There are three distinct, yet related, forms of neuromotor ability: fine motor, graphomotor, and gross motor coordination. Fine motor function reflects the ability to control the muscles and bones to produce small, exact movements. Deficits in fine motor function can disrupt the ability to communicate in written form, to excel in artistic and crafts activities, and can interfere with learning a musical instrument or mastering a computer keyboard. The term dyspraxia relates to difficulty in developing an ideomotor plan and activating coordinated and integrated visual-motor actions to complete a task or solve a motor problem, such as assembling a model. Graphomotor function refers to the specific motor aspects of written output. Several subtypes of graphomotor dysfunction can significantly impede writing. Children who harbor weaknesses of visualization during writing have trouble picturing the configurations of letters and words as they write (orthographics), with poorly legible written output with inconsistent spacing between words. Others have weaknesses in orthographic memory and may labor over individual letters and prefer printing (manuscript) to cursive writing. Some exhibit signs of finger agnosia and have trouble localizing their fingers while they write, needing to keep their eyes very close to the page and applying excessive pressure to the pencil. Others struggle producing the highly coordinated motor sequences needed for writing, a phenomenon also described
as dyspraxic dysgraphia. It is important to emphasize that a child may show excellent fine motor dexterity (as revealed in mechanical or artistic domains) but very poor graphomotor fluency (with labored or poorly legible writing).

**Gross motor function** refers to control of large muscles. Children with gross motor incoordination often have problems in processing “outer spatial” information to guide gross motor actions. Affected children may be inept at catching or throwing a ball because they cannot form accurate judgments about trajectories in space. Others demonstrate diminished body position sense. They do not efficiently receive or interpret proprioceptive and kinesthetic feedback from peripheral joints and muscles. They are likely to evidence difficulties when activities demand balance and ongoing tracking of body movement. Others are unable to satisfy the motor praxis demands of certain gross motor activities. It may be difficult for them to recall or plan complex motor procedures such as those needed for dancing, gymnastics, or swimming.

**Language**

Language is one of the most critical and complex cognitive functions and can be broadly divided into **receptive** (auditory comprehension/understanding) and **expressive** (speech and language production and/or communication) functions. Children who primarily experience receptive language problems may have difficulty understanding verbal information, following instructions and explanations, and interpreting what they hear. Expressive language weaknesses can result from problems with speech production and/or problems with higher-level language development. **Speech production difficulties** include oromotor problems affecting articulation, verbal fluency, and naming. Some children have trouble with sound sequencing within words. Others find it difficult to regulate the rhythm or prosody of their verbal output. Their speech may be dysfluent, hesitant, and inappropriate in tone. Problems with word retrieval can result in difficulty finding exact words when needed (as in a class discussion) or substituting definitions for words (circumlocution).

The basic components of language include **phonology** (ability to process and integrate the individual sounds in words), **semantics** (understanding the meaning of words), **syntax** (mastery of word order and grammatical rules), **discourse** (processing and producing paragraphs and passages), **metalinguistics** (ability to think about and analyze how language works and draw inferences), and **pragmatics** (social understanding and application of language). Children who
evidence higher-level expressive language impediments have trouble formulating sentences, using grammar acceptably, and organizing spoken (and possibly written) narratives.

To one degree or another, all academic skills are taught largely through language, and thus it is not surprising that children who experience language dysfunction often experience problems with academic performance. In fact, some studies suggest that up to 80% of children who present with a specific learning disorder also experience language-based weaknesses. Additionally, the role of language in executive functioning cannot be understated, since language serves to guide cognition and behavior.

**Visual-Spatial/Visual-Perceptual Function**

Important structures involved in the development and function of the visual system include the retina, optic cells (e.g., rods and cones), the optic chiasm, the optic nerves, the brainstem (control of automatic responses, e.g., pupil dilation), the thalamus (e.g., lateral geniculate nucleus for form, motion, color), and the primary (visual space and orientation) and secondary (color perception) visual processing regions located in and around the occipital lobe. Other brain areas, considered to be outside of the primary visual system, are also important to visual function, helping to process what (temporal lobe) is seen and where it is located in space (parietal lobe). It is now well documented that the left and right cerebral hemispheres interact considerably in visual processes, with each hemisphere possessing more specialized functions, including left hemisphere processing of details, patterns, and linear information and right hemisphere processing of the gestalt and overall form.

Critical aspects of visual processing development in the child include appreciation of **spatial relations** (ability to perceive objects accurately in space in relation to other objects), **visual discrimination** (ability to differentiate and identify objects based on their individual attributes, e.g., size, shape, color, form, position), and **visual closure** (ability to recognize or identify an object even when the entire object cannot be seen). Visual-spatial processing dysfunctions are rarely the cause of reading disorders, but some investigations have established that deficits in orthographic coding (visual-spatial analysis of character-based systems) can contribute to reading disorders. Spelling and writing can emerge as a weakness because children with visual processing problems usually have trouble with the precise visual configurations of words. In
mathematics, these children often have difficulty with visual-spatial orientation, with resultant difficulty aligning digits in columns when performing calculations and difficulty managing geometric material. In the social realm, intact visual processing allows a child to make use of visual or physical cues when communicating and interpreting the paralinguistic aspects of language. Secure visual functions are also necessary to process proprioceptive and kinesthetic feedback and to coordinate movements during physical activities.

**Intellectual Function**

A useful definition of intellectual function is the capacity to think in the abstract, reason, problem-solve, and comprehend. The concept of intelligence has had many definitions and theoretical models, including Spearman's unitary concept of “the g-factor,” the “verbal and nonverbal” theories (e.g., Binet, Thorndike), the 2-factor theory from Catell (crystallized vs fluid intelligence), Luria's simultaneous and successive processing model, and more recent models that view intelligence as a global construct composed of more-specific cognitive functions (e.g., auditory and visual-perceptual processing, spatial abilities, processing speed, working memory).

The expression of intellect is mediated by many factors, including language development, sensorimotor abilities, genetics, heredity, environment, and neurodevelopmental function. When an individual's measured intelligence is >2 standard deviations below the mean (a standard score of <70 on most IQ tests) and accompanied by significant weaknesses in adaptive skills, the diagnosis of intellectual disability may be warranted (see Chapter 53).

Functionally, some common characteristics distinguish children with deficient intellectual functioning from those with average or above-average abilities. Typically, those at the lowest end of the spectrum (e.g., profound or severe intellectual deficiencies) are incapable of independent function and require a highly structured environment with constant aid and supervision. At the other end of the spectrum are those with unusually well-developed intellect (“gifted”). Although this level of intellectual functioning offers many opportunities, it can also be associated with functional challenges related to socialization and learning and communication style. Individuals whose intellect falls in the below-average range (sometimes referred to as the “borderline” or “slow learner” range) tend to experience greater difficulty processing and managing information that is abstract, making connections between concepts and ideas, and generalizing.
information (e.g., may be able to comprehend a concept in one setting but are unable to carry it over and apply it in different situations). In general, these individuals tend to do better when information is presented in more concrete and explicit terms, and when working with rote information (e.g., memorizing specific material). Stronger intellect has been associated with better-developed concept formation, critical thinking, problem solving, understanding and formulation of rules, brainstorming and creativity, and metacognition (ability to “think about thinking”).

**Memory**

Memory is a term used to describe the cognitive mechanism by which information is acquired, retained, and recalled. Structurally, some major brain areas involved in memory processing include the hippocampus, fornix, temporal lobes, and cerebellum, with connections in and between most brain regions. The memory system can be partitioned into subsystems based on processing sequences; the form, time span, and method of recall; whether memories are conscious or unconsciously recalled; and the types of memory impairments that can occur.

Once information has been identified (through auditory, visual, tactile, and/or other sensory processes), it needs to be **encoded and registered**, a mental process that constructs a representation of the information into the memory system. The period (typically seconds) during which this information is being held and/or manipulated for registration, and ultimately encoded, consolidated, and retained, is referred to as **working memory**. Other descriptors include **short-term memory** and **immediate memory**. **Consolidation** and **storage** represent the process by which information in short-term memory is transferred into **long-term memory**. Information in long-term memory can be available for hours or as long as a life span. Long-term memories are generally thought to be housed, in whole or in part, in specific brain regions (e.g., cortex, cerebellum). Ordinarily, consolidation in long-term memory is accomplished in 1 or more of 4 ways: pairing 2 bits of information (e.g., a group of letters and the English sound it represents); storing procedures (consolidating new skills, e.g., the steps in solving mathematics problems); classifying data in categories (filing all insects together in memory); and linking new information to established rules, patterns, or systems of organization (rule-based learning).

Once information finds its way into long-term memory, it must be accessed. In
general, information can be retrieved spontaneously (a process known as free recall) or with the aid of cues (cued or recognition recall). Some other common descriptors of memory include anterograde memory (capacity to learn from a single point in time forward), retrograde memory (capacity to recall information that was already learned), and explicit memory (conscious awareness of recall), implicit memory (subconscious recall: no awareness that the memory system is being activated), procedural memory (memory for how to do things), and prospective memory or remembering to remember. Automatization reflects the ability to instantaneously access what has been learned in the past with no expenditure of effort. Successful students are able to automatically form letters, master mathematical facts, and decode words.

**Social Cognition**

The development of effective social skills is heavily dependent on secure social cognition, which consists of mental processes that allow an individual to understand and interact with the social environment. Although some evidence shows that social cognition exists as a discrete area of neurodevelopmental function, multiple cognitive processes are involved with social cognition. These include the ability to recognize, interpret, and make sense of the thoughts, communications (verbal and nonverbal), and actions of others; the ability to understand that others' perceptions, perspectives, and intentions might differ from one's own (commonly referred to as “theory of mind”); the ability to use language to communicate with others socially (pragmatic language); and the ability to make inferences about others and the environment based on contextual information. It can also be argued that social cognition involves processes associated with memory and EFs such as flexibility.

**Executive Function**

The development of EFs begins very early on in the developmental course (early indications of inhibitory control and even working memory have been found in infancy), matures significantly during the preschool years, and continues to develop through adolescence and well into adulthood. Some studies suggest that secure EF may be more important than intellectual ability for academic success and have revealed that a child's ability to delay gratification early in life predicts competency, attention, self-regulation, frustration tolerance, aptitude, physical
and mental health, and even substance dependency in adolescence and adulthood. Conversely, deficits in other areas of neurodevelopment, such as language development, impact EF.

**Attention** is far from a unitary, independent, or specific brain function. This may be best illustrated through the phenotype associated with ADHD (see Chapter 49). Disordered attention can result from faulty mechanisms in and across subdomains of attention. These subdomains include *selective* attention (ability to focus attention on a particular stimulus and to discriminate relevant from irrelevant information), *divided* attention (ability to orient to more than one stimulus at a given time), *sustained* attention (ability to maintain one's focus), and *alternating* attention (capacity to shift focus between stimuli).

Attention problems in children can manifest at any point, from arousal through output. Children with diminished alertness and arousal can exhibit signs of mental fatigue in a classroom or when engaged in any activity requiring sustained focus. They are apt to have difficulty allocating and sustaining their concentration, and their efforts may be erratic and unpredictable, with extreme performance inconsistency. Weaknesses of determining saliency often result in focusing on the wrong stimuli, at home, in school, and socially, and missing important information. **Distractibility** can take the form of listening to extraneous noises instead of a teacher, staring out the window, or constantly thinking about the future. Attention dysfunction can affect the output of work, behavior, and social activity. It is important to appreciate that most children with attentional dysfunction also harbor other forms of neurodevelopmental dysfunction that can be associated with academic disorders (with some estimates suggesting up to 60% comorbidity).

**Inhibitory control (IC)** can be described as one's ability to restrain, resist, and not act (cognitively or behaviorally/emotionally) on a thought. IC may also be seen as one's ability to stop thoughts or ongoing actions. Deficits in this behavioral/impulse regulation mechanism are a core feature of the combined or hyperactive impulsive presentation of ADHD and have a significant adverse impact on a child's overall functioning. In everyday settings, children with weak IC may exhibit difficulties with self-control and self-monitoring of their behavior and output (e.g., impulsivity), may not recognize their own errors or mistakes, and often act prematurely and without consideration of the potential consequences of their actions. In the social context, disinhibited children may interrupt others and demonstrate other impulsive behaviors that often interfere with interpersonal relationships. The indirect consequences of poor IC often lead
to challenges with behavior, emotional, and academic functioning and social interaction (Table 48.1).

</table>

**Working memory** (WM) can be defined as the ability to hold, manipulate, and store information for short periods. This function is critical to be able to complete multistep problems and more complex instructions and tasks. In its simplest form, WM involves the interaction of short-term verbal and visual processes (e.g., memory, phonologic, awareness, and spatial skills) with a centralized control mechanism that is responsible for coordinating all the cognitive processes involved (e.g., temporarily suspending information in memory while working with it). Developmentally, WM capacity can double or triple between the preschool years and adolescence. When doing math, a child with WM dysfunction might carry a number and then forget what he intended to do after carrying that number. WM is an equally important underlying function for reading, where it enables the child to remember the beginning of a paragraph when she arrives at the end of it. In writing, WM helps children remember what they intend to express in written form while they are performing another task,
such as placing a comma or working on spelling a word correctly. WM also enables the linkage between new incoming information in short-term memory with prior knowledge or skills held in longer-term memory.

**Initiation** refers to the ability to independently begin an activity, a task, or thought process (e.g., problem-solve). Children who present with initiation difficulties often have trouble “getting going” or “getting started.” This can be exhibited behaviorally, such that the child struggles to start on physical activities such as getting out of bed or beginning chores. Cognitively, weaknesses in initiation may manifest as difficulty coming up with ideas or generating plans. In school, children who have poor initiation abilities may be delayed in or unable to start homework assignments or tests. In social situations, initiation challenges may cause a child to have difficulty beginning conversations, calling on friends, or going out to be with friends.

Deficits in “primary” initiation are relatively rare and are often associated with significant neurologic conditions and treatments (e.g., traumatic brain injury, anoxia, effects of radiation treatment in childhood cancer). More often, initiation deficits are secondary to other executive problems (e.g., disorganization) or behavioral (e.g., oppositional/defiant behaviors), developmental (e.g., autism spectrum disorder), or emotional (e.g., depression, anxiety) disorders.

**Planning** refers to the ability to effectively generate, sequence, and put into motion the steps and procedures necessary to realize a specific goal. In real-world settings, children who struggle with planning are typically described by caregivers and teachers as being inept at independently gathering what is required to solve a problem, or as unable to complete more weighty assignments. Another common complaint is that these children exhibit poor time management skills. **Organization** is an ability that represents a child's proficiency in arranging, ordering, classifying, and categorizing information. Common daily life challenges associated with organizational difficulties in childhood include problems with gathering and managing materials or items. When children struggle with organization, indirect consequences may include becoming overwhelmed with information and being unable to complete a task or activity. Effective organization is a vital component in learning (more specifically, in memory/retention); many studies along with clinical experience have shown that poor organization significantly impacts how well a child recalls information. Planning and organizing depend on **discrimination** ability, which refers to the child’s ability to determine what is and is not valuable when trying to problem-solve or organize.
**Emotional control** is the ability to regulate emotions in order to realize goals and direct one's behavior, thoughts, and actions. It has been well established that affective/emotional states have an impact on many aspects of functioning. Conversely, executive function or dysfunction often contributes to modulation or affect. While emotional control is highly interrelated with different EFs (e.g., disinhibition, self-monitoring), separating it conceptually facilitates an appreciation for and recognition of the often-overlooked role that a child's emotional state plays in cognitive and behavioral functioning. Children with weak emotional control may exhibit explosive outbursts, poor temper/anger control, and oversensitivity. Clearly, understanding a child's emotional state is vital to understanding its impact not only on executive functioning, but also on functioning as a whole (e.g., socially, mentally, behaviorally, academically).

Any discussion involving emotional control should also recognize **motivation**. **Motivation/effort** may be defined as the reason or reasons one acts or behaves in a certain way. Less motivated children are less likely to engage and utilize all their abilities. Such a disposition not only interferes with application of executive skills, but also results in less than optimal performance and functioning. The less success a child feels, the less likely the child is to put forth effort and to persevere when things become more challenging. If a child's initial efforts are met with a negative reaction, the likelihood that the child will continue putting forth adequate effort diminishes. If left unchecked, a child's overall level of functioning will likely be compromised. More importantly, the child's sense of personal efficacy (e.g., self-esteem) and competence may suffer.

**Clinical Manifestations**

The symptoms and clinical manifestations of neurodevelopmental and executive dysfunction differ with age. **Preschool-age children** might present with delayed language development, including problems with articulation, vocabulary development, word finding, and rhyming. They often experience early challenges with learning colors, shapes, letters, and numbers; the alphabet; and days of the week. Children with visual processing deficits may have difficulty learning to draw and write and have problems with art activities. These children might also have trouble discriminating between left and right. They might encounter problems recognizing letters and words. Difficulty following instructions, overactivity, and distractibility may be early symptoms of emerging executive dysfunction. Difficulties with fine motor development (e.g., grasping
crayons/pencils, coloring, drawing) and social interaction may develop.

**School-age children** with neurodevelopmental and executive dysfunctions can vary widely in clinical presentations. Their specific patterns of academic performance and behavior represent final common pathways of neurodevelopmental strengths and deficits interacting with environmental, social, or cultural factors; temperament; educational experience; and intrinsic resilience (Table 48.2). Children with language weaknesses might have problems integrating and associating letters and sounds, decoding words, deriving meaning, and being able to comprehend passages. Children with early signs of a mathematics weakness might have difficulty with concepts of quantity or with adding or subtracting without using concrete representation (e.g., their fingers when calculating). Difficulty learning time concepts and confusion with directions (right/left) might also be observed. Poor fine motor control and coordination and poor planning can lead to writing problems. Attention and behavioral regulation weaknesses observed earlier can continue, and together with other executive functioning weaknesses (e.g., organization, initiation skills), further complicate the child's ability to acquire and generalize new knowledge. Children with weaknesses in WM may struggle to remember the steps necessary to complete an activity or problem-solve. In social settings, these children often have difficulty keeping up with more complex conversations.

</table>
Isolated neurodevelopmental dysfunction can lead to a specific academic disorder, but more often there is a combination of factors underlying weak academic performance. In addition to the dysfunction in neurodevelopmental domains as listed in the table, the clinician must also consider the possibility of limitations of intellectual and cognitive abilities or associated social and emotional problems.

In middle school children the shift in cognitive, academic, and regulatory demands can cause further difficulties for those with existing neurodevelopmental and executive challenges. In reading and writing, middle school children might present with transposition and sequencing errors; might struggle with root words, prefixes, and suffixes; might have difficulty with written expression; and might avoid reading and writing altogether. Challenges completing word problems in math are common. Difficulty with recall of information might also be experienced. Although observable in both lower and more advanced grades, behavioral, emotional, and social difficulties tend to become more salient in middle school children who experience cognitive or academic problems.

High school students can present with deficient reading comprehension, written expression, and slower processing efficiency. Difficulty in answering open-ended questions, dealing with abstract information, and producing executive control (e.g., self-monitoring, organization, planning, self-starting) is often reported.

**Academic Problems**

Reading disorders (see Chapter 50 ) can stem from any number of neurodevelopmental dysfunctions, as described earlier (see Table 48.2 ). Most often, language and auditory processing weaknesses are present, as evidenced by poor phonologic processing that results in deficiencies at the level of decoding individual words and, consequently, a delay in automaticity (e.g., acquiring a repertoire of words readers can identify instantly) that causes reading to be slow, laborious, and frustrating. Deficits in other core neurodevelopmental domains might also be present. Weak WM might make it difficult for a child to hold sounds and symbols in mind while breaking down words into their component
sounds, or might cause reading comprehension problems. Some children experience temporal-ordering weaknesses and struggle with reblending phonemes into correct sequences. Memory dysfunction can cause problems with recall and summarization of what was read. Some children with higher-order cognitive deficiencies have trouble understanding what they read because they lack a strong grasp of the concepts in a text. Although relatively rare as a cause of reading difficulty, problems with visual-spatial functions (e.g., visual perception) can cause children difficulty in recognizing letters. It is not unusual for children with reading problems to avoid reading practice, and a delay in reading proficiency becomes increasingly pronounced and difficult to remediate.

**Spelling and writing impairments** share many related underlying processing deficits with reading, so it is not surprising that the 2 disorders often occur simultaneously in school-age children (see Table 48.2). Core neurodevelopmental weaknesses that underlie spelling difficulties include phonologic and decoding difficulties, orthographic problems (coding letters and words into memory), and morphologic deficits (use of suffixes, prefixes, and root words). Problems in these areas can manifest as phonetically poor, yet visually comparable approximations to the actual word (*faght* for *fight*), spelling that is phonetically correct but visually incorrect (*fite* for *fight*), and inadequate spelling patterns (*played* as *plade*). Children with memory disorders might misspell words because of coding weaknesses. Others misspell because of poor auditory WM that interferes with their ability to process letters. Sequencing weaknesses often result in transposition errors when spelling.

