160.1**), especially SLE or an SLE-like syndrome, without an elevated antinuclear antibody level.

C4 is encoded by 2 genes, **C4A** and **C4B**. **C4 deficiency** represents absence of both gene products. Complete deficiency of only C4A, present in approximately 1% of the population, also predisposes to SLE, although C4 levels are only partially reduced. Patients with only C4B deficiency may be predisposed to infection. A few patients with **C5, C6, C7, or C8 deficiency** have SLE, but recurrent meningococcal infections are much more likely to be the major problem.

There are at least 2 possible reasons for the concurrence of complement component deficiencies, especially C1, C4, C2, or C3 deficiency, and autoimmune–immune complex diseases. First, deposition of C3 on autoimmune complexes facilitates their removal from the circulation through binding to complement receptor 1 (CR1) on erythrocytes and transport to the spleen and...
liver. Second, the early components, particularly C1q and C3, expedite the clearance of necrotic and apoptotic cells, which are sources of autoantigens.

Individuals with **C2 deficiency** carry the risk of life-threatening septicemic illnesses, usually caused by pneumococci. However, most have not had problems with other increased susceptibility to infection, presumably because of the protective function of the alternative pathway, particularly if enhanced by pneumococcal and *Haemophilus influenzae* immunization. The genes for C2, factor B, and C4 are situated close to each other on chromosome 6, and a partial depression of factor B levels can occur in conjunction with C2 deficiency. Persons with a deficiency of both proteins may be at particular risk. One percent of European Caucasians carry 1 null gene for C2.

Because C3 can be activated by C142 or by the alternative pathway, a defect in the function of either pathway can be compensated for, at least to some extent. Without C3, however, opsonization of bacteria is inefficient, and the chemotactic fragment from C5 (C5a) is not generated. Some organisms must be well opsonized in order to be cleared, and genetic **C3 deficiency** has been associated with recurrent, severe pyogenic infections caused by pneumococci, *H. influenzae*, and meningococci.

More than half the individuals reported to have congenital **C5, C6, C7, or C8 deficiency** have had meningococcal meningitis or extragenital gonococcal infection. **C9 deficiency** is most often reported in individuals of Japanese or Korean descent. C9-deficient individuals retain about one-third normal CH50 titers; some have had *Neisseria* disease. In studies of patients ≥10 yr old with systemic meningococcal disease, 3–15% have had a genetic deficiency of C5, C6, C7, C8, C9, or properdin. Among patients with infections caused by the uncommon *Neisseria meningitidis* serogroups (X, Y, Z, W135, 29E, or nongroupable; but not A, B, or C), 33–45% have an underlying complement deficiency. It is not clear why patients with a deficiency of one of the late-acting components have a particular predisposition to *Neisseria* infections. It may be that serum bacteriolysis is uniquely important in defense against this organism. Many persons with such a deficiency have no significant illness.

A few individuals have been identified with **deficiency of factor D or Factor B** of the alternative pathway, all with recurrent infections, most often neisserial or pneumococcal. Hemolytic complement activity and C3 levels in their serum were normal, but alternative pathway activity was markedly deficient or absent. Mutations in the structural gene encoding MBL or polymorphisms in the promoter region of the gene result in pronounced interindividual variation in the
level of circulating MBL. More than 90% of individuals with MBL deficiency do not express a predisposition to infection. Those with a very low level of MBL have a predisposition to recurrent respiratory infections in infancy and to serious pyogenic and fungal infections if there is another underlying defect of host defense. MBL-associated serine protease (MASP)-2 deficiency has been reported with SLE-like symptoms and recurrent pneumococcal pneumonia. Homozygous ficolin-3 deficiency has been associated with repeated pneumonia since early childhood, cerebral abscesses, and bronchiectasis.

Deficiencies of Plasma, Membrane, or Serosal Complement Control Proteins

Richard B. Johnston Jr.

Keywords

atypical hemolytic-uremic syndrome
properdin deficiency
hereditary angioedema
paroxysmal nocturnal hemoglobinuria
factor I deficiency

Congenital deficiencies of 5 plasma complement control proteins have been described (see Table 160.1). Factor I deficiency was reported originally as a deficiency of C3 resulting from hypercatabolism. The 1st patient described had suffered a series of severe pyogenic infections similar to those associated with agammaglobulinemia or congenital deficiency of C3. Factor I is an essential regulator of both pathways. Its deficiency permits prolonged existence of C3b as a part of the C3 convertase of the alternative pathway, C3bBb. This results in constant activation of the alternative pathway and cleavage of more C3 to C3b, in circular fashion. Intravenous infusion of plasma or purified factor I induced a prompt rise in serum C3 concentration in the patient and a return to normal of C3-dependent functions in vitro, such as opsonization.

The effects of factor H deficiency are similar to those of factor I deficiency because factor H also assists in dismantling the alternative pathway C3 convertase. A trigger event such as infection initiates uninhibited continuous activation of the alternative pathway, which consumes C3, factor B, total hemolytic activity, and alternative pathway activity. Patients have sustained systemic infections due to pyogenic bacteria, particularly Neisseria meningitidis. Many have had glomerulonephritis or atypical hemolytic-uremic syndrome (aHUS) (see Chapter 538.5). Mutations in genes encoding membrane cofactor
protein (MCP, CD46), factors I or B, C3, or the endothelial antiinflammatory protein thrombomodulin, or autoantibodies to factors H or B, are also associated with aHUS. The majority of patients with factor H deficiency and aHUS, typically <2 yr old, develop end-stage renal disease, and many die.

The few patients thus far reported as having **C4-binding protein deficiency** have approximately 25% of the normal levels of the protein and no typical disease presentation, although one patient had angioedema and Behçet disease.

Persons with **properdin deficiency** have a striking predisposition to *N. meningitidis* meningitis. All reported patients have been male. The predisposition to infection in these patients demonstrates clearly the need for the alternative pathway in defense against bacterial infection. Serum hemolytic complement activity is normal in these patients, and if the patient has specific antibacterial antibody from immunization or prior exposure, the need for the alternative pathway and properdin is greatly reduced. Several patients have had dermal vasculitis or discoid lupus.

**Hereditary angioedema** occurs in persons unable to synthesize normal levels of functional C1 inhibitor (C1 INH). In 85% of affected families, the patient has markedly reduced concentrations of inhibitor, averaging 30% of normal; the other 15% have normal or elevated concentrations of an immunologically cross-reacting but nonfunctional protein. Both forms of the disease are transmitted as autosomal dominant traits. C1 INH suppresses the complement proteases C1rs and MASP-2 and the activated proteases of the contact and fibrinolysis systems. In the absence of full C1 INH function, activation of any of these proteases tips the balance toward the protease. This activation leads to uncontrolled C1 and kallikrein activity with breakdown of C4 and C2 and release of bradykinin, which interacts with vascular endothelial cells to cause vasodilation, producing localized, nonpitting edema. The biochemical triggers that induce attacks of angioedema in these patients are not well understood.

Swelling of the affected part progresses rapidly, without urticaria, itching, discoloration, or redness and often without severe pain. Swelling of the intestinal wall, however, can lead to intense abdominal cramping, sometimes with vomiting or diarrhea. Concomitant subcutaneous edema is often absent, and patients have undergone abdominal surgery or psychiatric examination before the true diagnosis was established. Laryngeal edema can be fatal. Attacks last 2-3 days and then gradually abate. They may occur at sites of trauma, especially dental, after vigorous exercise, or with menses, fever, or emotional stress. Attacks begin in the 1st 5 yr of life in almost half of patients, but are usually not
severe until late childhood or adolescence. **Acquired C1 INH deficiency** can occur in association with B-cell cancer or autoantibody to C1 INH. SLE and glomerulonephritis have been reported in patients with the congenital disease (for treatment see Chapter 160.5).

Three of the membrane complement control proteins—CR1, MCP (CD46), and decay-accelerating factor (DAF)—prevent the formation of the full C3-cleaving enzyme, C3bBb, which is triggered by C3b deposition. CD59 (membrane inhibitor of reactive lysis) prevents the full development of the membrane attack complex that creates the “hole.” **Paroxysmal nocturnal hemoglobinuria** (PNH) is a hemolytic anemia that occurs when DAF and CD59 are not expressed on the erythrocyte surface. The condition is acquired as a somatic mutation in a hematopoietic stem cell of the PIGA gene on the X chromosome. The product of this gene is required for normal synthesis of a glycosyl-phosphatidylinositol molecule that anchors about 20 proteins to cell membranes, including DAF and CD59. One patient with **genetic isolated CD59 deficiency** had a mild PNH-like disease despite normal expression of membrane DAF. In contrast, **genetic isolated DAF deficiency** has not resulted in hemolytic anemia (for treatment see Chapter 160.5).

## 160.4 Secondary Disorders of Complement

*Richard B. Johnston Jr.*

### Keywords

- immune complex disease
- systemic lupus erythematosus
- SLE
- nephritic factor

Partial deficiency of C1q has occurred in patients with severe combined immunodeficiency disease or hypogammaglobulinemia, apparently secondary to the deficiency of IgG, which normally binds reversibly to C1q and prevents its rapid catabolism.

**Chronic membranoproliferative glomerulonephritis** can be caused by nephritic factor (NeF), an IgG autoantibody to the C3-cleaving enzyme of the classical pathway (C4b2a) or alternative pathway (C3bBb). NeF protects the enzyme from inactivation and promotes consumption of C3 and decreased
concentration of serum C3. Pyogenic infections, including meningitis, may occur if the serum C3 level drops to <10% of normal. This disorder has been found in children and adults with dense-deposit disease or partial lipodystrophy. Adipocytes are the main source of factor D and synthesize C3 and factor B; exposure to NeF induces their lysis. The IgG NeF that inhibits the classical pathway C3 convertase has been described in acute postinfectious nephritis and in SLE. The consumption of C3 that characterizes poststreptococcal nephritis and SLE could be caused by this factor, by immune complex activation, or by both.

Newborn infants have mild to moderate reductions in all plasma components of the complement system. Opsonization and generation of chemotactic activity in serum from full-term newborns can be markedly deficient through either the classical or the alternative pathway. Complement activity is even lower in preterm infants. Patients with severe chronic cirrhosis of the liver, hepatic failure, malnutrition, or anorexia nervosa can have significant deficiency of complement components and functional activity. Synthesis of components is depressed in these conditions, and serum from some patients with malnutrition also contains immune complexes that could accelerate depletion.

Patients with sickle cell disease have normal activity of the classical pathway, but some have defective function of the alternative pathway in opsonization of pneumococci, in bacteriolysis and opsonization of Salmonella, and in lysis of rabbit erythrocytes. Deoxygenation of erythrocytes from patients with sickle cell disease alters their membranes to increase exposure of phospholipids that can activate the alternative pathway and consume its components. This activation is accentuated during painful crisis. Children with nephrotic syndrome may have decreased serum levels of factors B and D and subnormal serum opsonizing activity.

Immune complexes initiated by microorganisms or their by-products can induce complement consumption. Activation occurs primarily through fixation of C1 and initiation of the classical pathway. Formation of immune complexes and consumption of complement have been demonstrated in lepromatous leprosy, bacterial endocarditis, infected ventriculojugular shunts, malaria, infectious mononucleosis, dengue hemorrhagic fever, and acute hepatitis B. Nephritis or arthritis can develop as a result of deposition of immune complexes and activation of complement in these infections. In SLE, immune complexes activate C142, and C3 is deposited at sites of tissue damage, including kidneys and skin; depressed synthesis of C3 is also noted. The syndrome of recurrent
urticaria, angioedema, eosinophilia, and hypocomplementemia secondary to activation of the classical pathway may be caused by autoantibody to C1q and circulating immune complexes. Circulating immune complexes and decreased C3 have been reported in some patients with dermatitis herpetiformis, celiac disease, primary biliary cirrhosis, and Reye syndrome.

Circulating bacterial products in sepsis or tissue factors released after severe trauma can initiate activation of the classical and alternative pathways, leading to increased serum levels of C3a, C5a, and C5b-9 and systemic inflammatory response syndrome (SIRS) and multi-organ failure. C5a and its receptors, particularly on neutrophils, appear to be central to the pathogenesis of SIRS. Intravenous injection of iodinated roentgenographic contrast medium can trigger a rapid and significant activation of the alternative pathway, which may explain the occasional reactions that occur in patients undergoing this procedure.

Burns can induce massive activation of the complement system, especially the alternative pathway, within a few hours after injury. Resulting generation of C3a and C5a stimulates neutrophils and induces their sequestration in the lungs, leading to shock lung. Cardiopulmonary bypass, extracorporeal membrane oxygenation, plasma exchange, or hemodialysis using cellophane membranes may be associated with a similar syndrome as a result of activation of plasma complement, with release of C3a and C5a. In patients with erythropoietic protoporphyria or porphyria cutanea tarda, exposure of the skin to light of certain wavelengths activates complement, generating chemotactic activity. This chemotactic activity leads to lysis of capillary endothelial cells, mast cell degranulation, and the appearance of neutrophils in the dermis.

Some tumor cells can avoid complement-mediated lysis by overexpressing DAF, MCP, CD59, CR1, or factor H, or by secreting proteases that cleave tumor-bound C3b. Microorganisms have evolved similar evasive mechanisms; for example, HIV-1 particles budding from infected cells acquire the membrane proteins DAF and CD59, and staphylococci can produce multiple complement inhibitors.

**Treatment of Complement Disorders**

*Richard B. Johnston Jr.*

**Keywords**

C1-esterase inhibitor
immunization
complement deficiency

No specific therapy is available at present for genetic deficiencies of the components of the classical, alternative, and lectin complement pathways. Much can be done, however, to protect patients with any of these disorders from serious complications; and specific treatment is available for 3 disorders caused by control-protein deficiencies: hereditary angioedema, aHUS, and PNH.
Management of hereditary angioedema starts with avoidance of precipitating factors, usually trauma. Infusion of C1 INH concentrate (nanofiltered C1-esterase inhibitor) was approved by the U.S. Food and Drug Administration (FDA) for use in children in 2016. An inhibitor of kallikrein (ecallantide) that blocks bradykinin production and an antagonist of the bradykinin receptor (icatibant) are approved in the United States for use in adolescents and adults for long-term prophylaxis, preparation for surgery or dental procedures, or treatment of acute attacks. The synthetic androgen oxandrolone increases the level of functional C1 INH several-fold and is approved for cautious use in children. Antihistamines, epinephrine, and corticosteroids have no effect.

Lanadelumab, a selective inhibitor of kallikrein, has potential as a prophylactic agent. Eculizumab, a humanized monoclonal antibody to C5, prevents generation of the membrane-attack complex C5b9 and is an effective treatment for PNH and aHUS.

Effective supportive management is available for other primary diseases of the complement system, and identification of a specific defect in the complement system can have an important impact on management. Concern for the associated complications, such as autoimmune disease and infection, should encourage vigorous diagnostic efforts and earlier institution of therapy. Individuals with SLE and a complement defect generally respond as well to therapy as do those without complement deficiency. With the onset of unexplained fever, cultures should be obtained and antibiotic therapy instituted more quickly and with less stringent indications than in a normal child.

The parent or patient should be given letters describing any predisposition to systemic bacterial infection or autoimmune disease associated with the patient's deficiency, along with the recommended initial approach to management, for possible use by school, camp, or emergency department physicians. The patient and close household contacts should be immunized against H. influenzae, Streptococcus pneumoniae, and N. meningitidis. High titers of specific antibody might opsonize effectively without the full complement system, and immunization of household members could reduce the risk of exposing patients to these particularly threatening pathogens. Repeat immunization of patients is advisable since complement deficiency can be associated with a blunted or shorter-lived antibody response than normal.

Heparin, which inhibits both classical and alternative pathways, has been used to prevent “postpump syndrome.”

Chapter 162 Hematopoietic Stem Cell Transplantation From Alternative Sources and Donors
Chapter 163 Graft-Versus-Host Disease, Rejection, and Venoocclusive Disease
Chapter 164 Infectious Complications of Hematopoietic Stem Cell Transplantation
Chapter 165 Late Effects of Hematopoietic Stem Cell Transplantation
Allogeneic (from a donor) or autologous (from the same individual) hematopoietic stem cells have been used to cure both malignant and nonmalignant disorders. Autologous transplantation is employed as a rescue strategy after delivering otherwise lethal doses of chemotherapy with or without radiotherapy in children with hematologic malignancies such as relapsed lymphoma or selected solid tumors (e.g., neuroblastoma, brain tumors). Allogeneic transplantation is used to treat children with genetic diseases of blood cells, such as hemoglobinopathies, primary immunodeficiency diseases, various inherited metabolic diseases, and bone marrow failure. Allogeneic transplant is also used as treatment for hematologic malignancies, such as leukemia and myelodysplastic syndromes. Bone marrow had represented the only source of hematopoietic progenitors employed. Growth factor (granulocyte colony-stimulating factor)—mobilized peripheral blood hematopoietic stem cells and umbilical cord blood hematopoietic progenitors have now also been regularly used in clinical practice to perform hematopoietic stem cell transplantation (HSCT).

An HLA-matched sibling was once the only type of donor employed. Currently, matched unrelated volunteers, full-haplotype mismatched family members, and unrelated cord blood donors have been largely employed to transplant patients lacking an HLA-identical relative.

Protocols for allogeneic HSCT consist of 2 parts: the preparative regimen and transplantation itself. During the preparative conditioning regimen, chemotherapy, at times associated with irradiation, is administered to destroy the
patient’s hematopoietic system and to suppress the immune system, especially T cells, so that graft rejection is prevented. In patients with malignancies, the preparative regimen also serves to significantly reduce the tumor burden. The patient then receives an intravenous infusion of hematopoietic cells from the donor. Less aggressive conditioning regimens, known as **reduced-intensity conditioning regimens**, are also used in pediatric patients. These regimens are mainly immnosuppressive and aim at inducing a state of reduced immune competence of the recipient to avoid the rejection of donor cells.

The immunology of HSCT is distinct from that of other types of transplant because, in addition to stem cells, the graft contains mature blood cells of donor origin, including T cells, B cells, natural killer cells, and dendritic cells. These cells repopulate the recipient’s lymphohematopoietic system and give rise to a new immune system, which helps eliminate residual leukemia cells that survive the conditioning regimen. This effect is known as the **graft-versus-leukemia (GVL)** effect.

The donor immune system exerts its T-cell–mediated GVL effect through alloreactions directed against histocompatibility antigens displayed on recipient leukemia cells. Because some of these histocompatibility antigens are also displayed on tissues, however, unwanted T-cell–mediated alloreactions may ensue. Specifically, donor alloreactive cytotoxic CD8+ effector T cells may attack recipient tissues, particularly the skin, gastrointestinal (GI) tract, and liver, causing acute **graft-versus-host disease (GVHD)**, a condition of varying severity that in some cases can be life threatening or even fatal (see Chapter 163).

The success of allogeneic HSCT is undermined by diversity between donors and recipients in major and minor histocompatibility antigens. The **human leukocyte antigens (HLA)**, including HLA-A, HLA-B, and HLA-C major histocompatibility complex (MHC) class I molecules, present peptides to CD8+ T cells, whereas the HLA-DR, HLA-DQ, and HLA-DP MHC class II molecules present peptides to CD4+ T cells. There are 100s of variant forms of each class I and class II molecule, and even small differences can elicit alloreactive T-cell responses that mediate graft rejection and/or GVHD. Disparities for HLA-A, -B, -C, or -DRB1 alleles in the donor-recipient pair are independent risk factors for both acute and chronic GVHD. There is also increasing evidence that HLA-DQ and HLA-DP may play a role, prompting some transplant centers to also explore matching at these alleles.

Minor histocompatibility antigens derive from differences between the HLA-
matched recipient and donor in peptides that are presented by the same HLA allotype. These antigens result from polymorphisms of non-HLA proteins, differences in the level of expression of proteins, or genetic differences between males and females. An example of the latter is represented by the H-Y antigens encoded by the Y chromosome, which can stimulate GVHD when a female donor is employed to transplant an HLA-identical male recipient. Thus, from this evidence, it is clear that GVHD may occur even when the donor and recipient are HLA identical.

The preferred donor for any patient undergoing HSCT is an HLA-identical sibling. Because polymorphic HLA genes are closely linked and usually constitute a single genetic locus, any pair of siblings has a 25% chance of being HLA identical. Thus, also in view of the limited family size in the developed countries, <25–30% of patients in need of an allograft can receive their transplant from an HLA-identical sibling. This percentage is even lower in patients with inherited disorders since affected siblings will not be considered donor candidates.

**HSCT From an HLA-Identical Sibling Donor**

Allogeneic HSCT from an HLA-compatible sibling is the treatment of choice for children with hematologic malignancies and various congenital or acquired diseases (Table 161.1). Best results are achieved in patients with congenital or acquired nonmalignant disorders because the risk of disease recurrence is low and the cumulative transplantation-related mortality is lower than in children receiving transplants for hematologic malignancies.

therapy
Not in remission at the end of the induction phase
Marked hypodiploidy (<43 chromosomes)
Minimal residual disease at the end of consolidation therapy

High-risk infant ALL
  Second complete remission
  Third or later complete remission

Acute myeloid leukemia in 1st complete remission or in advanced-disease phase
Philadelphia chromosome–positive chronic myeloid leukemia

Myelodysplastic syndromes
Hodgkin and non-Hodgkin lymphomas
Selected solid tumors
  Metastatic neuroblastoma
  Rhabdomyosarcoma refractory to conventional treatment
  Very-high-risk Ewing sarcoma

Anemias

  Severe acquired aplastic anemia
  Fanconi anemia
  Paroxysmal nocturnal hemoglobinemia
  Congenital dyskeratosis
  Diamond-Blackfan anemia
  Thalassemia major
  Sickle cell disease
  Shwachman-Diamond syndrome

Immunologic Disorders

  Variants of severe combined immunodeficiency
  Hyper-IgM syndrome
  Leukocyte adhesion deficiency
  Omenn syndrome
  Zap-70 kinase deficiency
  Cartilage-hair hypoplasia
PNP deficiency
CD40 ligand deficiency
MHC class II deficiency
Wiskott-Aldrich syndrome
Chédiak-Higashi syndrome
Kostmann syndrome (infantile malignant agranulocytosis)
Chronic granulomatous disease
Autoimmune lymphoproliferative syndrome
X-linked lymphoproliferative disease (Duncan syndrome)
IPEX syndrome
Interleukin-10 receptor deficiency
Hemophagocytic lymphohistiocytosis
Interferon-γ receptor deficiency
Griscelli disease
Granule deficiency

Other Disorders

Selected severe variants of platelet function disorders (e.g., Glanzmann thromboasthenia, congenital amegakaryocytic thrombocytopenia)
Selected types of mucopolysaccharidosis (e.g., Hurler disease) or other liposomal/peroxisomal disorders (e.g., Krabbe disease, adrenoleukodystrophy)
Infantile malignant osteopetrosis
Life-threatening cytopenia unresponsive to conventional treatments

IPEX, Immune dysregulation, polyendocrinopathy, enteropathy, X-linked; MHC, major histocompatibility complex; PNP, purine nucleoside phosphorylase.

Acute Lymphoblastic Leukemia

Allogeneic HSCT is used for pediatric patients with acute lymphoblastic leukemia (ALL), either in the 1st complete remission when a child is considered to be at high risk of leukemia recurrence (e.g., those carrying poor-risk cytogenetic characteristics or with high levels of minimal residual disease), or in
2nd or further complete remission after previous marrow relapse. ALL is the most common indication for HSCT in childhood. Several patient-, donor-, disease-, and transplant-related variables may influence the outcome of patients with ALL given an allogeneic HSCT. The long-term probabilities of event-free survival (EFS) for patients with ALL transplanted in the 1st or 2nd complete remission is 60–70% and 40–60%, respectively. Inferior results are obtained in patients receiving transplants in more advanced disease phases. The use of total body irradiation (TBI) during the preparative regimen offers an advantage in terms of better EFS compared to a regimen consisting of cytotoxic drugs alone (Fig. 161.1), but it can induce more long-term side effects. This has prompted more investigation into TBI-sparing alternatives. Less intensive GVHD prophylaxis is also associated with a better outcome. Bone marrow is generally still the preferred source of stem cells to be employed for transplantation, although this differs among transplant centers.

![Graph showing survival after HLA-matched sibling donor hematopoietic stem cell transplantation for acute lymphoblastic leukemia (ALL), age <18 yr, 2004–2014. Early, first complete remission (CR1); Intermediate, second or greater complete remission (CR2+); Advanced, active disease. (From D’Souza A, Zhu X: Current uses and outcomes of hematopoietic cell transplantation (HCT), CIBMTR Summary Slides, 2016. http://www.cibmtr.org.)](image)

Although the main benefit for allogeneic HSCT recipients with leukemia derives from the GVL effect displayed by immunocompetent cells, disease recurrence remains the main cause of treatment failure. The risk of failing to eradicate leukemia is influenced by many variables, including disease phase,
molecular lesions of tumor cells, and disparity for major or minor histocompatibility antigens in the donor/recipient pairs. To overcome the hurdle of tumor elusion caused by HLA loss on malignant cells, the use of non-HLA–restricted chimeric antigen receptors (CARs) has been proposed. This therapeutic strategy is based on genetic reprogramming of T cells through artificial immune receptors that reproducibly and efficiently redirect the antigen specificity of polyclonal T lymphocytes toward target antigens expressed by leukemic cells. When expressed by T cells, CARs mediate antigen recognition and tumor cytolysis in an MHC-unrestricted fashion and can target any molecule (protein, carbohydrate, or glycolipid) expressed on the surface of tumor cells, thus bypassing one of the major tumor escape mechanisms based on the downregulation of MHC molecules. CARs are composed of an extracellular specific antigen-binding moiety, obtained from the variable regions of a monoclonal antibody, linked together to form a single-chain antibody (scFv), and of an intracellular signaling component derived from the ζ chain of the T-cell–receptor (TCR)–CD3 complex. The addition to the CAR gene construct of co-stimulation signals and cytokines promoting T-cell expansion and survival improves the antitumor efficiency of the engineered T cells and their survival in the tumor milieu. Gamma retrovirus and lentiviruses are usually used to transduce CARs into T lymphocytes to be employed in the clinical setting. These vectors have been shown to efficiently infect T lymphocytes, integrate into the host genome, and produce robust expression of the gene in human T cells and their progeny.

**Acute Myeloid Leukemia**

Allogeneic HSCT from an HLA-identical sibling is largely employed as postremission treatment of pediatric patients with acute myeloid leukemia (AML). Children with AML in 1st complete remission who are given allogeneic HSCT as consolidation therapy have a better probability of EFS than those treated with either chemotherapy alone or autologous transplantation. Results obtained in patients given HSCT from an HLA-identical sibling after either a TBI-containing or a chemotherapy-based preparative regimen are similar, the probability of EFS being in the order of 70%. Therefore, for AML, conditioning regiments generally omit the use of TBI because of associated long-term side effects. Children with acute promyelocytic leukemia in molecular remission at the end of treatment with chemotherapy and all-trans-retinoic acid, or with
AML and translocation t(8;21); inversion of chromosome 16 (inv16), translocation t(16;16), or normal cytogenetics and presence of NPM1 or CEBP α mutation are no longer considered eligible for allogeneic HSCT in 1st complete remission in view of their improved prognosis with alternative treatments. Studies suggest restricting the use of HSCT to those patients with poor molecular lesions, such as FLT3-internal tandem duplication or mixed-lineage leukemia abnormalities, or with high levels of minimal residual disease at the end of induction therapy. Approximately 40–60% of pediatric patients with AML in the 2nd complete remission can be rescued by HSCT.

**Chronic Myelogenous Leukemia**

For many years, allogeneic HSCT has been considered the only proven curative treatment for children with Philadelphia-positive (Ph+) chronic myelogenous leukemia. Leukemia-free survival of chronic myelogenous leukemia patients after an allograft is 45–80%. The phase of disease (chronic phase, accelerated phase, blast crisis), recipient age, type of donor employed (related or unrelated), and time between diagnosis and HSCT are the main factors influencing the outcome. The best results are obtained in children transplanted during the chronic phase from an HLA-identical sibling within 1 yr from diagnosis. Unlike other forms of pediatric leukemia, infusion of donor leukocytes can reinduce a state of complete remission in a large proportion of patients experiencing leukemia relapse.

Treatment with the specific BCR-ABL tyrosine protein kinase inhibitors (imatinib mesylate, dasatinib, nilotinib), targeting the enzymatic activity of the BCR-ABL fusion protein, has modified the natural history of the disease and thus the indications for transplantation. The indication for HSCT in this population is thus evolving and is generally reserved for patients with a poor response to tyrosine kinase inhibitors or those who do not tolerate their side effects.

**Juvenile Myelomonocytic Leukemia**

Juvenile myelomonocytic leukemia (JMML) is a rare hematopoietic malignancy of early childhood, representing 2–3% of all pediatric leukemias. JMML is characterized by hepatosplenomegaly and organ infiltration, with
excessive proliferation of cells of monocytic and granulocytic lineages. Hypersensitivity to granulocyte-macrophage colony-stimulating factor (GM-CSF) and pathologic activation of the RAS-RAF-MAP (mitogen-activated protein) kinase signaling pathway play an important role in the pathophysiology. JMML usually runs an aggressive clinical course, with a median duration of survival for untreated children of <12 mo from diagnosis. Rare patients with CBL1 or N-RAS mutations can survive for years without an allograft.

HSCT is able to cure approximately 50–60% of patients with JMML. Patients who receive a transplant from an unrelated donor have comparable outcome to those given HSCT from an HLA-compatible related donor. Cord blood transplantation represents a suitable alternative option. Leukemia recurrence is the main cause of treatment failure in children with JMML after HSCT, with the relapse rate as high as 40–50%. Because children with JMML frequently have massive spleen enlargement, splenectomy has been performed before transplantation. However, spleen size at the time of HSCT and splenectomy before HSCT do not appear to affect the posttransplantation outcome. Unlike in CML, donor leukocyte infusion is not useful to rescue patients experiencing disease recurrence; a 2nd allograft can induce sustained remission in approximately one third of children with JMML relapsing after a 1st HSCT.

Myelodysplastic Syndromes Other Than Juvenile Myelomonocytic Leukemia

Myelodysplastic syndromes are a heterogeneous group of clonal disorders characterized by ineffective hematopoiesis leading to peripheral blood cytopenia and a propensity to evolve toward AML. HSCT is the treatment of choice for children with refractory anemia with excess of blasts (RAEB) and for those with RAEB in transformation (RAEB-t). The probability of survival without evidence of disease for these children is 65–70%. It is still unclear whether patients with myelodysplastic syndromes and a blast percentage >20% benefit from pretransplantation chemotherapy. HSCT from an HLA-identical sibling is also the preferred treatment for all children with refractory cytopenia. Transplantation from an alternative donor is also employed in children with refractory cytopenia associated with monosomy 7, complex karyotype, life-threatening infections, profound neutropenia, or transfusion dependency. For children with refractory cytopenia, the probability of EFS after HSCT may be as
high as 80%, disease recurrence being rarely observed. This observation has provided the rationale for testing reduced-intensity regimens in these patients.

**Non-Hodgkin Lymphoma and Hodgkin Disease**

Childhood non-Hodgkin lymphoma (NHL) and Hodgkin disease (HD) are very responsive to conventional chemoradiotherapy, but some patients have refractory disease or are at high risk for relapse. HSCT can cure a proportion of patients with relapsed NHL and HD and should be offered early after relapse, while the disease is still sensitive to therapy. If an HLA-matched donor is available, allogeneic transplantation can be offered to patients with NHL to take advantage of the GVL effect. Patients with sensitive disease and limited tumor burden have favorable outcomes, with EFS rates of 50–60%. Studies also suggest that patients with relapsed or refractory HD do well after autologous HSCT, with EFS of 50–60%. HD patients may also benefit from a GVL effect when given an allograft.

**Acquired Aplastic Anemia**

Because the probability of long-term survival for a matched-sibling bone marrow transplant (BMT) is reproducibly >80% for children and young adults, BMT is the treatment of choice for children and young adults with acquired severe aplastic anemia. Historically, the treatment of choice for children and young adults without an HLA-matched sibling has been intensive immunosuppression. Because the outcomes of matched unrelated donor transplant for children with acquired aplastic anemia have improved to probability of survival rates >75%, the use of unrelated donor HSCT upfront without prior immunosuppressive therapy is being considered more frequently; 2-year overall survival can be as high as 96% in upfront, matched unrelated donor recipients.

For patients who do not have a matched-sibling donor or well-matched unrelated donor, historically the transplant options were very disappointing. Fortunately, there is hope in current studies looking at haploidentical transplant for this disease. Although numbers are small, the use of posttransplant cyclophosphamide has shown significant improvement over prior experiences.
There is hope that all children and young adults who need a transplant for severe aplastic anemia will have the opportunity to do well with a BMT.