**Writing difficulties** have been classified as *disorder of written expression*, or *dysgraphia* (see Table 48.2). Although many of the same dysfunctions described for reading and spelling can contribute to problems with writing, written expression is the most complex of the language arts, requiring synthesis of many neurodevelopmental functions (e.g., auditory, visual-spatial, memory, executive; see Chapter 51.2). Weaknesses in these functions can result in written output that is difficult to comprehend, disjointed, and poorly organized. The child with WM challenges can lose track of what the child intended to write. Attention deficits can make it difficult for a child to mobilize and sustain the mental effort, pacing, and self-monitoring demands necessary for writing. In many cases, writing is laborious because of an underlying *graphomotor dysfunction* (e.g., fluency does not keep pace with ideation and language production). Thoughts may also be forgotten or underdeveloped during writing because the mechanical effort is so taxing.
Weaknesses in mathematical ability, known as mathematics disorder or dyscalculia, require early intervention because math involves the assimilation of both procedural knowledge (e.g., calculations) and higher-order cognitive processes (e.g., WM) (see Table 48.2). There are many reasons why children experience failure in mathematics (see Chapter 51.1). It may be difficult for some to grasp and apply math concepts effectively and systematically; good mathematicians are able to use both verbal and perceptual conceptualization to understand such concepts as fractions, percentages, equations, and proportion. Children with language dysfunctions have difficulty in mathematics because they have trouble understanding their teachers' verbal explanations of quantitative concepts and operations and are likely to experience frustration in solving word problems and in processing the vast network of technical vocabulary in math. Mathematics also relies on visualization. Children who have difficulty forming and recalling visual imagery may be at a disadvantage in acquiring mathematical skills. They might experience problems writing numbers correctly, placing value locations, and processing geometric shapes or fractions. Children with executive dysfunction may be unable to focus on fine detail (e.g., operational signs), might take an impulsive approach to problem solving, engage in little or no self-monitoring, forget components of the problem, or commit careless errors. When a child's memory system is weak, the child might have difficulty recalling appropriate procedures and automatizing mathematical facts (e.g., multiplication tables). Moreover, children with mathematical disabilities can have superimposed mathematics phobias; anxiety over mathematics can be especially debilitating.

Nonacademic Problems

The impulsivity and lack of effective self-monitoring of children with executive dysfunction can lead to unacceptable actions that were unintentional. Children struggling with neurodevelopmental dysfunction can experience excessive performance anxiety, sadness, or clinical depression; declining self-esteem; and chronic fatigue. Some children lose motivation. They tend to give up and exhibit learned helplessness, a sense that they have no control over their destiny. Therefore they feel no need to exert effort and develop future goals. These children may be easily led toward dysfunctional interpersonal relationships, detrimental behaviors (e.g., delinquency), and the development of mental health disorders, such as mood disorders (see Chapter 39) or conduct disorder (Chapter...
Assessment and Diagnosis

Pediatricians have a critical role in identifying and treating the child with neurodevelopmental or executive dysfunction (Fig. 48.1). They have knowledge of the child's medical and family history and social-environmental circumstances and have the benefit of longitudinal contact over the course of routine health visits. Focused surveillance and screening will lead to early identification of developmental-behavioral and preacademic difficulties and interventions to facilitate optimal outcomes.
Primary Care Approach to Neurodevelopmental and Executive Dysfunction

Early Identification

**Surveillance**
- Birth and perinatal history
- Medical and family history
- Parent/caregiver concerns
- School or behavioral problems

**Screening**
- Standardized developmental screening
  - Emotional-behavioral screening tests
  - School achievement test scores

Medical Assessment

**History and Examination**
- Sleep
- Associated medical conditions
- Medications; substance abuse
- Growth; dysmorphic features; exam

**Neurodevelopmental & Emotional Assessment**
- Abnormal movements; motor coordination;
- “soft” neurological signs; local findings
- Questionnaires; interview; mid-level tests
- Report cards; teacher reports

Referral

- School testing
- Psychologist; Educational Specialist
- Developmental-Behavioral Pediatrician
- Medical subspecialist; developmental therapist

Evaluation and Diagnosis

**Psychoeducational Assessment**
- Intellectual ability
- Academic achievement
- Executive function
- Emotional-behavioral function

**Developmental and/or Psychosocial Assessment**
- Speech-language; Physical and Occupational Therapy; Psychology; Social Work;
- Neuropsychology;
- Psychiatry; Neurology; Genetics

Treatment

**Medical Home**
- Ensure adequate sleep, nutrition, exercise
- Optimize management of associated conditions
- Prescribe and manage medications if needed
- Support child and parents
- Explain test findings and “demystify”
- Advocate for appropriate services; advise on nonstandard therapies

**Educational Developmental Mental Health**
- Accommodations: school and home
- Interventions; tutoring; special education
- Resource services; developmental therapies
- Address executive dysfunction: modeling; games; strategies; programs
- Strengthen strengths and leverage affinities
- Counseling
A family history of a parent who still struggles with reading or time management, or an older sibling who has failed at school, should spur an increased level of monitoring. Risk factors in the medical history, such as extreme prematurity or chronic medical conditions, should likewise be flagged. Children with low birthweight and those born prematurely who appear to have been spared more serious neurologic problems might only manifest academic problems later in their school career. Nonspecific physical complaints or unexpected changes in behavior might be presenting symptoms. Warning signs might be subtle or absent, and parents might have concerns about their child's learning progress but may be reluctant to share these with the pediatrician unless prompted, such as through completion of standardized developmental screening questionnaires or direct questioning regarding possible concerns. There should be a low threshold for initiating further school performance screening and assessment if there are any “red flags.”

Review of school report cards can provide very useful information. In addition to patterns of grades in the various academic skill areas, it is also important to review ratings of classroom behavior and work habits. Group-administered standardized tests provide further information, although interpretation is required because poor scores could result from a learning disorder, ADHD, anxiety, lack of motivation, or some combination. Conversely, a discrepancy between above-average scores on standardized tests and unsatisfactory classroom performance could signal motivation or adjustment issues. Challenges related to homework can provide further insight regarding executive, academic skill, and behavioral factors.

Underlying or associated medical problems should be ruled out. Any suspicion of sensory difficulty should warrant referral for vision or hearing testing. The influence of chronic medical problems or potential side effects of medications should be considered. Sleep deprivation is increasingly being recognized as a contributor to academic problems, especially in middle and high school. Substance abuse must always be a consideration as well, especially in the adolescent previously achieving well who has shown a rapid decline in academic performance.

The physician should be alert for dysmorphic physical features, minor
congenital anomalies, or constellations of physical findings (e.g., cardiac and palatal anomalies in velocardiofacial syndrome) and should perform a detailed neurologic examination, including an assessment of fine and gross motor coordination and any involuntary movements or soft neurologic signs. Special investigations (e.g., genetic deletion-duplication microarray, electroencephalogram, MRI) are not always indicated in the absence of specific medical findings or a family history. Measures of brain function, such as functional MRI, offer insight into possible areas of neurodevelopmental dysfunction but remain primarily research tools.

Early signs of executive dysfunction can also be subtle and easily overlooked or misinterpreted. Informal inquiry might include questions about how children complete schoolwork or tasks, how organized or disorganized they are, how much guidance they need, whether they think through problems or respond and react too quickly, what circumstances or individuals affect their ability to employ EFs, how easily they begin tasks and activities, and how well they plan, manage belongings, and control their emotions.

Pediatricians who are interested in performing further assessment before referral, or who are practicing in areas where psychological testing resources are limited, can utilize standardized rating scales and inventories or brief, individually administered tests to narrow potential diagnoses and guide next steps in diagnosis and treatment. Such instruments, completed by the parents, teachers, and the child (if old enough), can provide information about emotions and behavior, patterns of academic performance, and traits associated with specific neurodevelopmental dysfunctions (see Chapter 32). Screening instruments such as the Pediatric Symptom Checklist and behavioral questionnaires such as the Child Behavior Checklist (CBCL) and Behavior Assessment System for Children, Second Edition (BASC-2) can aid in evaluation. Instruments more specifically focused on academic disorders, such as the Learning Disabilities Diagnostic Inventory, can be completed by the child's teacher to reveal the extent to which skill patterns in a particular area (e.g., reading, writing) are consistent with those of individuals known to have a learning disability.

Executive functions can be further assessed by instruments such as the Behavior Rating Inventory of Executive Function, Second Edition (BRIEF2), which provides a comprehensive measure of real-world behaviors that are closely tied to executive functioning in children age 5-18 yr. An alternative rating inventory of EF in children is the Comprehensive Executive Function
Inventory (CEFI). Tests that can be directly administered to gauge intellectual functioning include the Kaufman Brief Intelligence Test, Second Edition (KBIT-2) and Peabody Picture Vocabulary Test, Fourth Edition (PPVT 4; assessing receptive vocabulary). A relatively brief test of academic skills is the Wide Range Achievement Test 4 (WRAT4). It should be recognized that these are midlevel tests that can provide descriptive estimates of function but are not diagnostic.

Children who are struggling academically are entitled to evaluations in school. Such assessments are guaranteed in the United States under Public Law 101-476, the Individuals with Disabilities Education Act (IDEA). One increasingly common type of evaluation supported by IDEA is referred to as a response to intervention (RtI) model (see Chapter 51.1). In this model, students who are struggling with academic skills are initially provided research-based instruction. If a child does not respond to this instruction, an individualized evaluation by a multidisciplinary team is conducted. Children found to have attentional dysfunction and other disorders might qualify for educational accommodations in the regular classroom under Section 504 of the Rehabilitation Act of 1973 (504 plan).

The pediatrician should advise and support parents regarding steps to request evaluations by the school. Multidisciplinary evaluations are focused primarily on determining whether a student meets the eligibility criteria for special education services and to assist in developing an individualized educational plan (IEP) for those eligible for these services. Independent evaluations can provide second opinions outside the school setting. The multidisciplinary team should include a psychologist and preferably an educational diagnostician who can undertake a detailed analysis of academic skills and subskills to pinpoint where breakdowns are occurring in the processes of reading, spelling, writing, and mathematics. Other professionals should become involved, as needed, such as a speech-language pathologist, occupational therapist, and social worker. A mental health specialist can be valuable in identifying family-based issues or psychiatric disorders that may be complicating or aggravating neurodevelopmental dysfunctions.

In some cases, more in-depth examination of a child's neurocognitive status is warranted. This is particularly true for children who present with developmental or cognitive difficulties in the presence of a medical condition (e.g., epilepsy, traumatic brain injury, childhood cancers/brain tumors, genetic conditions). A neuropsychological evaluation involves comprehensive
assessment to understand brain functions across domains. Neuropsychological data are often analyzed together with other tests, such as MRI, to look for supporting evidence of any areas of difficulty (e.g., memory weaknesses associated with temporal lobe anomalies). Neuropsychologists can also provide more in-depth evaluation of EFs. Assessment of EFs is typically completed in an examination setting using tools specifically designed to identify any weaknesses in these functions. Although few tools are currently available to assess EF in preschool-age children, the assessment of school-age children is better established. Problems with EFs should be evaluated across measures and in different settings, particularly within the context of the child's daily demands.

**Treatment**

In addition to addressing any underlying or associated medical problems, the pediatrician can play an important role as a **consultant and advocate** in overseeing and monitoring the implementation of a comprehensive multidisciplinary management plan for children with neurodevelopmental dysfunctions. Most children require several of the following forms of intervention.

**Demystification**

Many children with neurodevelopmental dysfunctions have little or no understanding of the nature or sources of their academic difficulties. Once an appropriate descriptive assessment has been performed, it is important to explain to the child the nature of the dysfunction while delineating the child's strengths. This explanation should be provided in nontechnical language, communicating a sense of optimism and a desire to be helpful and supportive.

**Bypass Strategies (Accommodations)**

Numerous techniques can enable a child to circumvent neurodevelopmental dysfunctions. Such bypass strategies are ordinarily used in the regular classroom. Examples of bypass strategies include using a calculator while solving mathematical problems, writing essays with a word processor, presenting oral instead of written reports, solving fewer mathematical problems, being seated near the teacher to minimize distraction, presenting correctly solved
mathematical problems visually, and taking standardized tests untimed. These bypass strategies do not cure neurodevelopmental dysfunctions, but they minimize their academic and nonacademic effects and can provide a scaffold for more successful academic achievement.

Treatment of Neurodevelopmental Dysfunctions

Interventions can be implemented at home and in school to strengthen the weak links in academic skills. Reading specialists, mathematics tutors, and other professionals can use diagnostic data to select techniques that use a student's neurodevelopmental strengths to improve decoding skills, writing ability, or mathematical computation skills. **Remediation** need not focus exclusively on specific academic areas. Many students need assistance in acquiring study skills, cognitive strategies, and productive organizational habits.

Early identification is critical so that appropriate instructional interventions can be introduced to minimize the long-term effects of academic disorders. Any interventions should be empirically supported (e.g., phonologically based reading intervention has been shown to significantly improve reading skills in school-age children). Remediation may take place in a resource room or learning center at school and is usually limited to children who have met the educational criteria for special education resource services described earlier.

Interventions that can be implemented at home could include drills to aid the automatization of subskills, such as arithmetic facts or letter formations, or the use of phonologically based reading programs.

Treatment of Executive Dysfunction

Interventions to strengthen EFs can be implemented throughout childhood but are most effective if started at a young age. Preschool-age children first experience EFs by way of the **modeling, boundaries, and rules** observed and put in place by their parents/caregivers, and this modeled behavior must gradually become “internalized” by the child. Early **play** has been shown to be effective in promoting executive skills in younger children with games such as peek-a-boo (WM); pat-a-cake (WM and IC); follow the leader, Simon says, and “ring around the rosie” (self-control); imitation activities (attention and impulse control); matching and sorting games (organization and attention); and imaginary play (attention, WM, IC, self-monitoring, cognitive flexibility).
In school-age children it is crucial to establish consistent **cognitive and behavioral routines** that foster and maximize independent, goal-oriented problem solving and performance through mechanisms that include modification of the child's environment, modeling and guidance with the child, and positive reinforcement strategies. Interventions should promote **generalization** (teaching executive routines in the context of a problem, not as a separate skill) and should move from the external to the internal (from “external support” with active and directive modeling to an “internal process”). An intervention could proceed from external modeling of multistep problem-solving routines and external guidance in developing and implementing everyday routines, to practicing application and use of routines in everyday situations, to a gradual fading of external support and cueing of internal generation and use of executive skills. Such approaches should make the child a part of intervention planning, should avoid labeling, reward effort not outcomes, make interventions positive, and hold the child responsible for his or her efforts. Studies have consistently shown that a combination of medication and behavioral treatments are most effective, although evidence for long term efficacy is lacking. It is important that any treatment plans aimed at bolstering attention and executive functioning also include interventions that address the specific deficits associated with any comorbid diagnoses.

In addition to behavioral approaches, computerized **training programs** have been shown to strengthen WM skills in children using a computer game model. Generalized and lasting improvements in WM have been reported. Also evidencing positive outcomes are curriculum-based **classroom programs**, such as the *Tools of the Mind* (Tools) and *Promoting Alternative Thinking Strategies* (PATHS). Other promising approaches to EF intervention include **aerobic exercise**, shown to improve EFs through prefrontal cortex stimulation. *Martial arts* such as tae kwon do, which stresses discipline and self-regulation, has demonstrated improvements that generalize in many aspects of EFs and attention (e.g., sustained focus). Approaches that use **mindfulness techniques** are also gaining prominence. Formal **parenting interventions** have also demonstrated strong evidence for effectiveness. Four programs that have the most empirical support are the *Triple P, Parent-Child Interaction Therapy* (PCIT), *Incredible Years*, and *New Forest Parenting Programme*.

**Table 48.3** outlines interventions to target the specific components of EF. Although interventions may target each component separately, success will be determined by how well treatments can be integrated across settings and generalized to other areas of function. Whenever possible, working with more
than one EF simultaneously is encouraged as a means of scaffolding intervention and building on previously mastered skills.

**Table 48.3**

**Executive Function Categories: Presenting Symptoms, Suggested Dysfunction, and Potential Interventions**

<table>
<thead>
<tr>
<th>SYMPTOM/PRESENTING COMPLAINT</th>
<th>SUSPECTED AREA OF DYSFUNCTION</th>
<th>POSSIBLE “REAL WORLD” INTERVENTIONS</th>
</tr>
</thead>
</table>
| Acts before thinking         | Disinhibition/impulsivity    | *Increase structure in environment to set limits for inhibition problems.*  
| Interrupts                   |                              | Make behavior and work expectations clear and explicit; review with child.  
| Poor behavioral and/or       |                              | Post rules in view; point to them when child breaks rule.  
| emotional control            |                              | Teach response-delay techniques (e.g., counting to 10 before acting). |
| Cannot follow multistep      | Working memory               | Repeat instructions as needed.  
| instructions                 |                              | Keep instructions clear and concise.

| complete tasks               |                              |                                     |
| Gets “stuck”                 | Flexibility/shifting         | *Increase routine to the day.*  
| Trouble transitioning        |                              | Make schedule clear and public.  
| Does not adapt to change     |                              | Forewarn of any changes in schedule.  
|                             |                              | Give “2-minute warning” of time to change.  
|                             |                              | Make changes from one task to the next or one topic to the next, clear and explicit.  
|                             |                              | Shifting may be a problem of inhibiting, so apply |
Developmental Therapy

Speech-language pathologists offer intervention for children with various forms of language disability. Occupational therapists focus on sensorimotor skills, including the motor skills of students with writing problems, and physical therapists address gross motor incoordination.

Curriculum Modifications

Many children with neurodevelopmental dysfunctions require alterations in the school curriculum to succeed, especially as they progress through secondary school. Students with memory weaknesses might need to have their courses selected for them so that they do not have an inordinate cumulative memory load in any single semester. The timing of foreign language learning, the selection of a mathematics curriculum, and the choice of science courses are critical issues for many of these struggling adolescents.

Strengthening of Strengths

Affected children need to have their affinities, potentials, and talents identified clearly and exploited widely. It is as important to augment strengths as it is to attempt to remedy deficiencies. Athletic skills, artistic inclinations, creative talents, and mechanical abilities are among the potential assets of certain students who are underachieving academically. Parents and school personnel need to create opportunities for such students to build on these assets and to achieve respect and praise for their efforts. These well-developed personal assets can ultimately have implications for the transition into young adulthood, including career or college selection.

Individual and Family Counseling

When academic difficulties are complicated by family problems or identifiable psychiatric disorders, psychotherapy may be indicated. Mental health professionals may offer long-term or short-term therapy. Such intervention may involve the child alone or the entire family. Cognitive-behavioral therapy is
especially effective for mood and anxiety disorders. It is essential that the therapist have a firm understanding of the nature of a child's neurodevelopmental dysfunctions.

**Nonstandard Therapies**

A variety of treatment methods for neurodevelopmental dysfunctions have been proposed that currently have little to no known scientific evidence of efficacy. This list includes dietary interventions (vitamins, elimination of food additives or potential allergens), neuromotor programs or medications to address vestibular dysfunction, eye exercises, filters, tinted lenses, and various technologic devices. Parents should be cautioned against expending the excessive amounts of time and financial resources usually demanded by these remedies. In many cases, it is difficult to distinguish the nonspecific beneficial effects of increased support and attention paid to the child from the supposed target effects of the intervention.

**Medication**

Psychopharmacologic agents may be helpful in lessening the toll of some neurodevelopmental dysfunctions. Most often, **stimulants** are used in the treatment of children with attention deficits. Although most children with attention deficits have other associated dysfunctions, such as language disorders, memory problems, motor weaknesses, or social skill deficits, medications such as methylphenidate, dextroamphetamine, lisdexamfetamine, and mixed amphetamine salts, as well as nonstimulants such as \( \alpha_2 \)-adrenergic agonists and **atomoxetine**, can be important adjuncts to treatment by helping some children focus more selectively and control their impulsivity. When depression or excessive anxiety is a significant component of the clinical picture, **antidepressants** or **anxiolytics** may be helpful. Other drugs may improve behavioral control (see Chapter 33). Children receiving medication need regular follow-up visits that include a history to check for side effects, a review of current behavioral checklists, a complete physical examination, and appropriate modifications of the medication dose. Periodic trials off medication are recommended to establish whether the medication is still necessary.
American Academy of Pediatrics, Committee on Children with Disabilities. The pediatrician's role in development and implementation of an Individual Education Plan (IEP) and/or an Individual Family Service Plan (IFSP). *Pediatrics*. 1999;104:124–127.

Attention-deficit/hyperactivity disorder (ADHD) is the most common neurobehavioral disorder of childhood, among the most prevalent chronic health conditions affecting school-aged children, and one of the most extensively studied neurodevelopmental disorders of childhood. ADHD is characterized by inattention, including increased distractibility and difficulty sustaining attention; poor impulse control and decreased self-inhibitory capacity; and motor overactivity and motor restlessness (Table 49.1 and Fig. 49.1). Definitions vary in different countries (Table 49.2). Affected children usually experience academic underachievement, problems with interpersonal relationships with family members and peers, and low self-esteem. ADHD often co-occurs with other emotional, behavioral, language, and learning disorders (Table 49.3). Evidence also suggests that for many people, the disorder continues with varying manifestations across the life cycle, leading to significant under- and unemployment, social dysfunction and increased risk of antisocial behaviors (e.g., substance abuse), difficulty maintaining relationships, encounters with the law, death from suicide, and, if untreated, accidents (Figs. 49.2 and 49.3).