**Inherited Bone Marrow Failure Syndromes**

Fanconi anemia and dyskeratosis congenita are genetic disorders associated with a high risk of developing pancytopenia. **Fanconi anemia** (FA) is an autosomal recessive disease characterized by spontaneous chromosomal fragility, which is increased after exposure of peripheral blood lymphocytes to DNA cross-linking agents, including clastogenic compounds such as diepoxybutane, mitomycin C, and melphalan. Patients with FA, besides being at risk for pancytopenia, show a high propensity to develop clonal disorders of hematopoiesis, such as myelodysplastic syndromes and AML. HSCT can rescue aplastic anemia and prevent the occurrence of clonal hematopoietic disorders. In view of their defects in DNA repair mechanisms, which are responsible for the chromosomal fragility, FA patients have an exquisite sensitivity to alkylating agents and radiation therapy. Thus, they must be prepared for the allograft with reduced doses of cyclophosphamide and only judicious use of radiation. Many FA patients were once successfully transplanted after receiving low-dose cyclophosphamide and thoracoabdominal irradiation. However, the use of this regimen is associated with an increased incidence of posttransplantation head and neck cancers. Low-dose cyclophosphamide combined with fludarabine has been very well tolerated in patients with FA who have a matched-related donor. The addition of low-dose TBI and antithymocyte globulin (ATG) for those with an unrelated donor has shown similar success. Currently, the 5-yr overall survival is >90% in patients with FA who receive HSCT before the transformation to hematologic malignancy. Because of their underlying disorder, however, patients with FA must be monitored closely in the years after transplant to assess for late effects, including secondary malignancies and endocrinopathies.

Allogeneic HSCT remains the only potentially curative approach for severe bone marrow failure associated with **dyskeratosis congenita**, a rare congenital syndrome characterized also by atrophy and reticular pigmentation of the skin, nail dystrophy, and leukoplakia of mucous membranes. Results of allograft in these patients have been relatively poor, with 10-yr survival of 20–30%, because of both early and late complications, reflecting increased sensitivity of
endothelial cells to radiotherapy and alkylating agents.

Thalassemia

Conventional treatment (i.e., regular blood transfusion and iron-chelation therapy) has dramatically improved both the survival and the quality of life of patients with thalassemia, changing a previously fatal disease with early death to a chronic, slowly progressive disease compatible with prolonged survival. However, HSCT remains the only curative treatment for patients with thalassemia. In these patients the risk of dying from transplant-related complications depends primarily on patient age, iron overload, and concomitant hepatic viral infections. Adults, especially when affected by chronic active hepatitis, have a poorer outcome than children. Among children, 3 classes of risk have been identified on the basis of 3 parameters: regularity of previous iron chelation, liver enlargement, and presence of portal fibrosis. In pediatric patients without liver disease who have received regular iron chelation (class 1 patients), the probability of survival with transfusion independence is >90%, whereas for patients with low compliance with iron chelation and signs of severe liver damage (class 3 patients), the probability of survival has been 60%.

With improvements in supportive care and conditioning regimens, even patients with more advanced liver disease have had excellent outcomes (Fig. 161.2). The most effective pharmacologic combinations (e.g., including cyclosporine and methotrexate) should be employed to prevent GVHD. The outcome of patients transplanted from an unrelated donor has been reported similar to that of HLA-identical sibling recipients. The increased use of umbilical cord blood and haploidentical donors in this population is being explored to expand the number of patients eligible for HSCT. Also, advancements in gene therapy are being made in thalassemia in early trials, which may eventually change the approach to this disease.
**Sickle Cell Disease**

Disease severity varies greatly among patients with sickle cell disease, with 5–20% of the overall population suffering significant morbidity from vasoocclusive crises and pulmonary, renal, or neurologic damage. Hydroxyurea, an agent favoring the synthesis of fetal hemoglobin, reduces the frequency and severity of vasoocclusive crises and improves the quality of life for patients with sickle cell disease; however allogeneic HSCT is the only curative treatment for this disease at this time. Although HSCT can cure homozygous hemoglobin S, hemoglobin Sβ0, or hemoglobin SC disease, selecting appropriate candidates for transplantation is difficult. Patients with sickle cell disease may survive for
decades, but some patients have a poor quality of life, with repeated hospitalizations for painful vasoocclusive crises and central nervous system (CNS) infarcts. The main indications for performing HSCT in patients with sickle cell disease are history of strokes, MRI of CNS lesions associated with impaired neuropsychologic function, failure to respond to hydroxyurea as shown by recurrent acute chest syndrome, and/or recurrent vasoocclusive crises, severe anemia, or osteonecrosis. The results of HSCT are best when performed in children with an HLA-identical sibling, with a probability of cure of 80–90%. However, the use of alternative donor transplants in this population, including matched unrelated donors and haploidentical donors, is being investigated through a number of clinical trials and may increase the number of patients eligible to undergo potentially curative HSCT. Reduced-intensity and reduced-toxicity regimens are also being explored to further decrease transplant-related morbidity and mortality, although graft failure remains an important issue in this patient population.

**Immunodeficiency Disorders**

HSCT is the treatment of choice for children affected by severe combined immunodeficiency (SCID), as well as for other inherited immunodeficiencies, including Wiskott-Aldrich syndrome, leukocyte adhesion deficiency (LAD), and chronic granulomatous disease (see Table 161.1). With an HLA-identical sibling, the probability of survival approaches 100%, with less favorable results for patients transplanted from an HLA–partially matched relative. Some children with SCID, mainly those without residual natural killer activity or maternal T-cell engraftment, may be transplanted without receiving any preparative regimen, the donor lymphoid cells usually being the only elements that engraft. Sustained donor engraftment is more difficult to achieve in children with Omenn syndrome, hemophagocytic lymphohistiocytosis, or LAD. Life-threatening opportunistic fungal and viral infections occurring before the allograft adversely affect the patient's outcome after HSCT. Because of this, patients with the most severe immunodeficiencies must be transplanted as early as possible to prevent infectious complications.

**Inherited Metabolic Diseases**
Inherited metabolic diseases are a broad group of diseases that result from the accumulation of substrate within tissues caused by dysfunction of the lysosome or peroxisome. The use of HSCT has been established for a variety of inherited metabolic diseases, including mucopolysaccharidosis type 1 (Hurler syndrome) and adrenoleukodystrophy (ALD). Although some of these diseases are treatable with exogenous enzyme replacement therapy, the clinical manifestations of disease tend to progress over time, especially disease in the CNS, where enzyme is unable to be reliably delivered. It is thought that undergoing HSCT results in the engraftment of microglial cells that are able to provide new enzyme to the areas where enzyme replacement therapy, if available, cannot have a substantial impact. Multiple studies have shown significantly improved outcomes for patients who are diagnosed with their underlying conditions relatively early and are able to undergo HSCT expeditiously, before significant damage from accumulated substrate that may be irreversible.

**Bibliography**

Two thirds of patients who need allogeneic hematopoietic stem cell transplantation (HSCT) do not have an available HLA-identical sibling. Alternative sources of hematopoietic stem cells (HSCs) are being increasingly used and include matched unrelated donors, unrelated umbilical cord blood, and HLA-haploidentical relatives. Each of these 3 options has advantages and limitations, but rather than being considered competing alternatives, they should be regarded as complementary strategies to be chosen after a careful evaluation of the relative risks and benefits in the patient's best interest. The choice of the donor will depend on various factors related to urgency of transplantation, patient-, disease-, transplant-related factors, center experience, and physician preference.

Unrelated Donor Transplants

One of the most widely used strategies for children who need an allograft and do not have an available HLA-identical sibling is to identify an unrelated HLA-matched donor in a registry (Fig. 162.1). Worldwide international registries include almost 27 million HLA-typed volunteer donors. HLA-A, -B, -C class I loci, and the DRB1 class II locus are the HLA loci most influencing outcome after HSCT from an unrelated volunteer. Other class II loci (namely, DQB1 and DP1 loci), as well as KIR haplotypes, are also being increasingly considered when choosing a donor, although their impact on outcome is less well studied.
Although in the past serologic (low-resolution) typing was used for HLA-A and HLA-B loci, currently the unrelated donors are selected using high-resolution (allelic) molecular typing of loci HLA-A, -B, -C, and -DRB1. Less stringent HLA typing is required for cord blood units, where only HLA-A, -B, and -DRB1 are used. The chance of finding an HLA-matched unrelated donor depends on the frequency of the HLA phenotype, which is closely linked to the ethnic origin of the registry donors. Data from the National Marrow Donor Program (NMDP) donor registry and banked cord blood units estimated that essentially every patient in need of a transplant would be able to find a donor in a timely fashion, despite the recipient's race/ethnic group, donor availability, and cell dose. However, many of those patients may not have access to an “ideal” graft, defined as HLA matching of 8/8 for bone marrow and 6/6 for cord blood. It is also estimated that an additional 5.5 million donors will be added to the registry by 2017, making it even more likely for a potential, and more ideal, donor to be identified.

Initially, HLA polymorphism and the intrinsic limitations of conventional (i.e., serologic) HLA-typing techniques unfavorably affected the accuracy of matching, thus increasing rejection rates and the incidence of acute and chronic graft-versus-host disease (GVHD). The advent of both high-resolution molecular HLA classes I and II loci typing coupled with progress in the prophylaxis and treatment of GVHD has resulted in a reduction of transplantation-related
mortality and improvement in outcome. Indeed, outcomes from a fully matched unrelated volunteer donor are now similar to those of HSCT from an HLA-identical sibling. The outcomes of haploidentical transplantation are similarly reaching that of matched unrelated donors as well as matched sibling donors.

Although a single locus disparity in patients with leukemia may be seen as beneficial by a reduction in the relapse rate caused by the graft-versus-leukemia (GVL) effect, in patients with nonmalignant disorders in whom GVL is not beneficial, optimal results are obtained only when a donor matched at the allelic level with the recipient is selected. In general, a single HLA disparity in the donor-recipient pair, irrespective of whether antigenic or allelic in nature, predicts a greater risk of nonleukemia mortality; multiple allelic disparities at different HLA loci have an additive detrimental effect and are associated with an even worse outcome. To reduce the risk of acute GVHD, **ex vivo T-cell depletion of the graft** has been employed, with variable efficacy. Studies are looking at selectively depleting donor α/β T cells, which are the T cells that drive GVHD, while preserving the T cells and natural killer (NK) cells, which may be responsible for GVL and protection from infection.

Although the majority of patients who have required a matched unrelated donor transplant have received a bone marrow or peripheral stem cell graft, for patients who urgently need a transplant, the time required to identify a suitable donor from a potential panel, establish eligibility, and harvest the cells may lead to relapse and failure to transplant. For this subset of patients who urgently need a transplant, attention has focused on unrelated cord blood and HLA-haploidentical, mismatched family donors.

**Umbilical Cord Blood Transplants**

**Umbilical cord blood transplantation (UCBT)** is a viable option for children who need allogeneic HSCT. UCBT offers the advantages of absence of risks to donors, reduced risk of transmitting infections, and for transplants from unrelated donors, immediate availability of cryopreserved cells, with the median time from start of search to transplantation only 3-4 wk. Compared with bone marrow transplantation (BMT), the advantages of UCBT are also represented by lower incidence of chronic GVHD and the possibility of using donors showing HLA disparities with the recipient. Despite these advantages, the large experience gained over the last 2 decades has demonstrated that UCBT patients may be exposed to an increased risk of early fatal complications, mainly because
of a lower engraftment rate of donor hematopoiesis, delayed kinetics of neutrophil recovery, and lack of adoptive transfer of pathogen-specific memory T cells. Transfer of donor-derived, memory T cells significantly contributes to early immunologic reconstitution of children after unmanipulated allogeneic bone marrow or peripheral blood stem cell transplantation.

Concerning the issues of engraftment and hematopoietic recovery, it has been demonstrated that an inverse correlation exists between the number of nucleated cord blood cells infused per kilogram recipient body weight and the risk of dying for transplantation-related causes. In particular, engraftment is a major concern when the nucleated cells are $<2.5 \times 10^7$/kg of recipient body weight. Since a cord blood unit usually contains between $1 \times 10^9$ and $1.8 \times 10^9$ cells, it is not surprising that UCBT has been less frequently employed for adolescents or adults with body weight $>40$ kg. Indeed, it can be estimated that only 30% of the UCB units available in the bank inventory could suffice for a 75 kg patient, according to the recommended threshold cell dose. Efforts have focused on approaches capable of increasing the number of UCB cells to be transplanted. Selection of the richest cord blood units, infusion of 2 units in the same recipient (i.e., double UCBT), and transplantation of ex vivo expanded progenitors have been explored to improve the results of UCBT, opening new scenarios for a wider application of the procedure. The results of these studies have been mixed, with one large study demonstrating no survival advantage for children and adolescents that receive double UCBT.

The long-term results of UCB transplants are similar to those after transplantation from other sources of HSCs for pediatric hematologic malignancies. In patients with hematologic malignancies, recipients of UCBT may be transplanted from donors with greater HLA disparities, receive 1-log fewer nucleated cells, have delayed neutrophil and platelet recovery, and show reduced incidence of GVHD compared with children given BMT from unrelated donors. In one study, there were similar rates of acute GVHD, but significantly less chronic GVHD in patients who received UCBT. Nevertheless, both the relapse rate and the overall survival probability did not differ in unrelated UCBT or BMT pediatric recipients. Thus, in the absence of an HLA-identical family donor, unrelated UCBT can be considered a suitable option for children with malignant and nonmalignant disorders. Results of UCBT have been of particular interest in children with certain nonmalignant disorders to proceed to transplant quickly and prevent further progression of disease. An additional benefit is the potential for lower rates of GVHD, which serves no benefit in a patient receiving
a transplant for a nonmalignant disorder.

**Haploidentical Transplants**

HSCT from an HLA-haploidentical (haplo-HSCT) donor offers an immediate source of HSCs to almost all patients who fail to find a matched donor, whether related or unrelated, or a suitable cord blood unit. Indeed, almost all children have at least 1 haploidentical–3 loci mismatched family member who is promptly available as donor. The few patients who reject the haploidentical transplant also have the advantage of another immediately available donor within the family. Moreover, this may represent an approach that would be attractive in the global health setting, where more sophisticated donor registries and cell-processing techniques are unavailable.

Efficient T-cell depletion of the graft has been demonstrated to prevent acute and chronic GVHD even when using haploidentical parental bone marrow differing at the 3 major HLA loci. This can be done ex vivo or in vivo with the use of chemotherapeutic agents before and after cell infusion. The use of **posttransplant cyclophosphamide** is one such in vivo technique now being widely incorporated into haploidentical transplant regimens. The benefits of T-cell depletion were first demonstrated in transplantation of children with severe combined immunodeficiency (SCID). More than 300 transplants in SCID patients using haploidentical donors have been performed worldwide, with a high rate of long-term partial or complete immune reconstitution.

The elimination of mature T cells from the graft, necessary for preventing GVHD in a context of great immune genetic disparity, results in recipients being unable to benefit from the adoptive transfer of donor memory T lymphocytes that, through their peripheral expansion, are the main factor responsible for protection from infections in the 1st few mo after transplantation. A state of profound immunodeficiency lasts for at least 4-6 mo after transplantation in haplo-HSCT recipients. Sophisticated strategies of adoptive infusions of T-cell lines or clones specific for the most common and life-threatening pathogens (Epstein-Barr virus [EBV], human cytomegalovirus, *Aspergillus*, adenovirus) have been successfully tested in a few pilot trials, to protect the recipients in the early posttransplant period.

Selective approaches of graft manipulation in haploidentical and unrelated donor transplant have also been developed. In particular, promising results have been obtained through a negative depletion of T lymphocytes carrying the α/β
chains of the T-cell receptor, which are believed to be the mediators of GVHD. B lymphocytes are also depleted to prevent EBV-related lymphoproliferative disease. Through this approach the patient can benefit from the adoptive transfer of committed hematopoietic progenitors, mature NK cells and γ/δ+ T cells, which can confer a protection against life-threatening infections as well as provide a GVL effect.

The outcomes of haplo-HSCT have been more extensively reported in adults than in children. The reported probability of survival at 3–4 yr after a haplo-HSCT in children with acute leukemia ranged from 18–48%. Survival was influenced by many factors, most importantly the state of remission at transplantation, with poorer outcomes in children with myeloid leukemias than in those with lymphoid leukemia. In haplotype-mismatched parent-to-child HSCT, patients with acute leukemia grafted from the mother had reduced relapse rates compared with recipients of paternal grafts, translating into better event-free survival.

For many years the absence of the T-cell–mediated GVL effect has been considered as rendering the recipients of a T-cell–depleted allograft more susceptible to leukemia relapse. However, it has been demonstrated that a GVL effect displayed by donor NK cells can compensate for this lack of T-specific alloreactivity when an HLA-disparate NK-alloreactive relative is employed as a donor.

**Donor Versus Recipient NK-Cell Alloreactivity**

Natural killer cells are the first lymphocytes derived from the donor to recover after allogeneic HCT. Donor vs recipient NK-cell alloreactivity derives from a mismatch between donor NK clones, carrying specific inhibitory receptors for self–major histocompatibility complex (MHC) class I molecules, and MHC class I ligands on recipient cells. NK cells are primed to kill by several activating receptors, which play an important role in the NK cell–mediated GVL effect. Human NK cells discriminate allelic forms of MHC molecules via killer cell immunoglobulin-like receptors (KIRs), which are clonally distributed with each cell in the repertoire bearing at least 1 receptor that is specific for self-MHC class I molecules. Because NK cells co-express inhibitory receptors for self-MHC class I molecules, autologous cells are not killed. When faced with
mismatched allogeneic targets, NK cells sense the missing expression of self–class I alleles and mediate alloreactions. In mismatched transplants, there are many donor recipient pairs in which the donor NK inhibitory cells do not recognize the recipient's class I alleles as self. Consequently, the donor NK cells are not blocked and are activated to lyse the recipient's lymphohematopoietic cells.

Haplo-HSCT trials demonstrate that MHC class I mismatches, which generate an alloreactive NK-cell response in the graft-vs-host direction, eradicate leukemia cells, improve engraftment, and protect from T-cell–mediated GVHD. The potential for donor vs recipient NK-cell alloreactivity, which can be predicted by standard HLA typing, is increasingly being examined when selecting the donor of choice. Although the importance of KIR haplotype in transplants other than haploidentical transplantation has still not been fully elucidated in the pediatric population, its role in preventing GVHD as well as relapse has been shown to be increasingly beneficial in the adult population.

**Autologous Hematopoietic Stem Cell Transplantation**

**Autologous transplantation**, using the patient's own stored marrow, is associated with a low risk of life-threatening transplant-related complications, although the main cause of failure is disease recurrence. Bone marrow was once the only source of stem cells employed in patients given an autograft. In the past few years, the vast majority of patients treated with autologous HSCT receive hematopoietic progenitors mobilized in peripheral blood by either cytokines alone (mainly granulocyte colony-stimulating factor) or by cytokines plus cytotoxic agents. A CXCR4 antagonist (plerixafor) can be extremely effective in mobilizing hematopoietic progenitors in the periphery. Compared with bone marrow, the use of peripheral blood progenitors is associated with a faster hematopoietic recovery and a comparable outcome. A major concern in patients with malignancies given autologous HSCT is represented by the risk of reinfusing malignant cells with the graft; tumor progenitors contained in the graft can contribute to recurrence of the original malignant disease. This observation has provided the rationale for **tumor purging** using elaborate strategies aimed at reducing or eliminating tumor contamination of the graft.

Autologous HSCT is employed primarily for selected children with relapsed
lymphomas and select solid tumors (Table 162.1).

Table 162.1

Indications for Autologous Hematopoietic Stem Cell Transplantation for Pediatric Diseases

- Relapsed Hodgkin or non-Hodgkin lymphoma
- Stage IV or relapsed neuroblastoma
- High-risk, relapsed, or resistant brain tumors
- Stage IV Ewing sarcoma
- Life-threatening autoimmune diseases resistant to conventional treatments

Patients with sensitive lymphomas and minimal tumor burden have favorable outcomes after autologous HSCT, with disease-free survival rates of 50–60%, whereas high-risk patients with bulky tumor or poorly responsive disease have a poor outcome, with survival rates of 10–20%.

Autologous HSCT in patients with high-risk neuroblastoma is associated with a better outcome than conventional chemotherapy. A Children's Oncology Group (COG) study demonstrated further survival advantage by performing 2 sequential, or tandem, transplants that use different chemotherapeutic agents. Because of these improved outcomes, tandem autologous transplants are now considered the standard recommended treatment. In these patients, posttransplantation infusion of a monoclonal antibody directed against a molecule (GD2) expressed on the surface of neuroblastoma cells confers a protection against the risk of tumor recurrence.

For children with brain tumors at high risk of relapse, or resistant to conventional chemotherapy and irradiation, the dose-limiting toxicity for intensifying therapy is myelosuppression, thus providing a role for stem cell rescue. Several studies provide encouraging results for patients with different histologic types of brain tumors treated with autologous HSCT.

Bibliography

A major cause of mortality and morbidity after allogeneic hematopoietic stem cell transplantation (HSCT) is **graft-versus-host disease (GVHD)**, which is caused by engraftment of immunocompetent donor T lymphocytes in an immunologically compromised host who shows histocompatibility differences with the donor. These differences between the donor and the host may result in donor T-cell activation against either recipient major histocompatibility complex (MHC) antigens or minor histocompatibility antigens. GVHD is usually subdivided in 2 forms: **acute GVHD**, which occurs within 3 mo after transplantation, and **chronic GVHD**, which, although related, is a different disease, occurring later and displaying some clinical and pathologic features that resemble those observed in selected autoimmune disorders (e.g., systemic sclerosis, Sjögren syndrome).

### Acute Graft-Versus-Host Disease

Acute GVHD is caused by the alloreactive, donor-derived T cells contained in the graft, which attack nonshared recipient's antigens on target tissues. A 3-step process generates the clinical syndrome. First, conditioning-induced tissue damage activates recipient antigen-presenting cells, which present recipient alloantigens to the donor T cells transferred with the graft and secrete **cytokines**, such as interleukin (IL)-12, favoring the polarization of T-cell response in the type 1 direction. Second, in response to recipient antigens, donor T cells become activated, proliferate, expand, and generate cytokines such as tumor necrosis factor (TNF)-α, IL-2, and interferon (IFN)-γ. In the 3rd step of the process, these
cytokines cause tissue damage and promote differentiation of cytotoxic CD8+ T cells, which, together with macrophages, kill recipient cells and further disrupt tissues.

Acute GVHD usually develops 2-8 wk after transplantation. The primary manifestations depend on the sites of involvement and may include an erythematous maculopapular rash (Figs. 163.1 and 163.2), persistent anorexia, vomiting and/or diarrhea, and liver disease with increased serum levels of bilirubin, alanine transaminase (ALT), aspartate transaminase (AST), and alkaline phosphatase (ALP). Diagnosis may benefit from skin, liver, or gastrointestinal (GI) biopsy for confirmation. Endothelial damage and lymphocytic infiltrates are seen in all affected organs. The epidermis and hair follicles of the skin are damaged, the hepatic small bile ducts show segmental disruption, and there is destruction of the crypts and mucosal ulceration of the GI tract. Grade I acute GVHD (skin rash alone) has a favorable prognosis and often requires no treatment, or topical treatment alone. Grade II GVHD is a moderately severe multiorgan disease requiring immunosuppressive therapy. Grade III GVHD is a severe multiorgan disease, and grade IV GVHD is a life-threatening, often fatal condition (Table 163.1).

FIG. 163.1 Acute graft-versus-host disease. Involvement of the scalp, ears, palms, and soles is common. (From Paller AS, Mancini AJ, editors: Hurwitz clinical pediatric dermatology, ed 5, Philadelphia, 2016, Elsevier, p 577.)

* Overall clinical grade (based on most severe target organ involvement):
Grade 0: no stage 1-4 of any organ.
Grade I: stage 1-2 skin without liver, upper GI, or lower GI involvement.
Grade II: stage 3 rash and/or stage 1 liver and/or stage 1 upper GI and/or stage 1 lower GI.
Grade III: stage 2-3 liver and/or stage 2-3 lower GI, with stage 0-3 skin and/or stage 0-1 upper GI.
Grade IV: stage 4 skin, liver, or lower GI involvement, with stage 0-1 upper GI.

GI, Gastrointestinal; BSA, body surface area.

The standard pharmacologic prophylaxis of GVHD after an unmanipulated allograft relies mainly on posttransplant administration of immunosuppressive drugs, such as cyclosporine or tacrolimus or combinations of either with methotrexate or prednisone, anti–T-cell antibodies, mycophenolate mofetil (MMF), and other immunosuppressive agents. Infusion of cyclophosphamide on days +3 and +5 after transplantation has been proposed as a strategy to deplete alloreactive donor T lymphocytes that become activated after exposure to recipient antigens. This approach has been successful in patients undergoing haploidentical transplantation. Pretransplantation infusion of either antithymocyte globulin (ATG) or monoclonal antibodies (mAbs) such as alemtuzumab is largely used to modulate alloreactivity of donor T cells, in particular in patients given the allograft from either an unrelated donor or a partially matched relative. An alternative approach, which has been widely used in clinical practice, is the removal of T lymphocytes from the graft (T-cell depletion). Other approaches, through clinical trials, are being used to selectively remove the α/β T cells, which are thought to be responsible for the development of GVHD, while preserving the γ/δ T cells in order to sustain GVL and the ability to fight infection. Any form of GVHD prophylaxis in itself may impair posttransplantation immunologic reconstitution, increasing the risk of infection-related deaths. Traditional T-cell depletion of the graft is also associated with an increased risk of leukemia recurrence in patients transplanted
from an HLA-identical sibling or an unrelated volunteer.

Despite prophylaxis, significant acute GVHD develops in approximately 30% of recipients of HSCT from matched siblings and in as many as 60% of HSCT recipients from unrelated donors. These numbers are estimates, and the actual risk of acute GVHD is highly variable depending on several factors. Risk for development of GVHD is increased by diagnosis of malignant disease, older donor and recipient age, and in patients given an unmanipulated allograft, GVHD prophylaxis including only 1 drug. The most important risk factor for acute GVHD is the presence of disparities for HLA molecules in the donor-recipient pair.

Acute GVHD is usually initially treated with glucocorticoids; approximately 40–50% of patients show a complete response to corticosteroids. The risk of transplantation-related mortality is much higher in patients who do not respond to corticosteroids than in those showing a complete response. Promising results in children with steroid-resistant acute GVHD have been obtained using mesenchymal stromal cells, which are able to blunt the inflammatory response associated with acute GVHD. MMF, pentostatin, or mAbs targeting molecules expressed on T cells or cytokines released during the inflammatory cascade (including infliximab and etanercept targeting TNF, and tocilizumab targeting IL-6), which underlies the pathophysiology of GVHD, have been used in patients with steroid-resistant acute GVHD. There are no clear data showing the superiority of one of these approaches over the others. Extracorporeal photopheresis is another second-line treatment for GVHD and is most efficacious for skin GVHD. A patient's peripheral blood is exposed to a photosensitive compound and then exposed to ultraviolet light. The cells are then reinfused into the patient. It is thought that this process results in an increase in apoptosis of lymphocytes responsible for GVHD as well as the upregulation of antiinflammatory cytokines and regulatory T cells.

**Chronic Graft-Versus-Host Disease**

Chronic GVHD develops or persists >3 mo after transplantation and is the most frequent late complication of allogeneic HSCT with an incidence of approximately 25% in pediatric patients. Chronic GVHD is the major cause of nonrelapse mortality and morbidity in long-term HSCT survivors. Acute GVHD is recognized as the most important factor predicting the development of the chronic form of the disease. The use of matched unrelated volunteers as donors
and use of peripheral blood as the stem cell source have increased the incidence and severity of chronic GVHD. Other factors that predict occurrence of chronic GVHD include older donor and recipient ages, female donor for male recipient, diagnosis of malignancy, and use of total body irradiation (TBI) as part of the preparative regimen.

Chronic GVHD is a disorder of immune regulation characterized by autoantibody production, increased collagen deposition and fibrosis, and clinical symptoms similar to those seen in patients with autoimmune diseases (Table 163.2). The predominant cytokines involved in the pathophysiology of chronic GVHD are usually type II cytokines such as IL-4, IL-5, and IL-13. IL-4 and IL-5 contribute to eosinophilia, B-cell hyperactivity with elevated IgM, IgG, and IgE titers. Associated monoclonal gammapathies indicate clonal dysregulation.

Chronic GVHD is dependent on the development and persistence of donor T cells that are not tolerant to the recipient. Maturation of transplanted stem cells within a damaged thymus could lead to errors in negative selection and production of cells that have not been tolerized to recipient antigens and are therefore autoreactive or, more accurately, recipient reactive. This ongoing immune reactivity results in clinical features resembling a systemic autoimmune disease with lichenoid and sclerodermatous skin lesions, malar rash, sicca syndrome, arthritis, joint contractures, bronchiolitis obliterans, and bile duct degeneration with cholestasis.

Hematology
Thrombocytopenia, eosinophilia, Howell-Jolly bodies (splenic dysfunction)

Patients with chronic GVHD involving only the skin and liver have a favorable course (Figs. 163.3 and 163.4). Extensive multiorgan disease may be associated with a very poor quality of life, recurrent infections associated with prolonged immunosuppressive regimens to control GVHD, and a high mortality rate. Morbidity and mortality are highest in patients with a **progressive onset** of chronic GVHD that directly follows acute GVHD, intermediate in those with a **quiescent onset** after resolution of acute GVHD, and lowest in patients with **de novo onset** in the absence of acute GVHD. Chronic GVHD can be classified as mild, moderate, or severe depending on extent of involvement. Single-agent prednisone is standard treatment at present, although other agents, including extracorporeal photopheresis, MMF, anti-CD20 mAb, and pentostatin, have been employed with variable success. Treatment with imatinib mesylate, which inhibits the synthesis of collagen, has been effective in some patients with chronic GVHD and sclerotic features. As a consequence of prolonged immunosuppression, patients with chronic GVHD are particularly susceptible to infections and should receive appropriate antibiotic prophylaxis, including trimethoprim/sulfamethoxazole (TMP/SMX). Chronic GVHD resolves in most pediatric patients but may require 1-3 yr of immunosuppressive therapy before the drugs can be withdrawn without the disease recurring. Chronic GVHD promotes the development of secondary neoplasms, in particular in patients with Fanconi anemia, and has a significant impact on quality of life.

**FIG. 163.3** Chronic graft-versus-host disease (GVHD), lichenoid. After bone marrow transplantation, this boy had acute GVHD and subsequently developed cutaneous scaling papules and plaques typical of lichen planus. (From Paller AS, Mancini AJ, editors: Hurwitz clinical pediatric dermatology, ed 5, Philadelphia, 2016, Elsevier, p 577.)
Graft Failure

Graft failure is a serious complication exposing patients to a high risk of fatal infection. **Primary graft failure** is defined as failure to achieve a neutrophil count of $0.5 \times 10^9 /L$ after transplantation. **Secondary graft failure** is loss of peripheral blood counts following initial transient engraftment of donor cells. Causes of graft failure after autologous and allogeneic transplantation include transplantation of an inadequate stem cell dose (more frequently observed in children given cord blood transplantation) and viral infections such as with cytomegalovirus or human herpesvirus type 6, which are often associated with activation of recipient macrophages. Graft failure after allogeneic
transplantation, however, is mainly caused by immunologically mediated rejection of the graft by residual recipient-type T cells that survive the conditioning regimen.

Diagnosis of graft failure resulting from immunologic mechanisms is based on examination of peripheral blood and marrow aspirate and biopsy, along with molecular analysis of chimerism status. Persistence of lymphocytes of host origin in allogeneic transplant recipients with graft failure indicates immunologic rejection. The risk of immune-mediated graft rejection is higher in patients given HLA-disparate, T-cell–depleted grafts, reduced-intensity conditioning regimens, and transplantation of low numbers of stem cells, and in recipients who are sensitized toward HLA antigens or, less frequently, minor histocompatibility antigens. Allosensitization develops as a consequence of preceding blood product transfusions and is observed particularly in recipients with aplastic anemia, sickle cell disease, and thalassemia. In HSCT for nonmalignant diseases, such as mucopolysaccharidoses, graft failure is also facilitated by the absence of previous treatment with cytotoxic and immunosuppressive drugs. In thalassemia, graft failure is promoted by expansion of recipient hematopoietic cells. GVHD prophylaxis with methotrexate, an antimetabolite, and antiinfective prophylaxis with TMP/SMX or ganciclovir may also delay engraftment.

**Treatment** of graft failure usually requires removing all potentially myelotoxic agents from the treatment regimen and attempting a short trial of hematopoietic growth factors, such as granulocyte colony-stimulating factor. A 2nd transplant, usually preceded by a highly immunosuppressive regimen, is frequently employed to rescue patients experiencing graft failure. High-intensity regimens are generally tolerated poorly if administered within 100 days from a 1st transplant because of cumulative toxicities, but this risk must be balanced with the risk of infection from prolonged neutropenia and lymphocytopenia.

**Venoocclusive Disease**

Hepatic venoocclusive disease (VOD), also known as **sinusoidal obstruction syndrome**, presents with hepatomegaly, right upper quadrant tenderness, jaundice, and weight gain from fluid retention and ascites. It results from endothelial damage within the liver, which can then progress to multiorgan dysfunction. Onset is usually within 30 days of transplantation, with an incidence of approximately 15%, depending on the intensity of the conditioning
Risk factors include young age, prior hepatic disease (fibrosis, cirrhosis), abdominal radiation, repeated transplantations, neuroblastoma, osteopetrosis, and familial hemophagocytic lymphohistiocytosis. The severe form of VOD has a high mortality rate (>80%) without treatment.