**Table 49.1**

**DSM-5 Diagnostic Criteria for Attention-Deficit/Hyperactivity Disorder (ADHD)**

A. A persistent pattern of inattention and/or hyperactivity/impulsivity that interferes with functioning or development, as characterized by (1) and/or (2):
1. **Inattention:** Six (or more) of the following symptoms of inattention have persisted for ≥6 mo to a degree that is inconsistent with development level and that negatively impacts directly on social and academic/occupational activities:
   a. Often fails to give close attention to details or makes careless mistakes in schoolwork, at work, or during other activities (e.g., overlooks or misses details, work is inaccurate).
   b. Often has difficulty sustaining attention in tasks or play activities.
   c. Often does not seem to listen when spoken to directly.
   d. Often does not follow through on instructions and fails to finish schoolwork, chores, or duties in the workplace (not due to oppositional behavior or failure to understand instructions).
   e. Often has difficulty organizing tasks and activities.
   f. Often avoids, dislikes, or is reluctant to engage in tasks that require sustained mental effort (e.g., schoolwork, homework).
   g. Often loses things necessary for tasks or activities (e.g., toys, school assignments, pencils, books, tools).
   h. Is often easily distracted by extraneous stimuli.
   i. Is often forgetful in daily activities.

2. **Hyperactivity/impulsivity:** Six (or more) of the following symptoms of inattention have persisted for ≥6 mo to a degree that is inconsistent with development level and that negatively impacts directly on social and academic/occupational activities.
   a. Often fidgets with hands or feet or squirms in seat.
   b. Often leaves seat in classroom or in other situations in which remaining seated is expected.
   c. Often runs about or climbs excessively in situations in which it is inappropriate (in adolescents or adults, may be limited to subjective feelings of restlessness).
   d. Often has difficulty playing or engaging in leisure activities quietly.
   e. Is often “on the go” or often acts as if “driven by a motor.”
f. Often talks excessively.
   Impulsivity.
g. Often blurts out answers before questions have been completed.
h. Often has difficulty awaiting turn.
i. Often interrupts or intrudes on others (e.g., butts into conversations or games).

B. Several inattentive or hyperactive/impulsive symptoms were present before 12 yr of age.

C. Several inattentive or hyperactive/impulsive symptoms are present in 2 or more settings (e.g., at school [or work] or at home) and is documented independently.

D. There is clear evidence of clinically significant impairment in social, academic, or occupational functioning.

E. Symptoms do not occur exclusively during the course of schizophrenia, or another psychotic disorder, and are not better accounted for by another mental disorder (e.g., mood disorder, anxiety disorder, dissociative disorder, personality disorder, substance intoxication or withdrawal).

**Code Based on Type**

314.01 Attention-deficit/hyperactivity disorder, combined presentation: if both Criteria A1 and A2 are met for the past 6 mo.
314.00 Attention-deficit/hyperactivity disorder, predominantly inattentive presentation: if Criterion A1 is met but Criterion A2 is not met for the past 6 mo.
314.01 Attention-deficit/hyperactivity disorder, predominantly hyperactive-impulsive presentation: if Criterion A2 is met but Criterion A1 is not met for the past 6 mo.
Specify if:

**Mild:** Few, if any, symptoms in excess of those required to make the diagnosis are present, and if the symptoms result in no more than minor impairments in social and occupational functioning.

**Moderate:** Symptoms or functional impairment between “mild” and “severe” are present.

**Severe:** Many symptoms in excess of those required to make the
diagnosis, or several symptoms that are particularly severe, are present, or the symptoms result in marked impairment in social or occupational functioning.

Note: Coexisting conditions with possible ADHD presentation include oppositional defiant disorder, anxiety disorders, conduct disorder, depressive disorders, learning disorders, and language disorders. Presence of one or more of the symptoms of these disorders can fall within the spectrum of normal behavior, whereas a range of these symptoms may be problematic but fall short of meeting the full criteria for the disorder.

**FIG. 49.2** Possible developmental impacts of attention-deficit/hyperactivity disorder. (From Verkuijl N, Perkins M, Fazel M: Childhood attention-deficit/hyperactivity disorder, *BMJ* 350:h2168, 2015, Fig 1, p 145.)
Etiology

No single factor determines the expression of ADHD; ADHD may be a final common pathway for a variety of complex brain developmental processes. Mothers of children with ADHD are more likely to experience birth complications, such as toxemia, lengthy labor, and complicated delivery. Maternal drug use has also been identified as a risk factor in the development of ADHD. Maternal smoking, alcohol use during pregnancy, and prenatal or postnatal exposure to lead are frequently linked to the attentional difficulties associated with development of ADHD, but less clearly to hyperactivity. Food coloring and preservatives have inconsistently been associated with increased hyperactivity in children with ADHD.

There is a strong genetic component to ADHD. Genetic studies have primarily implicated 2 candidate genes, the dopamine transporter gene (DAT1) and a
particular form of the dopamine 4 receptor gene \textit{(DRD4)}, in the development of ADHD. Additional genes that might contribute to ADHD include \textit{DOCK2}, associated with a pericentric inversion 46N inv(3)(p14:q21) involved in cytokine regulation; a sodium-hydrogen exchange gene; and \textit{DRD5, SLC6A3, DBH, SNAP25, SLC6A4,} and \textit{HTR1B}.

Structural and functional abnormalities of the brain have been identified in children with ADHD. These include dysregulation of the frontal subcortical circuits, small cortical volumes in this region, widespread small-volume reduction throughout the brain, and abnormalities of the cerebellum, particularly midline/vermian elements (see \textit{Pathogenesis}). Brain injury also increases the risk of ADHD. For example, 20% of children with severe traumatic brain injury are reported to have subsequent onset of substantial symptoms of impulsivity and inattention. However, ADHD may also increase the risk of traumatic brain injury.

Psychosocial family stressors can also contribute to or exacerbate the symptoms of ADHD, including poverty, exposure to violence, and undernutrition or malnutrition.

**Epidemiology**

Studies of the prevalence of ADHD worldwide have generally reported that 5–10% of school-age children are affected, although rates vary considerably by country, perhaps in part because of differing sampling and testing techniques. Rates may be higher if symptoms (inattention, impulsivity, hyperactivity) are considered in the absence of functional impairment. The prevalence rate in adolescent samples is 2–6%. Approximately 2% of adults meet criteria for ADHD. ADHD is often underdiagnosed in children and adolescents. Youth with ADHD are often undertreated with respect to what is known about the needed and appropriate doses of medications. Many children with ADHD also present with comorbid neuropsychiatric diagnoses, including oppositional defiant disorder, conduct disorder, learning disabilities, and anxiety disorders. The incidence of ADHD appears increased in children with neurologic disorders such as the epilepsies, neurofibromatosis, and tuberous sclerosis (see \textit{Table 49.3}).

**Pathogenesis**
Brain MRI studies in children with ADHD indicate a reduction or even loss of the normal hemispheric asymmetry in the brain, as well as smaller brain volumes of specific structures, such as the prefrontal cortex and basal ganglia. Children with ADHD have approximately a 5–10% reduction in the volume of these brain structures. MRI findings suggest low blood flow to the striatum. Functional MRI data suggest deficits in dispersed functional networks for selective and sustained attention in ADHD that include the striatum, prefrontal regions, parietal lobe, and temporal lobe. The prefrontal cortex and basal ganglia are rich in dopamine receptors. This knowledge, plus data about the dopaminergic mechanisms of action of medication treatment for ADHD, has led to the dopamine hypothesis, which postulates that disturbances in the dopamine system may be related to the onset of ADHD. Fluorodopa positron emission tomography (PET) scans also support the dopamine hypothesis through the identification of low levels of dopamine activity in adults with ADHD.

Clinical Manifestations

Development of the Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition (DSM-5) criteria leading to the diagnosis of ADHD has occurred mainly in field trials with children 5-12 yr of age (see Table 49.1 and Fig. 49.1). The DSM-5 notably expanded the accepted age of onset for symptoms of ADHD, and studies utilizing these broader criteria demonstrate a good correlation with data from DSM-IV criteria–based studies. The current DSM-5 criteria state that the behavior must be developmentally inappropriate (substantially different from that of other children of the same age and developmental level), must begin before age 12 yr, must be present for at least 6 mo, must be present in 2 or more settings and reported as such by independent observers, and must not be secondary to another disorder. DSM-5 identifies three presentations of ADHD. The inattentive presentation is more common in females and is associated with relatively high rates of internalizing symptoms (anxiety and low mood). The other two presentations, hyperactive-impulsive and combined, are more often diagnosed in males (see Fig. 49.1).

Clinical manifestations of ADHD may change with age (see Fig. 49.2). The symptoms may vary from motor restlessness and aggressive and disruptive behavior, which are common in preschool children, to disorganized, distractible, and inattentive symptoms, which are more typical in older adolescents and adults. ADHD is often difficult to diagnose in preschoolers because
Distractibility and inattention are often considered developmental norms during this period.

## Diagnosis and Differential Diagnosis

A diagnosis of ADHD is made primarily in clinical settings after a thorough evaluation, including a careful history and clinical interview to rule in or to identify other causes or contributing factors; completion of behavior rating scales by different observers from at least 2 settings (e.g., teacher and parent); a physical examination; and any necessary or indicated laboratory tests that arise from conditions suspected based on history and/or physical examination. It is important to systematically gather and evaluate information from a variety of sources, including the child, parents, teachers, physicians, and when appropriate, other caretakers, over the course of both diagnosis and subsequent management.

### Clinical Interview and History

The clinical interview allows a comprehensive understanding of whether the symptoms meet the diagnostic criteria for ADHD. During the interview, the clinician should gather information pertaining to the history of the presenting problems, the child's overall health and development, and the social and family history. The interview should emphasize factors that might affect the development or integrity of the central nervous system or reveal chronic illness, sensory impairments, sleep disorders, or medication use that might affect the child's functioning. Disruptive social factors, such as family discord, situational stress, and abuse or neglect, can result in hyperactive or anxious behaviors. A family history of first-degree relatives with ADHD, mood or anxiety disorders, learning disability, antisocial disorder, or alcohol or substance abuse might indicate an increased risk of ADHD and comorbid conditions.

### Behavior Rating Scales

Behavior rating scales are useful in establishing the magnitude and pervasiveness of the symptoms, but are not sufficient alone to make a diagnosis of ADHD. A variety of well-established behavior rating scales have obtained good results in discriminating between children with ADHD and controls. These measures include, but are not limited to, the Vanderbilt ADHD Diagnostic...
Rating Scale, the Conner Rating Scales (parent and teacher), ADHD Rating Scale 5, the Swanson, Nolan, and Pelham Checklist (SNAP), and the ADD-H: Comprehensive Teacher Rating Scale (ACTeRS). Other broad-band checklists, such as the Achenbach Child Behavior Checklist (CBCL) or Behavioral Assessment Scale for Children (BASC), are useful, particularly when the child may be experiencing coexisting problems in other areas (anxiety, depression, conduct problems). Some, such as the BASC, include a validation scale to help determine the reliability of a given observer's assessment of the child.

Physical Examination and Laboratory Findings

No laboratory tests are available to identify ADHD in children. The presence of hypertension, ataxia, or symptoms of a sleep or thyroid disorder should prompt further neurologic or endocrine diagnostic evaluation. Impaired fine motor movement and poor coordination and other subtle neurologic motor signs (difficulties with finger tapping, alternating movements, finger-to-nose, skipping, tracing a maze, cutting paper) are common but not sufficiently specific to contribute to a diagnosis of ADHD. The clinician should also identify any possible vision or hearing problems. The clinician should consider testing for elevated lead levels in children who present with some or all of the diagnostic criteria, if these children are exposed to environmental factors that might put them at risk (substandard housing, old paint, proximity to highway with deposition of lead in topsoil from automobile exhaust years ago). Behavior in the structured laboratory setting might not reflect the child's typical behavior in the home or school environment. Thus, computerized attentional tasks and electroencephalographic assessments are not needed to make the diagnosis, and compared to the clinical gold standard, these are subject to false-positive and false-negative errors. Similarly, observed behavior in a physician's office is not sufficient to confirm or rule-out the diagnosis of ADHD.

Differential Diagnosis

Chronic illnesses, such as migraine headaches, absence seizures, asthma/allergies, hematologic disorders, diabetes, and childhood cancer, affect up to 20% of U.S. children and can impair children's attention and school performance, because of either the disease itself or the medications used to treat or control the underlying illness (medications for asthma, corticosteroids,
anticonvulsants, antihistamines) (see Table 49.3). In older children and adolescents, substance abuse can result in declining school performance and inattentive behavior (see Chapter 140).

**Sleep disorders**, including those secondary to chronic upper airway obstruction from enlarged tonsils and adenoids, often result in behavioral and emotional symptoms that can resemble or exacerbate ADHD (see Chapter 31). Periodic leg movements of sleep/restless leg syndrome has been associated with attentional symptoms, and inquiry regarding this should be made during the history. Behavioral and emotional disorders can cause disrupted sleep patterns as well.

Depression and anxiety disorders can cause many of the same symptoms as ADHD (inattention, restlessness, inability to focus and concentrate on work, poor organization, forgetfulness) but can also be comorbid conditions (see Chapters 38 and 39). Obsessive-compulsive disorder can mimic ADHD, particularly when recurrent and persistent thoughts, impulses, or images are intrusive and interfere with normal daily activities. Adjustment disorders secondary to major life stresses (death of a close family member, parents' divorce, family violence, parents' substance abuse, a move, shared social trauma such as bombings or other attacks) or parent–child relationship disorders involving conflicts over discipline, overt child abuse and/or neglect, or overprotection can result in symptoms similar to those of ADHD.

Although ADHD is believed to result from primary impairment of attention, impulse control, and motor activity, there is a high prevalence of comorbidity with other neuropsychiatric disorders (see Table 49.3). Of children with ADHD, 15–25% have learning disabilities, 30–35% have developmental language disorders, 15–20% have diagnosed mood disorders, and 20–25% have coexisting anxiety disorders. Children with ADHD can also have concurrent diagnoses of sleep disorders, memory impairment, and decreased motor skills.

## Treatment

### Psychosocial Treatments

Once the diagnosis of ADHD has been established, the parents and child should be educated with regard to the ways ADHD can affect learning, behavior, self-esteem, social skills, and family function. The clinician should set goals for the family to improve the child's interpersonal relationships, develop study skills,
and decrease disruptive behaviors. Parent support groups with appropriate professional consultation to such groups can be very helpful.

**Behaviorally Oriented Treatments**

Treatments geared toward behavioral management often occur in the time frame of 8-12 sessions. The goal of such treatment is for the clinician to identify targeted behaviors that cause impairment in the child's life (disruptive behavior, difficulty in completing homework, failure to obey home or school rules) and for the child to work on progressively improving his or her skill in these areas. The clinician should guide the parents and teachers in setting appropriate expectations, consistently implementing rewards to encourage desired behaviors and consequences to discourage undesired behaviors. In short-term comparison trials, stimulants have been more effective than behavioral treatments used alone in improving core ADHD symptoms for most children. Behavioral interventions are modestly successful at improving core ADHD symptoms and are considered the first-line treatment in preschool-age children with ADHD. In addition, behavioral treatment may be particularly useful for children with comorbid anxiety, complex comorbidities, family stressors, and when combined with medication.

**Medications**

The most widely used medications for the treatment of ADHD are the presynaptic dopaminergic agonists, commonly called psychostimulant medications, including methylphenidate, dextmethylphenidate, amphetamine, and various amphetamine and dextroamphetamine preparations. Longer-acting, once-daily forms of each of the major types of stimulant medications are available and facilitate compliance with treatment and coverage over a longer period (see Table 49.3). When starting a stimulant, the clinician can select either a methylphenidate-based or an amphetamine-based compound. If a full range of methylphenidate dosages is used, approximately 25% of patients have an optimal response on a low dose (<0.5 mg/kg/day for methylphenidate, <0.25 mg/kg/day for amphetamines), 25% on a medium dose (0.5-1.0 mg/kg/day for methylphenidate, 0.25-0.5 mg/kg/day for amphetamines), and 25% on a high dose (1.0-1.5 mg/day for methylphenidate, 0.5-0.75 mg/kg/day for amphetamine); another 25% will be unresponsive or will have side effects, making that drug particularly unpalatable for the family (See Table 33.2 for more
Over the first 4 wk of treatment, the physician should increase the medication dose as tolerated (keeping side effects minimal to absent) to achieve maximum benefit. If this strategy does not yield satisfactory results, or if side effects prevent further dose adjustment in the presence of persisting symptoms, the clinician should use an alternative class of stimulants that was not used previously. If a methylphenidate compound is unsuccessful, the clinician should switch to an amphetamine product. If satisfactory treatment results are not obtained with the 2nd stimulant, clinicians may choose to prescribe atomoxetine, a noradrenergic reuptake inhibitor that has been approved by the U.S. Food and Drug Administration (FDA) for the treatment of ADHD in children, adolescents, and adults. Atomoxetine should be initiated at a dose of 0.3 mg/kg/day and titrated over 1-3 wk to a maximum total daily dosage of 1.2-1.4 mg/kg/day. The dose should be divided into twice-daily portions. Once-daily dosing appears to be associated with a high incidence of treatment failure. Long-acting guanfacine and clonidine are also FDA approved for the treatment of ADHD (see Chapter 33). These medications can also treat motor and vocal tics and so may be a reasonable choice in a child with a comorbid tic disorder. Drugs to treat ADHD do not increase the incidence of tics in children predisposed to a tic disorder. In the past, tricyclic antidepressants have been used to treat ADHD, but TCAs are rarely used now because of the risk of sudden death, particularly if an overdose is taken.

The clinician should consider careful monitoring of medication a necessary component of treatment in children with ADHD. When physicians prescribe medications for the treatment of ADHD, they tend to use lower-than-optimal doses. Optimal treatment usually requires somewhat higher doses than tend to be found in routine practice settings. All-day preparations are also useful to maximize positive effects and minimize side effects, and regular medication follow-up visits should be offered (≥4 times/yr) as opposed to the twice-yearly medication visits often used in standard community care settings.

Medication alone may not be sufficient to treat ADHD in children, particularly when children have multiple psychiatric disorders or a stressed home environment. When children do not respond to medication, it may be appropriate to refer them to a mental health specialist. Consultation with a child psychiatrist, developmental-behavioral pediatrician, or psychologist can also be beneficial to determine the next steps for treatment, including adding other components and supports to the overall treatment program. Evidence suggests that children who
receive careful medication management, accompanied by frequent treatment follow-up, all within the context of an educative, supportive relationship with the primary care provider, are likely to experience behavioral gains. Stimulant drugs used to treat ADHD may be associated with an increased risk of adverse cardiovascular events, including sudden cardiac death, myocardial infarction, and stroke, in young adults and rarely in children. In some of the reported cases, the patient had an underlying disorder, such as hypertrophic obstructive cardiomyopathy, which is made worse by sympathomimetic agents. These events are rare but nonetheless warrant consideration before initiating treatment and during monitoring of therapy with stimulants. Children with a positive personal or family history of cardiomyopathy, arrhythmias, or syncope require an electrocardiogram and possible cardiology consultation before a stimulant is prescribed (Fig. 49.4).

**FIG. 49.4** Cardiac evaluation of children and adolescents with ADHD receiving or being considered for stimulant medications. (From Perrin JM, Friedman RA, Knilans TK: Cardiovascular monitoring and stimulant drugs for attention-deficit/hyperactivity disorder, *Pediatrics* 122:451–453, 2008.)

**Prognosis**
A childhood diagnosis of ADHD often leads to persistent ADHD throughout the life span. From 60–80% of children with ADHD continue to experience symptoms in adolescence, and up to 40–60% of adolescents exhibit ADHD symptoms into adulthood. In children with ADHD, a reduction in hyperactive behavior often occurs with age. Other symptoms associated with ADHD can become more prominent with age, such as inattention, impulsivity, and disorganization, and these exact a heavy toll on young adult functioning. Risk factors in children with untreated ADHD as they become adults include engaging in risk-taking behaviors (sexual activity, delinquent behaviors, substance use), educational underachievement or employment difficulties, and relationship difficulties. With proper treatment, the risks associated with ADHD, including injuries, can be significantly reduced. Consistent treatment with medication and adjuvant therapies appears to lower the risk of adverse outcomes, such as substance abuse.

**Prevention**

Parent training can lead to significant improvements in preschool children with ADHD symptoms, and parent training for preschool youth with ADHD can reduce oppositional behavior. To the extent that parents, teachers, physicians, and policymakers support efforts for earlier detection, diagnosis, and treatment, prevention of long-term adverse effects of ADHD on affected children's lives should be reconsidered within the lens of prevention. Given the effective treatments for ADHD now available, and the well-documented evidence about the long-term effects of untreated or ineffectively treated ADHD on children and youth, prevention of these consequences should be within the grasp of physicians and the children and families with ADHD for whom we are responsible.

Spencer TJ. ADHD and comorbidity in childhood. *J Clin*
The most current definition of *dyslexia* is now codified in U.S. Federal law (First Step Act of 2018, PL: 115–391): “The term *dyslexia* means an unexpected difficulty in reading for an individual who has the intelligence to be a much better reader, most commonly caused by a difficulty in the phonological processing (the appreciation of the individual sounds of spoken language), which affects the ability of an individual to speak, read, and spell.” In typical readers, development of reading and intelligence quotient (IQ) are dynamically linked over time. In dyslexic readers, however, a developmental uncoupling occurs between reading and IQ (*Fig. 50.1*), such that reading achievement is significantly below what would be expected given the individual's IQ. The discrepancy between reading achievement and IQ provides the long-sought empirical evidence for the seeming paradox between cognition and reading in individuals with developmental dyslexia, and this discrepancy is now recognized in the Federal definition as unexpected difficulty in reading.
Etiology

Dyslexia is familial, occurring in 50% of children who have a parent with dyslexia, in 50% of the siblings of dyslexic persons, and in 50% of the parents of dyslexic persons. Such observations have naturally led to a search for genes responsible for dyslexia, and at one point there was hope that heritability would be related to a small number of genes. Genome-wide association studies (GWAS), however, have demonstrated that a large number of genes are involved, each producing a small effect. Advances in genetics have confirmed what the GWAS suggested, that complex traits such as reading are the work of thousands of genetic variants, working in concert (see Chapter 99). Thus, pediatricians should be wary of recommending any genetic test to their patients that purports to diagnose dyslexia in infancy or before language and reading have even emerged. It is unlikely that a single gene or even a few genes will reliably identify people with dyslexia. Rather, dyslexia is best explained by multiple genes, each contributing a small amount toward the expression of dyslexia.
Epidemiology

Dyslexia is the most common and most comprehensively studied of the learning disabilities, affecting 80% of children identified as having a learning disability. Dyslexia may be the most common neurobehavioral disorder affecting children, with prevalence rates ranging from 20% in unselected population-based samples to much lower rates in school-identified samples. The low prevalence rate in school-identified samples may reflect the reluctance of schools to identify dyslexia. Dyslexia occurs with equal frequency in boys and girls in survey samples in which all children are assessed. Despite such well-documented findings, schools continue to identify more boys than girls, probably reflecting the more rambunctious behavior of boys who come to the teacher’s attention because of misbehavior, while girls with reading difficulty, who are less likely to be misbehaving, are also less likely to be identified by the schools. Dyslexia fits a dimensional model in which reading ability and disability occur along a continuum, with dyslexia representing the lower tail of a normal distribution of reading ability.

Pathogenesis

Evidence from a number of lines of investigation indicates that dyslexia reflects deficits within the language system, and more specifically, within the phonologic component of the language system engaged in processing the sounds of speech. Individuals with dyslexia have difficulty developing an awareness that spoken words can be segmented into smaller elemental units of sound (phonemes), an essential ability given that reading requires that the reader map or link printed symbols to sound. Increasing evidence indicates that disruption of attentional mechanisms may also play an important role in reading difficulties.

Functional brain imaging in both children and adults with dyslexia demonstrates an inefficient functioning of left hemisphere posterior brain systems, a pattern referred to as the neural signature of dyslexia (Fig. 50.2). Although functional magnetic resonance imaging (fMRI) consistently demonstrates differences between groups of dyslexic compared to typical readers, brain imaging is not able to differentiate an individual case of a dyslexic reader from a typical reader and thus is not useful in diagnosing dyslexia.
Clinical Manifestations

Reflecting the underlying phonologic weakness, children and adults with dyslexia manifest problems in both spoken and written language. Spoken language difficulties are typically manifest by mispronunciations, lack of glibness, speech that lacks fluency with many pauses or hesitations and “ums,” word-finding difficulties with the need for time to summon an oral response, and the inability to come up with a verbal response quickly when questioned; these reflect sound-based, not semantic or knowledge-based, difficulties.

Struggles in decoding and word recognition can vary according to age and developmental level. The cardinal signs of dyslexia observed in school-age children and adults are a labored, effortful approach to reading involving decoding, word recognition, and text reading. Listening comprehension is typically robust. Older children improve reading accuracy over time, but without commensurate gains in reading fluency; they remain slow readers. Difficulties in spelling typically reflect the phonologically based difficulties observed in oral reading. Handwriting is often affected as well.

History often reveals early subtle language difficulties in dyslexic children. During the preschool and kindergarten years, at-risk children display difficulties
playing rhyming games and learning the names for letters and numbers. Kindergarten assessments of these language skills can help identify children at risk for dyslexia. Although a dyslexic child enjoys and benefits from being read to, the child might avoid reading aloud to the parent or reading independently.

Dyslexia may coexist with attention-deficit/hyperactivity disorder (see Chapter 49); this comorbidity has been documented in both referred samples (40% comorbidity) and nonreferred samples (15% comorbidity).

**Diagnosis**

A large achievement gap between typical and dyslexic readers is evident as early as 1st grade and persists (Fig. 50.3). These findings provide strong evidence and impetus for early screening and identification of and early intervention for young children at risk for dyslexia. One source of potentially powerful and highly accessible screening information is the teacher's judgment about the child's reading and reading-related skills. Evidence-based screening can be carried out as early as kindergarten, and also in grades 1-3, by the child's teacher. The teachers' responses to a small set of questions (10-12 questions) predict a pool of children who are at risk for dyslexia with a high degree of accuracy. Screening takes less than 10 minutes, is completed on a tablet, and is extremely efficient and economical. Children found to be at-risk will then have further assessment and, if diagnosed as dyslexic, should receive evidence-based intervention.
Dyslexia is a clinical diagnosis, and history is especially critical. The clinician seeks to determine through history, observation, and psychometric assessment, if there are unexpected difficulties in reading (based on the person's intelligence, chronological/grade, level of education or professional status) and associated linguistic problems at the level of phonologic processing. No single test score is pathognomonic of dyslexia. The diagnosis of dyslexia should reflect a thoughtful synthesis of all clinical data available.

Dyslexia is distinguished from other disorders that can prominently feature reading difficulties by the unique, circumscribed nature of the phonologic deficit, one that does not intrude into other linguistic or cognitive domains. A core assessment for the diagnosis of dyslexia in children includes tests of language, particularly phonology; reading, including real and pseudowords; reading fluency; spelling; and tests of intellectual ability. Additional tests of memory, general language skills, and mathematics may be administered as part of a more comprehensive evaluation of cognitive, linguistic, and academic function. Some schools use a response to intervention (RtI) approach to identifying reading disabilities (see Chapter 51.1 ). Once a diagnosis has been made, dyslexia is a permanent diagnosis and need not be reconfirmed by new assessments.
For informal screening, in addition to a careful history, the primary care physician in an office setting can listen to the child read aloud from the child's own grade-level reader. Keeping a set of graded readers available in the office serves the same purpose and eliminates the need for the child to bring in schoolbooks. Oral reading is a sensitive measure of reading accuracy and fluency. The most consistent and telling sign of a reading disability in an accomplished young adult is slow and laborious reading and writing. In attempting to read aloud, most children and adults with dyslexia display an effortful approach to decoding and recognizing single words, an approach in children characterized by hesitations, mispronunciations, and repeated attempts to sound out unfamiliar words. In contrast to the difficulties they experience in decoding single words, persons with dyslexia typically possess the vocabulary, syntax, and other higher-level abilities involved in comprehension.

The failure either to recognize or to measure the lack of fluency in reading is perhaps the most common error in the diagnosis of dyslexia in older children and accomplished young adults. Simple word identification tasks will not detect dyslexia in a person who is accomplished enough to be in honors high school classes or to graduate from college or obtain a graduate degree. Tests relying on the accuracy of word identification alone are inappropriate to use to diagnose dyslexia because they show little to nothing of the struggle to read. Because they assess reading accuracy but not automaticity (speed), the types of reading tests used for school-age children might provide misleading data on bright adolescents and young adults. The most critical tests are those that are timed; they are the most sensitive in detecting dyslexia in a bright adult. Few standardized tests for young adult readers are administered under timed and untimed conditions; the Nelson-Denny Reading Test is an exception. The helpful Test of Word Reading Efficiency (TOWRE) examines simple word reading under timed conditions. Any scores obtained on testing must be considered relative to peers with the same degree of education or professional training.

Management

The management of dyslexia demands a life-span perspective. Early in life the focus is on remediation of the reading problem. Applying knowledge of the importance of early language, including vocabulary and phonologic skills, leads to significant improvements in children's reading accuracy, even in predisposed children. As a child matures and enters the more time-demanding setting of
middle and then high school, the emphasis shifts to the important role of providing accommodations. Based on the work of the National Reading Panel, evidence-based reading intervention methods and programs are identified. Effective intervention programs provide systematic instruction in 5 key areas: phonemic awareness, phonics, fluency, vocabulary, and comprehension strategies. These programs also provide ample opportunities for writing, reading, and discussing literature.

Taking each component of the reading process in turn, effective interventions improve phonemic awareness: the ability to focus on and manipulate phonemes (speech sounds) in spoken syllables and words. The elements found to be most effective in enhancing phonemic awareness, reading, and spelling skills include teaching children to manipulate phonemes with letters; focusing the instruction on 1 or 2 types of phoneme manipulations rather than multiple types; and teaching children in small groups. Providing instruction in phonemic awareness is necessary but not sufficient to teach children to read. Effective intervention programs include teaching phonics, or making sure that the beginning reader understands how letters are linked to sounds (phonemes) to form letter-sound correspondences and spelling patterns. The instruction should be explicit and systematic; phonics instruction enhances children's success in learning to read, and systematic phonics instruction is more effective than instruction that teaches little or no phonics or teaches phonics casually or haphazardly. Important but often overlooked is starting children on reading connected text early on, optimally at or near the beginning of reading instruction.

**Fluency** is of critical importance because it allows the automatic, rapid recognition of words, and while it is generally recognized that fluency is an important component of skilled reading, it has proved difficult to teach. Interventions for vocabulary development and reading comprehension are not as well established. The most effective methods to teach reading comprehension involve teaching vocabulary and strategies that encourage active interaction between the reader and the text. Emerging science indicates that it is not only teacher content knowledge but the teacher's skill in engaging the student and focusing the student's attention on the reading task at hand that is required for effective instruction.

For those in high school, college, and graduate school, provision of accommodations most often represents a highly effective approach to dyslexia. Imaging studies now provide neurobiologic evidence of the need for extra time for dyslexic students; accordingly, college students with a childhood history of
dyslexia require extra time in reading and writing assignments as well as examinations. Many adolescent and adult students have been able to improve their reading accuracy, but without commensurate gains in reading speed. The accommodation of extra time reconciles the individual's often high cognitive ability and slow reading, so that the exam is a measure of that person's ability rather than his disability. Another important accommodation is teaching the dyslexic student to listen to texts. Excellent text-to-speech programs and apps available for Apple and Android systems include Voice Dream Reader, Immersive Reader (in OneNote as part of Microsoft Office), Kurzweil Firefly, Read & Write Gold, Read: OutLoud, and Natural Reader. Voice-to-text programs are also helpful, often part of the suite of programs as well as the popular Dragon Dictate. Voice to text is found on many smartphones. Other helpful accommodations include the use of laptop computers with spelling checkers, access to lecture notes, tutorial services, and a separate quiet room for taking tests.

In addition, the impact of the primary phonologic weakness in dyslexia mandates special consideration during oral examinations so that students are not graded on their lack of glibness or speech hesitancies but on their content knowledge. Unfortunately, speech hesitancies or difficulties in word retrieval often are wrongly confused with insecure content knowledge. The major difficulty in dyslexia, reflecting problems accessing the sound system of spoken language, causes great difficulty learning a 2nd language. As a result, an often-necessary accommodation is a waiver or partial waiver of the foreign language requirement; the dyslexic student may enroll in a course on the history or culture of a non–English-speaking country.

**Prognosis**

Application of evidence-based methods to young children (kindergarten to grade 3), when provided with sufficient intensity and duration, can result in improvements in reading accuracy and, to a much lesser extent, fluency. In older children and adults, interventions result in improved accuracy, but not an appreciable improvement in fluency. Accommodations are critical in allowing the dyslexic child to demonstrate his or her knowledge. Parents should be informed that with proper support, dyslexic children can succeed in a range of future occupations that might seem out of their reach, including medicine, law, journalism, and writing.

US Senate Resolution 576. *Calling on Congress, schools, and State and local educational agencies to recognize the significant educational implications of dyslexia that must be addressed*. [Washington, DC] 2016 [114th Congress, 2nd Session ed].
Data from the U.S. National Center for Educational Statistics for 2009 showed that 69% of U.S. high school graduates had taken algebra 1, 88% geometry, 76% algebra 2/trigonometry, and 35% precalculus. These percentages are considerably higher than those for 20 years earlier. However, concerns remain about the limited literacy level in mathematics for children, adolescents, and those entering the workforce; poor math skills predict numerous social, employment, and emotional challenges. The need for number and math literacy
extends beyond the workplace and into daily lives, and weaknesses in this area can negatively impact daily functioning. Research into the etiology and treatment of math disabilities falls far behind the study of reading disabilities (see Chapter 50). Therefore the knowledge needed to identify, treat, and minimize the impact of math challenges on daily functioning and education is limited.

Math Learning Disability Defined

Understanding learning challenges associated with mathematics requires a basic appreciation of domain-specific terminology and operations. The Diagnostic and Statistical Manual for Mental Disorders, Fifth Edition (DSM-5) has published diagnostic criteria for learning disorders. Specific types of learning challenges are subsumed under the broad term of specific learning disorder (SLD). The DSM identifies the following features of a SLD with an impairment in math: difficulties mastering number sense, number facts, or fluent calculation and difficulties with math reasoning. Symptoms must be present for a minimum of 6 mo and persist despite interventions to address the learning challenges. Number sense refers to a basic understanding of quantity, number, and operations and is represented as nonverbal and symbolic. Examples of number sense include an understanding that each number is 1 more or 1 less than the previous or following number; knowledge of number words and symbols; and the ability to compare the relative magnitude of numbers and perform simple arithmetic calculations.

The DSM-5 definition can be contrasted with an education-defined learning disability in mathematics. Two math-related areas are identified as part of the Individuals with Disabilities Education Act (IDEA): mathematics calculation and mathematics problem solving. Operationally, this is reflected in age-level competency in arithmetic and math calculation, word problems, interpreting graphs, understanding money and time concepts, and applying math concepts to solve quantitative problems. The federal government allows states to choose the way a learning disability (LD) is identified if the procedure is “research based.” Referred to specifically in IDEA as methods for identifying an LD are a discrepancy model and “use of a process based on the child's response to scientific, research-based intervention.” The former refers to identifying a LD based on a pronounced discrepancy between intellectual functioning and academic achievement. The latter, referred to as a response to intervention
(RtI) model, requires school systems to screen for a disability, intervene using empirically supported treatments for the identified disability, closely monitor progress, and make necessary adjustments to the intervention as needed. If a child is not responding adequately, a multidisciplinary team evaluation is used to develop an **individualized educational plan (IEP)**.

It is important that primary care providers understand the RtI process because many states require or encourage this approach to identifying LDs. Confusion can be avoided by helping concerned parents understand that a school may review their child's records, screen the skills of concern, and provide intervention with close progress monitoring, before initiating the process for an IEP. Traditional psychoeducation testing (IQ and achievement) may only be completed if a child has not responded well to specific interventions. The RtI approach is a valuable, empirically supported way to approach and identify a potential learning disability, but very different from a medical approach to diagnosis and treatment.

**Terminology**

The term **dyscalculia**, often used in medicine and research but seldom used by educators, is reserved for children with a SLD in math when there is a pattern of deficits in learning arithmetic facts and accurate, fluent calculations. The term **math learning disability (MLD)** is used generically here, with dyscalculia used when limiting the discussion to children with deficient math calculation skills. A distinction is also made between children with a MLD and those who are **low achieving (LA) in math**; both groups have received considerable research focus. Although not included in either definition above, research into math deficits typically requires that individuals identified with MLD have math achievement scores below the 10th percentile across multiple grade levels. These children start out poorly in math and continue poor performance across grades, despite interventions. LA math students consistently score below the 25th percentile on math achievement tests across grades, but show more typical entry-level math skills.

**Epidemiology**

**Prevalence**
Depending on how MLD is defined and assessed, the prevalence varies. Based on findings from multiple studies, approximately 7% of children will show a MLD profile before high school graduation. An additional 10% of students will be identified as LA. Because research in the area typically requires that individuals show deficits for consecutive years, the respective prevalence estimates are lower than the 10th percentile cutoff for being identified as MLD or the 25th percentile cutoff for being identified as LA. It is not unusual for children to score below the criterion one year and above the criterion in subsequent years. These children do not show the same cognitive deficits associated with a MLD. Unlike dyslexia, boys are at greater risk to experience MLD. This is found in epidemiologic research in the United States (risk ratio, 1.6-2.2 : 1) and various European countries.

**Risk Factors**

**Genetics**

The heritability of math skills is estimated to be approximately 0.50. The heritability or genetic influence on math skills is consistent across the continuum from high to low math skills. This research emphasizes that although math skills are learned across time, the stability of math performance is the result of genetic influences. Math heritability appears to be the product of multiple genetic markers, each having a small effect.

**Medical/Genetic Conditions**

Numerous genetic syndromes are associated with math problems. Although most children with **fragile X syndrome** have an *intellectual disability* (ID), approximately 50% of girls with the condition do not. Of those without an ID, ≥75% have a math disability by the end of 3rd grade and are already scoring below average in mathematics in kindergarten and 1st grade. For girls with fragile X MLD, weak working memory seems to play an important role. The frequency of MLD in girls with **Turner syndrome (TS)** is the same as found in girls with fragile X syndrome. A consistent finding is girls with TS complete math calculations at significantly slower speed than typically developing students. Although girls with TS have weak calculation skills, their ability to complete math problems not requiring explicit calculation is similar to that of their peers. The percentage of children with the **22q11.2 deletion syndrome**
(22q11.2ds) with MLD is not clear. Younger children with this genetic condition (6-10 yr old) showed similar number sense and calculation skills as typically developing children but weaker math problem solving. Older children with 22q11.2ds showed slower speed in their general number sense and calculations, but accuracy was maintained. Weak counting skills and magnitude comparison have been found in this group of children, suggesting weak visual-spatial processing. Children with myelomeningocele are at greater risk for math difficulties than their unaffected peers. Almost 30% of these children have MLD without an additional diagnosed learning disorder, and >50% have both math and reading learning disorders. While broad, deficits are most pronounced in speed of math calculation and written computation.

**Comorbidities**

It is estimated that 30–70% of those with MLD will also have reading disability. This is especially important because children with MLD are less likely to be referred for additional educational assistance and intervention than students with reading problems. Unfortunately, children identified with both learning challenges perform poorer across psychosocial and academic measures than children with MLD alone. Having a MLD places a child at greater risk for not only other learning challenges but also psychiatric disorders, including attention-deficit/hyperactivity disorder, oppositional defiant disorder, conduct disorder, generalized anxiety disorder, and major depressive disorder. Individuals with MLD have been found to have increased social isolation and difficulties developing social relationships in general.

**Causes of Math Learning Disability**

There is a consensus that individuals with MLD are a heterogeneous group, with multiple potential broad and specific deficits driving their learning difficulties. Research into the causes of MLD has focused on math-specific processes and broad cognitive deficits, with an appreciation that these two factors are not always independent.

**Broad Cognitive Processes**

*Intelligence*
Intelligence affects learning, but if intellectual functioning were the primary driver of poor math performance, the math skills of low-IQ children would be similar or worse than individuals with MLD. On the contrary, children with MLD have significantly poorer math achievement than children with low IQ. Children with MLD have severe deficits in math not accounted for by their cognitive functioning. Individuals with lower cognition may have difficulty learning mathematics, but their math skills are likely to be commensurate with their intelligence.

**Working Memory**

Working memory refers to the ability to keep information in mind while using the information in other mental processes. Working memory is composed of 3 core systems: the central executive, the language-related phonologic loop, and the visual-based sketch pad. The central executive coordinates the functioning of the other two systems. All three play a role in various aspects of learning and in the development and application of math skills in particular; children with MLD have shown deficits in each area.

**Processing Speed**

Individuals with MLD are often slower to complete math problems than their typically developing peers, a result of their poor fact retrieval rather than broader speed of processing deficits. However, young children later identified with a MLD when beginning school have number-processing speed that is considerably slower than same-age same-grade peers.

**Math-Specific Processes**

**Procedural Errors**

The type of errors made by children with a MLD are typical for any child, the difference being that children with a learning disability show a 2-3 yr lag in understanding the concept. An example of a common error a 1st grade child with a MLD might make when “counting on” is to undercount: “6 + 2= ?;” “6, 7” rather than starting at 6 and counting an additional 2 numbers. As children with math deficits get older, it is common to subtract a larger number from a smaller number. For example, in the problem “63 − 29 = 46,” the child makes the mistake of subtracting 3 from 9. Another common error is not decreasing the
number in the 10s column when borrowing: “64 − 39 = 35.” For both adding and subtracting, there is a lack of understanding of the commutative property of numbers and a tendency to use repeated addition rather than fact retrieval. It is not that children with a MLD do not develop these skills, it is that they develop them much later than their peers, thereby making the transition to complicated math concepts much more challenging.

Memory for Math Facts

Committing math facts to or retrieving facts from memory have consistently been found to be problematic for children with MLD. Weak fact encoding or retrieval alone do not determine a MLD diagnosis. Many math curricula in the United States do not include development of math facts as a part of the instructional process, resulting in children not knowing basic facts.

Unlike dyslexia, in which deficits have been isolated and identified as causal (see Chapter 50 ), factors involved in the development of a MLD are much more heterogeneous. Alone, none of the processes previously outlined fully accounts for MLD, although all have been implicated as problematic for those struggling with math.