Prophylaxis has traditionally used ursodeoxycholic acid and occasionally heparin; only defibrotide has demonstrated some efficacy in preventing and treating VOD. A phase 3 study demonstrated improvement in survival and response rate to VOD in patients treated with defibrotide. Defibrotide is a combination of porcine oligodeoxyribonucleotides that reduces procoagulant activity and enhances fibrinolytic properties of endothelial cells. Defibrotide is U.S. Food and Drug Administration (FDA) approved for the treatment of VOD in adult and pediatric patients with renal or pulmonary dysfunction after HSCT. Defibrotide is often used as prophylaxis in Europe, with data showing efficacy, but this use is not yet approved in the United States.

Bibliography

Hematopoietic stem cell transplantation (HSCT) recipients experience a transient but profound state of immune deficiency. The risk of infection depends on the stage after transplantation (pre- vs postengraftment), ongoing immunosuppression, disruption in barrier functions (indwelling catheters, graft-versus-host disease [GVHD], mucositis) and preexisting infections (Fig. 164.1). Management approaches may include the use of prophylactic antimicrobials, preemptive antimicrobials for infection prior to symptomatic disease, or antimicrobial treatment of documented or suspected infection.
Immediately after transplantation, the absence or paucity of neutrophils (neutropenia) renders patients susceptible to bacterial and fungal infections. Consequently, most centers start antipseudomonal and antifungal prophylaxis during the conditioning regimen. Despite these prophylactic measures, the majority of patients will develop fever and signs of infection in the early posttransplantation period. The common pathogens include enteric gram-negative bacteria and fungi. An indwelling central venous line, routinely employed in all children given HSCT, is a significant risk factor for infection. Staphylococcal species and Candida are the most frequent pathogens in catheter-related infections (see Chapter 206). Multidrug-resistant strains of Pseudomonas aeruginosa and Klebsiella pneumoniae are an emerging problem, with prevalence highly variable among centers. Severe lower respiratory tract disease caused by seasonal respiratory viruses, such as influenza, respiratory syncytial
virus (RSV), parainfluenza virus, and human metapneumovirus, can occur during the pre- or postengraftment phase. Published guidelines from the Infectious Disease Society of America and the U.S. Centers for Disease Control and Prevention (CDC) address the management of fever and neutropenia after HSCT.  

HSCT recipients remain at increased risk of developing severe infections even after the neutrophil count has normalized because of prolonged depression in T-cell number and function. The manifestations of GVHD, as well as the associated immunosuppressive therapy, are additional risk factors for fungal and viral opportunistic infections. After umbilical cord blood transplant (UCBT), infections are the consequence of both slow neutrophil engraftment and donor T-cell naïveté. In haploidentical transplantation, T-cell depletion results in an increased risk of infection in the first 4-6 mo. Recipients of this type of transplantation, as well as those receiving UBCT, do not have the benefit of adoptive transfer of donor-derived, antigen-experienced T cells. For HSCT recipients after engraftment, invasive fungal disease, herpesviruses, and adenovirus infections represent life-threatening complications that significantly affect outcomes. Additional pathogens to consider include nontuberculous mycobacteria, BK virus, *Clostridium difficile*, and norovirus.  

**Invasive fungal disease (IFD)** remains a significant cause of infectious morbidity and mortality in allogeneic HSCT recipients. Empirical treatment for IFD is considered for HSCT patients with persistent fever despite 96 hr of broad-spectrum antibiotic treatment. The most common organisms are *Aspergillus* and *Candida* species. Infections also occur with non-*Aspergillus* molds, including *Mucor* and *Rhizopus* species (among other agents of mucormycosis), *Fusarium*, and *Scedosporium* species. *Pneumocystis jiroveci* is a unique, noncultivatable cause of fungal pneumonia in immunocompromised patients. Despite prompt and aggressive administration of potent antifungal agents, proven cases of IFD carry case fatality rates of 20–70%. IFD can present early after transplant, although there is a shift toward presentation of infection in the postengraftment period in the presence of GVHD. The risk of developing IFD is mainly influenced by history of previous fungal infection, duration of neutropenia, use of corticosteroid therapy, mucosal tissue damage (GVHD, posttransplant CMV infection, viral respiratory tract infections), and for candidiasis, presence of central venous catheters.  

**Disseminated candidiasis** presents frequently as a central venous catheter–associated infection. However, up to 50% of patients with disseminated
candidiasis do not present with positive blood cultures. Patients with and without candidemia can have infection of normally sterile organs, including liver, spleen, kidney, brain, heart, and eye. Mortality rates in pediatric series range from 10–25%. **Echinocandins** (micafungin, caspofungin) are the initial drugs of choice for candidiasis in immunocompromised patients.

The most common presentation of invasive **aspergillosis** is pulmonary aspergillosis. The upper airway mucosa (nose and sinuses) can also be a site of initial infection. Infection progresses from lung or sinus sites by direct extension across tissue or angioinvasion resulting in hematogenous dissemination to brain and other organs. The earliest imaging finding is classically 1 or more small pulmonary nodules (**Figs. 164.2 and 164.3**). As a nodule enlarges, the dense central core of infarcted tissue may become surrounded by edema or hemorrhage, forming a hazy rim known as the *halo sign*. When bone marrow function recovers, the infarcted central core may cavitate, creating the *crescent sign*. Unfortunately, radiographic signs, including the halo sign, crescent sign, and cavitation, have low sensitivity in pediatric patients. Clinical criteria are used to diagnose proven or probable IFD, requiring direct or indirect microbiologic data. Direct, culture-based diagnosis requires invasive procedures, such as sinus endoscopy or lung biopsy. Indirect measures, known as *fungal biomarkers*, are used in adult HSCT patients to screen or diagnose for aspergillosis. Fewer data are available for pediatric patients, and currently no major guidelines support routine use of fungal biomarkers to diagnose IFD in immunocompromised children. **Galactomannan** from serum or bronchoalveolar lavage fluid is a promising adjunct to current diagnostic strategies because of a high negative predictive value for aspergillosis; however, lack of detection of mucormycosis limits its utility as a single diagnostic test. Other tests used in adult patients, such as (1 → 3)-β-D-glucan, are insufficiently studied for routine use in pediatric patients.
Fungal infection prevention includes isolation of the patient in a laminar airflow or positive pressure room. Universal prophylaxis to prevent *Pneumocystis* pneumonia is advocated until the return of T-cell function in HSCT patients; the primary agent for prophylaxis is trimethoprim/sulfamethoxazole. Alternative agents are pentamidine, dapsone, and atovaquone. For prevention and treatment of other IFD, liposomal
amphotericin B, azole compounds (itraconazole, voriconazole, posaconazole) and echinocandins (caspofungin, micafungin) are used. **Voriconazole** represents the treatment of choice for adult patients with invasive aspergillosis, but achieving adequate trough levels can be challenging in young children. The agents of mucormycosis are resistant to most azole and echinocandin medications, which makes liposomal amphotericin B the initial drug of choice. IFD often does not respond satisfactorily to antifungal agents alone, and infection may persist until immune function recovers.

**Herpesviruses**, including cytomegalovirus (CMV), Epstein-Barr virus (EBV), herpes simplex virus (HSV1 and HSV2), and varicella-zoster virus (VZV) are pathogens that can cause significant disease after HSCT. Because herpesviruses can establish latency in the human host, symptomatic infection can occur from viral reactivation as well as acquisition from the donor or de novo infection. Baseline susceptibility to disease and viremia before symptom development can be established with laboratory monitoring (pretransplant donor-recipient serology, posttransplant viral load monitoring) and can inform decisions on prophylactic and preemptive antiviral treatment.

**CMV infection** remains the most common and potentially severe viral complication in patients receiving allogeneic HSCT. Risk factors for CMV viremia include recipient seropositivity, UCBT, and acute GVHD. The period of maximal risk for CMV disease is 1-4 mo after transplantation. Late presentation of CMV disease is associated with GVHD. Until CMV-specific T-cell responses develop months after transplant, CMV infection may result in a variety of syndromes, including fever, leukopenia, thrombocytopenia, hepatitis, pneumonitis, retinitis, esophagitis, gastritis, and colitis. CMV pneumonia has been reported to occur in up to 15–20% of bone marrow transplant recipients, with a case fatality rate of 85% in the absence of early treatment. Tachypnea, hypoxia, and nonproductive cough signal respiratory involvement. Chest radiography often reveals bilateral interstitial or reticulonodular infiltrates, which begin in the periphery of the lower lobes and spread centrally and superiorly. Gastrointestinal CMV involvement may lead to ulcers of the esophagus, stomach, small intestine, and colon with complications of bleeding or perforation. Fatal CMV infections are often associated with persistent viremia and multiorgan involvement.

CMV disease has largely been prevented through prophylaxis or preemptive approaches. Prophylaxis is based on administration of antiviral drugs to at-risk transplanted patients for a median duration of 3 mo after transplantation. The
major drawbacks of this approach are drug toxicity, late CMV disease after withdrawal of prophylaxis, potential unnecessary treatment of patients who would not have reactivated CMV infection, and low cost-effectiveness. Preemptive therapy aims at treating only patients who experience CMV reactivation and thus are at risk of developing overt disease; it starts on detection of CMV in blood but before symptom development. The major drawback of this strategy is the need of serial monitoring of CMV by polymerase chain reaction (PCR) in blood. First-line therapy is usually ganciclovir, with foscarnet as an alternative for resistant strains or ganciclovir intolerance.

**EBV-related posttransplant lymphoproliferative disease (PTLD)** is a major complication in HSCT and solid-organ transplantation. In patients receiving HSCT, selective procedures of T-cell depletion–sparing B lymphocytes and use of HLA–partially matched family and unrelated donors are risk factors for the development of PTLD. PTLD usually presents in the first 4-6 mo after transplantation as high-grade, diffuse, large-cell B-cell lymphomas that are oligoclonal or monoclonal. High EBV viral loads in blood by PCR predict development of PTLD. Standard treatment of PTLD includes the reduction of immunosuppression, monoclonal antibodies directed against CD20 on B cells (rituximab), or cytotoxic chemotherapy. Prophylactic strategies with rituximab for EBV-positive recipients during conditioning for HSCT have also been employed. Histologic diagnosis of PTLD is required to assess for the emergence of neoplasms in which cells are CD19+ but CD20−, thus eliminating susceptibility to rituximab.

**Disseminated adenovirus infection** is a life-threatening complication of HSCT recipients. Clinical manifestations include fever, hepatitis, enteritis, meningoencephalitis, and pneumonia. Young children or recipients of donor cells naïve to adenovirus (T-cell–depleted grafts or UCBT) are at particular risk of developing this complication. Diagnosis is based on the demonstration of high viral loads by PCR in blood or recovery of virus in tissue biopsies. Pharmacologic treatment of adenovirus infections is with the antiviral cidofovir, which has significant renal toxicity and limited potency at controlling viral replication. Alternative delivery systems for this drug, such as enterally available prodrugs, are currently being investigated in research settings. Recovery of immune system function is associated with improved survival with disseminated adenovirus infection.

In immunocompromised hosts, severe viral infections, including PTLD and adenovirus infection, originate from a deficiency of virus-specific cytotoxic T
lymphocytes (CTLs). This finding provides the rationale for developing strategies of adoptive cell therapy to restore virus-specific immune competence. Multiple protocols are under development and available at some centers for the rapid generation of specific CTL lines of donor or third-party origin.

Bibliography

Pedicatriic hematopoietic stem cell transplantation (HSCT) is considered standard-of-care treatment for a number of malignant and nonmalignant conditions. Treatment generally involves exposure to chemotherapy and occasionally radiation to encourage engraftment of donor stem cells and prevent donor and recipient rejection. The period of time immediately after transplant is associated with the risk for a number of serious acute complications, including profound immunosuppression and subsequent risk for infection, graft-versus-host disease (GVHD), and organ toxicities. Fortunately, significant progress has been made in supportive care strategies to reduce the risk of acute complications and treat them more effectively if they do arise. This has resulted in a growing number of pediatric patients who are now long-term survivors following HSCT. The estimated total number of HSCT survivors in 2009 was 108,900, and this is expected to increase 5 times by 2030 to 502,000. Of these survivors, approximately 14% (64,000) in 2030 will have received a transplant in childhood (<18 yr of age).

Exposure to chemotherapy, radiation, or both places patients at similar long-term risks as the pediatric cancer population; the high doses and types of chemotherapy and radiation often amplify the risk for issues such as ovarian failure/infertility and neurocognitive difficulties. Total body irradiation (TBI) has been shown to increase dramatically the risk for late complications after transplant. In addition, late effects may be additive if the patient received therapy before HSCT for their underlying malignancy. Moreover, the indication for transplant in pediatric patients is not always related to malignancy, but rather an underlying immunodeficiency, bone marrow failure syndrome, or metabolic disorder. These patients are potentially at risk for late effects related to this
underlying disease alone and require different types of monitoring.

Essentially, every organ system can be impacted by the long-term effects of therapy, and each must be considered when undergoing late effects surveillance (Table 165.1). As a result of growing evidence of the importance of lifelong care for HSCT survivors, multiple groups have published recent consensus guidelines to help in caring for this patient population. As the field of survivorship continues to expand, we recommend the following reference for real-time evidence-based recommendations from the Children's Oncology Group: http://survivorshipguidelines.org.

* Focused on those late effects that can develop or persist even after cessation of therapy.
† At given total dose, risks greater for single-fraction vs fractionated total body irradiation (TBI); single-fraction myeloablative TBI (>500 cGy) now rarely used.
‡ Effects listed are those more likely to be associated with doses used in HSCT survivors (e.g., those given for leukemia treatment, <25 Gy); late effects are more likely if TBI also given.
** Include etoposide, teniposide.
Endocrine Effects

Children given HSCT before puberty may develop growth impairment, precluding achievement of the genetic target for adult height. The decrease in growth velocity is similar for boys and girls and is more frequently observed in patients given TBI as part of the preparative regimen. Chronic GVHD and its treatment with corticosteroids may also contribute to growth impairment.

Growth impairment of patients given TBI is mainly a result of direct damage of cartilage plates and to the effect of TBI on the hypothalamic-pituitary axis, which leads to an inappropriately low production of growth hormone (GH). GH deficiency is susceptible to at least partial correction through administration of hormonal replacement therapy. Annual growth evaluation should be performed in all children after HSCT. Children showing a decreased growth velocity should be further investigated through evaluation of bone age and secretion of GH in response to pharmacologic stimulus.

The use of TBI during the preparative regimen involves the thyroid gland in the irradiation field and may result in hypothyroidism. Younger children are at greater risk of developing hypothyroidism. Chemotherapy-only preparative regimens have far fewer adverse effects on normal thyroid function. The site of injury by irradiation is at the level of the thyroid gland rather than at the pituitary or hypothalamus. Therapy with thyroxine is very effective for overt hypothyroidism. The cumulative incidence of hypothyroidism increases over time, underscoring the importance of annual thyroid function studies.

Gonadal hormones are essential for normal pubertal growth, as well as for development of secondary sexual characteristics. A significant proportion of patients receiving TBI-containing preparative regimens as well as high doses of alkylating agents show delayed development of secondary sexual characteristics, resulting from primary ovarian or testicular failure. Laboratory evaluation of these patients reveals elevated follicle-stimulating hormone and luteinizing hormone levels with depressed estradiol and testosterone serum levels. These patients benefit from careful follow-up with evaluation of annual sexual maturity
rating (Tanner) scores and endocrine function. Supplementation of gonadal hormones is useful for primary gonadal failure and is administered with GH to promote pubertal growth. Infertility during adulthood remains a common problem of these children, especially those undergoing traditional myeloablative conditioning for HSCT. The use of reduced-intensity regimens may result in sparing fertility in a large proportion of patients, although conditioning regimens vary and studies are limited.

**Bone health** of HSCT survivors can also be impacted by hormonal changes as well as lifestyle practices, such as inadequate exercise and/or dietary intake of vitamin D. Prior exposures, including corticosteroid use, can result in changes to bone density as well as predispose to the development of avascular necrosis. Dual-energy x-ray absorptiometry (DXA) scans are routinely incorporated into the care of those patients at risk for low bone mineral density.

**Cardiovascular Effects**

Survivors of childhood HSCT are at risk for the future development of cardiovascular complications. This population can be prone to developing metabolic syndrome (dyslipidemia, hypertension, diabetes mellitus, obesity), especially those with a history of TBI exposure and subsequent hormonal derangements. Prior exposures such as anthracycline chemotherapy and chest radiation further increase the risk for cardiomyopathy as well as atherosclerosis. As a result, routine anthropometric, imaging, and laboratory screening should be performed in survivors of childhood HSCT to assess and monitor their cardiovascular health.

**Secondary Malignancy**

The overall risk of developing a secondary form of cancer is significantly higher after HSCT than in the general population. Although few studies have specifically analyzed pediatric patients, available evidence indicates that the cumulative incidence of 2nd malignancies shows a slight, but continuous, tendency to increase over time. The development of myelodysplastic syndrome as well as secondary leukemias must be considered in survivors of HSCT. Several other types of secondary tumors have been identified in patients given HSCT. The most frequently diagnosed neoplasms are thyroid carcinoma, brain
tumors, and epithelial cancers. Young age, male gender, use of TBI during the preparative regimen, chronic GVHD, and an intrinsic genetic predisposition to develop cancer (Fanconi anemia) have been reported to be risk factors for development of secondary malignancies after HSCT. Routine physical exams, including yearly skin in exams in those that received TBI are important in the care of these patients.

**Graft-Versus-Host Disease**

In the posttransplant period, multiple studies have shown that quality of life is severely impacted by the presence of GVHD, which is an issue that is also unique to HSCT (see Chapter 163).

**Other Effects**

HSCT patients can also experience complications related to their pulmonary function, renal function, dental health, and gastrointestinal system, often related to prior exposures as well as their conditioning regimen. It is also important to note that long-term survivors must be monitored for psychological issues because of their prior and current underlying health conditions. They may need extra assistance with school and vocational attainment. These patients are also often at higher risk for depression and anxiety; yearly psychosocial assessments can identify survivors who need additional therapy or psychotropic medication. Parents may also have posttraumatic stress from the experience.

**Special Considerations**

Certain patient populations who undergo HSCT are at increased risk for late effects. Young children appear to be at a heightened risk for late complications related to TBI, especially those related to growth, thyroid function, and neurocognition. Patients with an **underlying genetic condition** must also be monitored more closely for specific consequences of therapy, such as specific secondary malignancies in the Fanconi anemia population caused by an underlying DNA repair defect and patients with sickle cell anemia and thalassemia who are predisposed to iron overload.

Allergy and the Immunologic Basis of Atopic Disease

Cezmi A. Akdis, Scott H. Sicherer

Allergic or atopic patients have an altered state of reactivity to common environmental and food antigens that do not cause clinical reactions in unaffected people. Patients with clinical allergy usually produce immunoglobulin E (IgE) antibodies to the antigens that trigger their illness. The term allergy represents the clinical expression of IgE-mediated allergic diseases that have a familial predisposition and that manifest as hyperresponsiveness in target organs such as the lung, skin, gastrointestinal (GI) tract, and nose. The significant increase in the prevalence of allergic diseases in the last few decades is attributed to changes in environmental factors such as exposure to tobacco smoke, air pollution, indoor and outdoor allergens, respiratory viruses, obesity, and perhaps a decline in certain infectious diseases (hygiene hypothesis).

Key Elements of Allergic Diseases

Allergens

Allergens are almost always proteins, but not all proteins are allergens. For a protein antigen to display allergenic activity, it must induce IgE production, which must lead to a type 1 hypersensitivity response on subsequent exposure to the same protein. Biochemical properties of the allergen; stimulating factors of the innate immune response around the allergen substances at the time of exposure; stability of the allergen in the tissues, digestive system, skin, or mucosa; and the dose and time of stay in lymphatic organs during the interaction with the immune system are factors that may cause an antigen to become an allergen. This is distinguished from general antigen responses, which induce a
state of immune responsiveness without associated IgE production.

Most allergens are proteins with molecular weight of 10-70 kDa. Molecules <10 kDa do not bridge adjacent IgE antibody molecules on the surfaces of mast cells or basophils. Most molecules >70 kDa do not pass through mucosal surfaces, a feature needed to reach antigen-presenting cells (APCs) for stimulation of the immune system. Allergens frequently contain proteases, which promote skin and mucosal epithelial barrier dysfunction and increase allergen penetration into host tissues. Low-molecular-weight moieties, such as drugs, can become allergens by reacting with serum proteins or cell membrane proteins to be recognized by the immune system. Carbohydrate structures can also be allergens and are most relevant with the increasing use of biologics in clinical practice; patients with cetuximab-induced anaphylaxis have IgE antibodies specific for galactose-α-1,3-galactose.

**T Cells**

Everyone is exposed to potential allergens. Atopic individuals respond to allergen exposure with rapid expansion of T-helper type 2 (Th2) cells that secrete cytokines, such as interleukin (IL)-4, IL-5, and IL-13, favoring IgE synthesis and eosinophilia. Allergen-specific IgE antibodies associated with atopic response are detectable by serum testing or positive immediate reactions to allergen extracts on skin-prick testing. The Th2 cytokines IL-4 and IL-13 play a key role in immunoglobulin isotype switching to IgE (Fig. 166.1). IL-5 and IL-9 are important in differentiation and development of eosinophils. The combination of IL-3, IL-4, and IL-9 contributes to mast cell activation. IL-9 is responsible for mucus production. Th2 cytokines are important effector molecules in the pathogenesis of asthma and allergic diseases; acute allergic reactions are characterized by infiltration of Th2 cells into affected tissues. In addition, IL-25, IL-33, and thymic stromal lymphopoietin (TSLP) secreted from epithelial cells on exposure to allergens and respiratory viruses contribute to Th2 response and eosinophilia.
A fraction of the immune response to allergen results in proliferation of T-helper type 1 (Th1) cells. Th1 cells are typically involved in the eradication of intracellular organisms, such as mycobacteria, because of the ability of Th1 cytokines to activate phagocytes and promote the production of opsonizing and complement-fixing antibodies. The Th1 component of allergen-specific immune response contributes to chronicity and the effector phase in allergic disease. Activation and apoptosis of epithelial cells induced by Th1 cell–secreted interferon-γ (IFN-γ), tumor necrosis factor (TNF)-α, and Fas ligand constitute an essential pathogenetic event for the formation of eczematous lesions in atopic dermatitis and bronchial epithelial cell shedding in asthma.

Chronic lesions of allergic reactions are characterized by infiltration of Th1 and Th17 cells. This is important because Th1 cytokines such as IFN-γ can potentiate the function of allergic inflammatory effector cells such as eosinophils.
and thereby contribute to disease severity. Th17 and Th22 cells link the immune response to tissue inflammation; IL-17A and IL-17F and IL-22 are their respective prototype cytokines. Although both T-helper cell subsets play roles in immune defense to extracellular bacteria, IL-17 augments inflammation, whereas IL-22 plays a tissue-protective role. Cytokines in the IL-17 family act on multiple cell types, including epithelial cells and APCs, to cause the release of chemokines, antimicrobial peptides, and proinflammatory cytokines to enhance inflammation and antimicrobial responses. In addition, Th9 cells produce IL-9, but not other typical Th1, Th2, and Th17 cytokines, and constitute a distinct population of effector T cells that promotes tissue inflammation. Fig. 166.2 depicts the complex cytokine cascades involving Th1, Th2, Th9, Th17, and Th22 cells.

**Fig. 166.2 Effector T-cell subsets.** Following antigen presentation by dendritic cells (DCs), naïve T cells differentiate into Th1, Th2, Th9, Th17, Th22, and follicular helper (TFH) effector subsets. Their differentiation requires cytokines and other cofactors that are released from DCs and also expressed in the micromilieu. T-cell activation in the presence of interleukin-4 (IL-4) enhances differentiation and clonal expansion of Th2 cells, perpetuating the allergic response. IFN-γ, Interferon-γ; TGF-β, transforming growth factor-β. (From Akdis M, Palomares O, van de Veen W, et al: TH17 and TH22 cells: a confusion of antimicrobial response with tissue inflammation versus protection, J Allergy Clin Immunol 129:1438–1449, 2012.)
**T-regulatory** (or regulatory T) **cells (Tregs)** are a subset of T cells thought to play a critical role in expression of allergic and autoimmune diseases. These cells have the ability to suppress effector T cells of Th1, Th2, Th9, Th17, and Th22 phenotypes (Fig. 166.3). Tregs express CD4^+^ CD25^+^ surface molecules and immunosuppressive cytokines such as IL-10 and transforming growth factor-β (TGF-β_1^). The forkhead box/winged-helix transcription factor gene **FOXP3** is expressed specifically by CD4^+^ CD25^+^ Tregs and programs their development and function. Adoptive transfer of Tregs inhibits the development of airway eosinophilia and protects against airway hyperreactivity in animal models of asthma. T-cell response to allergens in healthy individuals shows a wide range, from no detectable response to involvement of active peripheral tolerance mechanisms mediated by different subsets of Tregs. Individuals who are not allergic even though they are exposed to high doses of allergens, such as beekeepers and cat owners, show a detectable allergen-specific IgG4 response accompanied by IL-10–producing Tregs. It is thought that CD4^+^ CD25^+^ Tregs play an important role in mitigating the allergic immune response, and that the lack of such cells may predispose to the development of allergic diseases. Patients with mutations in the human **FOXP3** gene lack CD4^+^ CD25^+^ Tregs and develop severe immune dysregulation, with polyendocrinopathy, food allergy, and high serum IgE levels (XLAAD/IPEX disease) (see Chapter 152). In addition to Treg cells, IL-10–secreting and allergen-specific Breg cells increase during allergen-specific immunotherapy and may play a role in allergen tolerance.
Innate Lymphoid Cells

Immune responses in populations of lymphoid cells that lack rearranged T- and B-cell antigen receptors and surface markers for myeloid and lymphoid lineages, such as T, B, and natural killer (NK) cells, show similarities to Th1, Th2, and Th17/Th22 types of immune responses. These latter cells are defined as the innate lymphoid cells ILC1s, ILC2s, and ILC3s, respectively, based on their transcription factors and cytokine production patterns. ILC1s mainly produce IFN-γ; ILC2s produce IL-5, IL-9, and IL-13; and ILC3s produce IL-17 and IL-22 without any need of antigen/allergen exposure. Strong evidence indicates that ILCs play substantial roles in protection against infection and the pathogenesis...
of inflammatory diseases, such as asthma, allergic diseases, and autoimmune diseases. ILCs control the mucosal environment through close interaction with epithelial cells and other tissue cells, cytokine production, and induction of chemokines that recruit suitable cell populations to initiate and promote distinct types of immune response development and tissue inflammation. ILC2s are likely involved in the induction of asthma, allergic rhinitis, eosinophilic esophagitis, and atopic dermatitis through activation by epithelium-derived cytokines (e.g., IL-33, IL-25, TSLP) and interaction with other immune cells.

**Antigen-Presenting Cells**

Dendritic cells (DCs), Langerhans cells, monocytes, and macrophages have the ability to present allergens to T cells and thereby modulate allergic inflammation by controlling the type of T-cell development. APCs are a heterogeneous group of cells that share the property of antigen presentation in the context of the major histocompatibility complex (MHC) and are found primarily in lymphoid organs and the skin. DCs and Langerhans cells are unique in their ability to prime naïve T cells and are responsible for the primary immune response, or the sensitization phase of allergy. Monocytes and macrophages are thought to contribute to activating memory T-cell responses on reexposure to allergen, which characterizes the elicitation phase of allergy.

Peripheral DCs residing in sites such as the skin, intestinal lamina propria, and lung are relatively immature. These immature DCs take up antigens in tissues and then migrate to the T-cell areas in locally draining lymph nodes. The DCs undergo phenotypic and functional changes during migration, characterized by increased expression of MHC class I, MHC class II, and co-stimulatory molecules that react with CD28 expressed on T cells. In the lymph nodes, they directly present processed antigens to resting T cells to induce their proliferation and differentiation.

Mature DCs have been designated as myeloid or plasmacytoid on the basis of their ability to favor Th1 or Th2 differentiation, respectively. The critical factor for polarization to Th1 cells is the level of IL-12 produced by myeloid DC. By contrast, plasmacytoid DCs have low levels of IL-12. Plasmacytoid DC particularly play a role in antiviral immunity by rapid production of high amounts of IFN-α and also help B cells for antibody production. There is considerable interest in the role of TSLP, which is overexpressed in the mucosal surfaces and skin of atopic individuals. TSLP enhances Th2 differentiation by
inducing expression of OX40L on immature myeloid DCs in the absence of IL-12 production.

Presence of allergen-specific IgE on the cell surfaces of APCs is a unique feature of atopy. Importantly, the formation of high-affinity IgE receptor I (FceRI)/IgE/allergen complexes on APC surfaces greatly facilitates allergen uptake and presentation. The clinical importance of this phenomenon is supported by the observation that FceRI-positive Langerhans cells bearing IgE molecules are a prerequisite for skin-applied, aeroallergen provocation of eczematous lesions in patients with atopic dermatitis. The role of the low-affinity IgE receptor II (FceRII, CD23) on monocytes/macrophages is less clear, although under certain conditions it apparently can also facilitate antigen capture. Cross-linking of FceRII, as well as FceRI, on monocytes/macrophages leads to the release of inflammatory mediators. There is a critical role for DCs in induction of oral tolerance; tolerogenic DCs are compartmentalized within the mucosa and present antigen through a mechanism designed to produce a Th1/Treg-suppressive response that ablates allergen-specific T cells.

**Immunoglobulin E and Its Receptors**

The acute allergic response depends on IgE and its ability to bind selectively to the α chain of the high-affinity FcεRI or the low-affinity FcεRII (CD23). Cross-linking of receptor-bound IgE molecules by allergen initiates a complex intracellular signaling cascade, followed by the release of various mediators of allergic inflammation from mast cells and basophils. The FcεRI molecule is also found on the surface of antigen-presenting DCs (e.g., Langerhans cells), but differs from the structure found on mast cells/basophils in that the FcεRI molecule found on DCs lacks the β chain. CD23 is found on B cells, eosinophils, platelets, and DCs. Cross-linking and FcεRI aggregation on mast cells and basophils can also lead to anaphylaxis (see Chapter 174). Differential expression of tyrosine kinases responsible for positive and negative regulation of mast cell/basophil degranulation are thought to be responsible for this aberrant allergic response.

The induction of IgE synthesis requires 2 major signals. The 1st signal (signal 1) initiates IL-4 or IL-13 activation of germline transcription at the ε Ig locus, which dictates isotype specificity. The 2nd signal (signal 2) involves the engagement of CD40 on B cells by CD40 ligand expressed on T cells. This engagement results in activation of the recombination machinery, resulting in
DNA switch recombination. Interactions between several co-stimulatory molecule pairs (CD28 and B7; lymphocyte function–associated antigen-1 and intercellular adhesion molecule-1; CD2 and CD58) can further amplify signal 1 and signal 2 to enhance IgE synthesis. Factors that inhibit IgE synthesis include Th1-type cytokines (IL-12, IFN-α, IFN-γ), IL-10 from Tregs, Breg cells, as well as regulatory DCs and microbial DNA containing CpG (cytosine-phosphate-guanine) repeats.

**Eosinophils**

Allergic diseases are characterized by peripheral blood and tissue eosinophilia. Eosinophils participate in both innate and adaptive immune responses and, like mast cells, contain dense intracellular granules that are sources of inflammatory proteins (see Fig. 155.1). These granule proteins include major basic protein, eosinophil-derived neurotoxin, peroxidase, and cationic protein. Eosinophil granule proteins damage epithelial cells, induce airway hyperresponsiveness, and cause degranulation of basophils and mast cells. Major basic protein released from eosinophils can bind to an acidic moiety on the M2 muscarinic receptor and block its function, thereby leading to increased acetylcholine levels and the development of increased airway hyperreactivity. Eosinophils are also a rich source of prostaglandins and leukotrienes; in particular, cysteinyl leukotriene C4 contracts airway smooth muscle and increases vascular permeability. Other secretory products of eosinophils include cytokines (IL-4, IL-5, TNF-α), proteolytic enzymes, and reactive oxygen intermediates, all of which significantly enhance allergic tissue inflammation.

Several cytokines regulate the function of eosinophils in allergic disease. Eosinophils develop and mature in the bone marrow from myeloid precursor cells activated by IL-3, IL-5, and granulocyte-macrophage colony-stimulating factor (GM-CSF). Allergen exposure of allergic patients causes resident hematopoietic CD34 cells to express the IL-5 receptor. The IL-5 receptor activation induces eosinophil maturation, causing eosinophils to synthesize granule proteins, prolonging their survival, potentiating degranulation of eosinophils, and stimulating release of eosinophils from the bone marrow. GM-CSF also enhances proliferation, cell survival, cytokine production, and degranulation of eosinophils. Certain chemokines, such as RANTES (regulated on activation, normal T-cell expressed and secreted), macrophage inflammatory protein-1α (MIP-1α), and eotaxins, are important for recruiting eosinophils into
local allergic tissue inflammatory reactions. Eotaxins mobilize IL-5–dependent eosinophil colony–forming progenitor cells from the bone marrow. These progenitors are rapidly cleared from the blood and either return to the bone marrow or are recruited to inflamed tissue sites.

**Mast Cells**

Mast cells are derived from CD34 hematopoietic progenitor cells that arise in bone marrow. On entering the circulation, they travel to peripheral tissue, where they undergo tissue-specific maturation. Mast cell development and survival relies on interactions between the tyrosine kinase receptor c-kit expressed on the surface of mast cells and the fibroblast-derived c-kit ligand, the stem cell factor. Unlike mature basophils, mature mast cells do not typically circulate in the blood. They are instead widely distributed throughout connective tissues, where they often lie adjacent to blood vessels and beneath epithelial surfaces that are exposed to the external environment, such as the respiratory tract, gastrointestinal (GI) tract, and skin. So placed, mast cells are positioned anatomically to participate in allergic reactions. At least 2 subpopulations of human mast cells are recognized: mast cells with tryptase and mast cells with both tryptase and chymase. Mast cells with tryptase are the predominant type found in the lung and small intestinal mucosa, whereas mast cells with both tryptase and chymase are the predominant type found in skin, the GI submucosa, and blood vessels.

Mast cells contain, or produce on appropriate stimulation, a diverse array of mediators that have different effects on allergic inflammation and organ function. They include preformed granule-associated mediators (histamine, serine proteases, proteoglycans) and membrane-derived lipid, cytokine, and chemokine mediators arising from de novo synthesis and release. The most important mast cell–derived lipid mediators are the **cyclooxygenase** and **lipoxygenase** metabolites of arachidonic acid, which have potent inflammatory activities. The major cyclooxygenase product of mast cells is **prostaglandin D₂**, and the major lipoxygenase products are the sulfidopeptide **leukotrienes** (LTs): LTC₄ and its peptidolytic derivatives LTD₄ and LTE₄. Mast cells also can produce cytokines that promote Th2-type responses (IL-4, IL-13, GM-CSF) and inflammation (TNF-α, IL-6) and regulate tissue remodeling (TGF, vascular endothelial cell growth factor). Immunologic activation of mast cells and basophils typically begins with cross-linkage of IgE bound to the FcεRI with
multivalent allergen. Mast cell surface FcεRI is increased by IL-4 and IgE. Surface levels of FcεRI decrease in patients receiving treatment with anti-IgE antibody that lowers serum IgE, which is of potential therapeutic interest.

**Mechanisms of Allergic Tissue Inflammation**

IgE-mediated immune responses can be classified chronologically according to 3 reaction patterns. The **early-phase response** is the immediate response after allergen is introduced into target organs. This response is characterized by mast cell degranulation and release of preformed mediators, occurring within an immediate time frame of 1-30 min after allergen exposure and resolving within 1-3 hr. Acute reactions are associated with increased local vascular permeability, which leads to leakage of plasma proteins, tissue swelling, and increased blood flow, as well as itching, sneezing, wheezing, and acute abdominal cramps in the skin, nose, lung, and GI tract, respectively, depending on the targeted organ.

A 2nd, **late-phase response** can occur within hours of allergen exposure, reaching a maximum at 6-12 hr and resolving by 24 hr. Late-phase responses are characterized in the skin by edema, redness, and induration; in the nose by sustained nasal blockage; and in the lung by airway obstruction and persistent wheezing. In general, late-phase responses are associated with early infiltration of neutrophils and eosinophils, followed by basophils, monocytes, macrophages, and Th2-type cells. Recruitment of inflammatory cells from the circulation requires increased expression of adhesion molecules on their cell surfaces and expression of their ligand on endothelial cells, which are under the control of cytokines. Several hours after allergen exposure, TNF-α released by activated mast cells induces the vascular endothelial expression of cell adhesion molecules, and this change leads to transendothelial migration of various inflammatory cells. Preferential accumulation of eosinophils occurs through interactions between selective adhesion molecules on the eosinophil cell surface (e.g., α4β1 integrin or very late antigen-4); vascular cell adhesion molecule-1 surface expression can be enhanced by IL-4 and IL-13 on endothelial cells. ILC2s receive signals from the epithelial cells, such as IL-33, TSLP, and IL-25, and are activated and start to release their cytokines IL-5 and IL-13 to initiate a type 2 immune response.

**Chemokines** are chemotactic cytokines that play a central role in tissue-
directed migration of inflammatory cells. RANTES, MIP-1α, monocyte chemotactic protein (MCP)-3, and MCP-4 are chemoattractants for eosinophils and mononuclear cells, whereas eotaxins are relatively selective for eosinophils. These chemoattractants have been detected in epithelium, macrophages, lymphocytes, and eosinophils at sites of late-phase responses and allergic tissue inflammation. Blockade of these chemokines leads to significant reduction in tissue-directed migration of allergic effector cells.

In the 3rd reaction pattern, **chronic allergic disease**, tissue inflammation can persist for days to years. Several factors contribute to persistent tissue inflammation, including recurrent exposure to allergens and microbial agents. The repeated stimulation of allergic effector cells such as mast cells, basophils, eosinophils, and Th2 cells contributes to unresolved inflammatory conditions. Additionally, Th2-type cytokines (IL-3, IL-5, GM-CSF) secreted during allergic reactions can prolong survival of allergic effector cells by delaying apoptosis. Local differentiation of tissue-infiltrating eosinophil precursors induced by IL-5 results in self-generation of eosinophils, further sustaining damage of local tissue. Tissue remodeling leading to irreversible changes in target organs is also a feature of chronic allergic disease. In asthma, **remodeling** involves thickening of the airway walls and submucosal tissue, as well as smooth muscle hypertrophy and hyperplasia, which are associated with a decline in lung function. This is an unexpected role for eosinophils in airway remodeling as well as chronic inflammation. In atopic dermatitis, lichenification is an obvious manifestation of skin remodeling.

Generally, it is considered that a type 2 immune response underlines a majority of asthma cases, atopic dermatitis, chronic rhinosinusitis, and allergic rhinitis as a general characteristic of an immune/inflammatory response. Type 2 immune response involves Th2 cells, type 2 B cells, ILC2, IL-4 secreting NK T cells, basophils, eosinophils and mast cells and their major cytokines. From a complex network of cytokines, IL-4, IL-5, IL-9, and IL-13 are mainly secreted from the immune system cells, and IL-25, IL-31, IL-33, and TSLP from tissue cells, particularly epithelial cells. Many asthma-related antigens, such as protease allergens, fungal extracts, and viral infection, trigger IL-33, TSLP, and IL-25 production from epithelial cells and various immune cells and induce eosinophilic asthma–like airway inflammation through activation of lung ILC2s.

IL-31, on the other hand, plays a role in pruritus in atopic dermatitis. Th2 cytokines do not only maintain allergic inflammation but also influence tissue remodeling by activating resident cells in target organs; IL-4, IL-9, and IL-13
induce mucus hypersecretion and metaplasia of mucus cells; IL-4 and IL-13 stimulate fibroblast growth and synthesis of extracellular matrix proteins; and IL-5 and IL-9 increase subepithelial fibrosis. TGF-β produced by eosinophils and fibroblasts can also enhance subepithelial fibrosis. IL-11 expressed by eosinophils and epithelial cells contributes to subepithelial fibrosis, in addition to enhancing deposition of collagen and the accumulation of fibroblasts. The resulting tissue injury amplifies further epithelial injury through proinflammatory cytokine release, extracellular matrix deposition in target organs, and angiogenesis. Genetic predisposition to aberrant injury-repair responses may contribute to chronicity of illness. Once the allergic immune response is established, it can be self-perpetuating due to a general type 2 immune response and can lead to chronic disease in genetically predisposed individuals. The subsequent infiltration of Th1 cells and Th17 cells enhances the inflammatory potential of allergic effector cells and contributes to chronic tissue inflammatory responses through the release of proinflammatory cytokines and chemokines. In addition, an autoimmune response might be playing a causative role in allergic inflammation resulting from possible mechanisms through IgE autoantibodies, IgG autoantibodies, and Th1-cell and Th17-cell autoreactivity.

Genetic Basis of Atopy

Allergic diseases are complex genetic conditions susceptible to environmental triggers. Several major groups of genes are associated with allergic diseases: genes that regulate systemic expression of atopy (increased IgE synthesis, eosinophilia, mast cell responses) and that are usually expressed among various allergic diseases, genes that control barrier function in specific target organs (e.g., skin in atopic dermatitis, lung in asthma, GI tract in food allergy), and genes encoding pattern-recognition receptors of the innate immune system that engage microbial pathogens and influence adaptive immune responses. Once allergic responses have been initiated, a genetic predisposition to chronic allergic inflammation and aberrant injury-repair responses contribute to tissue remodeling and persistent disease.

Atopic diseases have a strong familial predisposition, with approximately 60% heritability found in twin studies of asthma and atopic dermatitis. The 5q23-35 region comprises several genes implicated in allergic disease pathogenesis, including genes coding for Th2 cytokines (IL-3, IL-4, IL-5, IL-9, IL-13, GM-CSF). Among these, IL4 is a well-studied potential candidate gene. A nucleotide
change at position 589 of the *IL4* promoter region is associated with the formation of a unique binding site for NF-AT (nuclear factor for activated T cells) transcription factor, increased IL-4 gene transcription, higher NF-AT binding affinity, and increased IgE production. Similarly, *IL13* coding region variants have been associated with asthma and atopic dermatitis. An association has been found between atopy and a gain-of-function polymorphism on chromosome 16, which codes for the α subunit of the IL-4R. This finding is consistent with the important role of IL-4, IL-13, and their receptors in the immunopathogenesis of allergic diseases.

Genome-wide searches have also linked atopy to chromosome region 11q13. The gene encoding the β subunit of FcεRI-β has been proposed to be the candidate gene in this region. The β subunit gene modifies the FcεRI activity on mast cells, and several genetic variants of FcεRI-β are associated with asthma and atopic dermatitis. Chromosome 6 contains genes coding for human leukocyte antigen class I and class II molecules, which regulate the specificity and intensity of the immune responses to specific allergens. IgE responses to specific allergens, such as ragweed antigen Amb a V and mite allergen *Der p I*, have been linked to specific MHC class II loci. TNF-α, a key cytokine that contributes to the influx of inflammatory cells, is also located on chromosome 6. TNF-α polymorphisms are associated with asthma. A recent genome-wide association study showed that genetic polymorphisms in the gene encoding IL-33, which is a major activator of ILC2s, and its receptor IL-1RL1 (ST2) are strongly linked to asthma development.

Barrier dysfunction has a key role in the pathogenesis of allergic diseases. Genetic linkage studies of atopic dermatitis have demonstrated the importance of chromosome 1q21, which contains a cluster of genes involved in epidermal differentiation. Filaggrin is a protein that is essential in the formation of the stratum corneum. Null mutations of the filaggrin gene are strongly associated with early onset and severe atopic dermatitis. Mutations in the gene encoding the serine protease inhibitor SPINK5 has been shown to cause Netherton disease, a single-gene disorder associated with erythroderma, food allergy, and high serum IgE levels. A common polymorphism in SPINK5 (in particular, Glu420Lys) increases the risk of developing atopic dermatitis and asthma. SPINK5 is expressed in the outer epidermis and is thought to be critical to neutralizing the proteolytic activity of *Staphylococcus aureus* and common allergens such as *Der p I*, which use these proteases to penetrate the skin to induce allergic responses. Barrier dysfunction is involved in other allergic diseases, such as asthma and
rhinosinusitis, but likely involves other barrier genes, such as those encoding gap junctions.

Candidate genes associated with asthma susceptibility have been identified by positional cloning: *GPRA* (G-protein coupled receptor for asthma susceptibility on chromosome 7p14), *ADAM-33* (a disintegrin and metalloproteinase 33 on chromosome 20p), and *DPP10* (dipeptidyl peptidase 10 on chromosome 2q14). The functions of these genes do not fit into classical pathways of atopy and therefore provide new insights into asthma pathogenesis. *GPRA* encodes a G-protein coupled receptor, with isoforms expressed in bronchial epithelial cells and smooth muscle in asthmatic persons, suggesting an important role for these tissues in asthma. *ADAM-33* is expressed in bronchial smooth muscle and has been linked to bronchial hyperresponsiveness. *DPP10* encodes a dipeptidyl dipeptidase that can remove the terminal 2 peptides from certain proinflammatory chemokines, a change that may modulate allergic inflammation.

**Pattern-recognition receptors** of the innate immune system, which are expressed by epithelial cells and DCs, are associated with disease susceptibility. These receptors recognize specific microbial components. Polymorphisms in CD14 (engages endotoxin), Toll-like receptor 2 (which engages *S. aureus*), and T-cell immunoglobulin domain and mucin domain (which engage hepatitis A virus) correlate with asthma and/or atopic dermatitis susceptibility. Dysregulation of these frontline immune defense systems would permit abnormal response to common environmental allergens.

Sicherer SH, Leung DY. Advances in allergic skin disease,

Allergy History

Obtaining a complete history from the allergic patient involves eliciting a description of all symptoms along with their timing and duration, exposure to common allergens, and responses to previous therapies. Because patients often suffer from more than one allergic disease, the presence or absence of other allergic diseases, including allergic rhinoconjunctivitis, asthma, food allergy, eosinophilic esophagitis, atopic dermatitis, and drug allergy, should be determined. A family history of allergic disease is common and is one of the most important factors predisposing a child to the development of allergies. The risk of allergic disease in a child approaches 50% when 1 parent is allergic and 66% when both parents are allergic, with maternal history of atopy having a greater effect than paternal history.

Several characteristic behaviors are often seen in allergic children. Because of nasal pruritus and rhinorrhea, children with allergic rhinitis often perform the allergic salute by rubbing their nose upward with the palm of their hand. This repeated maneuver may give rise to the nasal crease, a horizontal wrinkle over the bridge of the nose. Characteristic vigorous grinding of the eyes with the thumb and side of the fist is frequently observed in children with allergic conjunctivitis. The allergic cluck is produced when the tongue is placed against the roof of the mouth to form a seal and withdrawn rapidly in an effort to scratch the palate. The presence of other symptoms, such as fever, unilateral nasal obstruction, and purulent nasal discharge, suggests other diagnoses.

The timing of onset and the progression of symptoms are relevant. The onset of recurrent or persistent nasal symptoms coinciding with placement in a daycare center might suggest recurrent infection rather than allergy. When patients
present with a history of episodic acute symptoms, it is important to review the setting in which symptoms occur as well as the activities and exposures that immediately precede their onset. Symptoms associated with lawn mowing suggest allergy to grass pollen or fungi, whereas if symptoms occur in homes with pets, animal dander sensitivity is an obvious consideration. Reproducible reactions after ingestion of a specific food raise the possibility of food allergy. When symptoms wax and wane but evolve gradually and are more chronic in duration, a closer look at whether the timing and progression of symptoms correlate with exposure to a seasonal aeroallergen is warranted.

**Aeroallergens**, such as pollens and fungal spores, are prominent causes of allergic disease. The concentrations of these allergens in outdoor air fluctuate seasonally. Correlating symptoms with seasonal pollination patterns of geographically relevant plants and trees along with information provided by local pollen counts can aid in identifying the allergen. Throughout most of the United States, trees pollinate in the early spring, grasses pollinate in the late spring and early summer, and weeds pollinate in late summer through the fall. The presence of fungal spores in the atmosphere follows a seasonal pattern in the northern United States, with spore counts rising with the onset of warmer weather and peaking in late summer months, only to recede again with the first frost through the winter. In warmer regions of the southern United States, fungal spores and grass pollens may cause symptoms on a perennial basis.

Rather than experiencing seasonal symptoms, some patients suffer allergic symptoms year-round. In these patients, sensitization to perennial allergens usually found indoors, such as dust mites, animal dander, cockroaches, and fungi, warrants consideration. Species of certain fungi, such as *Aspergillus* and *Penicillium*, are found indoors, whereas *Alternaria* is found in both indoor and outdoor environments. Cockroach and rodent allergens are often problematic in inner-city environments. Patients sensitive to perennial allergens often also become sensitized to seasonal allergens and experience baseline symptoms year-round with worsening during the pollen seasons.

The age of the patient is an important consideration in identifying potential allergens. Infants and young children are first sensitized to allergens that are in their environment on a continuous basis, such as dust mites, animal dander, and fungi. Sensitization to seasonal allergens usually takes several seasons of exposure to develop and is thus unlikely to be a significant trigger of symptoms in infants and toddlers.

Food allergies are more common in infants and young children, resulting
primarily in cutaneous, gastrointestinal, and, less frequently, respiratory and cardiovascular symptoms. Symptoms of immediate or IgE-mediated hypersensitivity food reactions develop within minutes to 2 hr after ingestion of the offending food. Symptoms of non–IgE-mediated food allergies are often delayed or chronic (see Chapter 176).

Complete information from previous evaluations and prior treatments for allergic disease should be reviewed, including impact of changes in local environment (e.g., home vs school), response to medications, elimination diets, and duration and impact of allergen immunotherapy (if applicable). Improvement in symptoms with medications or avoidance strategies used to treat allergic disease provides additional evidence for an allergic process.

A thorough environmental survey should be performed, focusing on potential sources of allergen and/or irritant exposure, particularly when respiratory symptoms (upper/lower) are reported. The age and type of the dwelling, how it is heated and cooled, the use of humidifiers or air filtration units, and any history of water damage should be noted. Forced air heating may stir up dust mite, fungi, and animal allergens. The irritant effects of wood-burning stoves, fireplaces, and kerosene heaters may provoke respiratory symptoms. Increased humidity or water damage in the home is often associated with greater exposure to dust mites and fungi. Carpentry serves as a reservoir for dust mites, fungi, and animal dander. The number of domestic pets and their movements about the house should be ascertained. Special attention should be focused on the bedroom, where a child spends a significant proportion of time. The age and type of bedding, the use of dust mite covers on pillows and mattresses, the number of stuffed animals, type of window treatments, and the accessibility of pets to the room should be reviewed. The number of smokers in the home, and what and where they smoke is useful information. Activities that might result in exposure to allergens or respiratory irritants such as paint fumes, cleansers, sawdust, or glues should be identified. Similar information should be obtained in other environments where the child spends long periods, such as a relative's home or school setting.

**Physical Examination**

In patients with **asthma**, **spirometry** should be performed. If **respiratory distress** is observed, **pulse oximetry** should be performed.

The child presenting with a chief complaint of rhinitis or rhinoconjunctivitis
should be observed for mouth breathing, paroxysms of sneezing, sniffing/snorting, throat clearing, and rubbing of the nose and eyes (representing pruritus). Infants should be observed during feeding for nasal obstruction severe enough to interfere with feeding or for more obvious signs of aspiration or gastroesophageal reflux. The frequency and nature of coughing that occurs during the interview and any positional change in coughing or wheezing should be noted. Children with asthma should be observed for congested or wet cough, tachypnea at rest, retractions, and audible wheezes, which may worsen with crying. Patients with atopic dermatitis should be monitored for repetitive scratching and the extent of skin involvement.

Because children with severe asthma as well as those receiving chronic or frequent oral corticosteroids may experience growth suppression, an accurate height should be plotted at regular intervals. Long-term follow-up studies suggest that use of inhaled glucocorticoids in prepubertal children is associated with a small initial decrease in attained height (1 cm) that may persist as a reduction in adult height. Poor weight gain in a child with chronic chest symptoms should prompt consideration of cystic fibrosis. Anthropometric measures are also important to monitor in those on restricted diets because of multiple food allergies or eosinophilic esophagitis. Blood pressure should be measured to evaluate for steroid-induced hypertension. The patient with acute asthma may present with pulsus paradoxus, defined as a drop in systolic blood pressure during inspiration >10 mm Hg. Moderate to severe airway obstruction is indicated by a decrease of >20 mm Hg. An increased heart rate may be the result of an asthma flare or the use of a β-agonist or decongestant. Fever is not caused by allergy alone and should prompt consideration of an infectious process, which may exacerbate asthma.

Parents are often concerned about blue-gray to purple discolorations beneath their child's lower eyelids, which can be attributed to venous stasis and are referred to as allergic shiners (Fig. 167.1). They are found in up to 60% of allergic patients and almost 40% of patients without allergic disease. Thus, “shiners” may suggest, but are not diagnostic of, allergic disease. In contrast, the Dennie-Morgan folds (Dennie lines) are a feature of atopic dermatitis (Fig. 167.1). These are prominent infraorbital skin folds that extend in an arc from the inner canthus beneath and parallel to the lower lid margin.
In patients with **allergic conjunctivitis**, involvement of the eyes is typically bilateral. Examination of the conjunctiva reveals varying degrees of lacrimation, conjunctival injection, and edema. In severe cases, periorbital edema involving primarily the lower eyelids or **chemosis** (conjunctival edema that is gelatinous in appearance) may be observed. The classic discharge associated with allergic conjunctivitis is usually described as “stringy” or “ropy.” In children with vernal conjunctivitis, a more severe, chronic phenotype, examination of the tarsal conjunctiva may reveal cobblestoning. **Keratoconus**, or protrusion of the cornea, may occur in patients with vernal conjunctivitis or periorbital atopic dermatitis as a result of repeated trauma produced by persistent rubbing of the eyes. Children treated with high-dose or chronic corticosteroids are at risk for development of posterior subcapsular cataracts.

The external ear should be examined for eczematous changes in patients with atopic dermatitis, including the postauricular area and base of the earlobe. Because otitis media with effusion is common in children with allergic rhinitis, pneumatic otoscopy should be performed to evaluate for the presence of fluid in
the middle ear and to exclude infection.

Examination of the nose in allergic patients may reveal the presence of a nasal crease. Nasal patency should be assessed, and the nose examined for structural abnormalities affecting nasal airflow, such as septal deviation, turbinate hypertrophy, and nasal polyps. Decrease or absence of the sense of smell should raise concern about chronic sinusitis or nasal polyps. Nasal polyps in children should raise concerns of cystic fibrosis. The nasal mucosa in allergic rhinitis is classically described as pale to purple compared with the beefy-red mucosa of patients with nonallergic rhinitis. Allergic nasal secretions are typically thin and clear. Purulent secretions suggest another cause of rhinitis. The frontal and maxillary sinuses should be palpated to identify tenderness to pressure that might be associated with acute sinusitis.

Examination of the lips may reveal cheilitis caused by drying of the lips from continuous mouth breathing or repeated licking of the lips in an attempt to replenish moisture and relieve discomfort (lip licker's dermatitis). Tonsillar and adenoidal hypertrophy along with a history of impressive snoring raises the possibility of obstructive sleep apnea. The posterior pharynx should be examined for the presence of postnasal drip and posterior pharyngeal lymphoid hyperplasia (“cobblestoning”).

Chest findings in asthmatic children vary significantly and may depend on disease duration, severity, and activity. In a child with well-controlled asthma, the chest should appear entirely normal on examination between asthma exacerbations. Examination of the same child during an acute episode of asthma may reveal hyperinflation, tachypnea, use of accessory muscles (retractions), wheezing, and decreased air exchange with a prolonged expiratory time. Tachycardia may be caused by the asthma exacerbation or accompanied by jitteriness after treatment with β-agonists. Decreased airflow or rhonchi and wheezes over the right chest may be noted in children with mucus plugging and right middle lobe atelectasis. The presence of cyanosis indicates severe respiratory compromise. Unilateral wheezing after an episode of coughing and choking in a small child without a history of previous respiratory illness suggests foreign body aspiration. Wheezing limited to the larynx in association with inspiratory stridor may be seen in older children and adolescents with vocal cord dysfunction. Digital clubbing is rarely seen in patients with uncomplicated asthma and should prompt further evaluation to rule out other potential chronic diagnoses, such as cystic fibrosis.

The skin of the allergic patient should be examined for evidence of
urticaria/angioedema or atopic dermatitis. **Xerosis**, or dry skin, is the most common skin abnormality of allergic children. **Keratosis pilaris**, often found on facial cheeks and extensor surfaces of the upper arms and thighs, is a benign condition characterized by skin-colored or slightly pink papules caused by keratin plugs lodged in the openings of hair follicles. Examination of the skin of the palms and soles may reveal thickened skin and exaggerated palmar and plantar creases (**hyperlinearity**) in children with moderate to severe atopic dermatitis.

**Diagnostic Testing**

**In Vitro Tests**

Allergic diseases are often associated with increased numbers of eosinophils circulating in the peripheral blood and invading the tissues and secretions of target organs. **Eosinophilia**, defined as the presence of >500 eosinophils/µL in peripheral blood, is the most common hematologic abnormality of allergic patients. Seasonal increases in the number of circulating eosinophils may be observed in sensitized patients after exposure to allergens such as tree, grass, and weed pollens. The number of circulating eosinophils can be suppressed by certain infections and systemic corticosteroids. In certain pathologic conditions, such as drug reactions, eosinophilic pneumonias, and eosinophilic esophagitis, significantly increased numbers of eosinophils may be present in the target organ in the absence of peripheral blood eosinophilia. Increased numbers of eosinophils are observed in a wide variety of disorders in addition to allergy; eosinophil counts >1500 without an identifiable etiology should suggest 1 of the 2 hypereosinophilic syndromes (Table 167.1; see Chapter 155).

**Infectious**

Parasitic (with tissue-invasive helminths, e.g., trichinosis, strongyloidiasis, pneumocystosis, filariasis, cysticercosis, cutaneous and visceral larva migrans, echinococcosis)

Bacterial (brucellosis, tularemia, cat-scratch disease, *Chlamydia*)

Fungal (histoplasmosis, blastomycosis, coccidioidomycosis, allergic bronchopulmonary aspergillosis)

Mycobacterial (tuberculosis, leprosy)

Viral (HIV-1, HTLV-1, hepatitis A, hepatitis B, hepatitis C, Epstein-Barr virus)

**Pulmonary**

Allergic (rhinitis, asthma)

Eosinophilic granulomatosis with polyangiitis (Churg-Strauss syndrome)

Loeffler syndrome

Hypersensitivity pneumonitis

Eosinophilic pneumonia (chronic, acute)

Pulmonary interstitial eosinophilia

**Dermatologic**

Atopic dermatitis

Pemphigus

Dermatitis herpetiformis

Infantile eosinophilic pustular folliculitis

Eosinophilic fasciitis (Schulman syndrome)

Eosinophilic cellulitis (Wells syndrome)

Kimura disease (angiolympoid hyperplasia with eosinophilia)

**Hematologic/Oncologic**

Neoplasm (lung, gastrointestinal, uterine)

Leukemia/lymphoma
Myelofibrosis
Myeloproliferative (FIP1L1-PDGFRα–positive) hypereosinophilic syndrome
Lymphatic hypereosinophilic syndrome
Systemic mastocytosis

**Immunologic**

T-cell immunodeficiencies
Hyper-IgE (Job) syndrome
Wiskott-Aldrich syndrome
Graft-versus-host disease
Drug hypersensitivity
Postirradiation
Postsplenectomy

**Endocrine**

Addison disease
Hypopituitarism

**Cardiovascular**

Loeffler disease (fibroplastic endocarditis)
Congenital heart disease
Hypersensitivity vasculitis
Eosinophilic myocarditis

**Gastrointestinal**

Benign proctocolitis
Inflammatory bowel disease
Eosinophilic gastrointestinal diseases (EGID)

FIP1L1-PDGFRα, FIP1-like 1–platelet-derived growth factor receptor α.
Nasal and bronchial secretions may be examined for the presence of eosinophils. The presence of eosinophils in the sputum of asthmatic patients is classic. An increased number of eosinophils in a smear of nasal mucus with Hansel stain is a more sensitive indicator of nasal allergies than peripheral blood eosinophilia and can aid in distinguishing allergic rhinitis from other causes of rhinitis. An elevated IgE value is often found in the serum of allergic patients, because IgE is the primary antibody associated with immediate hypersensitivity reactions. IgE values are measured in international units (IU), with 1 IU equal to 2.4 ng of IgE. Maternal IgE (unlike IgG) does not cross the placenta. Serum IgE levels gradually rise over the first years of life to peak in the teen years and decrease steadily thereafter. Additional factors, such as genetic influences, race, gender, certain diseases, and exposure to cigarette smoke and allergens, also affect serum IgE levels. Total serum IgE levels may increase 2- to 4-fold during and immediately after the pollen season and then gradually decline until the next pollen season. Comparison of total IgE levels among patients with allergic diseases reveals that those with atopic dermatitis tend to have the highest levels, whereas patients with allergic asthma generally have higher levels than those with allergic rhinitis. Although average total IgE levels are higher in populations of allergic patients than in comparable populations without allergic disease, the overlap in levels is such that the diagnostic value of a total IgE level is poor. Approximately half of patients with allergic disease have total IgE levels in the normal range. However, measurement of total IgE is indicated when the diagnosis of allergic bronchopulmonary aspergillosis is suspected because total serum IgE concentration >1,000 ng/mL is a criterion for diagnosis of this disorder (see Chapter 264.1). Total serum IgE may also be elevated in several nonallergic diseases (Table 167.2; see Chapter 152).

**Table 167.2**

**Nonallergic Diseases Associated With Increased Serum IgE Concentrations**

**Parasitic Infestations**

Guillain-Barré syndrome  
Kawasaki disease  
Liver disease  
Medication related  
Nephritis, drug-induced interstitial  
Nephrotic syndrome  
Pemphigus, bullous  
Polyarteritis nodosa, infantile  
Primary pulmonary hemosiderosis  
Juvenile idiopathic arthritis

The presence of IgE specific for a particular allergen can be documented in vivo by skin testing or in vitro by the measurement of **allergen-specific IgE (sIgE)** levels in the serum (Table 167.3). The first test for documenting the presence of sIgE was called the radioallergosorbent test (RAST) because it used a radiolabeled anti-IgE antibody. The RAST has been replaced by an improved generation of automated enzymatic sIgE immunoassays. These assays use solid-phase supports to which allergens of an individual allergen extract are bound. A small amount of the patient's serum is incubated with the allergen-coated support. The allergen-coated support bound to the patient's sIgE is then incubated with enzyme-conjugated antihuman IgE. Incubation of this sIgE–antihuman IgE complex with a fluorescent substrate of the conjugated enzyme results in the generation of fluorescence that is proportional to the amount of sIgE in the serum sample. The amount of sIgE is calculated by interpolation from a standard calibration curve and reported in arbitrary mass units (kilo-IU of allergen-specific antibody per unit volume of sample, kU_A /L). Laboratory reports may specify classes, counts, or units, but quantification of results in kU_A /L is most useful. The 3 commercial detection systems approved by the U.S.
Food and Drug Administration have excellent performance characteristics, but the individual systems do not measure sIgE antibodies with comparable efficiencies and thus are not interchangeable. **Component testing** refers to diagnostic tests where sIgE is measured to specific proteins that comprise allergens (e.g., Ara h 2 from peanut, Bet v 1 from birch pollen), rather than to a mixture of the allergens extracted from the source. Testing sIgE to component allergens may add additional diagnostic value by differentiating immune responses that are directed toward clinically relevant allergenic proteins.

* Skin testing may be the prick test or intradermal (ID) injection.

**In Vivo Tests**

**Allergen skin testing** is the primary in vivo procedure for the diagnosis of allergic disease. Mast cells with sIgE antibodies attached to high-affinity receptors on their surface reside in the skin of allergic patients. The introduction of minute amounts of an allergen into the skin of the sensitized patient results in cross-linking of IgE antibodies on the mast cell surface, thereby triggering local mast cell activation. Once activated, these mast cells release a variety of preformed and newly generated mediators that act on surrounding tissues. **Histamine** is the mediator most responsible for the immediate wheal and flare reactions observed in skin testing. Examination of the site of a positive skin test result reveals a pruritic wheal surrounded by erythema. The time course of these reactions is rapid in onset, reaching a peak within 10-20 min and usually resolving over the next 30 min.
Skin testing is performed using the **prick/puncture technique**. With this technique, a small drop of allergen is applied to the skin surface, and a tiny amount is introduced into the epidermis by lightly pricking or puncturing the outer layer of skin through the drop of extract with a small needle or other device. When the **skin-prick test (SPT)** result is negative but the history suggestive, selective skin testing (for vaccines, venom, drugs, and aeroallergens) using the **intradermal technique** may be performed. This technique involves using a 26-gauge needle to inject 0.01-0.02 mL of an allergen extract diluted 1,000- to 10-fold into the dermis of the arm. Intradermal skin tests are not recommended for use with food allergens because of the risk of triggering anaphylaxis. Irritant rather than allergic reactions can occur with intradermal skin testing if higher concentrations of extracts are used. Although skin-prick testing is less sensitive than intradermal skin testing, positive SPT results tend to correlate better with clinical symptoms.