Treatment and Interventions

The most effective interventions for MLD are those that include explicit instruction on solving specific types of problems and that take place over several weeks to several months. Skill-based instruction is a critical component; general math problem solving will not carry over across various math skills, unless the skill is part of a more complex math concept. Clear, comprehensive guidelines for effective interventions for students struggling with math have been provided by the U.S. Department of Education in the form of a Practice Guide released through the What Works Clearinghouse. This document gives excellent direction in the identification and treatment of children with math difficulties in the educational system. Although not intended for medical personnel or parents, the guide is available free of charge and can be helpful for parents when talking to teachers about their child's learning. Table 51.1 lists additional resources for parents concerned about their young child's development of math facts.

Awareness that most public school systems have implemented some form of a RtI to identify learning disabilities allows the primary care physician to encourage parents to return to the school seeking an intervention to address their child's concern. Receiving special education services in the form of an IEP may be necessary for some children. However, the current approach to identifying children with a learning disability allows school systems to intervene earlier, when problems arise, and potentially avoid the need for an IEP. Pediatricians with patients whose parents have received feedback from school with any of the risk factors outlined in Table 51.2 should encourage the parents to discuss an intervention plan with the child's teacher.

Table 51.2

Risk Factors for a Specific Learning Disability Involving Mathematics

The child is at or below the 20th percentile in any math area, as reflected by standardized testing or ongoing measures of progress monitoring. The teacher expresses concerns about the child's ability to “take the next step” in math.
There is a positive family history for math learning disability (this alone will not initiate an intervention). Parents think they have to “reteach” math concepts to their child.

Oral language is a complex process that typically develops in the absence of formal instruction. In contrast, written language requires instruction in acquisition (word reading), understanding (reading comprehension), and expression (spelling and composition). Unfortunately, despite reasonable pedagogy, a subset of children struggle with development in one or several of these areas. The disordered output of written language is currently referred to within the Diagnostic and Statistical Manual for Mental Disorders, Fifth Edition (DSM-5) as a specific learning disorder with impairment in written expression (Table 51.3).

**Table 51.3**

### DSM-5 Diagnostic Criteria for Specific Learning Disability With Impairment in Written Expression

A. Difficulties learning and using academic skills that have persisted for at least 6 mo, despite the provision of interventions that target those difficulties.

   Difficulties with written expression (e.g., makes multiple grammatical or punctuation errors within sentences; employs poor paragraph organization; written expression of ideas lacks clarity).

B. The affected academic skills are substantially and quantifiably below those expected for the individual's chronological age, and cause significant interference with academic or occupational performance, or with activities of daily living, as confirmed by individually administered standardized achievement measures and comprehensive clinical assessment. For individuals age 17 yr and older, a documented history of impairing learning difficulties may be substituted for the standardized assessment.

C. The learning difficulties begin during school-age years but may not become fully manifest until the demands for those affected academic skills exceed the individual's limited capacities (e.g., as in timed tests, reading or writing lengthy complex reports for a tight deadline, excessively heavy academic loads).

D. The learning difficulties are not better accounted for by intellectual disabilities, uncorrected visual or auditory acuity, other mental or
neurologic disorders, psychosocial adversity, lack of proficiency in the language of academic instruction, or inadequate educational instruction.

**315.2 (F81.81) With impairment in written expression:**
- Spelling accuracy
- Grammar and punctuation accuracy
- Clarity or organization of written expression

Specify current severity:

**Mild:** Some difficulties learning skills in 1 or 2 academic domains, but of mild enough severity that the individual may be able to compensate or function well when provided with appropriate accommodations or support services, especially during the school years.

**Moderate:** Marked difficulties learning skills in \( \geq 1 \) academic domain(s), so that the individual is unlikely to become proficient without some intervals of intensive and specialized teaching during the school years. Some accommodations or supportive services at least part of the day at school, in the workplace, or at home may be needed to complete activities accurately and efficiently.

**Severe:** Severe difficulties learning skills, affecting several academic domains, so that the individual is unlikely to learn those skills without ongoing intensive individualized and specialized teaching for most of the school years. Even with an array of appropriate accommodations or services at home, at school, or in the workplace, the individual may not be able to complete all activities efficiently.

Adapted from the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*, (Copyright 2013). American Psychiatric Association, pp 66–67.

Various terminology has been used when referring to individuals with writing deficits; this subchapter uses the term **impairment in written expression (IWE)** rather than “writing disorder” or “disorder of written expression.” **Dysgraphia** is often used when referring to children with writing problems, sometimes synonymously with IWE, although the two are related but distinct conditions. Dysgraphia is primarily a deficit in motor output (paper/pencil skills), and IWE is a conceptual weakness in developing, organizing, and elaborating on ideas in writing.
The diagnoses of a IWE and dysgraphia are made largely based on phenotypical presentation; spelling, punctuation, grammar, clarity, and organization are factors to consider with IWE concerns. Aside from these potentially weak writing characteristics, however, no other guidelines are offered. Based on clinical experience and research into the features of writing samples of children with disordered writing skills, one would expect to see limited output, poor organization, repetition of content, and weak sentence structure and spelling, despite the child taking considerable time to produce a small amount of content. For those with comorbid dysgraphia, the legibility of their writing product will also be poor, sometimes illegible.

Epidemiology

The incidence of IWE is estimated at 6.9–14.7%, with the relative risk for IWE 2-2.9 times higher for boys than girls. One study covering three U.S. geographic regions found considerably higher rates of IWE in the Midwest and Southeast than in the West.

The risk for writing problems is much greater among select populations; >50% of children with oral language disorders reportedly have IWE. The relationship between attention-deficit/hyperactivity disorder (ADHD) and learning disorders in general is well established, including IWE estimates in the 60% range for the combined and inattentive presentations of ADHD. Because of the importance of working memory and other executive functions in the writing process, any child with weakness in these areas will likely find the writing process difficult (see Chapter 48).

Skill Deficits Associated With Impaired Writing

Written language, much like reading, occurs along a developmental trajectory that can be seamless as children master skills critical to the next step in the process. Mastery of motor control that allows a child to produce letters and letter sequences frees up cognitive energy to devote to spelling words and eventually stringing words into sentences, paragraphs, and complex composition. Early in the development of each individual skill, considerable cognitive effort is required, although ideally the lower-level skills of motor production, spelling,
punctuation, and capitalization (referred to as writing mechanics or writing conventions) will gradually become automatic and require progressively less mental effort. This effort can then be devoted to higher-level skills, such as planning, organization, application of knowledge, and use of varied vocabulary. For children with writing deficits, breakdowns can occur at one, some, or every stage.

Transcription

Among preschool and primary grade children, there is a wide range of what is considered “developmentally typical” as it relates to letter production and spelling. However, evidence indicates that poor writers in later grades are slow to produce letters and write their name in preschool and kindergarten. Weak early spelling and reading skills (letter identification and phonologic awareness; see Chapter 50) and weak oral language have also been found to predict weak writing skills in later elementary grades. Children struggling to master early transcription skills tend to write slowly, or when writing at reasonable speed, the legibility of their writing degrades. Output in quantity and variety is limited, and vocabulary use in poor spellers is often restricted to words they can spell.

As children progress into upper elementary school and beyond, a new set of challenges arise. They are now expected to have mastered lower-level transcription skills, and the focus turns to the application of these skills to more complex text generation. In addition to transcription, this next step requires the integration of additional cognitive skills that have yet to be tapped by young learners.

Oral Language

Language, although not speech, has been found to be related to writing skills. Writing difficulties are associated with deficits in both expression and comprehension of oral language. Writing characteristics of children with specific language impairment (SLI) can differ from their unimpaired peers early in the school experience, and persist through high school (see Chapter 52). In preschool and kindergarten, as a group, children with language disorders show poorer letter production and ability to print their name. Poor spelling and weak vocabulary also contribute to the poor writing skills. Beyond primary grades, the written narratives of SLI children tend to be evaluated as “lower quality with
poor organization” and weaker use of varied vocabulary.

Pragmatic language and higher-level language deficits also negatively impact writing skills. Pragmatic language refers to the social use of language, including, though not limited to greeting and making requests; adjustments to language used to meet the need of the situation or listener; and following conversation rules verbally and nonverbally. Higher-level language goes beyond basic vocabulary, word form, and grammatical skills and includes making inferences, understanding and appropriately using figurative language, and making cause-and-effect judgments. Weaknesses in these areas, with or without intact foundational language, can present challenges for students in all academic areas that require writing. For example, whether producing an analytic or narrative piece, the writer must understand the extent of the reader's background knowledge and in turn what information to include and omit, make an argument for a cause-and-effect relationship, and use content-specific vocabulary or vocabulary rich in imagery and nonliteral interpretation.

Executive Functions

Writing is a complicated process and, when done well, requires the effective integration of multiple processes. Executive functions (EFs) are a set of skills that include planning, problem solving, monitoring and making adjustments as needed (see Chapter 48). Three recursive processes have consistently been reported as involved in the writing process: translation of thought into written output, planning, and reviewing. Coming up with ideas, while challenging for many, is simply the first step when writing a narrative (story). Once an idea has emerged, the concept must be developed to include a plot, characters, and story line and then coordinated into a coherent whole that is well organized and flows from beginning to end. Even if one develops ideas and begins to write them down, persistence is required to complete the task, which requires self-regulation. Effective writers rely heavily on EFs, and children with IWE struggle with this set of skills. Poor writers seldom engage in the necessary planning and struggle to self-monitor and revise effectively.

Working Memory

Working memory (WM) refers to the ability to hold, manipulate, and store information for short periods. The more space available, the more memory can
be devoted to problem solving and thinking tasks. Nevertheless, there is limited space in which information can be held, and the more effort devoted to one task, the less space is available to devote to other tasks. WM has consistently been shown to play an important role in the writing process, because weak WM limits the space available. Further, when writing skills that are expected to be automatic continue to require effort, precious memory is required, taking away what would otherwise be available for higher-level language.

The *Simple View of Writing* is an approach that integrates each of the 4 ideas just outlined to describe the writing process (Fig. 51.1). At the base of the triangle are transcription and executive functions, which support, within WM, the ability to produce text. Breakdowns in any of these areas can lead to poor writing, and identifying where the deficit(s) are occurring is essential when deciding to treat the writing problem. For example, children with weak graphomotor skills (e.g., dysgraphia) must devote considerable effort to the accurate production of written language, thereby increasing WM use devoted to lower-level transcription and limiting memory that can be used for developing discourse. The result might be painfully slow production of a legible story, or a passage that is largely illegible. If, on the other hand, a child's penmanship and spelling have developed well, but their ability to persist with challenging tasks or to organize their thoughts and develop a coordinated plan for their paper is limited, one might see very little information written on the paper despite considerable time devoted to the task. Lastly, even when skills residing at the base of this triangle are in place, students with a language disorder will likely produce text that is more consistent with their language functioning than their chronological grade or age (Fig. 51.1).
Treatment

Poor writing skills can improve with effective treatment. Weak graphomotor skills may not necessarily require intervention from an occupational therapist (OT), although Handwriting Without Tears is a curriculum frequently used by OTs when working with children with poor penmanship. An empirically supported writing program has been developed by Berninger, but it is not widely used inside or outside school systems (PAL Research-Based Reading and Writing Lessons). For children with dysgraphia, lower-level transcription skills should be emphasized to the point of becoming automatic. The connection between transcription skills and composition should be included in the instructional process; that is, children need to see how their work at letter production is related to broader components of writing. Further, because of WM constraints that frequently impact the instructional process for students with learning disorders, all components of writing should be taught within the same lesson.

Explicit instruction of writing strategies combined with implementation and coaching in self-regulation will likely produce the greatest gains for students with writing deficits. Emphasis will vary depending on the deficit specific to the child. A well-researched and well-supported intervention for poor writers is self-
regulated strategy development (SRSD). The 6 stages in this model include developing and activating a child's background knowledge; introducing and discussing the strategy that is being taught; modeling the strategy for the student; assisting the child in memorization of the strategy; supporting the child's use of the strategy during implementation; and independent use of the strategy. SRSD can be applied across various writing situations and is supported until the student has developed mastery. The model can emphasize or deemphasize the areas most needed by the child.

Educational Resources

Children with identified learning disorders can potentially qualify for formal education programming through special education or a section 504 plan. Special education is guided on a federal level by the Individual with Disabilities Education Act (IDEA) and includes development of an individual education plan (see Chapter 48). A 504 plan provides accommodations to help children succeed in the regular classroom. Accommodations that might be provided to a child with IWE, through an IEP or a 504 plan, include dictation to a scribe when confronted with lengthy writing tasks, additional time to complete exams that require writing, and use of technology such as keyboarding, speech-to-text software, and writing devices that record teacher instruction. When recommending that parents pursue assistive technology for their child as a potential accommodation, the physician should emphasize the importance of instruction to mastery of the device being used. Learning to use technology effectively requires considerable time and is initially likely to require additional effort, which can result in frustration and avoidance.

Most children learn to communicate in their native language without specific instruction or intervention other than exposure to a language-rich environment. Normal development of speech and language is predicated on the infant’s ability to hear, see, comprehend, remember, and socially interact with others. The infant must also possess sufficient motor skills to imitate oral motor movements.

**Normal Language Development**

Language can be subdivided into several essential components. **Communication** consists of a wide range of behaviors and skills. At the level of basic verbal ability, **phonology** refers to the correct use of speech sounds to form words, **semantics** refers to the correct use of words, and **syntax** refers to the appropriate use of grammar to make sentences. At a more abstract level, verbal skills include the ability to link thoughts together coherently and to maintain a topic of conversation. **Pragmatic** abilities include verbal and nonverbal skills that facilitate the exchange of ideas, including the appropriate choice of language for the situation and circumstance and the appropriate use of body language (i.e., posture, eye contact, gestures). Social pragmatic and behavioral skills also play an important role in effective interactions with communication partners (i.e., engaging, responding, and maintaining reciprocal exchanges).

It is customary to divide language skills into **receptive** (hearing and understanding) and **expressive** (talking) abilities. Language development usually follows a fairly predictable pattern and parallels general intellectual development (Table 52.1).

# Receptive Language Development

The peripheral auditory system is mature by 26 wk gestation, and the fetus responds to and discriminates speech sounds. Anatomic asymmetry in the *planum temporale*, the structural brain region specialized for language processing, is present by 31 wk gestation. At birth, the full-term newborn appears to have functionally organized neural networks that are sensitive to different properties of language input. The normal newborn demonstrates preferential response to human voices over inanimate sound and recognizes the mother's voice, reacting stronger to it than to a stranger's voice. Even more remarkable is the ability of the newborn to discriminate sentences in their “native” (mother's) language from sentences in a “foreign” language. In research settings, infants of monolingual mothers showed a preference for only that language, whereas infants of bilingual mothers showed a preference for both exposed languages over any other language.

Between 4 and 6 mo, infants visually search for the source of sounds, again showing a preference for the human voice over other environmental sounds. By 6 mo, infants can passively follow the adult's line of visual regard, resulting in a “joint reference” to the same objects and events in the environment. The ability to share the same experience is critical to the development of further language, social, and cognitive skills as the infant “maps” specific meanings onto his or her experiences. By 8-9 mo, the infant can actively show, give, and point to objects. Comprehension of words often becomes apparent by 9 mo, when the infant selectively responds to his or her name and appears to comprehend the word “no.” Social games, such as “peek-a-boo,” “so big,” and waving “bye-bye” can be elicited by simply mentioning the words. At 12 mo, many children can follow a simple, 1-step request without a gesture (e.g., “Give it to me”).

Between 1 and 2 yr, comprehension of language accelerates rapidly. Toddlers can point to body parts on command, identify pictures in books when named,
and respond to simple questions (e.g., “Where's your shoe?”). The 2 yr old is able to follow a 2-step command, employing unrelated tasks (e.g., “Take off your shoes, then go sit at the table”), and can point to objects described by their use (e.g., “Give me the one we drink from”). By 3 yr, children typically understand simple “wh-” question forms (e.g., who, what, where, why). By 4 yr, most children can follow adult conversation. They can listen to a short story and answer simple questions about it. A 5 yr old typically has a receptive vocabulary of more than 2000 words and can follow 3- and 4-step commands.

**Expressive Language Development**

Cooing noises are established by 4-6 wk of age. Over the 1st 3 mo of life, parents may distinguish their infant's different vocal sounds for pleasure, pain, fussing, tiredness, and so on. Many 3 mo old infants vocalize in a reciprocal fashion with an adult to maintain a social interaction (“vocal tennis”). By 4 mo, infants begin to make bilabial (“raspberry”) sounds, and by 5 mo, monosyllables and laughing are noticeable. Between 6 and 8 mo, polysyllabic babbling (“lalala” or “mamama”) is heard, and the infant might begin to communicate with gestures. Between 8 and 10 mo, babbling makes a phonologic shift toward the particular sound patterns of the child's native language (i.e., they produce more native sounds than nonnative sounds). At 9-10 mo, babbling becomes truncated into specific words (e.g., “mama,” “dada”) for their parents.

Over the next several months, infants learn 1 or 2 words for common objects and begin to imitate words presented by an adult. These words might appear to come and go from the child's repertoire until a stable group of 10 or more words is established. The rate of acquisition of new words is approximately 1 new word per week at 12 mo, but it accelerates to approximately 1 new word per day by 2 yr. The first words to appear are used primarily to label objects (nouns) or to ask for objects and people (requests). By 18-20 mo, toddlers should use a minimum of 20 words and produce jargon (strings of word-like sounds) with language-like inflection patterns (rising and falling speech patterns). This jargon usually contains some embedded true words. Spontaneous 2-word phrases (pivotal speech), consisting of the flexible juxtaposition of words with clear intention (e.g., “Want juice!” or “Me down!”), is characteristic of 2 yr olds and reflects the emergence of grammatical ability (syntax).

Two-word, combinational phrases do not usually emerge until children have acquired 50-100 words in their lexicon. Thereafter, the acquisition of new words
accelerates rapidly. As knowledge of grammar increases, there is a proportional increase in verbs, adjectives, and other words that serve to define the relation between objects and people (predicates). By 3 yr, sentence length increases, and the child uses pronouns and simple present-tense verb forms. These 3-5 word sentences typically have a subject and verb but lack conjunctions, articles, and complex verb forms. The Sesame Street character Cookie Monster (“Me want cookie!”) typifies the “telegraphic” nature of the 3 yr old's sentences. By 4-5 yr, children should be able to carry on conversations using adult-like grammatical forms and use sentences that provide details (e.g., “I like to read my books”).

Variations of Normal

Language milestones have been found to be largely universal across languages and cultures, with some variations depending on the complexity of the grammatical structure of individual languages. In Italian (where verbs often occupy a prominent position at the beginning or end of sentences), 14 mo olds produce a greater proportion of verbs compared with English speaking infants. Within a given language, development usually follows a predictable pattern, paralleling general cognitive development. Although the sequences are predictable, the exact timing of achievement is not. There are marked variations among normal children in the rate of development of babbling, comprehension of words, production of single words, and use of combinational forms within the first 2-3 yr of life.

Two basic patterns of language learning have been identified, analytic and holistic. The analytic pattern is the most common and reflects the mastery of increasingly larger units of language form. The child's analytic skills proceed from simple to more complex and lengthy forms. Children who follow a holistic or gestalt learning pattern might start by using relatively large chunks of speech in familiar contexts. They might memorize familiar phrases or dialog from movies or stories and repeat them in an overgeneralized fashion. Their sentences often have a formulaic pattern, reflecting inadequate mastery of the use of grammar to flexibly and spontaneously combine words appropriately in the child's own unique utterance. Over time, these children gradually break down the meanings of phrases and sentences into their component parts, and they learn to analyze the linguistic units of these memorized forms. As this occurs, more original speech productions emerge, and the child is able to assemble thoughts in a more flexible manner. Both analytic and holistic learning processes are
necessary for normal language development to occur.

**Language and Communication Disorders**

**Epidemiology**

Disorders of speech and language are very common in preschool-age children. Almost 20% of 2 yr olds are thought to have delayed onset of language. By age 5 yr, approximately 6% of children are identified as having a speech impairment, 5% as having both speech and language impairment, and 8% as having language impairment. Boys are nearly twice as likely to have an identified speech or language impairment as girls.

**Etiology**

Normal language ability is a complex function that is widely distributed across the brain through interconnected neural networks that are synchronized for specific activities. Although clinical similarities exist between acquired aphasia in adults and childhood language disorders, unilateral focal lesions acquired in early life do not seem to have the same effects in children as in adults. Risk factors for **neurologic injury** are absent in the vast majority of children with language impairment.

**Genetic** factors appear to play a major role in influencing how children learn to talk. Language disorders cluster in families. A careful family history may identify current or past speech or language problems in up to 30% of first-degree relatives of proband children. Although children exposed to parents with language difficulty might be expected to experience poor language stimulation and inappropriate language modeling, studies of twins have shown the concordance rate for low language test score and/or a history of speech therapy to be approximately 50% in dizygotic pairs, rising to over 90% in monozygotic pairs. Despite strong evidence that language disorders have a genetic basis, consistent genetic mutations have not been identified. Instead, multiple genetic regions and epigenetic changes may result in heterogeneous genetic pathways causing language disorders. Some of these genetic pathways disrupt the timing of early prenatal neurodevelopmental events affecting migration of nerve cells from the germinal matrix to the cerebral cortex. Several single nucleotide polymorphisms (SNPs) involving noncoding regulatory genes, including
CNTNAP2 (contactin-associated-protein-like-2) and KIAA0319, are strongly associated with early language acquisition and are also believed to affect early neuronal structural development.