The number of skin tests performed should be individualized, with the allergens suggested by the history. A positive and negative control SPT, using histamine and saline, respectively, is performed with each set of skin tests. A negative control is necessary to assess for **dermatographism**, in which reactions are caused merely by applying pressure to overly sensitive skin. A positive control is necessary to establish the presence of a cutaneous response to histamine. Medications with antihistaminic properties, in addition to adrenergic agents such as ephedrine and epinephrine, suppress skin test responses and should be avoided for appropriate intervals (approximately 5 half-lives) before skin testing. Prolonged courses of systemic corticosteroids may suppress cutaneous reactivity by decreasing the number of tissue mast cells as well as their ability to release mediators.

Whether identified via serologic or skin testing, detection of sIgE denotes a sensitized state (i.e., atopy or a tendency toward development of allergic disease) but is not equivalent to a clinically relevant allergic diagnosis. *Many children with positive tests have no clinical symptoms on exposure to the allergen*. Increasingly strong test results (higher serum sIgE results or larger SPT wheal sizes) generally correlate with increasing likelihood of clinical reactivity (but not severity). Neither serologic testing nor skin testing for allergy is predictive of reaction severity or threshold of reactivity, and these tests will be negative when the allergy is not IgE mediated, such as in food protein–induced enterocolitis syndrome. The limitations of these test modalities underscore the need for a detailed medical history that can guide the selection and interpretation of test
results. Large panels of indiscriminately performed screening tests may provide misleading information and are not recommended.

Both serum sIgE tests and SPT are sensitive and have similar diagnostic properties. The benefits of the serologic immunoassays are that performance is not limited by presence of skin disease (i.e., active atopic dermatitis) or medication use (i.e., antihistamines). Advantages of skin testing are that they provide rapid results to the patient/family during the clinic visit, do not require venipuncture, and are less costly.

Under certain circumstances, **provocation testing** is performed to examine the association between allergen exposure and the development of symptoms. The bronchial provocation test most frequently performed clinically is the **methacholine challenge**, which causes potent bronchoconstriction of asthmatic but not of normal airways; it is performed to document the presence and degree of bronchial hyperreactivity in a patient with suspected asthma. After baseline spirometry values are obtained, increasing concentrations of nebulized methacholine are inhaled until a drop occurs in lung function, specifically a 20% decrease in FEV$_1$ (forced expiratory volume in 1st second of expiration), or the patient is able to tolerate the inhalation of a set concentration of methacholine, typically 25 mg/mL.

**Oral food challenges** are performed to determine whether a specific food causes symptoms or whether a suspected food can be added to the diet. Food challenges are performed when the history and results of skin tests and immunoassays for sIgE fail to clarify the diagnosis of an allergy. These challenges may be performed in an open single-blind, double-blind, or double-blind placebo-controlled manner and involve the ingestion of gradually increasing amounts of the suspected food at set intervals until the patient either experiences a reaction or tolerates a normal portion (i.e., 1 serving size) of the food openly. Although the double-blind placebo-controlled food challenge is currently the gold standard test for diagnosing food allergy, it is typically only performed in research studies due to the time and labor-intensive nature of this method. Because of the potential for significant allergic reactions, oral food challenges should be performed only in an appropriately equipped facility with personnel experienced in the performance of food challenges and the treatment of anaphylaxis, including cardiopulmonary resuscitation.

**Upper gastrointestinal endoscopy** is required to confirm the diagnosis of eosinophilic esophagitis. One or more biopsy specimens from the proximal and distal esophagus must show eosinophil-predominant inflammation. With few
exceptions, 15 eosinophils/hpf (high-power field) (peak value) is considered a minimum threshold for the diagnosis.

Bibliography

Allergic rhinitis (AR) is a common chronic disease affecting 20–30% of children. AR is an inflammatory disorder of the nasal mucosa marked by nasal congestion, rhinorrhea, and itching, often accompanied by sneezing and conjunctival inflammation. Its recognition as a major chronic respiratory disease of children derives from its high prevalence, detrimental effects on quality of life and school performance, and comorbidities. Children with AR often have related conjunctivitis, sinusitis, otitis media, serous otitis, hypertrophic tonsils and adenoids, and eczema. Childhood AR is associated with a 3-fold increase in risk for asthma at an older age. Over the past 50 yr an upsurge in AR has been observed throughout the world, with some symptom surveys reporting incidence rates approaching 40%. Heritability of allergic conditions attests to genetic factors, but the increase stems from changes in the environment, diet, and the microbiome. The symptoms may appear in infancy; with the diagnosis generally established by the time the child reaches age 6 yr. The prevalence peaks late in childhood.

Risk factors include family history of atopy and serum IgE higher than 100 IU/mL before age 6 yr. Early life exposures and/or their absence have a profound influence on the development of the allergic phenotype. The risk increases in children whose mothers smoke heavily, even before delivery and above all before the infants reach 1 yr, and those with heavy exposure to indoor allergens. A critical period exists early in infancy when the genetically susceptible child is at greatest risk of sensitization. Delivery by cesarean section is associated with AR and atopy in children with a parental history of asthma or allergies. This association may be explained by the lack of exposure to the maternal microbiota through fecal/vaginal flora during delivery.

Children between 2 and 3 yr old who have elevated anticockroach and
antimouse IgE are at increased risk of wheezing, AR, and atopic dermatitis. The occurrence of 3 or more episodes of rhinorrhea in the 1st yr of life is associated with AR at age 7 yr. Favorably, the exposure to dogs, cats, and endotoxin early in childhood protects against the development of atopy. Prolonged breastfeeding, not necessarily exclusive, is beneficial. There is also a decreased risk of asthma, AR, and atopic sensitization with early introduction to wheat, rye, oats, barley, fish, and eggs. However, reduced diversity of the intestinal microbiota during infancy is associated with increased risk of allergic disease at school age.

Etiology and Classification

Two factors necessary for expression of AR are sensitivity to an allergen and the presence of the allergen in the environment. AR classification as seasonal or perennial is giving way to the designations intermittent and persistent. The 2 sets of terms are based on different suppositions, but inhalant allergens are the main cause of all forms of AR irrespective of terminology. AR may also be categorized as mild-intermittent, moderate-severe intermittent, mild-persistent, and moderate-severe persistent (Fig. 168.1). The symptoms of intermittent AR occur on <4 days per week or for <4 consecutive weeks. In persistent AR, symptoms occur on >4 days per week and/or for >4 consecutive weeks. The symptoms are considered mild when they are not troublesome, the sleep is normal, there is no impairment in daily activities, and there is no incapacity at work or school. Severe symptoms result in sleep disturbance and impairment in daily activities and school performance.

**FIG. 168.1** ARIA classification of allergic rhinitis. Every box can be subclassified
Further into seasonal or perennial on the basis of timing of symptoms or when causative and allergen therapeutic factors are considered. For example, a UK patient with grass pollen allergy might have moderate-severe persistent seasonal rhinitis in June and July and may be suitable for specific allergen immunotherapy. ARIA, Global Allergic Rhinitis and its Impact on Asthma. (From Scadding GK, Durham SR, Mirakian R, et al: BASCI guidelines for the management of allergic and non-allergic rhinitis, Clin Exp Allergy 38:19–42, 2008.)

In temperate climates, airborne pollen responsible for exacerbation of intermittent AR appear in distinct phases: trees pollinate in the spring, grasses in the early summer, and weeds in the late summer. In temperate climates, mold spores persist outdoors only in the summer, but in warm climates they persist throughout the year. Symptoms of intermittent AR typically cease with the appearance of frost. Knowledge of the time of symptom occurrence, the regional patterns of pollination and mold sporulation, and the patient's allergen-specific IgE (sIgE) is necessary to recognize the cause of intermittent AR. Persistent AR is most often associated with the indoor allergens: house dust mites, animal danders, mice, and cockroaches. Cat and dog allergies are of major importance in the United States. The allergens from saliva and sebaceous secretions may remain airborne for a prolonged time. The ubiquitous major cat allergen, Fel d 1, may be carried on cat owners’ clothing into such “cat-free” settings as schools and hospitals.

Pathogenesis

The exposure of an atopic host to an allergen leads to the production of sIgE, which is strongly associated with eczema throughout childhood and with asthma and rhinitis after age 4 yr. The clinical reactions on reexposure to the allergen have been designated as early-phase and late-phase allergic responses. Bridging of the IgE molecules on the surface of mast cells by allergen initiates the early-phase allergic response, characterized by degranulation of mast cells and release of preformed and newly generated inflammatory mediators, including histamine, prostaglandin 2, and the cysteinyl leukotrienes. The late-phase allergic response appears 4-8 hr following allergen exposure. Inflammatory cells, including basophils, eosinophils, neutrophils, mast cells, and mononuclear cells, infiltrate the nasal mucosa. Eosinophils release proinflammatory mediators, including cysteinyl leukotrienes, cationic proteins, eosinophil peroxidase, and major basic protein, and serve as a source of interleukin-3 (IL-3), IL-5, granulocyte-macrophage colony-stimulating factor, and IL-13. Repeated intranasal introduction of allergens causes “priming”—a more brisk response even with a
lesser provocation. Over the course of an allergy season, a multifold increase in submucosal mast cells takes place. These cells, once thought to have a role exclusively in the early-phase allergic response, have an important function in sustaining chronic allergic disease.

**Clinical Manifestations**

Symptoms of AR may be ignored or mistakenly attributed to a respiratory infection. Older children blow their noses, but younger children tend to sniff and snort. Nasal itching brings on grimacing, twitching, and picking of the nose that may result in epistaxis. Children with AR often perform the **allergic salute**, an upward rubbing of the nose with an open palm or extended index finger. This maneuver relieves itching and briefly unblocks the nasal airway. It also gives rise to the **nasal crease**, a horizontal skin fold over the bridge of the nose. The diagnosis of AR is based on symptoms in the absence of an upper respiratory tract infection and structural abnormalities. Typical complaints include intermittent nasal congestion, itching, sneezing, clear rhinorrhea, and conjunctival irritation. Symptoms increase with greater exposure to the responsible allergen. The patients may lose their sense of smell and taste. Some experience headaches, wheezing, and coughing. Preschoolers with chronic wheezing and rhinitis experience more severe wheezing than children without rhinitis. Nasal congestion is often more severe at night, inducing mouth breathing and snoring, interfering with sleep, and rousing irritability.

Signs on physical examination include abnormalities of facial development, dental malocclusion, the **allergic gape** (continuous open-mouth breathing), chapped lips, **allergic shiners** (dark circles under the eyes; see Fig. 167.1), and the transverse nasal crease. Conjunctival edema, itching, tearing, and hyperemia are frequent findings. A nasal exam performed with a source of light and a speculum may reveal clear nasal secretions; edematous, boggy, and bluish mucus membranes with little or no erythema; and swollen turbinates that may block the nasal airway. It may be necessary to use a topical decongestant to perform an adequate examination. Thick, purulent nasal secretions indicate the presence of infection.

**Differential Diagnosis**
Evaluation of AR entails a thorough history, including details of the patient's environment and diet and a family history of allergic conditions (e.g., eczema, asthma, AR), physical examination, and laboratory evaluation. The history and laboratory findings provide clues to the provoking factors. Symptoms such as sneezing, rhinorrhea, nasal itching, and congestion and lab findings of elevated IgE, sIgE antibodies, and positive allergy skin test results typify AR. Intermittent AR differs from persistent AR by history and skin test results. Nonallergic rhinitides give rise to sporadic symptoms; their causes are often unknown. Nonallergic inflammatory rhinitis with eosinophils imitates AR in presentation and response to treatment, but without elevated IgE antibodies. Vasomotor rhinitis is characterized by excessive responsiveness of the nasal mucosa to physical stimuli. Other nonallergic conditions, such as infectious rhinitis, structural problems (e.g., nasal polyps, septal deviation), rhinitis medicamentosa (caused by overuse of topical vasoconstrictors), hormonal rhinitis associated with pregnancy or hypothyroidism, neoplasms, vasculitides, and granulomatous disorders may mimic AR (Table 168.1 and Fig. 168.2).

Occupational risks for rhinitis include exposure to allergens (grain dust, insects, latex, enzymes) and irritants (wood dust, paint, solvents, smoke, cold air).

NONALLERGIC RHINITIS WITH EOSINOPHILIA SYNDROME
PERENNIAL NONALLERGIC RHINITIS (VASOMOTOR RHINITIS)
EMOTIONAL FACTORS

From Skoner DP: Allergic rhinitis: definition, epidemiology, pathophysiology, detection, and diagnosis, J Allergy Clin Immunol 108(1 Suppl);108:S2–S8, 2001 (original source).

FIG. 168.2 Diagnostic algorithm for rhinitis. Nasal allergen challenge is a research procedure and is not undertaken routinely. CNS, Central nervous system; NSAID, nonsteroidal antiinflammatory drug. (From Greiner AN, Hellings PW, Rotiroti G, Scadding GK: Allergic rhinitis, Lancet 378:2112–2120, 2011.)
Complications

AR is associated with complications and comorbid conditions. Undertreated AR detracts from the quality of life, aggravates asthma, and enhances its progression. Children with AR experience frustration over their appearance. Allergic conjunctivitis, characterized by itching, redness, and swelling of the conjunctivae, has been reported in at least 20% of the population and >70% of patients with AR, most frequently in older children and young adults. The 2 conditions share pathophysiologic mechanisms and epidemiologic characteristics (see Chapter 172 ). Chronic sinusitis is a common complication of AR, sometimes associated with purulent infection, but most patients have negative bacterial cultures despite marked mucosal thickening, and sinus opacification. The inflammatory process is characterized by marked eosinophilia.

Allergens, possibly fungal, are the inciting agents. The sinusitis of triad asthma (asthma, sinusitis with nasal polyposis, and aspirin sensitivity) often responds poorly to therapy. Patients who undergo repeated endoscopic surgery derive diminishing benefit with each successive procedure.

Rhinitis that coexists with asthma may be taken too lightly or completely overlooked. Up to 78% of patients with asthma have AR, and 38% of patients with AR have asthma. Aggravation of AR coincides with exacerbation of asthma, and treatment of nasal inflammation reduces bronchospasm, asthma-related emergency department visits, and hospitalizations. Postnasal drip associated with AR commonly causes persistent or recurrent cough. Eustachian tube obstruction and middle ear effusion are frequent complications. Chronic allergic inflammation causes hypertrophy of adenoids and tonsils that may be associated with eustachian tube obstruction, serous effusion, otitis media, and obstructive sleep apnea. AR is linked to snoring in children. The association between rhinitis and sleep abnormalities and subsequent daytime fatigue is well documented and may require multidisciplinary intervention.

The Pediatric Rhinoconjunctivitis Quality of Life Questionnaire (PRQLQ) is suitable for children 6-12 yr old, and the Adolescent Rhinoconjunctivitis Quality of Life Questionnaire (ARQLQ) is appropriate for patients 12-17 yr. Children with rhinitis have anxiety and physical, social, and emotional issues that affect learning and the ability to integrate with peers. The disorder contributes to headaches and fatigue, limits daily activities, and interferes with sleep. There is
evidence of impaired cognitive functioning and learning that may be exacerbated by the adverse effects of sedating medications. AR causes an estimated 824,000 missed school days and 4,230,000 days of decline in quality-of-life activities. Patients with AR report an impairment in the activities of daily living similar to patients with moderate to severe asthma. Some (but not many) patients improve during their teenage years, only to develop symptoms again as young adults. Symptoms often abate in the 5th decade of life.

**Laboratory Findings**

Epicutaneous skin tests provide the best method for detection of sIgE, with a positive predictive value (PPV) of 48.7% for epidemiologic diagnosis of AR. Skin tests are inexpensive and sensitive, and the risks and discomfort are minimal. Responses to seasonal respiratory allergens are rare before 2 seasons of exposure, and children <1 yr old seldom display positive skin test responses to these allergens. To avoid false-negative results, montelukast should be withheld for 1 day, most sedating antihistamine preparations for 3-4 days, and nonsedating antihistamines for 5-7 days. Serum immunoassays for sIgE provide a suitable alternative (PPV of 43.5%) for patients with dermatographism or extensive dermatitis, those taking medications that interfere with mast cell degranulation, others at high risk for anaphylaxis, and some who cannot cooperate with the procedure. Presence of eosinophils in the nasal smear supports the diagnosis of AR, and neutrophils suggest infectious rhinitis. Eosinophilia and measurements of total serum IgE concentrations have relatively low sensitivity.

**Treatment**

Guideline-directed management has been shown to improve disease control. *Global Allergic Rhinitis and its Impact on Asthma (ARIA)* provides an evidence-based approach to treatment and includes quality-of-life measures useful for the evaluation of symptoms and the assessment of the response to therapy. Safe effective prevention and relief of symptoms are the current goals of treatment. Specific measures to limit indoor allergen exposure may reduce the risk of sensitization and symptoms of allergic respiratory disease. Sealing the patient's mattress, pillow, and covers in allergen-proof encasings reduces the
exposure to mite allergen. Bed linen and blankets should be washed every week in hot water (>54.4°C [130°F]). The only effective measure for avoiding animal allergens in the home is the removal of the pet. Avoidance of pollen and outdoor molds can be accomplished by staying in a controlled environment. Air conditioning allows for keeping windows and doors closed, reducing the pollen exposure. High-efficiency particulate air (HEPA) filters lower the counts of airborne mold spores.

Oral antihistamines help reduce sneezing, rhinorrhea, and ocular symptoms. Administered as needed, antihistamines provide acceptable treatment for mild-intermittent disease. Antihistamines have been classified as first generation (relatively sedating) or second generation (relatively nonsedating). Antihistamines usually are administered by mouth but are also available for topical ophthalmic and intranasal use. Both first- and second-generation antihistamines are available as nonprescription drugs. Second-generation antihistamines are preferred because they cause less sedation. Preparations containing pseudoephedrine, typically in combination with other agents, are used for relief of nasal and sinus congestion and pressure and other symptoms such as rhinorrhea, sneezing, lacrimation, itching eyes, oronasopharyngeal itching, and cough. Pseudoephedrine is available without prescription (generally in fixed combination with other agents such as first-generation antihistamines: brompheniramine, chlorpheniramine, tripolidine; second-generation antihistamines: desloratadine, fexofenadine, loratadine; antipyretics: acetaminophen, ibuprofen; antitussives: guaifenesin, dextromethorphan; anticholinergic: methscopolamine). Pseudoephedrine is an oral vasoconstrictor distrusted for causing irritability and insomnia and for its association with infant mortality. Because younger children (2-3 yr) are at increased risk of overdosage and toxicity, some manufacturers of oral nonprescription cough and cold preparations have voluntarily revised their product labeling to warn against the use of preparations containing pseudoephedrine for children <4 yr old. Pseudoephedrine is misused as a starting material for the synthesis of methamphetamine and methcathinone. Tables 168.2, 168.3, and 168.4 provide examples of prescription, nonprescription, and combined oral agents, respectively, for treatment of AR.

Table 168.4
Combined Antihistamine + Sympathomimetic (Examples)
The anticholinergic nasal spray ipratropium bromide is effective for the treatment of serous rhinorrhea (Table 168.5). Intranasal decongestants (oxymetazoline and phenylephrine) should be used for <5 days and should not to be repeated more than once a month to avoid rebound nasal congestion. Sodium cromoglycate (available as nonprescription drug) is effective but requires frequent administration, every 4 hr. Leukotriene-modifying agents have a modest effect on rhinorrhea and nasal blockage (see Chapter 169 for additional indications and side effects). Nasal saline irrigation is a good adjunctive option with all other treatments of AR. Patients with more persistent, severe symptoms require intranasal corticosteroids, the most effective therapy for AR, which may also be beneficial for concomitant allergic conjunctivitis (Table 168.6). These agents reduce the symptoms of AR with eosinophilic inflammation, but not those of rhinitis associated with neutrophils or free of inflammation. Beclomethasone, triamcinolone, and flunisolide are absorbed from the gastrointestinal tract, as well as from the respiratory tract; budesonide, fluticasone, mometasone, and ciclesonide offer greater topical activity with lower systemic exposure. More severely affected patients may benefit from simultaneous treatment with oral antihistamines and intranasal corticosteroids.

**Allergen-specific immunotherapy is a well-defined treatment for IgE-mediated allergic disease.** It may be administered by subcutaneous or sublingual routes. **Sublingual immunotherapy** (SLIT) has been used successfully in Europe and South America and is now approved by the U.S. Food and Drug Administration.
Allergy immunotherapy (AIT) is an effective treatment for AR and allergic conjunctivitis. In addition to reducing symptoms, it may change the course of allergic disease and induce allergen-specific immune tolerance. Immunotherapy should be considered for children in whom IgE-mediated allergic symptoms cannot be adequately controlled by avoidance and medication, especially in the presence of comorbid conditions. Immunotherapy for AR prevents the onset of asthma. Moreover, progress in molecular characterization of allergens raises the possibility of defined vaccines for allergen immunotherapy. Omalizumab (anti-IgE antibody) is effective for difficult-to-control asthma and is likely to have a beneficial effect on coexisting AR.

Typically, treatment of AR with oral antihistamines and nasal corticosteroids provides sufficient relief for most patients with coexisting allergic conjunctivitis. If it fails, additional therapies directed primarily at allergic conjunctivitis may be added (see Chapter 172). Intranasal corticosteroids are of some value for the treatment of ocular symptoms, but ophthalmic corticosteroids remain the most potent pharmacologic agents for ocular allergy, although they carry the risk of adverse effects such as delayed wound healing, secondary infection, elevated intraocular pressure, and formation of cataracts. Ophthalmic corticosteroids are only suited for the treatment of allergic conjunctivitis that does not respond to the medications previously discussed. Sound practice calls for the assistance of an ophthalmologist.

Prognosis

Therapy with nonsedating antihistamines and topical corticosteroids, when taken appropriately, improves health-related quality-of-life measures in patients with allergic rhinitis. The reported rates of remission among children are 10–23%. Pharmacotherapy that will target cells and cytokines involved in inflammation and treat allergy as a systemic process is on the horizon, and more selective targeting of drugs based on the development of specific biomarkers and genetic profiling may soon be realized.

**Asthma** is a chronic inflammatory condition of the lung airways resulting in episodic airflow obstruction. This chronic inflammation heightens the twitchiness of the airways—**airways hyperresponsiveness (AHR)**—to common provocative exposures. Asthma management is aimed at reducing airways inflammation by minimizing proinflammatory environmental exposures, using daily controller antiinflammatory medications, and controlling comorbid conditions that can worsen asthma. Less inflammation typically leads to better asthma control, with fewer exacerbations and decreased need for quick-reliever asthma medications. Nevertheless, exacerbations can still occur. Early intervention with systemic corticosteroids greatly reduces the severity of such episodes. Advances in asthma management and especially pharmacotherapy enable all but the uncommon child with difficult asthma to live normally.

**Etiology**

Although the cause of childhood asthma has not been determined, a combination of environmental exposures and inherent biologic and genetic susceptibilities has been implicated (Fig. 169.1). In the susceptible host, immune responses to common airways exposures (e.g., respiratory viruses, allergens, tobacco smoke, air pollutants) can stimulate prolonged, pathogenic inflammation and aberrant repair of injured airways tissues (Fig. 169.2). Lung dysfunction (AHR, reduced airflow) and airway remodeling develop. These pathogenic processes in the growing lung during early life adversely affect airways growth and differentiation, leading to altered airways at mature ages. Once asthma has developed, ongoing inflammatory exposures appear to worsen it, driving disease persistence and increasing the risk of severe exacerbations.
FIG. 169.1  Etiology and pathogenesis of asthma. A combination of environmental and genetic factors in early life shape how the immune system develops and responds to ubiquitous environmental exposures. Respiratory microbes, inhaled allergens, and pollutants that can inflame the lower airways target the disease process to the lungs. Aberrant immune and repair responses to airways injury underlie persistent disease. AHR, Airways hyperresponsiveness; ETS, environmental tobacco smoke.
Genetics

To date, more than 100 genetic loci have been linked to asthma, although
relatively few have consistently been linked to asthma in different study cohorts. Consistent loci include genetic variants that underlie susceptibility to common exposures such as respiratory viruses and air pollutants.

Environment

Recurrent wheezing episodes in early childhood are associated with common respiratory viruses, especially rhinoviruses, respiratory syncytial virus (RSV), influenza virus, adenovirus, parainfluenza virus, and human metapneumovirus. This association implies that host features affecting immunologic host defense, inflammation, and the extent of airways injury from ubiquitous viral pathogens underlie susceptibility to recurrent wheezing in early childhood. Other airways exposures can also exacerbate ongoing airways inflammation, increase disease severity, and drive asthma persistence. Home allergen exposures in sensitized individuals can initiate airways inflammation and hypersensitivity to other irritant exposures and are causally linked to disease severity, exacerbations, and persistence. Consequently, eliminating the offending allergen(s) can lead to resolution of asthma symptoms and can sometimes cure asthma. Environmental tobacco smoke and common air pollutants can aggravate airways inflammation and increase asthma severity. Cold, dry air, hyperventilation from physical play or exercise, and strong odors can trigger bronchoconstriction. Although many exposures that trigger and aggravate asthma are well recognized, the causal environmental features underlying the development of host susceptibilities to the various common airway exposures are not as well defined. Living in rural or farming communities may be a protective environmental factor.

Epidemiology

Asthma is a common chronic disease, causing considerable morbidity. In 2011, >10 million children (14% of U.S. children) had ever been diagnosed with asthma, with 70% of this group reporting current asthma. Male gender and living in poverty are demographic risk factors for having childhood asthma in the United States. About 15% of boys vs 13% of girls have had asthma; and 18% of all children living in poor families (income <$25,000/yr), vs 12% of children in families not classified as poor, have had asthma.

Childhood asthma is among the most common causes of childhood emergency department visits, hospitalizations, and missed school days. In the United States
in 2006, childhood asthma accounted for 593,000 emergency department (ED) visits, 155,000 hospitalizations, and 167 deaths. A disparity in asthma outcomes links high rates of asthma hospitalization and death with poverty, ethnic minorities, and urban living. In the past 2 decades, black children have had 2-7 times more ED visits, hospitalizations, and deaths as a result of asthma than nonblack children. Although current asthma prevalence is higher in black than in nonblack U.S. children (in 2011, 16.5% vs 8.1% for white and 9.8% for Latino children), prevalence differences cannot fully account for this disparity in asthma outcomes.

Worldwide, childhood asthma appears to be increasing in prevalence, despite considerable improvements in our management and pharmacopeia to treat asthma. Although childhood asthma may have plateaued in the United States after 2008, numerous studies conducted in other countries have reported an increase in asthma prevalence of approximately 50% per decade. Globally, childhood asthma prevalence varies widely in different locales. A study of childhood asthma prevalence in 233 centers in 97 countries (International Study of Asthma and Allergies in Childhood, Phase 3) found a wide range in the prevalence of current wheeze in 6-7 yr (2.4–37.6%) and 13-14 yr old children (0.8–32.6%). Asthma prevalence correlated well with reported allergic rhinoconjunctivitis and atopic eczema prevalence. Childhood asthma seems more prevalent in modern metropolitan locales and more affluent nations, and is strongly linked with other allergic conditions. In contrast, children living in rural areas of developing countries and farming communities with domestic animals are less likely to experience asthma and allergy.

Approximately 80% of all asthmatic patients report disease onset prior to 6 yr of age. However, of all young children who experience recurrent wheezing, only a minority go on to have persistent asthma in later childhood. Early childhood risk factors for persistent asthma have been identified (Table 169.1) and have been described as major (parent asthma, eczema, inhalant allergen sensitization) and minor (allergic rhinitis, wheezing apart from colds, ≥4% peripheral blood eosinophils, food allergen sensitization) risk factors. Allergy in young children with recurrent cough and/or wheeze is the strongest identifiable factor for the persistence of childhood asthma.

Environmental tobacco smoke exposure  
Reduced lung function at birth  
Formula feeding rather than breastfeeding  

* Major risk factors.

Types of Childhood Asthma

There are 2 common types of childhood asthma based on different natural courses: (1) **recurrent wheezing** in *early* childhood, primarily triggered by common respiratory viral infections, usually resolves during the preschool/lower school years; and (2) **chronic asthma** associated with *allergy* that persists into later childhood and often adulthood (*Table 169.2*). School-age children with mild-moderate persistent asthma generally improve as teenagers, with some (about 40%) developing intermittent disease. Milder disease is more likely to remit. Inhaled corticosteroid controller therapy for children with persistent asthma does not alter the likelihood of outgrowing asthma in later childhood; however, because children with asthma generally improve with age, their need for controller therapy subsequently lessens and often resolves. Reduced growth and progressive decline in lung function can be features of persistent, problematic disease.

*Table 169.2*
Asthma Patterns in Childhood, Based on Natural History and Asthma Management

**Transient Nonatopic Wheezing**

- Common in early preschool years
- Recurrent cough/wheeze, primarily triggered by common respiratory viral infections
- Usually resolves during the preschool and lower school years, without increased risk for asthma in later life
- Reduced airflow at birth, suggestive of relatively narrow airways; AHR near birth; improves by school age

**Persistent Atopy-Associated Asthma**

- Begins in early preschool years
- Associated with atopy in early preschool years:
  - Clinical (e.g., atopic dermatitis in infancy, allergic rhinitis, food allergy)
  - Biologic (e.g., early inhalant allergen sensitization, increased serum IgE, increased blood eosinophils)
  - Highest risk for persistence into later childhood and adulthood
- Lung function abnormalities:
  - Those with onset before 3 yr of age acquire reduced airflow by school age.
  - Those with later onset of symptoms, or with later onset of allergen sensitization, are less likely to experience airflow limitation in childhood.

**Asthma With Declining Lung Function**

- Children with asthma with progressive increase in airflow limitation
- Associated with hyperinflation in childhood, male gender

**Asthma Management Types**
Severity Classification*

- Intrinsic disease severity while not taking asthma medications

  **Intermittent**

  **Persistent:**
  - Mild
  - Moderate
  - Severe

Control Classification*

- Clinical assessment while asthma being managed and treated

  **Well controlled**

  **Not well controlled**

  **Very poorly controlled**

Management Patterns

- **Easy-to-control:** well controlled with low levels of daily controller therapy
- **Difficult-to-control:** well controlled with multiple and/or high levels of controller therapies
- **Exacerbators:** despite being well controlled, continue to have severe exacerbations
- **Refractory:** continue to have poorly controlled asthma despite multiple and high levels of controller therapies

AHR, Airways hyperresponsiveness.

Asthma is also classified by disease severity (e.g., intermittent or persistent [mild, moderate, or severe]) or control (e.g., well, not well, or very poorly controlled), especially for asthma management purposes. Because most children with asthma can be well controlled with conventional management guidelines, children with asthma can also be characterized according to treatment response and medication requirements as being (1) easy to control: well controlled with low levels of controller therapy; (2) difficult to control: not as well controlled with multiple and/or high levels of controller therapies; (3) exacerbators: despite being controlled, continue to have severe exacerbations; and (4) refractory asthma: continue to have poorly controlled asthma despite multiple and high levels of controller therapies (Table 169.2). Different airways pathologic processes, causing airways inflammation, AHR, and airways congestion and blockage, are believed to underlie these different types of asthma.

**Pathogenesis**

Airflow obstruction in asthma is the result of numerous pathologic processes. In the small airways, airflow is regulated by smooth muscle encircling the airway lumen; bronchoconstriction of these bronchiolar muscular bands restricts or blocks airflow. A cellular inflammatory infiltrate and exudates distinguished by eosinophils, but also including other inflammatory cell types (neutrophils, monocytes, lymphocytes, mast cells, basophils), can fill and obstruct the airways and induce epithelial damage and desquamation into the airways lumen. Helper T lymphocytes and other immune cells that produce proallergic, proinflammatory cytokines (interleukin [IL]-4, IL-5, IL-13), and chemokines (eotaxins) mediate this inflammatory process (see Fig. 169.2). Pathogenic immune responses and inflammation may also result from a breach in normal immune regulatory processes (e.g., regulatory T lymphocytes that produce IL-10 and transforming growth factor-β) that dampen effector immunity and inflammation when they are no longer needed. Hypersensitivity or susceptibility
to a variety of provocative exposures or triggers (Table 169.3) can lead to airways inflammation, AHR, edema, basement membrane thickening, subepithelial collagen deposition, smooth muscle and mucous gland hypertrophy, and mucus hypersecretion—all processes that contribute to airflow obstruction.

### Table 169.3

**Asthma Triggers**

**COMMON VIRAL INFECTIONS OF RESPIRATORY TRACT AEROALLERGENS IN SENSITIZED ASTHMATIC PATIENTS**

- Nitrogen dioxide
- Sulfur dioxide
- Particulate matter
- Wood- or coal-burning smoke
- Mycotoxins
- Endotoxin
- Dust
Clinical Manifestations and Diagnosis

Intermittent dry coughing and expiratory wheezing are the most common chronic symptoms of asthma. Older children and adults report associated shortness of breath and chest congestion and tightness; younger children are more likely to report intermittent, nonfocal chest pain. Respiratory symptoms can be worse at night, associated with sleep, especially during prolonged exacerbations triggered by respiratory infections or inhalant allergens. Daytime symptoms, often linked with physical activities (exercise-induced) or play, are reported with greatest frequency in children. Other asthma symptoms in children can be subtle and nonspecific, including self-imposed limitation of physical
activities, general fatigue (possibly resulting from sleep disturbance), and difficulty keeping up with peers in physical activities. Asking about previous experience with asthma medications (bronchodilators) may provide a history of symptomatic improvement with treatment that supports the diagnosis of asthma. Lack of improvement with bronchodilator and corticosteroid therapy is inconsistent with underlying asthma and should prompt more vigorous consideration of asthma-masquerading conditions.

Asthma symptoms can be triggered by numerous common events or exposures: physical exertion and hyperventilation (laughing), cold or dry air, and airways irritants (see Table 169.3). Exposures that induce airways inflammation, such as infections with common respiratory pathogens (rhinovirus, RSV, metapneumovirus, parainfluenza virus, influenza virus, adenovirus, Mycoplasma pneumoniae, Chlamydia pneumoniae), and inhaled allergens in sensitized children, also increase AHR to dry, cold air and irritant exposures. An environmental history is essential for optimal asthma management.

The presence of risk factors, such as a history of other allergic conditions (allergic rhinitis, allergic conjunctivitis, atopic dermatitis, food allergies), parental asthma, and/or symptoms apart from colds, supports the diagnosis of asthma. During routine clinic visits, children with asthma typically present without abnormal signs, emphasizing the importance of the medical history in diagnosing asthma. Some may exhibit a dry, persistent cough. The chest findings are often normal. Deeper breaths can sometimes elicit otherwise undetectable wheezing. In clinic, quick resolution (within 10 min) or convincing improvement in symptoms and signs of asthma with administration of an inhaled short-acting β-agonist (SABA; e.g., albuterol) is supportive of the diagnosis of asthma.

Asthma exacerbations can be classified by their severity based on symptoms, signs, and functional impairment (Table 169.4). Expiratory wheezing and a prolonged exhalation phase can usually be appreciated by auscultation. Decreased breath sounds in some of the lung fields, commonly the right lower posterior lung field, are consistent with regional hypoventilation caused by airways obstruction. Rhonchi and crackles (or rales) can sometimes be heard, resulting from excess mucus production and inflammatory exudate in the airways. The combination of segmental crackles and poor breath sounds can indicate lung segmental atelectasis that is difficult to distinguish from bronchial pneumonia and can complicate acute asthma management. In severe exacerbations the greater extent of airways obstruction causes labored breathing and respiratory distress, which manifests as inspiratory and expiratory wheezing,
increased prolongation of exhalation, poor air entry, suprasternal and intercostal retractions, nasal flaring, and accessory respiratory muscle use. In extremis, airflow may be so limited that wheezing cannot be heard (silent chest).

</table>
Hypercapnia (hypoventilation) develops more readily in young children than in adults and adolescents.

Notes:

† Normal breathing rates in awake children by age: <2 mo, <60 breaths/min; 2-12 mo, <50 breaths/min; 1-5 yr, <40 breaths/min; 6-8 yr, <30 breaths/min.

‡ Normal pulse rates in children by age: 2-12 mo, <160 beats/min; 1-2 yr, <120 beats/min; 2-8 yr, <110 beats/min.

§ Peak expiratory flow testing may not be needed in very severe attacks.

• The presence of several parameters, but not necessarily all, indicates the general classification of the exacerbation.

• Many of these parameters have not been systematically studied, especially as they correlate with each other; thus they serve only as general guides.

• The emotional impact of asthma symptoms on the patient and family is variable but must be recognized and addressed and can affect approaches to treatment and follow-up.

Differential Diagnosis

Many childhood respiratory conditions can present with symptoms and signs similar to those of asthma (Table 169.5). Besides asthma, other common causes of chronic, intermittent coughing include gastroesophageal reflux (GER) and rhinosinusitis. Both GER and chronic sinusitis can be challenging to diagnose in children. Often, GER is clinically silent in children, and children with chronic sinusitis do not report sinusitis-specific symptoms, such as localized sinus pressure and tenderness. In addition, both GER and rhinosinusitis are often comorbid with childhood asthma and, if not specifically treated, may make asthma difficult to manage.

Table 169.5

Differential Diagnosis of Childhood Asthma

Upper Respiratory Tract Conditions
Allergic rhinitis*
Chronic rhinitis*
Sinusitis*
Adenoidal or tonsillar hypertrophy
Nasal foreign body

**Middle Respiratory Tract Conditions**

Laryngotracheobronchomalacia*
Laryngotracheobronchitis (e.g., pertussis)*
Laryngeal web, cyst, or stenosis
Exercise-induced laryngeal obstruction
Vocal cord dysfunction*
Vocal cord paralysis
Tracheoesophageal fistula
Vascular ring, sling, or external mass compressing on the airway (e.g., tumor)
Endobronchial tumor
Foreign body aspiration*
Chronic bronchitis from environmental tobacco smoke exposure*
Repaired tracheoesophageal fistula
Toxic inhalations

**Lower Respiratory Tract Conditions**

Bronchopulmonary dysplasia (chronic lung disease of preterm infants)
Viral bronchiolitis*
Gastroesophageal reflux*
Causes of bronchiectasis:
  • Cystic fibrosis
  • Immunodeficiency
  • Allergic bronchopulmonary mycoses (e.g., aspergillosis)
  • Chronic aspiration
Primary ciliary dyskinesia, immotile cilia syndrome
Bronchiolitis obliterans
Interstitial lung diseases
Hypersensitivity pneumonitis
Eosinophilic granulomatosis with angiitis
Eosinophilic pneumonia
Pulmonary hemosiderosis
Tuberculosis
Pneumonia
Pulmonary edema (e.g., congestive heart failure)
Vasculitis
Sarcoidosis

Medications associated with chronic cough:
  • Acetylcholinesterase inhibitors
  • β-Adrenergic antagonists
  • Angiotensin-converting enzyme inhibitors

* More common asthma masqueraders.

In early life, chronic coughing and wheezing can indicate recurrent aspiration, **tracheobronchomalacia** (congenital anatomic abnormality of airways), foreign body aspiration, cystic fibrosis, or bronchopulmonary dysplasia.

In older children and adolescents, **vocal cord dysfunction (VCD)** can manifest as intermittent daytime wheezing. The vocal cords involuntarily close inappropriately during inspiration and sometimes exhalation, producing shortness of breath, coughing, throat tightness, and often audible laryngeal wheezing and/or stridor. In most cases of VCD, spirometric lung function testing reveals truncated and inconsistent inspiratory and expiratory flow-volume loops, a pattern that differs from the reproducible pattern of airflow limitation in asthma that improves with bronchodilators. VCD can coexist with asthma. Hypercarbia and severe hypoxia are uncommon in VCD. Flexible rhinolaryngoscopy in the patient with symptomatic VCD can reveal paradoxical vocal cord movements with anatomically normal vocal cords. Prior to the diagnosis, patients with VCD are often treated unsuccessfully with multiple different classes of asthma medications. This condition can be well managed with specialized speech therapy training in the relaxation and control of vocal cord movement. Furthermore, treatment of underlying causes of vocal cord irritability (e.g., high GER/aspiration, allergic rhinitis, rhinosinusitis, asthma)
can improve VCD. During acute VCD exacerbations, relaxation breathing techniques in conjunction with inhalation of heliox (a mixture of 70% helium and 30% oxygen) can relieve vocal cord spasm and VCD symptoms. In some locales, hypersensitivity pneumonitis (farming communities, homes of bird owners), pulmonary parasitic infestations (rural areas of developing countries), or tuberculosis may be common causes of chronic coughing and/or wheezing. Rare mimics of asthma in childhood are noted in Table 169.5. Chronic pulmonary diseases often produce clubbing, but clubbing is a very unusual finding in childhood asthma.

**Laboratory Findings**

Lung function tests can help to confirm the diagnosis of asthma and to determine disease severity.

**Pulmonary Function Testing**

*Forced expiratory airflow* measures are helpful in diagnosing and monitoring asthma and in assessing efficacy of therapy. Lung function testing is particularly helpful in children with asthma who are poor perceivers of airflow obstruction, or when physical signs of asthma do not occur until airflow obstruction is severe. Many asthma guidelines promote spirometric measures of airflow and lung volumes during forced expiratory maneuvers as standard for asthma assessment. *Spirometry* is a helpful objective measure of airflow limitation (Fig. 169.3). Spirometry is an essential assessment tool in children who are at risk for severe asthma exacerbations and those who have poor perception of asthma symptoms. Valid spirometric measures depend on a patient's ability to properly perform a full, forceful, and prolonged expiratory maneuver, usually feasible in children >6 yr old (with some younger exceptions).
In asthma, airways blockage results in reduced airflow with forced exhalation (see Fig. 169.3). Because asthmatic patients typically have hyperinflated lungs, forced expiratory volume in 1 sec (FEV₁) can be simply adjusted for full expiratory lung volume—the forced vital capacity (FVC)—with an FEV₁/FVC ratio. Generally, an FEV₁/FVC ratio <0.80 indicates airflow obstruction (Table 169.6). Normative values for FEV₁ have been determined for children by height, gender, and ethnicity. Abnormally low FEV₁ as a percentage of predicted norms is 1 of 6 criteria used to determine asthma severity and control in asthma management guidelines sponsored by the U.S. National Institutes of Health (NIH) and the Global Initiative for Asthma (GINA).

**Table 169.6**

Lung Function Abnormalities in Asthma and
Assessment of Airway Inflammation

**Spirometry** (in clinic) ‡†:

Airflow limitation:
- Low FEV₁ (relative to percentage of predicted norms)
- FEV₁/FVC ratio <0.80

**Bronchodilator response** (to inhaled β-agonist) assesses reversibility of airflow limitation.

*Reversibility* is determined by an increase in either FEV₁ >12% or predicted FEV₁ >10% after inhalation of a short-acting β-agonist (SABA)*

**Exercise challenge**:  
- Worsening in FEV₁ ≥15%*

**Daily peak expiratory flow (PEF)‡ or FEV₁ monitoring**: day-to-day and/or AM -to-PM variation ≥20%*

**Exhaled nitric oxide (FeNO)**
- A value of >20 ppb supports the clinical diagnosis of asthma in children
- FeNO can be used to predict response to ICS therapy:
  - <20 ppb: Unlikely to respond to ICS because eosinophilic inflammation unlikely
  - 20-35 ppb: Intermediate, may respond to ICS
  - >35 ppb: Likely to respond to ICS because eosinophilic inflammation is likely

FEV₁, forced expiratory volume in 1 sec; FVC, forced vital capacity; ICS, inhaled corticosteroid; ppb, parts per billion.

‡ PEF variability is insensitive, while being highly specific for asthma.

† Of note, >50% of children with mild to moderate asthma will have a normal FEV₁ and will not have a significant bronchodilator response.

* Main criteria consistent with asthma.
Such measures of airflow alone are not diagnostic of asthma, because numerous other conditions can cause airflow limitation. In addition, approximately 50% of children with mild-moderate persistent asthma will have normal spirometric values when well. **Bronchodilator response** to an inhaled β-agonist (e.g., albuterol) is greater in asthmatic patients than nonasthmatic persons; an improvement in FEV\textsubscript{1} ≥12% is consistent with asthma. **Bronchoprovocation challenges** can be helpful in diagnosing asthma and optimizing asthma management. Asthmatic airways are hyperresponsive and therefore more sensitive to inhaled methacholine, mannitol, and cold or dry air. The degree of AHR to these exposures correlates to some extent with asthma severity and airways inflammation. Although bronchoprovocation challenges are carefully dosed and monitored in an investigational setting, their use is rarely practical in general practice. **Exercise challenges** (aerobic exertion or “running” for 6-8 min) can help to identify children with exercise-induced bronchospasm. Although the airflow response of nonasthmatic persons to exercise is to increase functional lung volumes and improve FEV\textsubscript{1} slightly (5–10%), exercise often provokes airflow obstruction in persons with inadequately treated asthma. Accordingly, in asthmatic patients, FEV\textsubscript{1} typically decreases during or after exercise by >15% (see Table 169.6). The onset of exercise-induced bronchospasm usually begins within 5 min, reaching a peak at 15 min following vigorous exercise, and often spontaneously resolves within 30-60 min. Studies of exercise challenges in school-age children typically identify an additional 5–10% with exercise-induced bronchospasm and previously unrecognized asthma. There are 2 caveats regarding exercise challenges: (1) treadmill challenges in the clinic are not completely reliable and can miss exertional asthma that can be demonstrated on the playing field; and (2) exercise challenges can induce severe exacerbations in at-risk patients. Careful patient selection for exercise challenges and preparedness for severe asthma exacerbations are required.

**Peak expiratory flow (PEF)** monitoring devices provide simple and inexpensive home-use tools to measure airflow and can be helpful in a number of circumstances (Fig. 169.4). Similar to spirometry in clinics, poor perceivers of asthma may benefit by monitoring PEFs at home to assess their airflow as an indicator of asthma control or problems. PEF devices vary in the ability to detect airflow obstruction; they are less sensitive and reliable than spirometry to detect airflow obstruction, such that, in some patients, PEF values decline only when airflow obstruction is severe. Therefore, PEF monitoring should be started by measuring morning and evening PEFs (best of 3 attempts) for several weeks for
patients to practice the technique, to determine diurnal variation and a “personal best,” and to correlate PEF values with symptoms (and ideally spirometry). Diurnal variation in PEF >20% is consistent with asthma (see Fig. 169.4 and Table 169.6).

**Fig. 169.4** Example of the role of peak expiratory flow (PEF) monitoring in childhood asthma. A, PEFs performed and recorded twice daily, in the morning (AM) and evening (PM), over 1 mo in an asthmatic child. This child’s “personal best” PEF value is 220 L/min; therefore the green zone (>80–100% of best) is 175-220 L/min; the yellow zone (50–80%) is 110-175 L/min; and the red zone (<50%) is <110 L/min. Note that this child’s PM PEF values are almost always in the green zone, whereas his AM PEFs are often in the yellow or red zone. This pattern illustrates the typical diurnal AM-to-PM variation of inadequately controlled asthma. B, PEFs performed twice daily, in the morning (AM) and evening (PM), over 1 mo in an asthmatic child in whom an asthma exacerbation developed from a viral respiratory tract infection. Note that the child’s PEF values were initially in the green zone. A viral respiratory tract infection led to asthma worsening, with a decline in PEF to the yellow zone that continued to worsen until PEF values were in the red zone. At that point, a 4-day prednisone course was administered, followed by improvement in PEF back to the green zone.
Exhaled Nitric Oxide (FeNO)

Exhaled nitric oxide is a noninvasive measure of allergic airways inflammation used in clinical settings. Nitric oxide (NO) is a marker of allergic/eosinophilic inflammation that is easily and quickly measured in exhaled breath. Children as young as 5 yr can perform this test. FeNO can be used to distinguish asthma from other airways diseases that are mediated by nonallergic/noneosinophilic inflammation, such as GER, VCD, and cystic fibrosis. FeNO can substantiate the diagnosis of asthma, complement the assessment of asthma control, predict response to inhaled corticosteroid (ICS) therapy, assess adherence with ICS therapy, predict loss of control with ICS tapering, and predict future asthma exacerbations.

Radiology

The findings of chest radiographs (posteroanterior and lateral views) in children with asthma often appear to be normal, aside from subtle and nonspecific findings of hyperinflation (e.g., flattening of the diaphragms) and peribronchial thickening (Fig. 169.5). Chest radiographs can help identify abnormalities that are hallmarks of asthma mimics (aspiration pneumonitis, hyperlucent lung fields in bronchiolitis obliterans) and complications during asthma exacerbations (atelectasis, pneumomediastinum, pneumothorax). Some lung abnormalities can be better appreciated with high-resolution, thin-section chest CT scans. **Bronchiectasis**, which is sometimes difficult to appreciate on chest radiograph but is clearly seen on CT scan, implicates an asthma mimic such as cystic fibrosis, allergic bronchopulmonary mycoses (aspergillosis), ciliary dyskinesias, or immune deficiencies.
Other tests, such as allergy testing to assess sensitization to inhalant allergens, help with the management and prognosis of asthma. In a comprehensive U.S. study of 5-12 yr old asthmatic children, the **Childhood Asthma Management Program (CAMP)**, 88% of patients had inhalant allergen sensitization according to results of allergy skin-prick testing.

**Treatment**

The NIH-sponsored **National Asthma Education and Prevention Program's Expert Panel Report 3 (EPR3)**, *Guidelines for the Diagnosis and Management of Asthma 2007*, is available online.* Similar guidelines from GINA, *Global Strategy for Asthma Management and Prevention, 2016*, are also available (www.ginasthma.org). The key components to optimal asthma management are specified (Fig. 169.6). Management of asthma should have the following components: (1) assessment and monitoring of disease activity; (2) education to enhance patient and family knowledge and skills for self-management; (3) identification and management of precipitating factors and comorbid conditions that worsen asthma; and (4) appropriate selection of medications to address the patient’s needs. The long-term goal of asthma management is attainment of optimal asthma control.
Component 1: Regular Assessment and Monitoring

Regular assessment and monitoring are based on the concepts of asthma severity, asthma control, and responsiveness to therapy. **Asthma severity** is the intrinsic intensity of disease, and assessment is generally most accurate in patients not receiving controller therapy. Therefore, assessing asthma severity directs the initial level of therapy. The 2 general categories are **intermittent** asthma and **persistent** asthma, the latter being further subdivided into **mild**, **moderate**, and **severe**. In contrast, **asthma control** is dynamic and refers to the day-to-day variability of an asthmatic patient. In children receiving controller therapy,
assessment of asthma control is important in adjusting therapy and is categorized in 3 levels: well controlled, not well controlled, and very poorly controlled. **Responsiveness to therapy** is the ease or difficulty with which asthma control is attained by treatment.

Classification of asthma severity and control is based on the domains of **impairment** and **risk**. These domains do not necessarily correlate with each other and may respond differently to treatment. Childhood asthma is characterized by minimal day-to-day impairment, with the potential for frequent, severe exacerbations most often triggered by viral infections, whereas adults with asthma have greater impairment with less potential for risk. The NIH guidelines have distinct criteria for 3 childhood age groups—0-4 yr, 5-11 yr, and ≥12 yr—for the evaluation of both severity (Table 169.7) and control (Table 169.8). The level of asthma severity or control is based on the most severe impairment or risk category. In assessing asthma severity, **impairment** consists of an assessment of the patient's recent symptom frequency (daytime and nighttime, with subtle differences in numeric cutoffs between the 3 age-groups), SABA use for quick relief, ability to engage in normal or desired activities, and airflow compromise evaluated by spirometry in children ≥5 yr. **Risk** refers to the likelihood of developing severe asthma exacerbations. Of note, even in the absence of frequent symptoms, persistent asthma can be diagnosed and long-term controller therapy initiated. For children ≥5 yr, 2 exacerbations requiring oral corticosteroids in 1 yr, and for infants and preschool-aged children who have risk factors for asthma (see earlier) and 4 or more episodes of wheezing over the past year that lasted longer than 1 day and affected sleep, or 2 or more exacerbations in 6 mo requiring systemic corticosteroids, qualifies them as having persistent asthma.

| | In 2-6 wk, depending on severity, evaluate level of asthma control that is achieved. |
| | • Children 0-4 yr old: If no clear benefit is observed in 4-6 wk, stop treatment and consider alternative diagnoses or adjusting therapy accordingly. |
| | • Children 5-11 yr old: Adjust therapy accordingly. |

*Notes:*

† Normal FEV<sub>1</sub>/FVC: 8-19 yr, 85%; 20-39 yr, 80%.

• Level of severity is determined by both impairment and risk. Assess impairment domain by patient's/caregiver's recall of previous 2-4 wk. Symptom assessment for longer periods should reflect a global assessment, such as inquiring whether a patient's asthma is better or worse since
the last visit. Assign severity to the most severe category in which any feature occurs.

• At present, there are inadequate data to correspond frequencies of exacerbations with different levels of asthma severity. For treatment purposes, patients who had ≥2 exacerbations requiring oral systemic corticosteroids in the past 6 mo, or ≥4 wheezing episodes in the past year, and who have risk factors for persistent asthma, may be considered the same as patients who have persistent asthma, even in the absence of impairment levels consistent with persistent asthma.

FEV$_1$, Forced expiratory volume in 1 sec; FVC, forced vital capacity; CS, corticosteroid; ICS, inhaled corticosteroid; EIB, exercise-induced bronchospasm.

**RECOMMENDED ACTION FOR TREATMENT**

| Maintain current step. Regular follow-up every 1-6 mo to maintain control. Consider step down if well controlled for at least 3 mo. | Step up ‡ (1 step) and reevaluate in 2-6 wk. If no clear benefit in 4-6 wk, consider alternative diagnoses or adjusting therapy. For side effects, consider alternative options. | Consider short course of oral corticosteroids. Step up § (1-2 steps) and reevaluate in 2 wk. If no clear benefit in 4-6 wk, consider alternative diagnoses or adjusting therapy. For side effects, consider alternative options. |

* Notes:

† Validated questionnaires for the impairment domain (the questionnaires do not assess lung function or the risk domain) and definition of minimal important difference (MID) for each:

‡ ACQ values of 0.76-1.40 are indeterminate regarding well-controlled asthma.

§ Before step-up therapy: (a) review adherence to medications, inhaler technique, and environmental control; (b) if alternative treatment option was used in a step, discontinue it and use preferred treatment for that step.

• The stepwise approach is meant to assist, not replace, the clinical decision making required to meet individual patient needs.

• The level of control is based on the most severe impairment or risk category. Assess impairment domain by caregiver's recall of previous 2-4 wk. Symptom assessment for longer periods should reflect a global assessment, such as inquiring whether the patient's asthma is better or worse since the last visit.

• At present, there are inadequate data to correspond frequencies of exacerbations with different levels of asthma control. In general, more frequent and intense exacerbations (e.g., requiring urgent, unscheduled care, hospitalization, or intensive care unit admission) indicate poorer disease control. For treatment purposes, patients who had ≥2 exacerbations requiring oral systemic corticosteroids in the past year may be considered the same as patients who have not-well-controlled asthma, even in the absence of impairment levels consistent with not-well-controlled asthma.

• ATAQ, Asthma Therapy Assessment Questionnaire; MID = 1.0.

• ACQ, Asthma Control Questionnaire; MID = 0.5.

• ACT, Asthma Control Test; MID not determined.

FEV₁, Forced expiratory volume in 1 sec; FVC, forced vital capacity; EIB, exercise-induced
Asthma management can be optimized through regular clinic visits every 2-6 wk until good asthma control is achieved. For children on controller medication therapy, management is tailored to the child's level of control. The NIH guidelines provide tables for evaluating asthma control for the 3 age-groups (see Table 169.8). In evaluation of asthma control, as in severity assessment, impairment includes an assessment of the patient's symptom frequency (daytime and nighttime), SABA use for quick relief, ability to engage in normal or desired activities, and for older children, airflow measurements. Validated asthma control questionnaires such as the Asthma Control Test (ACT, for adults and children ≥12 yr) and the Childhood ACT (C-ACT, for children 4-11 yr) can also be used to assess level of control. An ACT score of ≥20 indicates a child with well-controlled asthma, a value of 16-19 indicates not well-controlled asthma, and ≤15 indicates very poorly controlled asthma. For the C-ACT, a score ≥20 indicates well controlled, 13-19 indicates not well controlled; and ≤12 indicates very poorly controlled.

Assessment of risk, in addition to considering severity and frequency of exacerbations requiring systemic corticosteroids, includes tracking the lung growth of older children, in an attempt to identify those with reduced and/or progressive loss of lung function, and monitoring adverse effects of medications. The degree of impairment and presence of risk are used to determine the patient's level of asthma control as well controlled, not well controlled, or very poorly controlled. Children with well-controlled asthma have daytime symptoms ≤2 days/wk and need a rescue bronchodilator ≤2 days/wk; an FEV₁ of >80% of predicted (and FEV₁/FVC ratio >80% for children 5-11 yr); no interference with normal activity; and <2 exacerbations in the past year and an ACT score of ≥20. The impairment criteria vary slightly depending on age-group. Children whose status does not meet all the criteria of well-controlled asthma are determined to have either not well-controlled or very poorly controlled asthma, which is determined by the single criterion with the poorest rating.

Two to four asthma checkups per year are recommended for reassessing and maintaining good asthma control. Lung function testing (spirometry) is recommended at least annually and more often if asthma is poorly perceived, is inadequately controlled, and/or lung function is abnormally low. PEF monitoring
at home can be helpful in the assessment of asthmatic children with poor symptom perception, moderate to severe asthma, or a history of severe asthma exacerbations. PEF monitoring is feasible in children as young as 4 yr who are able to master this skill. Use of a stoplight zone system tailored to each child's “personal best” PEF values can optimize effectiveness and interest (see Fig. 169.4): The green zone (80–100% of personal best) indicates good control; the yellow zone (50–80%) indicates less-than-optimal control and necessitates increased awareness and treatment; and the red zone (<50%) indicates poor control and greater likelihood of an exacerbation, requiring immediate intervention. In actuality, these ranges are approximate and may need to be adjusted for many asthmatic children by raising the ranges that indicate inadequate control (e.g., yellow zone, 70–90% in children with poor perception and those with lung hyperinflation). Once-daily PEF monitoring is preferable in the morning when peak flows are typically lower. Adherence to PEF monitoring is difficult, results may be variable and PEF monitoring alone is not more effective than symptoms monitoring on influencing asthma outcomes. Therefore, although PEF may be helpful in some circumstances to monitor those who are poor perceivers of airway obstruction, PEF monitoring is no longer generally recommended.

Component 2: Patient Education

Specific educational elements in the clinical care of children with asthma are believed to make an important difference in home management and in adherence of families to an optimal plan of care, eventually impacting patient outcomes (Table 169.9). Every visit presents an important opportunity to educate the child and family, allowing them to become knowledgeable partners in asthma management, because optimal management depends on their daily assessments and implementation of any management plan. Effective communications take into account sociocultural and ethnic factors of children and their families, provide an open forum for concerns about asthma and its treatment to be raised and addressed, and include patients and families as active participants in the development of treatment goals and selection of medications. Self-management skills should be reevaluated regularly (e.g., inhaler medication technique).

Table 169.9

Key Elements of Productive Clinic Visits for
**Asthma**

Standardize assessment of asthma control (e.g., Asthma Control Test, exacerbations in past 12 mo)

Specify goals of asthma management

Explain basic facts about asthma:
- Contrast normal vs asthmatic airways.
- Link airways inflammation, “twitchiness,” and bronchoconstriction.
- Long-term-control and quick-relief medications
- Address concerns about potential adverse effects of asthma pharmacotherapy.

Teach, demonstrate, and have patient show proper technique for:
- Inhaled medication use (spacer use with metered-dose inhaler)

Investigate and manage factors that contribute to asthma severity:
- Environmental exposures
- Comorbid conditions

Create written 2-part Asthma Action Plan (see Fig. 169.7):
- Daily management
- Action plan for asthma exacerbations

Regular follow-up visits:
- Twice yearly (more often if asthma not well controlled)
- Monitor lung function at least annually

During initial patient visits, a basic understanding of the pathogenesis of asthma (chronic inflammation and AHR underlying a clinically intermittent presentation) can help children with asthma and their parents understand the importance of recommendations aimed at reducing airways inflammation to achieve and maintain good asthma control. It is helpful to specify the expectations of good asthma control resulting from optimal asthma management (see *Fig. 169.6*). Addressing concerns about potential adverse effects of asthma pharmacotherapeutic agents, especially their risks relative to their benefits, is essential in achieving long-term adherence with asthma pharmacotherapy and environmental control measures.

*All children with asthma should benefit from a written Asthma Action Plan (Fig. 169.7).* This plan has two main components: (1) a daily “routine”
management plan describing regular asthma medication use and other measures to keep asthma under good control; and (2) an action plan to manage worsening asthma, describing indicators of impending exacerbations, identifying what medications to take, and specifying when and how to contact the regular physician and/or obtain urgent/emergency medical care.
Asthma Action Plan

For: ____________________________  Doctor: ____________________________  Date: ____________________________

Doctor's Phone Number: ____________________________  Hospital/Emergency Department Phone Number: ____________________________

Doing Well

- No cough, wheezes, chest tightness, or shortness of breath during the day or night.
- Can do usual activities.
- And, if a peak flow meter is used,
  Peak Flow: ___________
  (60 percent or more of my best peak flow)
  My best peak flow is ___________

Take these long-term control medicines each day (include an anti-inflammatory)!

<table>
<thead>
<tr>
<th>Medicine</th>
<th>How much to take</th>
<th>When to take it</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

Below exercise:
- 2 or 4 puffs every 25 minutes for up to 1 hour prior to activity.
- Or, as needed.

Asthma Is Getting Worse

- Cough, wheezes, chest tightness or shortness of breath, or
- Making it hard to get air.

- On:
  Peak Flow: ___________
  (50 to 79 percent of my best peak flow)

Add: quick-relief medicine—and keep taking your GREEN ZONE medicine.

<table>
<thead>
<tr>
<th></th>
<th>short-acting, every 4 to 6 hours</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>2 or 4 puffs per treatment</td>
</tr>
</tbody>
</table>

If your symptoms (and peak flow, if used) return to GREEN ZONE after 1 hour of above treatment:

- Continue, monitoring to be sure you stay in the green zone.

- On:
  Peak Flow: ___________
  (50 to 79 percent of my best peak flow)

If your symptoms (and peak flow, if used) do not return to GREEN ZONE after 1 hour of above treatment:

- Take:
  Peak Flow: ___________
  (20 percent or less of my best peak flow)

- Add:
  short-acting, every 4 to 6 hours
  mg per day
  For 1 to 10 days

- Call the doctor: 5 to 00

Medical Alert!

- Very short of breath,
- Cough relieved medication has not helped, or
- Cannot do usual activities, or
- Symptoms are same or get worse after 24 hours in Yellow Zone

- On:
  Peak Flow: ___________
  (20 percent or less of my best peak flow)

Add:
- short-acting, every 4 to 6 hours
- mg per day

Then call your doctor NOW: Go to the hospital or call an ambulance:
- You are still in the red zone after 15 minutes AND
- You have not reached your doctor.

DANGER SIGNS
- Trouble talking to each other or shortness of breath
- Lips or fingertips are blue
- Take 2 or 4 puffs of your quick-relief medicine AND
- Go to the hospital or call for an ambulance

See the reverse side for things you can do to avoid your asthma triggers.

How To Control Things That Make Your Asthma Worse

This guide tells you things you can do to avoid your asthma triggers. For a check list of the triggers that you know make your asthma worse and ask your doctor to help you find out if you have other triggers as well. Then decide with your doctor what steps you will take.

1. Allergens
   - Animal Dander
   - Some people are allergic to the flakes of skin or dander that comes from animals with fur or feathers.
   - The best thing to do:
     - Avoid furry or feathered pets in your home.
     - If you can't keep the pet outdoors, then:
       - Keep the pet out of your bedroom and other sleeping areas at all times, and
       - Keep the door closed.
     - Remove carpets and furniture covered with cloth from your home. If that is not possible, keep the pet away from fabric-covered furniture and carpets.

   - Dual Nines
   - When people with asthma are allergic to dual nines, dust mites are tiny bugs that are found in every home—in mattresses, pillows, carpets, upholstered furniture, bedcovers, clothes, bedding, toys, and fabric or other cloth-covered items.

   - Things that can help:
     - Encourage your mattress in a spine proof cover or the place each week in hot water. Water must be 130°F or hot water.
     - Cool or warm water used with detergent and bleach can also be effective.
     - Wash the sheets and blankets on your bed each week in hot water.
     - Use hypoallergenic detergent to help wash the dust mites out of your dust mite.
     - Use a dehumidifier to help keep indoor humidity below 50 percent (likely between 30–50 percent).
     - Dehumidifiers or central air conditioners can also help.
     - Try to keep the air in your dust mite-free area as cool as possible.
     - If you can't do this, keep the air in your dust mite-free area from having dust mites and cloth dust mites in your home. If you can, keep your dust mite-free area free of dust mites and cloth dust mites. If you can't do this, keep the air in your dust mite-free area clean and dry.

   - Cockroaches
   - When people with asthma are allergic to the all dust mites and remains of cockroaches.

   - Things to do:
     - Keep food and fluids in a sealed containers. Neat, store food out.
     - Use double-bed sheets, pillows, and quilts for example, beds, beds.
     - You can also use traps.
     - If a pet is used to eat food, stay out of the room until the odor goes away.

2. Indoor Molds
   - Make sure your home is decluttered, carpeted, or other sources of heat that may not have mold.
   - Keep the indoor humidity below 50 percent (likely between 30–50 percent).
   - Make sure that the air in your dust mite-free area is clean and dry.

3. Pollen and Outdoor Air
   - What to do during your allergy season (when pollen or mold spores count are high):
     - Stay indoors; stay outside in the morning or afternoon and
     - When you go outside, keep your windows closed.
     - Stay indoors; stay outside in the morning or afternoon and
     - When you go outside, keep your windows closed.

4. Tobacco Smoke
   - If you smoke, ask your doctor to help you quit. Ask family members to quit, too.
   - Do not allow smoking in your home or car.

5. Smokes, Scenters, and Scents
   - If possible, do not use a wood-burning stove, aerosol air freshener, or smoke. Ask others to stop smoking near you.