In addition, other environmental, hormonal, and nutritional factors may exert epigenetic influences by dysregulating gene expression and resulting in aberrant sequencing of the onset, growth, and timing of language development.

Pathogenesis

Language disorders are associated with a fundamental deficit in the brain's capacity to process complex information rapidly. Simultaneous evaluation of words (semantics), sentences (syntax), prosody (tone of voice), and social cues can overtax the child's ability to comprehend and respond appropriately in a verbal setting. Limitations in the amount of information that can be stored in verbal working memory can further limit the rate at which language information is processed. Electrophysiologic studies show abnormal latency in the early phase of auditory processing in children with language disorders. Neuroimaging studies identify an array of anatomic abnormalities in regions of the brain that are central to language processing. MRI scans in children with specific language impairment (SLI) may reveal white matter lesions and volume loss, ventricular enlargement, focal gray matter heterotopia within the right and left parietotemporal white matter, abnormal morphology of the inferior frontal gyrus, atypical patterns of asymmetry of language cortex, or increased thickness of the corpus callosum in a minority of affected children. Postmortem studies of children with language disorders found evidence of atypical symmetry in the plana temporale and cortical dysplasia in the region of the sylvian fissure. In support of a genetic mechanism affecting cerebral development, a high rate of atypical perisylvian asymmetries has also been documented in the parents of children with SLI.

Clinical Manifestations

Primary disorders of speech and language development are often found in the absence of more generalized cognitive or motor dysfunction. However, disorders of communication are also the most common comorbidities in persons with generalized cognitive disorders (intellectual disability or autism), structural anomalies of the organs of speech (e.g., velopharyngeal insufficiency from cleft
palate), and neuromotor conditions affecting oral motor coordination (e.g.,
dysarthria from cerebral palsy or other neuromuscular disorders).

**Classification**

Each professional discipline has adopted a somewhat different classification
system, based on cluster patterns of symptoms. The American Psychiatric
Association (APA) *Diagnostic and Statistical Manual of Mental Disorders, Fifth
Edition* (DSM-5) organized communication disorders into: (1) language disorder
(which combines expressive and mixed receptive-expressive language
disorders), speech sound disorder (phonologic disorder), and childhood-onset
fluency disorder (stuttering); and (2) social (pragmatic) communication disorder,
which is characterized by persistent difficulties in the social uses of verbal and
nonverbal communication (*Table 52.2*). In clinical practice, childhood speech
and language disorders occur as a number of distinct entities.

**Table 52.2**

**DSM-5 Diagnostic Criteria for**

**Communication Disorders**

**Language Disorder**

A Persistent difficulties in the acquisition and use of language across
modalities (i.e., spoken, written, sign language, or other) due to deficits in
comprehension or production that include the following:

1. Reduced vocabulary (word knowledge and use).
2. Limited sentence structure (ability to put words and word endings
together to form sentences based on the rules of grammar and
morphology).
3. Impairments in discourse (ability to use vocabulary and connect
sentences to explain or describe a topic or series of events or have
a conversation).

B. Language abilities are substantially and quantifiably below those expected
for age, resulting in functional limitations in effective communication,
social participation, academic achievement, or occupational performance,
individually or in any combination.

C. Onset of symptoms is in the early developmental period.

D. The difficulties are not attributable to hearing or other sensory impairment,
motor dysfunction, or another medical or neurologic condition and are not better explained by intellectual disability (intellectual developmental disorder) or global developmental delay.

**Speech Sound Disorder**

A. Persistent difficulty with speech sound production that interferes with speech intelligibility or prevents verbal communication of messages.

B. The disturbance causes limitations in effective communication that interfere with social participation, academic achievement, or occupational performance, individually or in any combination.

C. Onset of symptoms is in the early developmental period.

D. The difficulties are not attributable to congenital or acquired conditions, such as cerebral palsy, cleft palate, deafness or hearing loss, traumatic brain injury, or other medical or neurologic conditions.

**Social (Pragmatic) Communication Disorder**

A. Persistent difficulties in the social use of verbal and nonverbal communication as manifested by all of the following:

1. Deficits in using communication for social purposes, such as greeting and sharing information, in a manner that is appropriate for the social context.

2. Impairment of the ability to change communication to match context or the needs of the listener, such as speaking differently in a classroom than on a playground, talking differently to a child than to an adult, and avoiding use of overly formal language.

3. Difficulties following rules for conversation and storytelling, such as taking turns in conversation, rephrasing when misunderstood, and knowing how to use verbal and nonverbal signals to regulate interaction.

4. Difficulties understanding what is not explicitly stated (e.g., making inferences) and nonliteral or ambiguous meanings of language (e.g., idioms, humor, metaphors, multiple meanings that depend on the context for interpretation).

B. The deficits result in functional limitations in effective communication,
social participation, social relationships, academic achievement, or occupational performance, individually or in combination.

C. The onset of the symptoms is in the early developmental period (but deficits may not become fully manifest until social communication demands exceed limited capacities).

D. The symptoms are not attributable to another medical or neurologic condition or to low abilities in the domains of word structure and grammar, and are not better explained by autism spectrum disorder, intellectual disability (intellectual developmental disorder), global developmental delay, or another mental disorder.

**Language Disorder or Specific Language Impairment**

The condition DSM-5 refers to as language disorder is also referred to as specific language impairment (SLI), developmental dysphasia, or developmental language disorder. SLI is characterized by a significant discrepancy between the child's overall cognitive level (typically nonverbal measures of intelligence) and functional language level. These children also follow an atypical pattern of language acquisition and use. Closer examination of the child's skills might reveal deficits in understanding and use of word meaning (semantics) and grammar (syntax). Often, children are delayed in starting to talk. Most significantly, they usually have difficulty understanding spoken language. The problem may stem from insufficient understanding of single words or from the inability to deconstruct and analyze the meaning of sentences. Many affected children show a holistic pattern of language development, repeating memorized phrases or dialog from movies or stories (echolalia). In contrast to their difficulty with spoken language, children with SLI appear to learn visually and demonstrate their ability on nonverbal tests of intelligence.

After children with SLI become fluent talkers, they are generally less proficient at producing oral narratives than their peers. Their stories tend to be shorter and include fewer propositions, main story ideas, or story grammar elements. Older children include fewer mental state descriptions (e.g., references to what their characters think and how they feel). Their narratives contain fewer cohesive devices, and the story line may be difficult to follow.
Many children with SLI show difficulties with social interaction, particularly with same-age peers. Social interaction is mediated by oral communication, and a child deficient in communication is at a distinct disadvantage in the social arena. Children with SLI tend to be more dependent on older children or adults, who can adapt their communication to match the child's level of function. Generally, social interaction skills are more closely correlated with language level than with nonverbal cognitive level. Using this as a guide, one usually sees a developmental progression of increasingly more sophisticated social interaction as the child's language abilities improve. In this context, social ineptitude is not necessarily a sign of asocial distancing (e.g., autism) but rather a delay in the ability to negotiate social interactions.

**Higher-Level Language Disorder**

As children mature, the ability to communicate effectively with others depends on mastery of a range of skills that go beyond basic understanding of words and rules of grammar. Higher-level language skills include the development of advanced vocabulary, the understanding of word relationships, reasoning skills (including drawing correct inferences and conclusions), the ability to understand things from another person's perspective, and the ability to paraphrase and rephrase with ease. In addition, higher-order language abilities include pragmatic skills that serve as the foundation for social interactions. These skills include knowledge and understanding of one's conversational partner, knowledge of the social context in which the conversation is taking place, and general knowledge of the world. Social and linguistic aspects of communication are often difficult to separate, and persons who have trouble interpreting these relatively abstract aspects of communication typically experience difficulty forming and maintaining relationships.

DSM-5 identified social (pragmatic) communication disorder (SPCD) as a category of communication disorder (Table 52.2). Symptoms of pragmatic difficulty include extreme literalness and inappropriate verbal and social interactions. Proper use and understanding of humor, slang, and sarcasm depend on correct interpretation of the meaning and the context of language and the ability to draw proper inferences. Failure to provide a sufficient referential base to one's conversational partner—to take the perspective of another person—results in the appearance of talking or behaving randomly or incoherently. SPCD often occurs in the context of another language disorder and has been recognized as a symptom of a wide range of disorders, including right-hemisphere damage
to the brain, Williams syndrome, and nonverbal learning disabilities. SPCD can also occur independently of other disorders. Children with **autism spectrum disorder (ASD)** often have symptoms of SPCD, but SPCD is not diagnosed in these children because the symptoms are a component of ASD. In school settings, children with SPCD may be socially ostracized and bullied.

**Intellectual Disability**

Most children with a mild degree of intellectual disability learn to talk at a slower-than-normal rate; they follow a normal sequence of language acquisition and eventually master basic communication skills. Difficulties may be encountered with higher-level language concepts and use. Persons with moderate to severe degrees of intellectual disability can have great difficulty in acquiring basic communication skills. About half of persons with an intelligence quotient (IQ) of <50 can communicate using single words or simple phrases; the rest are typically nonverbal.

**Autism Spectrum Disorder**

A disordered pattern of language development is one of the core features of ASD (see **Chapter 54**). The language profile of children with ASD is often indistinguishable from that in children with SLI or SPCD. The key characteristics of ASD that distinguish it from SLI or SPCD are lack of reciprocal social relationships; limitation in the ability to develop functional, symbolic, or pretend play; hyper- or hyporeactivity to sensory input; and an obsessive need for sameness and resistance to change. Approximately 40% of children with ASD also have intellectual disability, which can limit their ability to develop functional communication skills. Language abilities can range from absent to grammatically intact, but with limited pragmatic features and odd prosody patterns. Some individuals with ASD have highly specialized, but isolated, “savant” skills, such as calendar calculations and **hyperlexia** (the precocious ability to recognize written words beyond expectation based on general intellectual ability). Parents report regression in language and social skills (**autistic regression**) in approximately 20–25% of children with ASD, usually between 12 and 36 mo of age. The cause of the regression is not known, but it tends to be associated with an increased risk for comorbid intellectual disability and more severe ASD (**Fig. 52.1**).
Asperger Syndrome

Asperger syndrome is characterized by difficulties in social interaction, eccentric behaviors, and abnormally intense and circumscribed interests despite normal cognitive and verbal ability. Affected individuals may engage in long-winded, verbose monologs about their topics of special interest, with little regard to the reaction of others. Adults with Asperger syndrome generally have a more favorable prognosis of than those with “classic” autism. Prior to 2013, Asperger syndrome was classified as distinct from autism; however, DSM-5 no longer recognizes Asperger as a separate neurodevelopmental disorder. More severely affected individuals are now considered to be at the “high functioning” end of the autism spectrum (see Chapter 54), whereas mildly impaired individuals may be diagnosed with SPCD.

Selective Mutism

Selective mutism is defined as a failure to speak in specific social situations despite speaking in other situations, and it is typically a symptom of an underlying anxiety disorder. Children with selective mutism can speak normally in certain settings, such as within their home or when they are alone with their parents. They fail to speak in other social settings, such as at school or at other places outside their home. Other symptoms associated with selective mutism can include excessive shyness, withdrawal, dependency on parents, and oppositional behavior. Most cases of selective mutism are not the result of a single traumatic event, but rather the manifestation of a chronic pattern of
anxiety. Mutism is not passive-aggressive behavior. Selectively mute children often report that they want to speak in social settings but are afraid to do so. Often, one or both parents of a child with selective mutism has a history of anxiety symptoms, including childhood shyness, social anxiety, or panic attacks. Mutism is highly functional for the child in that it reduces anxiety and protects the child from the perceived challenge of social interaction. Treatment of selective mutism should utilize cognitive behavioral strategies focused on reducing the general anxiety and increasing speaking in social situation (see Chapter 38). Occasionally, selective serotonin reuptake inhibitors are helpful in conjunction with cognitive-behavioral therapy. Selective mutism reflects a difficulty of social interaction, not a disorder of language processing.

**Isolated Expressive Language Disorder**

More often seen in boys than girls, isolated expressive language disorder (“late talker syndrome”) is a diagnosis best made in retrospect. These children have age-appropriate receptive language and social ability. Once they start talking, their speech is clear. There is no increased risk for language or learning disability as they progress through school. A family history of other males with a similar developmental pattern is often reported. This pattern of language development likely reflects a variation of normal.

**Motor Speech Disorders**

**Dysarthria**

Motor speech disorders can originate from neuromotor disorders such as cerebral palsy, muscular dystrophy, myopathy, and facial palsy. The resulting dysarthria affects both speech and nonspeech functions (smiling and chewing). Lack of strength and muscular control manifests as slurring of words and distorting of vowels. Speech patterns are often slow and labored. Poor velopharyngeal function can result in mixed nasal resonance (hyper- or hyponasal speech). In many cases, feeding difficulty, drooling, open-mouth posture, and protruding tongue accompany the dysarthric speech.

**Childhood Apraxia of Speech**
Difficulty in planning and coordinating movements for speech production can result in inconsistent distortion of speech sounds. The same word may be pronounced differently each time. Intelligibility tends to decline as the length and complexity of the child's speech increases. Consonants may be deleted and sounds transposed. As they try to talk spontaneously, or imitate other's speech, children with childhood apraxia of speech may display oral groping or struggling behaviors. Children with childhood apraxia of speech frequently have a history of early feeding difficulty, limited sound production as infants, and delayed onset of spoken words. They may point, grunt, or develop an elaborate gestural communication system in an attempt to overcome their verbal difficulty. Apraxia may be limited to oral-motor function, or it may be a more generalized problem affecting fine and/or gross motor coordination.

**Speech Sound Disorder**

Children with speech sound disorder (SSD), previously called phonologic disorder, are often unintelligible, even to their parents. Articulation errors are not the result of neuromotor impairment, but rather seem to reflect an inability to correctly process the words they hear (Table 52.2). As a result, they lack understanding of how to fit sounds together properly to create words. In contrast to children with childhood apraxia of speech, those SSD are fluent, although unintelligible, and produce a consistent, highly predictable pattern of articulation errors. Children with SSD are at high risk for later reading and learning disability.

**Hearing Impairment**

Hearing loss can be a major cause of delayed or disordered language development (see Chapter 655). Approximately 16-30 per 1,000 children have mild to severe hearing loss, significant enough to affect educational progress. In addition to these “hard of hearing” children, approximately another 1 : 1,000 are deaf (profound bilateral hearing loss). Hearing loss can be present at birth or acquired postnatally. Newborn screening programs can identify many forms of congenital hearing loss, but children can develop progressive hearing loss or acquire deafness after birth.

The most common types of hearing loss are attributable to conductive (middle ear) or sensorineural deficit. Although it is not possible to accurately predict the
impact of hearing loss on a child's language development, the type and degree of hearing loss, the age of onset, and the duration of the auditory impairment clearly play important roles. Children with significant hearing impairment often have problems developing facility with language and often have related academic difficulties. Presumably, the language impairment is caused by lack of exposure to fluent language models, starting in infancy.

Approximately 30% of hearing-impaired children have at least 1 other disability that affects development of speech and language (e.g., intellectual disability, cerebral palsy, craniofacial anomalies). Any child who shows developmental warning signs of a speech or language problem should have a hearing assessment by an audiologist.

Hydrocephalus

Some children with hydrocephalus may be described as having “cocktail-party syndrome.” Although they may use sophisticated words, their comprehension of abstract concepts is limited, and their pragmatic conversational skills are weak. As a result, they speak superficially about topics and appear to be carrying on a monolog (see Chapter 609.11).

Rare Causes of Language Impairment

Hyperlexia

Hyperlexia is the precocious development of reading single words that spontaneously occurs in some young children (2-5 yr) without specific instruction. It is often associated with ASD or SLI. It stands in contrast to precocious reading development in young children who do not have any other developmental disorders. A typical manifestation is a child with SLI orally reading single words or matching pictures with single words. Although hyperlexic children show early and well-developed word-decoding skills, they usually do not have precocious ability for comprehension of text. Rather, text comprehension is closely intertwined with oral comprehension, and children who have difficulty decoding the syntax of language are also at risk for having reading comprehension problems.
Landau-Kleffner Syndrome (Verbal Auditory Agnosia)

Children with Landau-Kleffner syndrome have a history of normal language development until they experience a regression in their ability to comprehend spoken language, **verbal auditory agnosia**. The regression may be sudden or gradual, and it usually occurs between 3 and 7 yr of age. Expressive language skills typically deteriorate, and some children may become mute. Despite their language regression, these children typically retain appropriate play patterns and the ability to interact in a socially appropriate manner. An electroencephalogram (EEG) might show a distinct pattern of status epilepticus in sleep (continuous spike wave in slow-wave sleep), and up to 80% of children with Landau-Kleffner syndrome eventually exhibit clinical seizures. A number of treatment approaches have been reported, including antiepileptic medication, corticosteroids, and intravenous gamma globulin, with varying results. The prognosis for return of normal language ability is uncertain, even with resolution of the EEG abnormality. Epileptic interictal discharges are more frequently found on EEGs of children with language impairments than in otherwise normally developing children, even in those without any history of language regression. However, this phenomenon is believed to represent a manifestation of an underlying disorder of brain structure or function that is distinct from the language impairment, because there has been little evidence of improvement in language function when the EEG was normalized after antiepileptic administration. Unless there is a clear pattern of either seizure symptoms or regression in language ability, a routine EEG is not recommended as part of the evaluation for a child with speech and/or language impairment.

Metabolic and Neurodegenerative Disorders

(See also Part X.)

Regression of language development may accompany loss of neuromotor function at the outset of a number of metabolic diseases, including lysosomal storage disorders (metachromatic leukodystrophy), peroxisomal disorders (adrenal leukodystrophy), ceroid lipofuscinosis (Batten disease), and mucopolysaccharidosis (Hunter disease, Hurler disease). Recently, creatine transporter deficiency was identified as an X-linked disorder that manifests with language delay in boys and with mild learning disability in female carriers.
Screening

Developmental surveillance at each well child visit should include specific questions about normal language developmental milestones and observations of the child's behavior. **Clinical judgment**, defined as eliciting and responding to parents' concerns, can detect the majority of children with speech and language problems. The AAP recommends clinicians employ standardized developmental screening questionnaires and observation checklists at select well child visits. (see Chapter 28).

In 2015 the U.S. Preventive Services Task Force reviewed screening for SLI in young children in primary care settings and found inadequate evidence to support screening in the absence of parental or clinician concern about children's speech, language, hearing, or development. When either parents or physicians are concerned about speech or language development for reasons such as highlighted in Table 52.3, the child should be referred for further evaluation and intervention (see Diagnostic Evaluation).

Noncauses of Language Delay

Twinning, birth order, “laziness,” exposure to multiple languages (bilingualism), tongue-tie (ankyloglossia), or otitis media are not adequate explanations for significant language delay. Normal twins learn to talk at the same age as normal
single-born children, and birth-order effects on language development have not been consistently found. The drive to communicate and the rewards for successful verbal interaction are so strong that children who let others talk for them usually cannot talk for themselves and are not “lazy.” Toddlers exposed to more than one language can show a mild delay in starting to talk, and they can initially mix elements (vocabulary and syntax) of the different languages they are learning (code switching). However, they learn to segregate each language by 24-30 mo and are equal to their monolingual peers by 3 yr of age. An extremely tight lingual frenulum (tongue-tie) can affect feeding and speech articulation but does not prevent the acquisition of language abilities. Prospective studies also show that frequent ear infections and serous otitis media in early childhood do not result in persisting language disorder.

**Diagnostic Evaluation**

It is important to distinguish developmental delay (abnormal timing) from abnormal patterns or sequences of development. A child's language and communication skills must also be interpreted within the context of the child's overall cognitive and physical abilities. It is also important to evaluate the child's use of language to communicate with others in the broadest sense (communicative intent). Thus a multidisciplinary evaluation is often warranted. At a minimum, this should include psychologic evaluation, neurodevelopmental pediatric assessment, and speech-language examination.

**Psychologic Evaluation**

There are two main goals for the psychologic evaluation of a young child with a communication disorder. Nonverbal cognitive ability must be assessed to determine if the child has an intellectually disability, and the child's social behaviors must be assessed to determine whether ASD is present. Additional diagnostic considerations may include emotional disorders such as anxiety, depression, mood disorder, obsessive-compulsive disorder, academic learning disorders, and attention-deficit/hyperactivity disorder (ADHD).

**Cognitive Assessment**

*Intellectual disability* is defined as deficits in cognitive abilities and adaptive behaviors. In this context, children with intellectual disability show delayed development of communication skills; however, delayed communication does
not necessarily signal intellectual disability. Therefore, a broad-based cognitive assessment is an important component to the evaluation of children with language delays, including evaluation of both verbal and nonverbal skills. If a child has intellectual disability, both verbal and nonverbal scores will be low compared to norms (≤2nd percentile). In contrast, a typical cognitive profile for a child with SLI includes a significant difference between nonverbal and verbal abilities, with nonverbal IQ being greater than verbal IQ and the nonverbal score being within an average range.

**Evaluation of Social Behaviors**

Social interest is the key difference between children with a primary language disorder (SLI) and those with a communication disorder secondary to ASD. Children with SLI have an interest in social interaction, but they may have difficulty enacting their interest because of their limitations in communication. In contrast, autistic children show little social interest.

**Relationship of Language and Social Behaviors to Mental Age**

Cognitive assessment provides a mental age for the child, and the child's behavior must be evaluated in that context. Most 4 yr old children typically engage peers in interactive play, but most 2 yr olds are playful but primarily focused on interactions with adult caretakers. A 4 yr old with mild to moderate intellectual disability and a mental age of 2 yr might not yet play with peers because of cognitive limitation, not a lack of desire for social interaction.

**Speech and Language Evaluation**

A certified speech-language pathologist should perform a speech and language evaluation. A typical evaluation includes assessment of language, speech, and the physical mechanisms associated with speech production. Both expressive and receptive language is assessed by a combination of standardized measures and informal interactions and observations. All components of language are assessed, including syntax, semantics, pragmatics, and fluency. Speech assessment similarly uses a combination of standardized measures and informal observations. Assessment of physical structures includes oral structures and function, respiratory function, and vocal quality. In many settings, a speech-
language pathologist works in conjunction with an **audiologist**, who can do appropriate hearing evaluation of the child. If an audiologist is not available in that setting, a separate referral should be made. No child is too young for a speech-language or hearing evaluation. A referral for evaluation is appropriate whenever there is suspicion of language impairment.

**Medical Evaluation**

Careful history and physical examination should focus on the identification of potential contributors to the child's language and communication difficulties. A **family history** of delay in talking, need for speech and language therapy, or academic difficulty can suggest a genetic predisposition to language disorders. A **Pregnancy history** might reveal risk factors for prenatal developmental anomalies, such as polyhydramnios or decreased fetal movement patterns. Small size for gestational age at birth, symptoms of neonatal encephalopathy, or early and persistent oral-motor feeding difficulty may presage speech and language difficulty. **Developmental history** should focus on the age when various language skills were mastered and the sequences and patterns of milestone acquisition. Regression or loss of acquired skills should raise immediate concern.

**Physical examination** should include measurement of height (length), weight, and head circumference. The skin should be examined for lesions consistent with phakomatosis (e.g., tuberous sclerosis, neurofibromatosis, Sturge-Weber syndrome) and other disruptions of pigment (e.g., hypomelanosis of Ito). Anomalies of the head and neck, such as white forelock and hypertelorism (Waardenburg syndrome), ear malformations (Goldenhar syndrome), facial and cardiac anomalies (Williams syndrome, velocardiofacial syndrome), retrognathism of the chin (Pierre Robin anomaly), or cleft lip/palate, are associated with hearing and speech abnormalities. **Neurologic examination** might reveal muscular hypertonia or hypotonia, both of which can affect neuromuscular control of speech. Generalized muscular hypotonia, with increased range of motion of the joints, is frequently seen in children with SLI. The reason for this association is not clear, but it might account for the fine and gross motor clumsiness often seen in these children. However, mild hypotonia is not a sufficient explanation for the impairment of expressive and receptive language.

No routine diagnostic studies are indicated for SLI or isolated language
disorders. When language delay is a part of a generalized cognitive or physical disorder, referral for further genetic evaluation, chromosome testing (e.g., fragile X testing, microarray comparative genomic hybridization), neuroimaging studies, and EEG may be considered, if clinically indicated.

**Treatment**

The federal Individuals with Disabilities Education Act (IDEA) requires that schools provide early intervention and special education services to children who have learning difficulties. This includes children with speech and language disorders. Services are provided to children from birth through 21 yr of age. States have various methods for providing services, including speech and language therapy for young children, such as Birth-to-Three, Early Childhood, and Early Learning programs. Children can also receive therapy from nonprofit service agencies, hospital and rehabilitation centers, and speech pathologists in private practice.

Of concern is that many children with identified speech and language deficits do not receive appropriate intervention services. Population-based surveys in both the United States and Canada have found that less than half of children identified by kindergarten entry receive speech and language interventions, even when their parents have been educated about the nature of their child's condition. In one study, children with deficits in speech sound production were much more likely to receive services (41%) than those who had problems with language alone (9%). These findings are troubling because poor educational outcome, especially in reading, and impaired social-behavioral adjustment are more highly associated with language than with speech sound disorders. Therefore the children at greatest risk are least likely to receive intervention services. Boys were twice as likely to receive speech intervention as girls, regardless of their speech-language diagnosis. Social and demographic factors did not appear to influence whether identified children received interventions services.

Speech-language therapy includes a variety of goals. Sometimes both speech and language activities are incorporated in therapy. The speech goals focus on development of more intelligible speech. Language goals can focus on expanding vocabulary (lexicon) and understanding of the meaning of words (semantics), improving syntax by using proper forms or learning to expand single words into sentences, and social use of language (pragmatics). Therapy
can include individual sessions, group sessions, and mainstream classroom integration. Individual sessions may use drill activities for older children or play activities for younger children to target specific goals. Group sessions can include several children with similar language goals to help them practice peer communication activities and to help them bridge the gap into more naturalistic communication situations. Classroom integration might include the therapist team-teaching or consulting with the teacher to facilitate the child's use of language in common academic situations.

For children with severe language impairment, alternative methods of communication are often included in therapy, such as manual sign language, use of pictures (e.g., Picture Exchange Communication System), and computerized devices for speech output. Often the ultimate goal is to achieve better spoken language. Early use of signs or pictures can help the child establish better functional communication and understand the symbolic nature of words to facilitate the language process. There is no evidence that use of signs or pictures interferes with development of oral language if the child has the capacity to speak. Many clinicians believe that these alternative methods accelerate the learning of language. These methods also reduce the frustration of parents and children who cannot communicate for basic needs.

Parents can consult with their child's speech-language therapist about home activities to enhance language development and extend therapy activities through appropriate language-stimulating activities and recreational reading. Parents' language activities should focus on emerging communication skills that are within the child's repertoire, rather than teaching the child new skills. The speech pathologist can guide parents on effective modeling and eliciting communication from their child.

Recreational reading focuses on expanding the child's comprehension of language. Sometimes the child's avoidance of reading is a sign that the parent is presenting material that is too complex for the child. The speech-language therapist can guide the parent in selecting an appropriate level of reading material.

**Prognosis**

Children with mild isolated expressive language disorder (“late talkers”) have an excellent prognosis for both language, learning, and social-emotional adjustment.
Over time, children with SLI respond to therapeutic/educational interventions and show a trend toward improvement of communication skills. Adults with a history of childhood language disorder continue to show evidence of impaired language ability, even when surface features of the communication difficulty have improved considerably. This suggests that many persons find successful ways of adapting to their impairment. Although the majority of children improve their communication ability with time, 50–80% of preschoolers with language delay and normal nonverbal intelligence continue to experience difficulty with language and social development up to 20 yr beyond the initial diagnosis. Language disorders often interfere with the child's ability to conceptualize the increasingly complex and ambiguous worlds of social relationship and emotions. Consequently, in later childhood and adolescence, children with persisting symptoms of SLI are about twice as likely as their typical-language peers to show clinical levels of emotional problems and twice as likely to show behavioral difficulties.

A Danish study found that adults with SLI were less likely to have completed formal education beyond high school, and that they had lower occupational and socioeconomic success than the general population; 56% had a paid job (vs 84% of same-age general population), of whom 35% were unskilled and 40% skilled workers. About 80% of the adults reported difficulty reading while in school, most had received remedial teaching, and 50% continued to report reading difficulty as adults (vs 5% of Danish adults). Lower nonverbal intelligence and comorbid psychiatric or neurologic disorders independently contributed to a worse prognosis. These results were consistent with previous reports of adult outcomes of children with SLI from Canada and the United Kingdom.

**Academic Disorders**

Early language difficulty is strongly related to later reading disorder. Approximately 50% of children with early language difficulty develop reading disorder, and 55% of children with reading disorder have a history of impaired early oral language development. By the time they enter kindergarten, many children with early language deficits may have improved significantly, and they may begin to show early literacy skills, identifying and sounding out letters. However, as they progress through school, they are often unable to keep up with the increasing demands for both oral and written language. Despite their ability to read words, these children lack oral and reading comprehension, may read
slowly, and struggle with a wide range of academic subjects. This “illusory recovery” of early language skill may result in children losing speech-language services or other special education support in early grades, only to be identified later with academic problems. In addition, children with subtle but persisting language impairments may appear inattentive or anxious in language-rich classroom environments and may be misdiagnosed as having an attention disorder.

A study from Australia found that at 7-9 yr of age, children with communication impairments were reported by their parents and teachers to be making slower progress in reading, writing, and overall school achievement than other children their age. The children reported a higher incidence of bullying, poorer peer relationships, and less overall enjoyment of school than their typically developing peers.

Comorbid Disorders

Emotional and Behavioral Difficulty

Early language disorder, particularly difficulty with auditory comprehension, appears to be a specific risk factor for later emotional dysfunction. Boys and girls with language disorder have a higher-than-expected rate of anxiety disorder (principally social phobia). Boys with language disorder are more likely to develop symptoms of ADHD, conduct disorder, and antisocial personality disorder compared with normally developing peers. Language disorders are common in children referred for psychiatric services, but they are often underdiagnosed, and their impact on children's behavior and emotional development is often overlooked.

Preschoolers with language difficulty frequently express their frustration through anxious, socially withdrawn, or aggressive behavior. As their ability to communicate improves, parallel improvements are usually noted in their behavior, suggesting a cause-and-effect relationship between language and behavior. However, the persistence of emotional and behavioral problems over the life span of persons with early language disability suggests a strong biologic or genetic connection between language development and subsequent emotional disorders.

The full impact of environmental and education support on these emotional and behavioral difficulties is not known at this time, but many children with SLI
need psychologic support. Efforts should be made to support the child's resilience, emotional competency, and coping abilities. Parents and teachers should be encouraged to strengthen the child's prosocial behavior and reduce noncompliant and aggressive behaviors.

Motor and Coordination Delays

Approximately one third to one half of children with speech and/or language disorders have some degree of motor coordination impairment that may have an important impact on their ability to carry out activities of daily living (dressing, eating, bathing), school tasks (writing, drawing, coloring), and social/recreational activities (participation in sports and other playground activities). Motor difficulties are not related to the type of language impairment (i.e., they are found both in children with only receptive delays and in those with both expressive and receptive delays). The patterns of motor difficulty seen in children with language impairment are not distinctly “abnormal,” and the motor profiles of children with language impairment resemble those of younger children, suggesting that they result from delayed maturation of motor development rather than from a neurologic impairment. Several researchers have postulated that language impairments and motor difficulties may have a common neurodevelopmental basis. Because attention may be focused on the child's language delays, the need for intervention and support for the child's comorbid motor impairment may be overlooked.

52.1

Childhood-Onset Fluency Disorder

Kenneth L. Grizzle

Keywords
childhood-onset fluency disorder
cluttering
physical concomitants
stammering, stuttering

**Developmental stuttering** is a childhood speech disorder that is not associated with stroke, traumatic brain injury, or other possible medical conditions and that interrupts the normal flow of speech through repeated or prolonged sounds, syllables, or single-syllable words. (*Table 52.4* lists definitions of terminology.) All speakers experience *speech dysfluencies*. During the toddler and preschool years, children often make repetitions of sounds, syllables, or words, particularly at the beginning of sentences (normal dysfluencies). However, dysfluencies found in individuals who stutter are distinct from those experienced by typically developing speakers. Specifically, children who stutter show greater part-word repetition (“b-b-b-b-but”), single-syllable word repetition (“My, my, my”), and sound prolongation (“MMMMMMM-an”), and the frequency of their stuttering is much greater than found in normal dysfluencies. Other types of dysfluency that are not exclusive to children who stutter include *interjections* (“well, uhh, umm”), *revisions* (“I thought…I mean”), and *phrase repetitions* (“Did you say–Did you say”). The perspective of the speaker also characterizes differences between those children who stutter and a typical dysfluency. Children who stutter have decided on a word to use but are unable to “get the word out,” while a typically developing child may struggle to express herself because she is unable to retrieve the word, changes thought, or is distracted.

**Table 52.4**

<td>Dysfluency</td>
<td>Speech disruptions that can occur in normal or disordered speech</td>
</tr>
</tbody>
</table>

Multiple nonspeech features can accompany stuttering. **Physical concomitants** that occur at the onset and as the condition persists include
movements of the head (head turning or jerking), face (eye blinking/squinting, grimacing, opening or tightly closing the jaw), and neck (tightening) and irregular inhalations and exhalations. Fear and anxiety about speaking in a large-group setting, such as in front of a class or in interpersonal social interactions, are emotional symptoms associated with stuttering. As with all social beings, children closely monitor the reactions of those with whom they associate, especially as they get older. It is not difficult to imagine the impact a single or series of negative interactions or comments could have on a child's future attempts to interact verbally with another or in a large social setting. Consider also the potential social challenges associated with entering a classroom for the first time, transitioning to middle/high school/college, beginning a job, dating, and so on. Not surprisingly, avoidance is a common way of coping with the anxiety created by the fear of stuttering.

In the Diagnostic and Statistical Manual for Mental Disorders, Fifth Edition (DSM-5), the term stuttering has been removed from the diagnostic classification, and the disorder is referred to as childhood-onset fluency disorder (Table 52.5). Note that impact on functional behavior is a component of the psychiatric diagnosis of this condition. In contrast, communication disorder specialists would consider possible anxiety and avoidance of various activities and situations a common concomitant of childhood-onset fluency disorder (stuttering) and not necessarily a requirement for the diagnosis to be made.

**Table 52.5**

**DSM-5 Diagnostic Criteria for Childhood-Onset Fluency Disorder (Stuttering)**

A. Disturbances in the normal fluency and time patterning of speech that are inappropriate for the individual's age and language skills, persist over time, and are characterized by frequent and marked occurrences of one (or more) of the following:

1. Sound and syllable repetitions.
2. Sound prolongations of consonants as well as vowels.
3. Broken words (e.g., pauses within a word).
4. Audible or silent blocking (filled or unfilled pauses in speech).
5. Circumlocutions (word substitutions to avoid problematic words).
6. Words produced with an excess of physical tension.
7. Monosyllabic whole-word repetitions (e.g., “I-I-I-I see him”).

B. The disturbance causes anxiety about speaking or limitations in effective communication, social participation, or academic or occupational performance, individually or in any combination.

C. The onset of symptoms is in the early developmental period.
   Note: Later-onset cases are diagnosed as 307.0 [F98.5] adult-onset fluency disorder.

D. The disturbance is not attributable to a speech-motor or sensory deficit, dysfluency associated with neurologic insult (e.g., stroke, tumor, trauma), or another medical condition and is not better explained by another mental disorder.

From the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*, (Copyright 2013). American Psychiatric Association, pp 45–46.)

Stuttering is distinct from other disordered speech output conditions such as cluttering in several ways. Unlike stuttering, for which distinct episodes can be identified and even counted, cluttering affects the entire speech output. In addition to elevated repetitions of partial words (as in stuttering), whole words, and phrases, those who clutter show speech bursts that are often choppy, and articulation can be slurred and imprecise. The level of awareness of how their speech affects those listening, unlike children who stutter, is minimal for those who clutter. Stammering and stuttering are terms used interchangeably, although the former is used in the United Kingdom and the latter in the United States. “Stammer” is also used informally to describe when an individual is struggling to express himself and may speak in a halting or “bumbling” manner.

**Epidemiology**

Although prevalence studies have produced a range of estimates for developmental stuttering, it appears that 0.75–1% of the population is experiencing this condition at any one time. Incidence rates are considerably higher: Estimates to date suggest an incidence rate of approximately 5%, with rates considerably higher among young children than older children or adolescents. Seldom does a child begin stuttering before 2 yr of age or after 12 yr; in fact, the mean age of onset is 2–4 yr, and most children stop stuttering
within 4 yr of onset. Symptoms will disappear within 4 wk for a minority of children. Although studies have consistently shown that the male:female ratio favors males, the magnitude of the pattern increases as children get older. The ratio among children <5 yr is approximately 2:1 and jumps to 4:1 among adolescents and young adults.

**Genetics**

There is convergent evidence of a genetic link for childhood-onset fluency disorder. Concordance rates among MZ twins range from 20–83%, and for DZ twins, 4–19%. Family aggregation studies suggest increased incidence rate of approximately 15% among first-degree relatives of those affected, 3 times higher than the 5% rate for the general population. The variance in risk for stuttering attributed to genetic effects is high, ranging from 70–85%. Although evidence is limited, stuttering appears to be a polygenic condition, and several genes increase susceptibility.

**Etiology**

Brain structure and function abnormalities found in stutterers include deficits in white matter in the left hemisphere, overactivity in the right cortical region, and underactivity in the auditory cortex. Abnormal basal ganglia activation has also been identified among stutterers.

**Comorbidities**

Despite the widely held belief in a high degree of comorbidity between childhood-onset fluency disorder and other communication disorders, research to date does not necessarily support this assertion. Speech-language pathologists (SLPs) consistently report higher rates of comorbidity on their caseload, although this would be expected in clinical samples. Speech sound (phonologic) disorders are the most commonly reported comorbidities, and 30–40% of children on SLP caseloads are also experiencing problems with phonology. However, studies have not found greater incidence of phonologic disorders among those who stutter compared to a control group. Similarly, SLPs report a much higher percentage of children with language disorders among their patients.
who stutter than the approximately 7% expected in the population at large, yet the language functioning among stutters apparently is no different than in the general population. The same pattern holds for learning disorder (LD). The incidence of various types of LDs associated with a language disorder is well documented, so one would expect to see increased frequency within a clinical population.

The perception of communication disorder professionals and people in general is that children who stutter experience more anxiety than their nonstuttering peers. This in fact is supported by clinical research that has found considerably higher rates of psychopathology, specifically social anxiety and generalized anxiety disorder, among adolescents who stutter. The frequency of reported anxiety increases with age. To date, however, the lack of controlled studies should not lead to the assumption that stuttering itself places a child or adolescent at greater risk for a psychiatric disorder of any type. This is not meant to suggest that anxiety has no impact on a stuttering child's behavior in specific situations; as indicated earlier in this chapter, children who stutter frequently avoid situations that demand speaking.

Children who stutter have consistently been found to be bullied more than peers. In one study, stutterers were almost 4 times more likely to be bullied than their nonstuttering counterparts. About 45% of those who stuttered reported being the victim of bullying.

**Developmental Progression**

Onset of stuttering typically occurs between 2 and 4 yr of age. Severity of symptoms vary, from pronounced stuttering within a few days of onset to gradual worsening of symptoms across months. Symptoms may ebb and flow, including disappearing for weeks before returning, especially among young children. From 40–75% of young children who stutter will stop spontaneously, typically within months of starting. Although predicting which child will stop stuttering is difficult, risk factors for persisting include stuttering for >1 yr, continued stuttering after age 6 yr, and experiencing other speech or language problems.

**Treatment**
Several factors should be considered when deciding to refer a younger child with childhood-onset fluency disorder for therapy. If there is a positive family history for stuttering, if symptoms have been present for >4 wk, and if the dysfluencies are impacting the child's social, behavioral, and emotional functioning, referral is warranted. Although there is no cure for stuttering, behavioral therapies are available that are developed and implemented by SLPs. Treatment emphasizes managing stuttering while speaking by regulating rate of speech and breathing and helping the child gradually progress from the fluent production of syllables to more complex sentences. Approaches to treatment may include parents directly in the process, although even if not active participants, parents play an important role in the child coping with stuttering. Treatment in preschool-age children has been shown to improve stuttering. Management of stuttering is also emphasized in older children. For school-age children, treatment includes improving not only fluency but also concomitants of the condition. This includes recognizing and accepting stuttering and appreciating others' reaction to the child when stuttering, managing secondary behaviors, and addressing avoidance behaviors. The broad focus allows for minimizing the adverse effects of the condition. To date, no evidence supports the use of a pharmacologic agent to treat stuttering in children and adolescents.

Preschool children with normal developmental dysfluency can be observed with parental education and reassurance. Parents should not reprimand the child or create undue anxiety.

Preschool or older children with stuttering should be referred to a speech pathologist. Therapy is most effective if started during the preschool period. In addition to the risks noted in Table 52.5, indications for referral include 3 or more dysfluencies per 100 syllables (b-b-but; th-th-the; you, you, you), avoidances or escapes (pauses, head nod, blinking), discomfort or anxiety while speaking, and suspicion of an associated neurologic or psychotic disorder.

Most preschool children respond to interventions taught by speech pathologists and to behavioral feedback by parents. Parents should not yell at the child, but should calmly praise periods of fluency (“That was smooth”) or nonjudgmentally note episodes of stuttering (“That was a bit bumpy”). The child can be involved with self-correction and respond to requests (“Can you say that again?”) made by a calm parent. Such treatment greatly improves dysfluency, but it may never be eliminated.

Intellectual disability (ID) refers to a group of disorders that have in common deficits of adaptive and intellectual function and an age of onset before maturity is reached.

Definition

Contemporary conceptualizations of ID emphasize functioning and social interaction rather than test scores. The definitions of ID by the World Health Organization (WHO) *International Classification of Diseases, Tenth Edition* (ICD-10), the U.S. Individuals with Disabilities Education Act (IDEA), the American Psychiatric Association (APA) *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition* (DSM-5), and the American Association on Intellectual and Developmental Disabilities (AAIDD) all include significant impairment in general intellectual function (reasoning, learning, problem solving), social skills, and adaptive behavior. This focus on conceptual, social, and practical skills enables the development of individual treatment plans designed to enhance functioning. Consistent across these definitions is onset of symptoms before age 18 yr or adulthood.