6. Other things that bring on asthma symptoms in some people:

   - Vacuum Cleaning
     - Try to keep your home clean by the following:
     - Use a vacuum cleaner at least twice a week to remove dust mites and dust mites in your home. If you can, use a vacuum cleaner at least twice a week to remove dust mites and dust mites in your home.

   - Other Things That Can Make Asthma Worse
     - Don't smoke or be around smoke. If you're a smoker, quit and stay away from secondhand smoke. If you're a non-smoker, stay away from smoke.
     - Other things to do:
       - Keep your house clean, dry, and mold-free. Avoid mold, dust mites, and other allergens that can make your asthma worse.

NIH Publication No. 13-4821
April 2013
Regular follow-up visits are recommended to help to maintain optimal asthma control. In addition to determining disease control level, revising PEF values daily and exacerbation management plans accordingly, follow-up visits are important teaching opportunities to encourage open communication of concerns with asthma management recommendations (e.g., daily administration of controller medications). Reassessing patients’ and parents’ understanding of the role of different medications in asthma management and control, and their technique in using inhaled medications, can be insightful and can help guide teaching to improve adherence to a management plan that might not have been adequately or properly implemented.

**Adherence**

Asthma is a chronic condition that is usually best managed with daily controller medication. However, symptoms wax and wane, severe exacerbations are infrequent, and when asthma is asymptomatic, a natural tendency is to reduce or discontinue daily controller therapies. As such, adherence to a daily controller regimen is frequently suboptimal; ICSs are underused 60% of the time. In one study, children with asthma who required an oral corticosteroid course for an asthma exacerbation had used their daily controller ICS 15% of the time. Misconceptions about controller medication time to onset, efficacy, and safety often underlie poor adherence and can be addressed by asking about such concerns at each visit.

**Component 3: Control of Factors Contributing to Asthma Severity**

Controllable factors that can worsen asthma can be generally grouped as (1) environmental exposures and (2) comorbid conditions (Table 169.10).

<table>
<thead>
<tr>
<th>Control of Factors Contributing to Asthma</th>
</tr>
</thead>
</table>

**FIG. 169.7** Asthma action plan for home use. This plan has two main components: (1) a daily management plan to keep asthma in good control; and (2) an action plan to recognize and manage worsening asthma. (From US Department of Health and Human Services, National Institutes of Health, National Heart, Lung, and Blood Institute, NIH Pub No 07-5251, April 2007. https://www.nhlbi.nih.gov/health/resources/lung/asthma-action-plan).
Severity

Eliminate or Reduce Problematic Environmental Exposures

- Environmental tobacco smoke elimination or reduction in home and automobiles
- Allergen exposure elimination or reduction in sensitized asthmatic patients:
  - Animal danders: pets (cats, dogs, rodents, birds)
  - Pests (mice, rats)
  - Dust mites
  - Cockroaches
  - Molds
- Other airway irritants:
  - Wood- or coal-burning smoke
  - Strong chemical odors and perfumes (e.g., household cleaners)
  - Dusts

Treat Comorbid Conditions

- Rhinitis
- Sinusitis
- Gastroesophageal reflux

Eliminating and Reducing Problematic Environmental Exposures

Most children with asthma have an **allergic component** to their disease; steps should be taken to investigate and minimize allergen exposures in sensitized asthmatic patients. The medical history should identify exposure to smoke, pollutant, and potential allergen triggers (see later), especially in the patient's home. Since often patients have chronic symptoms and cannot identify potential triggers, **allergy testing** should be considered for at least those with persistent asthma. For asthmatic patients who are allergic to allergens in their homes and/or schools or daycare centers, reducing or eliminating these indoor allergen exposures can reduce asthma symptoms, medication requirements, AHR, severe exacerbations, and disease persistence. Common home, school, and daycare
allergen exposures include furred or feathered animals as pets (cats, dogs, rodents, birds) or as pests (mice, rats, cockroaches), and occult indoor allergens such as dust mites and molds. Although removing or eradicating these exposures from the home, school, and daycare setting of sensitized asthmatic patients is the most effective means of greatly reducing problematic allergen exposures, it can take ≥6 mo for the levels of these indoor allergens to drop significantly. Dust mite allergen exposure can be reduced by (1) encasing bedding and pillows in allergen-impermeable covers; (2) washing bedding weekly in hot water (>130°F); (3) removing wall-to-wall carpeting and upholstered furniture; and (4) reducing and maintaining indoor humidity <50%.

Tobacco, wood and coal smoke, dusts, strong odors, and noxious air pollutants (e.g., nitrogen dioxide from inadequately vented gas stoves and furnaces) can aggravate asthma. These airway irritants should be eliminated from or reduced in the homes, schools/daycare centers, and automobiles/school transportation used by children with asthma. Annual influenza vaccination continues to be recommended for all children with asthma to reduce the risk of severe complications, although influenza is not responsible for the large majority of virus-induced asthma exacerbations experienced by children.

**Treating Comorbid Conditions**

Rhinitis, sinusitis, and GER often accompany asthma and worsen disease severity. They can also mimic asthma symptoms and lead to misclassification of asthma severity and control. Indeed, these conditions, along with asthma are the most common causes of chronic cough. Effective management of these comorbid conditions may improve asthma symptoms and disease severity, such that less asthma medication is needed to achieve good asthma control.

**Gastroesophageal reflux** is common in children with persistent asthma (see Chapter 349). GER may worsen asthma through 2 postulated mechanisms: (1) aspiration of refluxed gastric contents (micro- or macro-aspiration); and (2) vagally mediated reflex bronchospasm. Occult GER should be suspected in individuals with difficult-to-control asthma, especially patients who have prominent nocturnal asthma symptoms or who prop themselves up in bed to reduce nocturnal symptoms. GER can be demonstrated by reflux of barium into the esophagus during a barium swallow procedure or by esophageal probe monitoring. Because radiographic studies lack sufficient sensitivity and specificity, extended esophageal monitoring is the method of choice for diagnosing GER. If significant GER is noted, reflux precautions should be
instituted (no food 2 hr before bedtime, head of bed elevated 6 inches, avoidance of caffeinated beverages), and medications such as proton pump inhibitors (omeprazole, lansoprazole) or H₂-receptor antagonists (cimetidine, ranitidine) administered for 8-12 wk. Of note, proton pump inhibition did not improve asthma control in a study of children with persistent, poorly controlled asthma and GER.

**Rhinitis** is usually comorbid with asthma, detected in about 90% of children with asthma. Rhinitis can be seasonal and/or perennial, with allergic and nonallergic components. Rhinitis complicates and worsens asthma via numerous direct and indirect mechanisms. Nasal breathing may improve asthma and reduce exercise-induced bronchospasm by humidifying and warming inspired air and filtering out allergens and irritants that can trigger asthma and worsen airway inflammation. Reduction of nasal congestion and obstruction can help the nose to perform these humidifying, warming, and filtering functions. In asthmatic patients, improvement in rhinitis is also associated with modest reductions in AHR, airways inflammation, asthma symptoms, and asthma medication use. Optimal rhinitis management in children is similar to asthma management in regard to the importance of interventions to reduce nasal inflammation (see Chapter 168).

Radiographic evidence for **sinus disease** is common in patients with asthma. There is usually significant improvement in asthma control in patients diagnosed and treated for sinus disease. A coronal, “screening” or “limited” CT scan of the sinuses is the gold standard test for sinus disease and can be helpful if recurrent sinusitis has been suspected and repeatedly treated without such evidence. In comparison, sinus radiographs are inaccurate and should be avoided. If the patient with asthma has clinical and radiographic evidence for sinusitis, topical therapy to include nasal saline irrigations, intranasal corticosteroids, and a 2-3 wk course of antibiotics should be considered.

**Component 4: Principles of Asthma Pharmacotherapy**

The current version of NIH asthma guidelines (2007) provides treatment recommendations that vary by level of asthma severity and age-groups (Table 169.11). There are 6 treatment steps. Patients at **Treatment Step 1** have intermittent asthma. Children with mild persistent asthma are at **Treatment Step 2**. Children with moderate persistent asthma can be at **Treatment Step 3 or 4**.
Children with severe persistent asthma are at Treatment Steps 5 and 6. The goals of therapy are to achieve a well-controlled state by reducing the components of both impairment (e.g., preventing or minimizing symptoms, infrequently needing quick-reliever medications, maintaining “normal” lung function and normal activity levels) and risk (e.g., preventing recurrent exacerbations, reduced lung growth, and medication adverse effects). The recommendations for initial therapy are based on assessment of asthma severity, while level of control determines any modifications of treatment in children who are already using controller therapy. A major objective of this approach is to identify and treat all “persistent” and inadequately controlled asthma with antiinflammatory controller medication. Management of Treatment Step 1 (intermittent asthma) is simply the use of a SABA as needed for symptoms and for pretreatment in those with exercise-induced bronchospasm (see Table 169.11).

Each step: Patient education, environmental control, and management of comorbidities.
Age ≥5 yr: Steps 2-4: Consider subcutaneous allergen immunotherapy for patients who have allergic asthma.

**QUICK-RELIEF MEDICATION FOR ALL PATIENTS**

SABA as needed for symptoms. Intensity of treatment depends on severity of symptoms: up to 3 treatments as needed. Short course of oral systemic corticosteroids may be needed.

**Caution:** Use of SABA >2 days/wk for symptom relief (not prevention of exercise-induced bronchospasm) indicates inadequate control and the need to step up treatment.

For ages 0-4 yr: With viral respiratory infection: SABA q4-6h up to 24 hr (longer with physician consultation) or short course of systemic corticosteroids if exacerbation is severe or patient has history of previous severe exacerbations.

**Notes:**

† Alphabetical order is used when more than 1 treatment option is listed within either preferred or alternative therapy.

- The stepwise approach is meant to assist, not replace, the clinical decision making required to meet individual patient needs.
- If alternative treatment is used and response is inadequate, discontinue it and use the preferred treatment before stepping up.
- If clear benefit is not observed within 4-6 wk and patient/family medication technique and adherence are satisfactory, consider adjusting therapy or alternative diagnosis.
- Studies on children age 0-4 yr are limited.
- Clinicians who administer immunotherapy or omalizumab should be prepared and equipped to identify and treat anaphylaxis that may occur.
• Theophylline is a less desirable alternative because of the need to monitor serum concentration levels. The 2016 GINA guidelines do not recommend the use of theophylline as a controller medication and in IV forms to treat status asthmaticus due to its severe adverse effects profile.

• Zileuton is less desirable alternative because of limited studies as adjunctive therapy and the need to monitor liver function.

ICS, Inhaled corticosteroid; LABA, inhaled long-acting $\beta_2$ -agonist; LTRA, leukotriene receptor antagonist; OCS, oral corticosteroid; prn, as needed; SABA, inhaled short-acting $\beta_2$ -agonist.

The preferred treatment for all patients with persistent asthma is ICS therapy, as monotherapy or in combination with adjunctive therapy. The type(s) and amount(s) of daily controller medications to be used are determined by the asthma severity and control rating.

Low-dose ICS therapy is the treatment of choice for all children at Treatment Step 2 (mild persistent asthma). Alternative medications include a leukotriene-modifying agent (montelukast), nonsteroidal antiinflammatory drugs (cromolyn, nedocromil), and theophylline. There are 4 co-equal choices for the treatment of school-aged children at Treatment Step 3 (moderate persistent asthma): medium-dose ICS, combination low-dose ICS and inhaled long-acting $\beta_2$ -agonist (LABA), a leukotriene receptor antagonist (LTRA), or theophylline. In a study of children with uncontrolled asthma receiving low-dose ICS, the addition of LABA provided greater improvement than either adding an LTRA or increasing ICS dosage. However, some children had a good response to medium-dose ICS or the addition of an LTRA, justifying them as step-up controller therapy options. The preferred therapy for children at Treatment Step 4 (also moderate persistent asthma) is medium-dose ICS/LABA combination. Alternatives include medium-dose ICS with either theophylline or an LTRA. For young children (≤4 yr) at Treatment Step 3, medium-dose ICS is recommended, while medium-dose ICS plus either an LABA or an LTRA are recommended for preschool-age children at Treatment Step 4.

Children with severe persistent asthma (Treatment Steps 5 and 6) should receive combination high-dose ICS plus LABA. Long-term administration of oral corticosteroids as controller therapy is effective but is rarely required. In addition, omalizumab can be used in children ≥6 yr old with severe allergic asthma, while mepolizumab is approved for children ≥12 yr with severe asthma eosinophilic asthma. A rescue course of systemic corticosteroids may be necessary at any step for very poorly controlled asthma. For children age ≥5 yr
with allergic asthma requiring Treatment Steps 2-4 care, allergen immunotherapy can also be considered.

**“Step-Up, Step-Down” Approach**

The NIH guidelines emphasize initiating higher-level controller therapy at the outset to establish prompt control, with measures to “step-down” therapy once good asthma control is achieved. Initially, airflow limitation and the pathology of asthma may limit the delivery and efficacy of ICS such that stepping up to higher doses and/or combination therapy may be needed to gain asthma control. Furthermore, ICS requires weeks to months of daily administration for optimal efficacy to occur. Combination pharmacotherapy can achieve relatively immediate improvement while also providing daily ICS to improve long-term control and reduce exacerbation risk.

Asthma therapy can be stepped down after good asthma control has been achieved and maintained for at least 3 mo. By determining the lowest number or dose of daily controller medications that can maintain good control, the potential for medication adverse effects is reduced. Regular follow-up is still emphasized because the variability of asthma's course is well recognized. When asthma is not well controlled, therapy should be escalated by increasing controller treatment step by 1 level and closely monitoring for clinical improvement. For a child with very poorly controlled asthma, the recommendations are to consider a short course of prednisone, or to increase therapy by 2 steps, with reevaluation in 2 wk. If step-up therapy is being considered, it is important to check inhaler technique and adherence, implement environmental control measures, and identify and treat comorbid conditions.

**Referral to Asthma Specialist**

Referral to an asthma specialist for consultation or co-management is recommended if there are difficulties in achieving or maintaining good asthma control. For children <4 yr, referral is recommended if the patient requires at least Treatment Step 3 care, and should be considered if the patient requires Treatment Step 2 care. For children ≥5 yr, consultation with a specialist is recommended if the patient requires Treatment Step 4 care or higher, and should be considered if Treatment Step 3 is required. Referral is also recommended if allergen immunotherapy or biologic therapy is being considered.
Long-Term Controller Medications

All levels of persistent asthma should be treated with ICS therapy to reduce airway inflammation and improve long-term control (see Table 169.11 ). Other long-term controller medications include LABAs, leukotriene modifiers, cromolyn, sustained-release theophylline, and tiotropium in adolescents. Omalizumab (Xolair) and mepolizumab (Nucala) are approved by the U.S. Food and Drug Administration (FDA) for use as an add-on therapy in children ≥6 yr and ≥12 yr who have severe allergic asthma or eosinophilic asthma, respectively, that remains difficult to control. Corticosteroids are the most potent and most effective medications used to treat both the acute (administered systemically) and the chronic (administered by inhalation) manifestations of asthma. They are available in inhaled, oral, and parenteral forms (Tables 169.12 and 169.13 ).

Inhaled Corticosteroids

ICS therapy improves lung function; reduces asthma symptoms, AHR, and use of “rescue” medications; improves quality of life; and most importantly reduces the need for prednisone, urgent care visits, and hospitalizations by approximately 50%. Epidemiologic studies have also shown that ICS therapy substantially lowers the risk of death attributable to asthma if used regularly. Because ICS therapy can achieve all the goals of asthma management, it is viewed as first-line treatment for persistent asthma.

Seven ICSs are FDA approved for use in children. The NIH and GINA guidelines provide equivalence classifications (see Table 169.13), although direct comparisons of efficacy and safety outcomes are lacking. ICSs are available in metered-dose inhalers (MDIs) using hydrofluoroalkane (HFA) as their propellant, in dry powder inhalers (DPIs), or in suspension for nebulization. Fluticasone propionate, fluticasone furoate, mometasone furoate, ciclesonide, and to a lesser extent budesonide are considered “second-generation” ICSs, in that they have greater antiinflammatory potency and less systemic bioavailability (and thus potential for systemic adverse effects) because of their extensive first-pass hepatic metabolism. The selection of the initial ICS dose is based on the determination of disease severity.

Even though ICSs can be very effective, there has been some reluctance to...
treat children with ICSs due to parental and occasionally physician concerns regarding their potential for adverse effects with chronic use. The adverse effects that occur with long-term systemic corticosteroid therapy have not been seen or have only rarely been reported in children receiving ICSs in recommended doses. The risk of adverse effects from ICS therapy is related to the dose and frequency of administration (Table 169.14). High doses (≥1,000 µg/day in children) and frequent administration (4 times/day) are more likely to have both local and systemic adverse effects. Children who receive maintenance therapy with higher ICS doses are also likely to require frequent systemic corticosteroid courses for asthma exacerbations, further increasing their risk of corticosteroid adverse effects.

Table 169.14

Risk Assessment for Corticosteroid Adverse Effects

<table>
<thead>
<tr>
<th>CONDITIONS</th>
<th>RECOMMENDATIONS</th>

* Indicates risk factors that may increase the risk of adverse effects from corticosteroid therapy.
Risk factors for osteoporosis: presence of other chronic illness(es), medications (corticosteroids, anticonvulsants, heparin, diuretics), low body weight, family history of osteoporosis, significant fracture history disproportionate to trauma, recurrent falls, impaired vision, low dietary calcium and vitamin D intake, and lifestyle factors (decreased physical activity, smoking, alcohol intake).

DEXA, Dual-energy x-ray absorptiometry; ICS, inhaled corticosteroid; OCS, oral corticosteroid; TSH, thyroid-stimulating hormone.

The most commonly encountered ICS adverse effects are local: oral candidiasis (thrust) and dysphonia (hoarse voice). Thrush results from propellant-induced mucosal irritation and local immunosuppression, and dysphonia is the result of vocal cord myopathy. These effects are dose dependent and are most common in individuals receiving high-dose ICS or oral corticosteroid therapy. The incidence of these local effects can be greatly minimized by using a spacer with an MDI with the ICS, because spacers reduce oropharyngeal deposition of the drug and propellant. Mouth rinsing using a “swish and spit” technique after ICS use is also recommended.

The potential for growth suppression and osteoporosis with long-term ICS use had been an unanswered concern. However, a long-term, prospective NIH-sponsored study (CAMP) followed the growth and bone mineral density (BMD) of >1,000 children (age 6-12 yr at entry) with mild to moderate asthma until they reached adulthood and found slight growth suppression and osteopenia in some children who received long-term ICS therapy. A small (1.1 cm), limited (1 year) growth suppressive effect was noted in children receiving budesonide, 200 µg twice daily, after 5 yr of therapy. Height was then followed until all children had reached adulthood (mean age 25 yr). Those who received ICS therapy remained approximately 1 cm shorter than those who received placebo. Thus, children treated with long-term ICS therapy are likely to be about 1 cm shorter than expected as an adult, which is of little clinical significance. BMD was no different in those receiving budesonide vs placebo during the duration of the study, while a follow-up study after a mean of 7 years found a slight dose-dependent effect of ICS therapy on bone mineral accretion only among males. A much greater effect on BMD was observed with increasing numbers of oral corticosteroid bursts for acute asthma, as well as an increase in risk for osteopenia, which was again limited to males. These findings were with use of low-dose budesonide; higher ICS doses, especially of agents with increased potency, have a greater potential for adverse effects. Thus, corticosteroid adverse effects screening and osteoporosis prevention measures are recommended for patients receiving higher ICS doses, since these patients are also likely to require systemic courses for exacerbations (see Table 169.14).
Systemic Corticosteroids

The development of second-generation ICSs, especially when used in combination with a LABA in a single device, have allowed the vast majority of children with asthma to achieve and maintain good control without need for maintenance oral corticosteroid (OCS) therapy. Thus, OCSs are used primarily to treat asthma exacerbations and, rarely, in children with very severe disease. In these patients, every attempt should be made to exclude comorbid conditions and to keep the OCS dose at ≤20 mg every other day. Doses exceeding this amount are associated with numerous adverse effects (see Chapter 593). To determine the need for continued OCS therapy, tapering of the OCS dose over several weeks should be attempted, with close monitoring of the patient's symptoms and lung function.

Prednisone, prednisolone, and methylprednisolone are rapidly and completely absorbed, with peak plasma concentrations occurring within 1-2 hr. Prednisone is an inactive prodrug that requires biotransformation via first-pass hepatic metabolism to prednisolone, its active form. Corticosteroids are metabolized in the liver into inactive compounds, with the rate of metabolism influenced by drug interactions and disease states. Anticonvulsants (phenytoin, phenobarbital, carbamazepine) increase the metabolism of prednisolone, methylprednisolone, and dexamethasone, with methylprednisolone most significantly affected. Rifampin also enhances the clearance of corticosteroids and can result in diminished therapeutic effect. Other medications (ketoconazole, oral contraceptives) can significantly delay corticosteroid metabolism. Some macrolide antibiotics, such as erythromycin and clarithromycin, delay the clearance of only methylprednisolone.

Long-term OCS therapy can result in a number of adverse effects over time (see Chapter 595). Some occur immediately (metabolic effects), whereas others can develop insidiously over several months to years (growth suppression, osteoporosis, cataracts). Most adverse effects occur in a cumulative dose- and duration-dependent manner. Children who require routine or frequent short courses of OCSs, especially with concurrent high-dose ICSs, should receive corticosteroid adverse effects screening (see Table 169.14) and osteoporosis preventive measures (see Chapter 726).

Long-Acting Inhaled β-Agonists

Although considered daily controller medications, LABAs (salmeterol,
formoterol) are not intended for use as monotherapy for persistent asthma because they can increase the risk for serious asthma exacerbations (ICU admission, endotracheal intubation) and asthma-related deaths when used without an ICS. The likely mechanism involves the ability of LABAs to “mask” worsening asthma inflammation and asthma severity, leading to a delay in seeking urgent care and increased risk of a life-threatening exacerbation. Although both salmeterol and formoterol have a prolonged duration of effect (≥12 hr), salmeterol has a prolonged onset of effect (60 min), while formoterol’s onset of effect is rapid (5-10 min) after administration. Given their long duration of action, LABAs are well suited for patients with nocturnal asthma and for individuals who require frequent use of SABA inhalations during the day to prevent exercise-induced bronchospasm (EIB), but only in combination with ICSs. Of note, the FDA requires all LABA-containing medications to be labeled with a warning of an increase in severe asthma episodes associated with these agents. In addition, the FDA recommends that once a patient is well controlled on combination ICS/LABA therapy, the LABA component should be discontinued while continuing treatment with the ICS.

**Combination ICS/LABA Therapy**

Combination ICS/LABA therapy is recommended for patients who are suboptimally controlled with ICS therapy alone and those with moderate or severe persistent asthma. In those inadequately controlled with ICS alone, combination ICS/LABA therapy is superior to add-on therapy with either an LTRA or theophylline or doubling the ICS dose. Benefits include improvement in baseline lung function, less need for rescue SABA therapy, improved quality of life, and fewer asthma exacerbations. A large study by the NIH-sponsored CARE Network found that in children inadequately controlled with low-dose ICS therapy, combination low-dose fluticasone/salmeterol (100 µg/21 µg) twice daily was almost twice as effective as other step-up regimens, including fluticasone (250 µg) twice daily or low-dose fluticasone (100 µg twice daily) plus montelukast once daily, with the greatest improvement in reducing exacerbations requiring prednisone and study withdrawals due to poorly controlled asthma. In addition, combination fluticasone/salmeterol was as effective as medium-dose fluticasone and was superior to combination fluticasone/montelukast therapy in black children, arguing against the notion that black children are more prone to serious asthma exacerbations than white children when treated with combination ICS/LABA therapy.
Despite their efficacy and widespread use, the long-term safety of LABAs, even when used in combination with ICS in a single inhaler, has been questioned. To address this concern of rare, severe asthma-related events with LABA/ICS use, large randomized controlled trials (RCTs) compared the safety of combination ICS/LABA vs ICS monotherapy. Two studies of >23,000 adults and adolescents ≥12 yr old with various levels of asthma severity were randomized to receive ICS (low or medium dose) monotherapy vs equivalent ICS/LABA (fluticasone vs fluticasone/salmeterol; budesonide vs budesonide/formoterol) over 26 weeks to determine if small but significant differences might occur in asthma hospitalization, intubation, or death attributable to ICS/LABA. No intubations or asthma deaths occurred during the study, and no differences in asthma hospitalizations between treatment groups were observed. The similar pediatric study enrolled >6,000 children age 4-11 yr with various levels of asthma severity to receive either fluticasone (low or medium dose) or equivalent fluticasone/salmeterol dose over 26 weeks, with similar findings of no significant differences in severe asthma-related events between treatment groups. These results strongly suggest that the use of combination ICS/LABA products in children and adults with moderate to severe persistent asthma is both effective and safe.

**Leukotriene-Modifying Agents**

Leukotrienes are potent proinflammatory mediators that can induce bronchospasm, mucus secretion, and airways edema. Two classes of leukotriene modifiers have been developed: inhibitors of leukotriene synthesis and leukotriene receptor antagonists (LTRAs). Zileuton, the only synthesis inhibitor, is not approved for use in children <12 yr. Because zileuton can result in elevated liver function enzyme values in 2–4% of patients, and interacts with medications metabolized via the cytochrome P450 system, it is rarely prescribed for children with asthma.

LTRAs have bronchodilator and targeted antiinflammatory properties and reduce exercise-, aspirin-, and allergen-induced bronchoconstriction. LTRAs are recommended as an alternative treatment for mild persistent asthma and as an add-on medication with ICS for moderate persistent asthma. Two LTRAs with FDA-approved use in children are montelukast and zafirlukast. Both medications improve asthma symptoms, decrease the need for rescue β-agonist use, and modestly improve lung function. **Montelukast** is approved for use in children ≥1 yr of age and is administered once daily, whereas **zafirlukast** is approved in
children ≥5 yr and is given twice daily. LTRAs are less effective than ICSs in patients with mild persistent asthma (e.g., ICSs improve baseline lung function 5–15%, whereas LTRAs improve lung function 2.5–7.5%). LTRAs have few, if any, significant adverse effects, although case reports have described mood changes and suicidality in adolescents soon after instituting montelukast. When initially prescribing montelukast, a precaution is to inform the child and family that, if mood changes are noted after starting montelukast, they should discontinue its use and contact their physician.

**Nonsteroidal Antiinflammatory Agents**

*Cromolyn* and *nedocromil* are considered nonsteroidal antiinflammatory drugs (NSAIDs), although they have little efficacy as a long-term controller for asthma. They can block EIB and bronchospasm caused by allergen challenge. Although both drugs are considered alternative controller agents for children with mild persistent asthma, *the 2016 GINA guidelines no longer recommend cromolyn or nedocromil*. Because they inhibit EIB and allergen-triggered responses, cromolyn (nedocromil is no longer available in the United States) can be used as an alternative or add-on to SABAs for these specific circumstances.

*Theophylline* is a phosphodiesterase inhibitor with bronchodilator and antiinflammatory effects that can reduce asthma symptoms and rescue SABA use. Although the National Heart, Lung, and Blood Institute (NHLBI) guidelines continue to include theophylline as an add-on agent to ICS in school-age children at Treatment Step 3 and beyond, it is rarely used in children today because of its potential toxicity. Theophylline has a narrow therapeutic window, with overdosage associated with headaches, vomiting, cardiac arrhythmias, seizures, and death. Therefore, when used, serum theophylline levels need to be carefully and routinely monitored, especially if the patient has a viral illness associated with a fever or is concomitantly taking a medication known to delay theophylline clearance. As a result, *the 2016 GINA guidelines no longer recommend theophylline* at any level of asthma severity or control.

**Long-Acting Inhaled Anticholinergics**

*Tiotropium* is a long-acting anticholinergic agent (24-hr duration of action) that is FDA approved for use in children with asthma ≥12 yr old. Studies in adults and adolescents have found tiotropium to be equivalent to a LABA when used in combination with an ICS. It has also been found to reduce exacerbations and
improve lung function in patients with inadequately controlled asthma despite
treatment with combination ICS/LABA products.

**Allergen Immunotherapy**

Allergen immunotherapy (AIT) involves administering gradually increasing
doses of allergens to a person with allergic disease to reduce or eliminate the
patient's allergic response to those allergens, including allergic
rhinoconjunctivitis and asthma. When properly administered to an appropriate
candidate, AIT is a safe, effective therapy capable not only of reducing or
preventing symptoms, but also of potentially altering the natural history of the
disease by minimizing disease duration and preventing disease progression.
Conventional AIT is given subcutaneously (subcutaneous immunotherapy, SCIT
) under the direction of an experienced allergist. Sublingual immunotherapy
(SLIT ) is less potent but can still be effective, and has less potential for severe
allergic adverse reactions.

The goal of SCIT or SLIT is to increase the dose of allergen extract
administered in order to reach a therapeutic maintenance dose of each major
allergen, in a manner that minimizes the likelihood of systemic allergic
reactions. For SCIT, allergen extracts are formulated for each patient based on
documented allergen sensitizations and problematic exposures. Maintenance
doses are generally given monthly for SCIT or daily for SLIT, to complete a 3-5
yr course. Most of the controlled trials examining AIT efficacy on seasonal or
perennial allergic asthma are favorable. A meta-analysis of 20 trials examining
the effects of SCIT on allergic asthma revealed significant improvement with
fewer symptoms, improved lung function, less need for medication, and AHR
reduction.

Although AIT is regarded as safe, the potential for anaphylaxis always exists
when patients receive extracts containing allergens to which they are sensitized.
Local transient allergic reactions are common (SCIT: injection site allergic
reaction; SLIT: mild oral itching). Systemic allergic reactions have been very
rarely reported with SLIT, such that it is typically administered at home. In
comparison, systemic allergic reactions occur more often with SCIT, with fatal
anaphylaxis occurring in approximately 1 per 2 million injections. Because of
the risks of systemic allergic reactions to SCIT, standard precautions include
administering SCIT in medical settings where a physician with access to
emergency equipment and medications required for the treatment of anaphylaxis
is available (see Chapter 174 ). Patients should be observed in the office for 30
min after each injection because most systemic reactions to SCIT begin within this time frame. SCIT should never be given at home or by untrained personnel. Because of the complexities and risks of administration, SCIT should only be administered by an experienced allergist.

AIT should be discontinued in patients who have not shown improvement after 1 yr of receiving maintenance doses of an appropriate allergen extract(s), or who have a serious systemic allergic or adverse reaction.

**Biologic Therapies**

Biologic therapies are genetically engineered proteins derived from human genes and designed to inhibit specific immune mediators of disease. Several are FDA approved as add-on controller therapies (i.e., in addition to conventional controller therapies) for severe asthma in adults and children.

**Omalizumab (Anti-IgE Antibody).**

Omalizumab is a humanized monoclonal antibody (mAb) that binds IgE and prevents its binding to the high-affinity IgE receptor, thereby blocking IgE-mediated allergic responses and inflammation. It is FDA approved for patients >6 yr old with severe allergic asthma who continue to have inadequate disease control despite treatment with high-dose ICS and/or OCS. Omalizumab is given every 2-4 wk subcutaneously, with the dosage based on body weight and serum IgE levels. Omalizumab can improve asthma control while allowing ICS and/or OCS dose reduction. Omalizumab has been studied in inner-city children with exacerbation-prone asthma. When added to guideline-based controller management, omalizumab reduced exacerbations (50%) that peak in the spring and fall seasons. A follow-up prospective preseasonal treatment study confirmed the effect on fall seasonal exacerbations and demonstrated how omalizumab restores antiviral (IFN-α) immune responses to rhinovirus (the most common infectious trigger of exacerbations) that are impaired by IgE-mediated mechanisms. Omalizumab is well tolerated, although local injection site reactions can occur. Hypersensitivity reactions (including anaphylaxis) have been reported following approximately 0.1% of injections. As a result, omalizumab has an FDA black box warning of potentially serious and life-threatening anaphylactic adverse reactions.

**Mepolizumab (Anti–IL-5 Antibody).**
Mepolizumab, an anti–IL-5 antibody that blocks IL-5-mediated eosinophilopoiesis, reduces severe asthma exacerbations and lowers sputum and blood eosinophils while allowing for a significant reduction in OCS dose in adults with severe exacerbation-prone eosinophilic asthma. It is administered subcutaneously every 4 wk and is FDA approved for severe eosinophilic asthmatic children ≥12 yr old. Reslizumab, another anti–IL-5 antibody therapeutic, is administered intravenously and is FDA approved for severe asthmatics ≥18 yr old (i.e., not currently approved for use in children).

**Dupilumab (Anti–IL-4 Receptor α Antibody).**

Dupilumab, an anti–IL-4 receptor antibody that inhibits both IL-4 and IL-13 production (both cytokines share the same IL-4 receptor) and atopic immune responses, reduces exacerbations and symptoms and improves lung function in moderate to severe asthmatic patients with persistent eosinophilia. Although not yet FDA approved, studies are ongoing in both children and adults.

**Quick-Reliever Medications**

Quick-reliever or “rescue” medications (SABAs, inhaled anticholinergics, and short-course systemic corticosteroids) are used in the management of acute asthma symptoms (Table 169.15).

Short-Acting Inhaled β-Agonists

Given their rapid onset of action, effectiveness, and 4-6 hr duration of action, SABAs (albuterol, levalbuterol, terbutaline, pirbuterol) are the drugs of choice for acute asthma symptoms (“rescue” medication) and for preventing EIB. β-Adrenergic agonists cause bronchodilation by inducing airway smooth muscle relaxation, reducing vascular permeability and airways edema, and improving mucociliary clearance. Levalbuterol, the R-isomer of albuterol, is associated with less tachycardia and tremor, which can be bothersome to some asthmatic patients. Overuse of β-agonists is associated with an increased risk of death or near-death episodes from asthma. This is a major concern for some patients with asthma who rely on the frequent use of SABAs as a “quick fix” for their asthma, rather than using controller medications in a preventive manner. It is helpful to monitor the frequency of SABA use, in that use of at least 1 MDI/mo or at least 3 MDIs/year (200 inhalations/MDI) indicates inadequate asthma control and necessitates improving other aspects of asthma therapy and management.

Anticholinergic Agents

As bronchodilators, the anticholinergic agents (e.g., ipratropium bromide) are less potent than the β-agonists. Inhaled ipratropium is used primarily in the treatment of acute severe asthma. When used in combination with albuterol, ipratropium can improve lung function and reduce the rate of hospitalization in children who present to the ED with acute asthma. Ipratropium has few central nervous system adverse effects and is available in both MDI and nebulizer formulations. Although widely used in all children with asthma exacerbations, it is FDA approved for use in children >12 yr old. A combination ipratropium/albuterol product is also available in both nebulized (generic and Duoneb) and mist formulations (Combivent Respimat).

Delivery Devices and Inhalation Technique

Inhaled medications are delivered in aerosolized form in a MDI, as a DPI formulation, or in a suspension form delivered via a nebulizer. Spacer devices, recommended for the administration of all MDI medications, are simple and
inexpensive tools that (1) decrease the coordination required to use MDIs, especially in young children; (2) improve the delivery of inhaled drug to the lower airways; and (3) minimize the risk of drug and propellant-mediated oropharyngeal adverse effects (dysphonia and thrush). Optimal inhalation technique for each puff of MDI-delivered medication is a slow (5 sec) inhalation, then a 5-10 sec breathhold. No waiting time is required between puffs of medication. Preschool-age children cannot perform this inhalation technique. As a result, MDI medications in this age-group are delivered with a spacer and mask, using a different technique: Each puff is administered with regular breathing for about 30 sec or 5-10 breaths; a tight seal must be maintained; and talking, coughing, or crying will blow the medication out of the spacer. This technique will not deliver as much medication per puff as the optimal MDI technique used by older children and adults.

**Dry powder inhaler devices** (e.g., Diskus, Flexhaler, Autohaler, Twistrhaler, Aerolizer, Ellipta) are popular because of their simplicity of use, although adequate inspiratory flow is needed. DPIs are breath-actuated devices (the drug comes out only as it is breathed in), and spacers are not needed. Mouth rinsing is recommended after ICS use to remove ICS deposited on the oral mucosa and reduce the swallowed ICS and the risk of thrush.

**Nebulizers** are the mainstay of aerosol treatment for infants and young children. An advantage of using nebulizers is the simple technique required of relaxed breathing. The preferential nasal breathing, small airways, low tidal volume, and high respiratory rate of infants greatly increase the difficulty of inhaled drug therapy targeting the lung airways. Disadvantages of nebulizers include need for a power source, inconvenience in that treatments take about 5 min, expense, and potential for bacterial contamination.

**Asthma Exacerbations and Their Management**

Asthma exacerbations are acute or subacute episodes of progressively worsening symptoms and airflow obstruction. Airflow obstruction during exacerbations can become extensive, resulting in life-threatening respiratory insufficiency. Often, asthma exacerbations worsen during sleep (between midnight and 8 AM), when airways inflammation and hyperresponsiveness are at their peak. Importantly, SABAs, which are first-line therapy for asthma symptoms and exacerbations, increase pulmonary blood flow through obstructed, unoxygenated areas of the lungs with increasing dosage and frequency. When airways obstruction is not
resolved with SABA use, ventilation/perfusion mismatching can cause hypoxemia, which can perpetuate bronchoconstriction and further worsen the condition. Severe, progressive asthma exacerbations need to be managed in a medical setting, with administration of supplemental oxygen as first-line therapy and close monitoring for potential worsening. Complications that can occur during severe exacerbations include atelectasis (common) and air leaks in the chest (pneumomediastinum, pneumothorax; rare).

A severe exacerbation of asthma that does not improve with standard therapy is termed **status asthmaticus**. Immediate management of an asthma exacerbation involves a rapid evaluation of the severity of obstruction and assessment of risk for further clinical deterioration (Fig. 169.8; see Tables 169.14 and 169.15). For most patients, exacerbations improve with frequent bronchodilator treatments and a course of systemic (oral or intravenous) corticosteroid. However, the optimal management of a child with an asthma exacerbation should include a more comprehensive assessment of the events leading up to the exacerbation and the underlying disease severity. Indeed, the frequency and severity of asthma exacerbations help define the severity of a patient's asthma. Whereas most children who experience life-threatening asthma episodes have moderate to severe asthma by other criteria, some children with asthma appear to have mild disease except when they have severe, even near-fatal exacerbations. The biologic, environmental, economic, and psychosocial risk factors associated with asthma morbidity and death can further guide this assessment (Table 169.16).
FIG. 169.8 Algorithm for treatment of acute asthma symptoms. PEF, Peak expiratory flow; ED, emergency department; PCP, primary care physician.
Table 169.16

Risk Factors for Asthma Morbidity and Mortality

**Biologic**

- Previous severe asthma exacerbation (intensive care unit admission, intubation for asthma)
- Sudden asphyxia episodes (respiratory failure, arrest)
- Two or more hospitalizations for asthma in past year
- Three or more emergency department visits for asthma in past year
- Increasing and large diurnal variation in peak flows
- Use of >2 canisters of short-acting β-agonists per month
- Poor response to systemic corticosteroid therapy
- Male gender
- Low birthweight
- Nonwhite (especially black) ethnicity
- Sensitivity to *Alternaria*

**Environmental**

- Allergen exposure
- Environmental tobacco smoke exposure
- Air pollution exposure
- Urban environment

**Economic and Psychosocial**

- Poverty
- Crowding
- Mother <20 yr old
- Mother with less than high school education
- Inadequate medical care:
Asthma exacerbations characteristically vary among individuals but tend to be similar in the same patient. Severe asthma exacerbations, resulting in respiratory distress, hypoxia, hospitalization, and respiratory failure, are the best predictors of future life-threatening exacerbations or a fatal asthma episode. In addition to distinguishing such high-risk children, some experience exacerbations that develop over days, with airflow obstruction resulting from progressive inflammation, epithelial sloughing, and cast impaction of small airways. When such a process is extreme, respiratory failure as a result of fatigue can ensue, necessitating mechanical ventilation for numerous days. In contrast, some children experience abrupt-onset exacerbations that may result from extreme AHR and physiologic susceptibility to airways closure. Such exacerbations, when extreme, are asphyxial in nature, often occur outside medical settings, are initially associated with very high arterial partial pressure of carbon dioxide (\(P_{\text{CO}}\)) levels, and tend to require only brief periods of supportive ventilation. Recognizing the characteristic differences in asthma exacerbations is important for optimizing their early management.

**Home Management of Asthma Exacerbations**

Families of all children with asthma should have a **written Asthma Action Plan** (see Fig. 169.7) to guide their recognition and management of exacerbations, along with the necessary medications and tools to manage them. Early recognition of asthma exacerbations in order to intensify treatment early can often prevent further worsening and keep exacerbations from becoming severe. A written home action plan can reduce the risk of asthma death by 70%. The NIH guidelines recommend immediate treatment with “rescue” medication
(inhaled SABA, up to 3 treatments in 1 hr). A good response is characterized by resolution of symptoms within 1 hr, no further symptoms over the next 4 hr, and improvement in PEF value to at least 80% of personal best. The child's physician should be contacted for follow-up, especially if bronchodilators are required repeatedly over the next 24-48 hr. If the child has an incomplete response to initial treatment with rescue medication (persistent symptoms and/or PEF <80% of personal best), a short course of OCS therapy (prednisone, 1-2 mg/kg/day [not to exceed 60 mg/day] for 4 days) should be instituted, in addition to inhaled β-agonist therapy. The physician should also be contacted for further instructions. Immediate medical attention should be sought for severe exacerbations, persistent signs of respiratory distress, lack of expected response or sustained improvement after initial treatment, further deterioration, or high-risk factors for asthma morbidity or mortality (e.g., previous history of severe exacerbations). For patients with severe asthma and/or a history of life-threatening episodes, especially if abrupt in onset, an epinephrine autoinjector and perhaps portable oxygen at home can be considered. Use of either of these extreme measures for home management of asthma exacerbations would be an indication to call 911 for emergency support services.

**Emergency Department Management of Asthma Exacerbations**

In the ED, the primary goals of asthma management include correction of hypoxemia, rapid improvement of airflow obstruction, and prevention of progression or recurrence of symptoms. Interventions are based on clinical severity on arrival, response to initial therapy, and presence of risk factors associated with asthma morbidity and mortality (see Table 169.16). Indications of a severe exacerbation include breathlessness, dyspnea, retractions, accessory muscle use, tachypnea or labored breathing, cyanosis, mental status changes, a silent chest with poor air exchange, and severe airflow limitation (PEF or FEV<sub>1</sub> value <50% of personal best or predicted values). Initial treatment includes supplemental oxygen, inhaled β-agonist therapy every 20 min for 1 hr, and, if necessary, oral or intravenous (IV) systemic corticosteroids (see Table 169.15 and Fig. 169.8). In the ED, single oral, intravenous, or intramuscular (IM) dose dexamethasone (0.6 mg/kg, maximum 16 mg) has been found to be an effective alternative to prednisone and with a lower incidence of emesis. In addition, a second dose of dexamethasone should be given the next day whether discharged
or admitted to the hospital. Inhaled ipratropium may be added to the β-agonist treatment if no significant response is seen with the 1st inhaled β-agonist treatment. An IM injection of epinephrine or other β-agonist may be administered in severe cases. Oxygen should be administered and continued for at least 20 min after SABA administration to compensate for possible ventilation/perfusion abnormalities caused by SABAs.

Close monitoring of clinical status, hydration, and oxygenation are essential elements of immediate management. A poor response to intensified treatment in the 1st hr suggests that the exacerbation will not remit quickly. The patient may be discharged home if there is sustained improvement in symptoms, normal physical findings, PEF >70% of predicted or personal best, and oxygen saturation >92% while the patient is breathing room air for 4 hr. Discharge medications include administration of an inhaled β-agonist up to every 3-4 hr plus a 3-7 day course of an OCS. Optimizing controller therapy before discharge is also recommended. The addition of ICS to a course of OCS in the ED setting reduces the risk of exacerbation recurrence over the subsequent month.

Hospital Management of Asthma Exacerbations

For patients with severe exacerbations that do not adequately improve within 1-2 hr of intensive treatment, observation and/or admission to the hospital, at least overnight, is likely to be needed. Other indications for hospital admission include high-risk features for asthma morbidity or death (see Table 169.16). Admission to an intensive care unit (ICU) is indicated for patients with severe respiratory distress, poor response to therapy, and concern for potential respiratory failure and arrest.

Supplemental oxygen, frequent or continuous administration of an inhaled bronchodilator, and systemic corticosteroid therapy are the conventional interventions for children admitted to the hospital for status asthmaticus (see Table 169.15). Supplemental oxygen is administered because many children hospitalized with acute asthma have or eventually have hypoxemia, especially at night and with increasing SABA administration. SABAs can be delivered frequently (every 20 min to 1 hr) or continuously (at 5-15 mg/hr). When administered continuously, significant systemic absorption of β-agonist occurs, and thus continuous nebulization can obviate the need for IV β-agonist therapy. Adverse effects of frequently administered β-agonist therapy include tremor, irritability, tachycardia, and hypokalemia; lactic acidosis is an uncommon
complication. Patients requiring frequent or continuous nebulized β-agonist therapy should have ongoing cardiac monitoring. Because frequent β-agonist therapy can cause ventilation/perfusion mismatch and hypoxemia, oximetry is also indicated. Inhaled ipratropium is often added to albuterol every 6 hr if patients do not show a remarkable improvement, although there is little evidence to support its use in hospitalized children receiving aggressive inhaled β-agonist therapy and systemic corticosteroids. In addition to its potential to provide a synergistic effect with a β-agonist agent in relieving severe bronchospasm, ipratropium may be beneficial in patients who have mucus hypersecretion or who are receiving β-blockers.

Short-course systemic corticosteroid therapy is recommended for use in moderate to severe asthma exacerbations to hasten recovery and prevent recurrence of symptoms. Corticosteroids are effective as single doses administered in the ED, short courses in the clinic setting, and both oral and IV formulations in hospitalized children. Studies in children hospitalized with acute asthma have found corticosteroids administered orally to be as effective as IV corticosteroids. Accordingly, OCS therapy can often be used, although children with sustained respiratory distress and those unable to tolerate oral preparations or liquids are obvious candidates for IV corticosteroid therapy.

Patients with persistent severe dyspnea and high-flow oxygen requirements require additional evaluation, such as complete blood count, arterial blood gases, serum electrolytes, and chest radiograph, to monitor for respiratory insufficiency, comorbidities, infection, and dehydration. Hydration status monitoring is especially important in infants and young children, whose increased respiratory rate (insensible losses) and decreased oral intake put them at higher risk for dehydration. Further complicating this situation is the association of increased antidiuretic hormone secretion with status asthmaticus. Administration of fluids at or slightly below maintenance fluid requirements is recommended. Chest physical therapy, incentive spirometry, and mucolytics are not recommended during the early acute period of asthma exacerbations because they can trigger severe bronchoconstriction.

Despite intensive therapy, some asthmatic children remain critically ill and at risk for respiratory failure, intubation, and mechanical ventilation. Complications (e.g., air leaks) related to asthma exacerbations increase with intubation and assisted ventilation, so every effort should be made to relieve bronchospasm and prevent respiratory failure. Several therapies, including parenteral β-agonists, magnesium sulfate (25-75 mg/kg, maximum dose 2.5 g,
given intravenously over 20 min), and inhaled heliox (helium and oxygen mixture) have demonstrated some benefit as adjunctive therapies in patients with severe status asthmaticus. Administration of magnesium sulfate requires monitoring of serum levels and cardiovascular status. Parenteral (SC, IM, or IV) epinephrine or terbutaline sulfate may be effective in patients with life-threatening obstruction that is not responding to high doses of inhaled β-agonists, because inhaled medication may not reach the lower airway in such patients.

Rarely, a severe asthma exacerbation in a child results in respiratory failure, and intubation and mechanical ventilation become necessary. Mechanical ventilation in severe asthma exacerbations requires the careful balance of enough pressure to overcome airways obstruction while reducing hyperinflation, air trapping, and the likelihood of barotrauma (pneumothorax, pneumomediastinum) (see Chapter 439). To minimize the likelihood of such complications, mechanical ventilation should be anticipated, and asthmatic children at risk for the development of respiratory failure should be managed in a pediatric ICU. Elective tracheal intubation with rapid-induction sedatives and paralytic agents is safer than emergency intubation. Mechanical ventilation aims to achieve adequate oxygenation while tolerating mild to moderate hypercapnia (P\textsubscript{CO\textsubscript{2}} 50-70 mm Hg) to minimize barotrauma. Volume-cycled ventilators, using short inspiratory and long expiratory times, 10-15 mL/kg tidal volume, 8-15 breaths/min, peak pressures <60 cm H\textsubscript{2}O, and without positive end-expiratory pressure are starting mechanical ventilation parameters that can achieve these goals. As measures to relieve mucus plugs, chest percussion and airways lavage are not recommended because they can induce further bronchospasm. One must consider the nature of asthma exacerbations leading to respiratory failure; those of rapid or abrupt onset tend to resolve quickly (hours to 2 days), whereas those that progress gradually to respiratory failure can require days to weeks of mechanical ventilation. Such prolonged cases are further complicated by corticosteroid-induced myopathy, which can lead to severe muscle weakness requiring prolonged rehabilitation.

In children, management of severe exacerbations in medical centers is usually successful, even when extreme measures are required. Consequently, asthma deaths in children rarely occur in medical centers; most occur at home or in community settings before lifesaving medical care can be administered. This point highlights the importance of home and community management of asthma exacerbations, early intervention measures to keep exacerbations from becoming
severe, and steps to reduce asthma severity. A follow-up appointment within 1-2 wk of a child's discharge from the hospital after resolution of an asthma exacerbation should be used to monitor clinical improvement and to reinforce key educational elements, including action plans and controller medications.

**Special Management Circumstances**

**Management of Infants and Young Children**

Recurrent wheezing episodes in preschool-age children are common, occurring in as much as one third of this population. Of these, most improve and even become asymptomatic during the prepubescent school-age years, whereas others have lifelong persistent asthma. All require management of their recurrent wheezing problems (see Tables 169.5, 169.6, and 169.11). The NIH guidelines recommend risk assessment to identify preschool-age children who are likely to have persistent asthma. One implication of this recommendation is that these at-risk children may be candidates for conventional asthma management, including daily controller therapy and early intervention with exacerbations (see Tables 169.7, 169.8, and 169.11). For young children with a history of moderate to severe exacerbations, nebulized budesonide is FDA approved, and its use as a controller medication could prevent subsequent exacerbations.

Using aerosol therapy in infants and young children with asthma presents unique challenges. There are 2 delivery systems for inhaled medications for this age-group: the nebulizer and the MDI with spacer/holding chamber and face mask. Multiple studies demonstrate the effectiveness of both nebulized albuterol in acute episodes and nebulized budesonide in the treatment of recurrent wheezing in infants and young children. In such young children, inhaled medications administered via MDI with spacer and face mask may be acceptable, although perhaps not preferred because of limited published information and lack of FDA approval for children <4 yr of age.

**Asthma Management During Surgery**

Patients with asthma are at risk from disease-related complications from surgery, such as bronchoconstriction and asthma exacerbation, atelectasis, impaired coughing, respiratory infection, and latex exposure, which may induce asthma complications in patients with latex allergy. All patients with asthma should be evaluated before surgery, and those who are inadequately controlled should
allow time for intensified treatment to improve asthma stability before surgery, if possible. A systemic corticosteroid course may be indicated for the patient who is having symptoms and/or FEV\textsubscript{1} or PEF values <80% of the patient's personal best. In addition, patients who have received >2 wk of systemic corticosteroid and/or moderate- to high-dose ICS therapy may be at risk for intraoperative adrenal insufficiency. For these patients, anesthesia services should be alerted to provide “stress” replacement doses of systemic corticosteroid for the surgical procedure and possibly the postoperative period.

**Prognosis**

Recurrent coughing and wheezing occurs in 35% of preschool-age children. Of these, approximately one third continue to have persistent asthma into later childhood, and approximately two thirds improve on their own through their teen years. Asthma severity by ages 7-10 yr is predictive of asthma persistence in adulthood. Children with moderate to severe asthma and with lower lung function measures are likely to have persistent asthma as adults. Children with milder asthma and normal lung function are likely to improve over time, with some becoming periodically asthmatic (disease-free for months to years); however, complete remission for 5 yr in childhood is uncommon.

**Prevention**

Although chronic airways inflammation may result in pathologic remodeling of lung airways, conventional antiinflammatory interventions—the cornerstone of asthma control—do not help children outgrow their asthma. Although controller medications reduce asthma morbidities, most children with moderate to severe asthma continue to have symptoms into young adulthood. Investigations into the environmental and lifestyle factors responsible for the lower prevalence of childhood asthma in rural areas and farming communities suggest that early immunomodulatory intervention might prevent asthma development. A *hygiene hypothesis* purports that naturally occurring microbial exposures in early life might drive early immune development away from allergic sensitization, persistent airways inflammation, and remodeling through early microbiome and innate immune development. If these natural microbial exposures truly have an asthma-protective effect, without significant adverse health consequences, these
findings may foster new strategies for asthma prevention.

Several nonpharmacotherapeutic measures with numerous positive health attributes—avoidance of environmental tobacco smoke (beginning prenatally), prolonged breastfeeding (>4 mo), an active lifestyle, and a healthy diet—might reduce the likelihood of asthma development. Immunizations are currently not considered to increase the likelihood of development of asthma; therefore all standard childhood immunizations are recommended for children with asthma, including varicella and annual influenza vaccines.

Bibliography

Bacharier LB. Reducing exposure to mouse allergen among children and adolescents with asthma is achievable, but is it enough? JAMA. 2017;317(10):1023–1024.

Atopic dermatitis (AD), or eczema, is the most common chronic relapsing skin disease seen in infancy and childhood. It affects 10–30% of children worldwide and frequently occurs in families with other atopic diseases. Infants with AD are predisposed to development of food allergy, allergic rhinitis, and asthma later in childhood, a process called the atopic march.

**Etiology**

AD is a complex genetic disorder that results in a defective skin barrier, reduced skin innate immune responses, and polarized adaptive immune responses to environmental allergens and microbes that lead to chronic skin inflammation.

**Pathology**

Acute AD skin lesions are characterized by spongiosis, or marked intercellular edema, of the epidermis. In AD, dendritic antigen-presenting cells (APCs) in the epidermis, such as Langerhans cells, exhibit surface-bound IgE molecules with cell processes that reach into upper epidermis to sense allergens and pathogens. These APCs play an important role in cutaneous responses to type 2 immune responses (see Chapter 166). There is marked perivenular T-cell and inflammatory monocyte-macrophage infiltration in acute AD lesions. Chronic, lichenified AD is characterized by a hyperplastic epidermis with hyperkeratosis and minimal spongiosis. There are predominantly IgE-bearing Langerhans cells in the epidermis, and macrophages in the dermal mononuclear cell infiltrate. Mast cell and eosinophil numbers are increased, contributing to skin
Pathogenesis

AD is associated with multiple phenotypes and endotypes that have overlapping clinical presentations. **Atopic eczema** is associated with IgE-mediated sensitization (at onset or during the course of eczema) and occurs in 70–80% of patients with AD. **Nonatopic eczema** is not associated with IgE-mediated sensitization and is seen in 20–30% of patients with AD. Both forms of AD are associated with eosinophilia. In atopic eczema, circulating T cells expressing the skin homing receptor **cutaneous lymphocyte-associated antigen** produce increased levels of T-helper type 2 (Th2) cytokines, including interleukin (IL)-4 and IL-13, which induce isotype switching to IgE synthesis. Another cytokine, IL-5, plays an important role in eosinophil development and survival. Nonatopic eczema is associated with lower IL-4 and IL-13 but increased IL-17 and IL-23 production than in atopic eczema. Age and race have also been found to affect the immune profile in AD.

Compared with the skin of healthy individuals, both unaffected skin and acute skin lesions of patients with AD have an increased number of cells expressing IL-4 and IL-13. Chronic AD skin lesions, by contrast, have fewer cells that express IL-4 and IL-13, but increased numbers of cells that express IL-5, granulocyte-macrophage colony-stimulating factor, IL-12, and interferon (IFN)-γ than acute AD lesions. Despite increased type 1 and type 17 immune responses in chronic AD, IL-4 and IL-13 as well as other type 2 cytokines (e.g. TSLP, IL-31, IL-33) predominate and reflect increased numbers of Type 2 innate lymphoid cells and Th2 cells. The infiltration of IL-22–expressing T cells correlates with severity of AD, blocks keratinocyte differentiation, and induces epidermal hyperplasia. The importance of IL-4 and IL-13 in driving severe persistent AD has been validated by multiple clinical trials now demonstrating that biologics blocking IL-4 and IL-13 action lead to clinical improvement in moderate to severe AD.

In healthy people the skin acts as a protective barrier against external irritants, moisture loss, and infection. Proper function of the skin depends on adequate moisture and lipid content, functional immune responses, and structural integrity. **Severely dry skin is a hallmark of AD.** This results from compromise of the epidermal barrier, which leads to excess transepidermal water loss, allergen penetration, and microbial colonization. **Filaggrin**, a structural protein in the
epidermis, and its breakdown products are critical to skin barrier function, including moisturization of the skin. Genetic mutations in the filaggrin gene (*FLG*) family have been identified in patients with ichthyosis vulgaris (dry skin, palmar hyperlinearity) and in up to 50% of patients with severe AD. *FLG* mutation is strongly associated with development of food allergy and eczema herpeticum. Nonetheless, up to 60% of carriers of a *FLG* mutation do not develop atopic diseases. Cytokines found in allergic inflammation, such as IL-4, IL-13, IL-22, IL-25, and tumor necrosis factor, can also reduce filaggrin and other epidermal proteins and lipids. AD patients are at increased risk of bacterial, viral, and fungal infection related to impairment of innate immunity, disturbances in the microbiome, skin epithelial dysfunction, and overexpression of polarized immune pathways, which dampen host antimicrobial responses.

**Clinical Manifestations**

AD typically begins in infancy. Approximately 50% of patients experience symptoms in the 1st yr of life, and an additional 30% are diagnosed between 1 and 5 yr of age. Intense **pruritus**, especially at night, and **cutaneous reactivity** are the cardinal features of AD. Scratching and excoriation cause increased skin inflammation that contributes to the development of more pronounced eczematous skin lesions. Foods (cow's milk, egg, peanut, tree nuts, soy, wheat, fish, shellfish), aeroallergens (pollen, grass, animal dander, dust mites), infection (*Staphylococcus aureus*, herpes simplex, coxsackievirus, molluscum), reduced humidity, excessive sweating, and irritants (wool, acrylic, soaps, toiletries, fragrances, detergents) can trigger pruritus and scratching.

Acute AD skin lesions are intensely pruritic with eryhematos papules (*Figs. 170.1 and 170.2*). Subacute dermatitis manifests as eryhematos, excoriated, scaling papules. In contrast, chronic AD is characterized by **lichenification** (*Fig. 170.3*), or thickening of the skin with accentuated surface markings, and **fibrotic papules**. In chronic AD, all 3 types of skin reactions may coexist in the same individual. Most patients with AD have dry, lackluster skin regardless of their stage of illness. Skin reaction pattern and distribution vary with the patient's age and disease activity. AD is generally more acute in infancy and involves the face, scalp, and extensor surfaces of the extremities. The diaper area is usually spared. Older children and children with chronic AD have lichenification and localization of the rash to the flexural folds of the extremities. AD can go into remission as the patient grows older, however, many children with AD have
persistent eczema as an adult (Fig. 170.1C).

**FIG. 170.1** Typical clinical appearance and locations of atopic dermatitis at different ages. Top row, In infants, atopic dermatitis is generally acute, with lesions mainly on the face and the extensor surfaces of the limbs. The trunk might be affected, but the napkin area is typically spared. Middle row, From age 1-2 yr onward, polymorphous manifestations with different types of skin lesions are seen, particularly in flexural folds. Bottom row, Adolescents and adults often present lichenified and excoriated plaques at flexures, wrists, ankles, and eyelids; in the head and neck type, the upper trunk, shoulders, and scalp are involved. Adults might have only chronic hand eczema or present with prurigo-like lesions. (From Weidinger S, Novak N: Atopic dermatitis, *Lancet* 387:1111, 2016.)
FIG. 170.2 Crusted lesions of atopic dermatitis on the face. (From Eichenfield LF, Friedan IJ, Esterly NB: Textbook of neonatal dermatology, Philadelphia, 2001, Saunders, p 242.)

FIG. 170.3 Lichenification of the popliteal fossa from chronic rubbing of the skin in atopic dermatitis. (From Weston WL, Lane AT, Morelli JG: Color textbook of pediatric dermatology, ed 2, St Louis, 1996, Mosby, p 33.)
Laboratory Findings

There are no specific laboratory tests to diagnose AD. Many patients have peripheral blood eosinophilia and increased serum IgE levels. Serum IgE measurement or skin-prick testing can identify the allergens (foods, inhalant/microbial allergens) to which patients are sensitized. The diagnosis of clinical allergy to these allergens requires confirmation by history and environmental challenges.

Diagnosis and Differential Diagnosis

AD is diagnosed on the basis of 3 major features: pruritus, an eczematous dermatitis that fits into a typical pattern of skin inflammation, and a chronic or chronically relapsing course (Table 170.1). Associated features, such as a family history of asthma, hay fever, elevated IgE, and immediate skin test reactivity, reinforce the diagnosis of AD.

Many inflammatory skin diseases, immunodeficiencies, skin malignancies, genetic disorders, infectious diseases, and infestations share symptoms with AD and should be considered and excluded before a diagnosis of AD is established (Tables 170.2 and 170.3). Severe combined immunodeficiency (see Chapter 152.1) should be considered for infants presenting in the first yr of life with diarrhea, failure to thrive, generalized scaling rash, and recurrent cutaneous and/or systemic infection. Histiocytosis should be excluded in any infant with AD and failure to thrive (see Chapter 534). Wiskott-Aldrich syndrome, an X-linked recessive disorder associated with thrombocytopenia, immune defects, and recurrent severe bacterial infections, is characterized by a rash almost indistinguishable from that in AD (see Chapter 152.2). One of the hyper-IgE syndromes is characterized by markedly elevated serum IgE values, recurrent deep-seated bacterial infections, chronic dermatitis, and refractory dermatophytosis. Many of these patients have disease as a result of autosomal dominant STAT3 mutations. In contrast, some patients with hyper-IgE syndrome present with increased susceptibility to viral infections and an autosomal recessive pattern of disease inheritance. These patients may have a DOCK8 (dedicator of cytokinesis 8 gene) mutation. This diagnosis should be considered in young children with severe eczema, food allergy, and disseminated skin viral infections.

Adolescents who present with an eczematous dermatitis but no history of childhood eczema, respiratory allergy, or atopic family history may have allergic contact dermatitis (see Chapter 674.1). A contact allergen may be the problem in any patient whose AD does not respond to appropriate therapy. Sensitizing chemicals, such as parabens and lanolin, can be irritants for patients with AD and are commonly found as vehicles in therapeutic topical agents. Topical glucocorticoid contact allergy has been reported in patients with chronic dermatitis receiving topical corticosteroid therapy. Eczematous dermatitis has also been reported with HIV infection as well as with a variety of infestations such as scabies. Other conditions that can be confused with AD include psoriasis, ichthyosis, and seborrheic dermatitis.

## Treatment

The treatment of AD requires a systematic, multifaceted approach that incorporates skin moisturization, topical antiinflammatory therapy, identification and elimination of flare factors (Table 170.4), and, if necessary, systemic therapy. Assessment of the severity also helps direct therapy (Table 170.5).
Counseling and Aggravating Factors for Patients With Atopic Dermatitis (AD)

Maintain cool temperature in bedroom, and avoid too many bed covers. Increase emollient use with cold weather.
Avoid exposure to herpes sores; urgent visit if flare of unusual aspect.  
**Clothing:** Avoid skin contact with irritating fibers (wool, large-fiber textiles).
  - Do not use tight and too-warm clothing, to avoid excessive sweating.
  - New, nonirritating clothing designed for AD children is being evaluated.

**Tobacco:** Avoid exposure.

**Vaccines:** Normal schedule in noninvolved skin, including egg-allergic patients (see text).

**Sun exposure:** No specific restriction.
  - Usually helpful because of improvement of epidermal barrier.
  - Encourage summer holidays in altitude or at beach resorts.

**Physical exercise, sports:** no restriction.
  - If sweating induces flares of AD, progressive adaptation to exercise.
  - Shower and emollients after swimming pool.

**Food allergens:**
  - Maintain breastfeeding exclusively to 4-6 mo if possible.
  - Consider evaluation for early introduction of allergens (see Chapter 176).
  - Otherwise normal diet, unless an allergy workup has proved the need to exclude a specific food.

**Indoor aeroallergens:** House dust mites
  - Use adequate ventilation of housing; keep the rooms well aerated even in winter.
  - Avoid wall-to-wall carpeting.
  - Remove dust with a wet sponge.
  - Vacuum floors and upholstery with an adequately filtered cleaner once a week.
  - Avoid soft toys in bed (cradle), except washable ones.
Wash bedsheets at a temperature higher than 55°C (131°F) every 10 days. Use bed and pillow encasings made of Gore-Tex or similar material.

*Furred pets:* Advise to avoid. If allergy is demonstrated, be firm on avoidance measures, such as pet removal.

*Pollen:* Close windows during peak pollen season on warm and dry weather days, and restrict, if possible, time outdoors.

  - Windows may be open at night and early in the morning or during rainy weather.
  - Avoid exposure to risk situations (lawn mowing).
  - Use pollen filters in motor vehicles.
  - Clothes and pets can vectorize aeroallergens, including pollen.

**Table 170.5**

**Categorization of Physical Severity of Atopic Eczema**

- **Clear** — Normal skin, with no evidence of atopic eczema
- **Mild** — Areas of dry skin, infrequent itching (with or without small areas of redness)
- **Moderate** — Areas of dry skin, frequent itching, redness (with or without excoriation and localized skin thickening)