*Significant impairment in general intellectual function* refers to performance on an individually administered test of intelligence that is approximately 2 standard deviations (SD) below the mean. Generally these tests provide a standard score that has a mean of 100 and SD of 15, so that intelligence quotient (IQ) scores <70 would meet these criteria. If the standard error of measurement is considered, the upper limits of significantly impaired intellectual function may
extend to an IQ of 75. Using a score of 75 to delineate ID might double the number of children with this diagnosis, but the requirement for impairment of adaptive skills limits the false positives. Children with ID often show a variable pattern of strengths and weaknesses. Not all their subtest scores on IQ tests fall into the significantly impaired range.

*Significant impairment in adaptive behavior* reflects the degree that the cognitive dysfunction impairs daily function. **Adaptive behavior** refers to the skills required for people to function in their everyday lives. The AAIDD and DSM-5 classifications of adaptive behavior addresses three broad sets of skills: conceptual, social, and practical. **Conceptual skills** include language, reading, writing, time, number concepts, and self-direction. **Social skills** include interpersonal skills, personal and social responsibility, self-esteem, gullibility, naïveté, and ability to follow rules, obey laws, and avoid victimization. Representative **practical skills** are performance of activities of daily living (dressing, feeding, toileting/bathing, mobility), instrumental activities of daily living (e.g., housework, managing money, taking medication, shopping, preparing meals, using phone), occupational skills, and maintenance of a safe environment. For a deficit in adaptive behavior to be present, a significant delay in at least 1 of the 3 skill areas must be present. The rationale for requiring only 1 area is the empirically derived finding that people with ID can have varying patterns of ability and may not have deficits in all 3 areas.

The requirement for adaptive behavior deficits is the most controversial aspect of the diagnostic formulation. The controversy centers on two broad areas: whether impairments in adaptive behavior are necessary for the construct of ID, and what to measure. The adaptive behavior criterion may be irrelevant for many children; adaptive behavior is impaired in virtually all children who have IQ scores <50. The major utility of the adaptive behavior criterion is to confirm ID in children with IQ scores in the 65-75 range. It should be noted that deficits in adaptive behavior are often found in disorders such as autism spectrum disorder (ASD; see Chapter 54) and attention-deficit/hyperactivity disorder (ADHD; see Chapter 49) in the presence of typical intellectual function.

The issues of measurement are important as well. The independence of the 3 domains of adaptive behavior has not been validated. The relationship between adaptive behavior and IQ performance is insufficiently explored. Most adults with mild ID do not have significant impairments in practical skills. Adaptive behavior deficits also must be distinguished from *maladaptive behavior* (e.g., aggression, inappropriate sexual contact).
Onset before age 18 yr or adulthood distinguishes dysfunctions that originate during the developmental period. The diagnosis of ID may be made after 18 yr of age, but the cognitive and adaptive dysfunction must have been manifested before age 18.

The term “mental retardation” should not be used because it is stigmatizing, has been used to limit the achievements of the individual, and has not met its initial objective of assisting people with the disorder. The term intellectual disability is increasingly used in its place, but has not been adopted universally. In the United States, Rosa's law (Public Law 111-256) was passed in 2010 and now mandates that the term mental retardation be stripped from federal health, education, and labor policy. As of 2013, at least 9 states persist in using the outdated terminology. In Europe the term learning disability is often used to describe ID.

Global developmental delay (GDD) is a term often used to describe young children whose limitations have not yet resulted in a formal diagnosis of ID. In DSM-5, GDD is a diagnosis given to children <5 yr of age who display significant delay (>2 SD) in acquiring early childhood developmental milestones in 2 or more domains of development. These domains include receptive and expressive language, gross and fine motor function, cognition, social and personal development, and activities of daily living. Typically, it is assumed that delay in 2 domains will be associated with delay across all domains evaluated, but this is not always the case. Furthermore, not all children who meet criteria for a GDD diagnosis at a young age go on to meet criteria for ID after age 5 yr. Reasons for this might include maturational effects, a change in developmental trajectory (possibly from an intervention), reclassification to a different disability category, or imprecise use of the GDD diagnosis initially. Conversely, in patients with more severe delay, the GDD term is often inappropriately used beyond the point when the child clearly has ID, often by 3 yr of age.

It is important to distinguish the medical diagnosis of GDD from the federal disability classification of “developmental delay” that may be used by education agencies under IDEA. This classification requires that a child have delays in only 1 domain of development with subsequent need for special education. Each state determines its own precise definition and terms of eligibility under the broader definition outline by IDEA, and many states use the label for children up to age 9 yr.
Etiology

Numerous identified causes of ID may occur prenatally, during delivery, postnatally, or later in childhood. These include infection, trauma, prematurity, hypoxia-ischemia, toxic exposures, metabolic dysfunction, endocrine abnormalities, malnutrition, and genetic abnormalities. However, more than two thirds of persons with ID will not have a readily identifiable underlying diagnosis that can be linked to their clinical presentation, meriting further medical evaluation. For those who then undergo further genetic and metabolic workup, about two thirds will have an etiology that is subsequently discovered. There does appear to be 2 overlapping populations of children with ID with differing corresponding etiologies. Mild ID (IQ 50-70) is associated more with environmental influences, with the highest risk among children of low socioeconomic status. Severe ID (IQ <50) is more frequently linked to biologic and genetic causes. Accordingly, diagnostic yield is generally higher among persons with more severe disability (>75%) than among those with mild disability (<50%). With continued advancement of technologic standards and expansion of our knowledge base, the number of identified biologic and genetic causes is expected to increase.

Nongenetic risk factors that are often associated with mild ID include low socioeconomic status, residence in a developing country, low maternal education, malnutrition, and poor access to healthcare. The most common biologic causes of mild ID include genetic or chromosomal syndromes with multiple, major, or minor congenital anomalies (e.g., velocardiofacial, Williams, and Noonan syndromes), intrauterine growth restriction, prematurity, perinatal insults, intrauterine exposure to drugs of abuse (including alcohol), and sex chromosomal abnormalities. Familial clustering is common.

In children with severe ID, a biologic cause (usually prenatal) can be identified in about three fourths of all cases. Causes include chromosomal (e.g., Down, Wolf-Hirschhorn, and deletion 1p36 syndromes) and other genetic and epigenetic disorders (e.g., fragile X, Rett, Angelman, and Prader-Willi syndromes), abnormalities of brain development (e.g., lissencephaly), and inborn errors of metabolism or neurodegenerative disorders (e.g., mucopolysaccharidoses) (Table 53.1). Nonsyndromic severe ID may be a result of inherited or de novo gene mutations, as well as microdeletions or microduplications not detected on standard chromosome analysis. Currently, >700 genes are associated with nonsyndromic ID. Inherited genetic
abnormalities may be mendelian (autosomal dominant de novo, autosomal recessive, X-linked) or nonmendelian (imprinting, methylation, mitochondrial defects; see Chapter 97). De novo mutations may also cause other phenotypic features such as seizures or autism; the presence of these features suggests more pleotropic manifestations of genetic mutations. Consistent with the finding that disorders altering early embryogenesis are the most common and severe, the earlier the problem occurs in development, the more severe its consequences tend to be.

Etiologic workup is recommended in all cases of GDD or ID. Although there are only about 80 disorders (all of which are metabolic in nature) for which treatment may ameliorate the core symptoms of ID, several reasons beyond disease modification should prompt providers to seek etiologic answers in patients with ID. These include insight into possible associated medical or behavioral comorbidities; information on prognosis and life expectancy; estimation of recurrence risk for family planning counseling, potential validation, and closure for the family; increased access to services or specific supports; and better understanding of underlying pathology with the hope of new
eventual treatment options. When surveyed, families of children with ID with no identified underlying etiology almost universally report that they would want to know of an etiologic diagnosis if given the choice.

**Epidemiology**

The prevalence of ID depends on the definition, method of ascertainment, and population studied, both in terms of geography and age. According to the statistics of a normal distribution, 2.5% of the population should have ID (based on IQ alone), and 75% of these individuals should fall into the mild to moderate range. Variability in rates across populations likely results from the heavy influence of external environmental factors on the prevalence of mild ID. The prevalence of severe ID is relatively stable. Globally, the prevalence of ID has been estimated to be approximately 16.4 per 1,000 persons in low-income countries, approximately 15.9/1,000 for middle-income countries, and approximately 9.2/1,000 in high-income countries. A meta-analysis of worldwide studies from 1980–2009 yielded an overall prevalence of 10.4/1000. ID occurs more in boys than in girls, at 2:1 in mild ID and 1.5:1 in severe ID. In part this may be a consequence of the many X-linked disorders associated with ID, the most prominent being fragile X syndrome (see Chapter 98.5).

In 2014–2015 in the United States, approximately 12/1000 students 3-5 yr old and 6.2/1000 students 6-21 yr old received services for ID in federally supported school programs. In 2012 the National Survey of Children's Health reported an estimated prevalence of ID among American children (age 2-17 yr) of 1.1%. For several reasons, fewer children than predicted are identified as having mild ID. Because it is more difficult to diagnose mild ID than the more severe forms, professionals might defer the diagnosis and give the benefit of the doubt to the child. Other reasons that contribute to the discrepancy are use of instruments that underidentify young children with mild ID, children diagnosed as having ASD without their ID being addressed, misdiagnosis as a language disorder or specific learning disability, and a disinclination to make the diagnosis in poor or minority students because of previous overdiagnosis. In some cases, behavioral disorders may divert the focus from the cognitive dysfunction.

Beyond potential underdiagnosis of mild ID, the number of children with mild ID may be decreasing as a result of public health and education measures to prevent prematurity and provide early intervention and Head Start programs. However, although the number of schoolchildren who receive services under a
federal disability classification of ID has decreased since 1999, when developmental delay is included in analysis of the data, the numbers have not changed appreciably.

The prevalence of severe ID has not changed significantly since the 1940s, accounting for 0.3–0.5% of the population. Many of the causes of severe ID involve genetic or congenital brain malformations that can neither be anticipated nor treated at present. In addition, new populations with severe ID have offset the decreases in the prevalence of severe ID that have resulted from improved healthcare. Although prenatal diagnosis and subsequent pregnancy terminations could lead to a decreasing incidence of Down syndrome (see Chapter 98.2), and newborn screening with early treatment has virtually eliminated ID caused by phenylketonuria and congenital hypothyroidism, continued high prevalence of fetal exposure to illicit drugs and improved survival of very-low-birthweight premature infants has counterbalanced this effect.

Pathology and Pathogenesis

The limitations in our knowledge of the neuropathology of ID are exemplified by 10–20% of brains of persons with severe ID appearing entirely normal on standard neuropathologic study. Most of these brains show only mild, nonspecific changes that correlate poorly with the degree of ID, including microcephaly, gray matter heterotopias in the subcortical white matter, unusually regular columnar arrangement of the cortex, and neurons that are more tightly packed than usual. Only a minority of the brain shows more specific changes in dendritic and synaptic organization, with dysgenesis of dendritic spines or cortical pyramidal neurons or impaired growth of dendritic trees. The programming of the central nervous system (CNS) involves a process of induction; CNS maturation is defined in terms of genetic, molecular, autocrine, paracrine, and endocrine influences. Receptors, signaling molecules, and genes are critical to brain development. The maintenance of different neuronal phenotypes in the adult brain involves the same genetic transcripts that play a crucial role in fetal development, with activation of similar intracellular signal transduction mechanisms.

As the ability to identify genetic aberrations that correspond to particular phenotypes expands through the use of next-generation sequencing, more will be elucidated about the pathogenesis of ID at a genetic and molecular level. This expanding pathophysiologic knowledge base may serve as a framework with
which to develop targeted therapies to bypass or correct newly identified defects. For example, use of histone deacetylase (HDAC) inhibitors has been shown to rescue structural and functional neural deficits in mouse models of Kabuki syndrome, a disorder of histone methylation that leads to variable levels of ID and characteristic facial features (see Chapter 100).

**Clinical Manifestations**

Early diagnosis of ID facilitates earlier intervention, identification of abilities, realistic goal setting, easing of parental anxiety, and greater acceptance of the child in the community. Most children with ID first come to the pediatrician's attention in infancy because of dysmorphisms, associated developmental disabilities, or failure to meet age-appropriate developmental milestones (Tables 53.2 and 53.3). There are no specific physical characteristics of ID, but dysmorphisms may be the earliest signs that bring children to the attention of the pediatrician. They might fall within a genetic syndrome such as Down syndrome or might be isolated, as in microcephaly or failure to thrive. Associated developmental disabilities include seizure disorders, cerebral palsy, and ASD.

- Broad thumb: Rubinstein-Taybi syndrome
- Syndactyly: de Lange syndrome
- Transverse palmar crease: Down syndrome
- Joint laxity: Down syndrome, fragile X syndrome, Ehlers-Danlos syndrome
- Phocomelia: Cornelia de Lange syndrome

**Spine**
- Sacral dimple/hairy patch: spina bifida

**Skin**
- Hypopigmented macules/adenoma sebaceum: tuberous sclerosis
- Café au lait spots and neurofibromas: neurofibromatosis
- Linear depigmented nevi: hypomelanosis of Ito
- Facial port-wine hemangioma: Sturge-Weber syndrome
- Nail hypoplasia or dysplasia: fetal alcohol syndrome, trisomies

* Increased incidence of minor anomalies have been reported in cerebral palsy, intellectual disability, learning disabilities, and autism.
† The presence of 3 or more minor anomalies implies a greater chance that the child has a major anomaly and a diagnosis of a specific syndrome.

CHARGE, Coloboma, heart defects, atresia choanae, retarded growth, genital anomalies, ear anomalies (deafness).

Most children with ID do not keep up with their peers' developmental skills. In early infancy, failure to meet age-appropriate expectations can include a lack of visual or auditory responsiveness, unusual muscle tone (hypo- or hypertonia) or posture, and feeding difficulties. Between 6 and 18 mo of age, gross motor delay (lack of sitting, crawling, walking) is the most common complaint. Language delay and behavior problems are common concerns after 18 mo (Table 53.4). For some children with mild ID, the diagnosis remains uncertain during the early school years. It is only after the demands of the school setting increase over the years, changing from “learning to read” to “reading to learn,” that the child's limitations are clarified. Adolescents with mild ID are typically up to date on current trends and are conversant as to “who,” “what,” and “where.” It is not until the “why” and “how” questions are asked that their limitations become apparent. If allowed to interact at a superficial level, their mild ID might not be appreciated, even by professionals, who may be their special education teachers or healthcare providers. Because of the stigma associated with ID, adolescents
may use euphemisms to avoid being thought of as “stupid” or “retarded” and may refer to themselves as learning disabled, dyslexic, language disordered, or slow learners. Some people with ID emulate their social milieu to be accepted. They may be social chameleons and assume the morals of the group to whom they are attached. Some would rather be thought “bad” than “incompetent.”

Children with ID have a nonprogressive disorder; loss of developmental milestones or progressive symptoms suggest another disorder (see Chapter 53.1).

Diagnostic Evaluation

Intellectual disability is one of the most frequent reasons for referral to pediatric genetic providers, with separate but similar diagnostic evaluation guidelines put forth by the American College of Medical Genetics, the American Academy of Neurology, the American Academy of Pediatrics (AAP), and the American Academy of Child and Adolescent Psychiatry. ID is a diagnosis of great clinical heterogeneity, with only a subset of syndromic etiologies identifiable through classic dysmorphology. If diagnosis is not made after conducting an appropriate history and physical examination, chromosomal microarray is the recommended first step in the diagnostic evaluation of ID. Next-generation sequencing represents the new diagnostic frontier, with extensive gene panels (exome or whole genome) that increase the diagnostic yield and usefulness of genetic testing in ID. Other commonly used medical diagnostic testing for children with
ID includes neuroimaging, metabolic testing, and electroencephalography (Fig. 53.1).

![Algorithm for the evaluation of the child with unexplained global developmental delay (GDD) or intellectual disability (ID).](image)

Decisions to pursue an etiologic diagnosis should be based on the medical and family history, physical examination, and the family's wishes. Table 53.5 summarizes clinical practice guidelines and the yields of testing to assist in decisions about evaluating the child with GDD or ID. Yield of testing tends increase with worsening severity of delays.

</tbody>
</table>

EEG, Electroencephalogram; CGH, comparative genomic hybridization; MECP2, methyl CpG-binding protein 2; T<sub>4</sub>, thyroxine; TSH, thyroid-stimulating hormone.

Microarray analysis has replaced a karyotype as first-tier testing given that it discerns abnormalities that are far below the resolution of a karyotype. Microarray analysis may identify variants of unknown significance or benign variants and therefore should be used in conjunction with a genetic consultation. Karyotyping has a role when concerns for inversions, balanced insertions, and reciprocal translocations are present. Fluorescence in situ hybridization (FISH) and subtelomeric analysis have been largely replaced by microarray analysis but are occasionally used for specific indications. If microarray analysis is not diagnostic, whole exome sequencing increases the diagnostic yield in many children with nonsyndromic severe ID. Starting with whole exome sequencing may be more cost-effective and may substantially reduce time to diagnosis with higher ultimate yields compared with the traditional diagnostic pathway.

Molecular genetic testing for fragile X syndrome is recommended for all children presenting with GDD. Yields are highest in males with moderate ID, unusual physical features, and/or a family history of ID, or for females with more subtle cognitive deficits associated with severe shyness and a relevant family history, including premature ovarian failure or later-onset ataxia-tremor symptoms. For children with a strong history of X-linked ID, specific testing of genes or the entire chromosome may be revealing. Testing for Rett syndrome (MECP2, methyl CpG–binding protein 2) should be considered in girls with moderate to severe disability.

A child with a progressive neurologic disorder, developmental regression, or acute behavioral changes needs metabolic investigation as shown in Figure 53.1. Some are advocating that metabolic testing should be done more frequently in children with ID because of the possibility of detecting a condition that could be treatable (Fig. 53.2 and Table 53.6). A child with seizure-like episodes should have an electroencephalogram (EEG), although this testing is generally not helpful outside the scope of ruling out seizures. MRI of the brain may provide useful information in directing the care of a child with micro- or macrocephaly, change in head growth trajectory, asymmetric head shape, new or focal neurologic findings, or seizure. MRI can detect a significant number of subtle markers of cerebral dysgenesis in children with ID, but these markers do not usually suggest a specific etiologic diagnosis.
Summary of treatable inherent errors of metabolism (IEM) that can be detected by metabolic tests in affected children, each of which is affordable and accessible and has the potential to identify at least 2 IEM (and up to 22). Each bar represents the yield of the specific screening test and lists the number and types of treatable IEM it can identify. PAA, Plasma amino acids; tHcy, total homocysteine; ACP, plasma acylcarnitine profile; UOA, urine organic acids. (From van Karnebeek CD, Stockler S: Treatable inborn errors of metabolism causing intellectual disability: a systematic literature review, Mol Genet Metab 105:368–381, 2012, Fig 1, p 374.)

IEM, Inborn errors of metabolism; CSF, cerebrospinal fluid; CGH, comparative genomic hybridization; CoQ, coenzyme Q (ubiquinone).

* Low threshold for ordering tests.

Some children with subtle physical or neurologic findings can also have determinable biologic causes of their ID (see Tables 53.2 and 53.3). How intensively one investigates the cause of a child's ID is based on the following factors:

◆ What is the degree of delay, and what is the age of the child? If milder or less pervasive delays are present, especially in a younger child, etiologic yield is likely to be lower.
◆ Is the medical history, family history, or physical exam suggestive of a specific disorder, increasing the likelihood that a diagnosis will be made? Are the parents planning on having additional children, and does the patient have siblings? If so, one may be more
likely to intensively seek disorders for which prenatal diagnosis or a specific early treatment option is available.

◆ What are the parents' wishes? Some parents have little interest in searching for the cause of the ID, whereas others become so focused on obtaining a diagnosis that they have difficulty following through on interventions until a cause has been found. The entire spectrum of responses must be respected, and supportive guidance should be provided in the context of the parents' education.

**Differential Diagnosis**

One of the important roles of pediatricians is the early recognition and diagnosis of cognitive deficits. The developmental surveillance approach to early diagnosis of ID should be multifaceted. Parents' concerns and observations about their child's development should be listened to carefully. Medical, genetic, and environmental risk factors should be recognized. Infants at high risk (prematurity, maternal substance abuse, perinatal insult) should be registered in newborn follow-up programs in which they are evaluated periodically for developmental lags in the 1st 2 yr of life; they should be referred to early intervention programs as appropriate. Developmental milestones should be recorded routinely during healthcare maintenance visits. The AAP has formulated a schema for developmental surveillance and screening (see Chapter 28).

Before making the diagnosis of ID, other disorders that affect cognitive abilities and adaptive behavior should be considered. These include conditions that mimic ID and others that involve ID as an associated impairment. Sensory deficits (severe hearing and vision loss), communication disorders, refractory seizure disorders, poorly controlled mood disorders, or unmanaged severe attention deficits can mimic ID; certain progressive neurologic disorders can appear as ID before regression is appreciated. Many children with cerebral palsy
Differentiation of isolated cerebral palsy from ID relies on motor skills being more affected than cognitive skills and on the presence of pathologic reflexes and tone changes. In autism spectrum disorders, language and social adaptive skills are more affected than nonverbal reasoning skills, whereas in ID, there are usually more equivalent deficits in social, fine motor, adaptive, and cognitive skills.

### Diagnostic Psychologic Testing

The formal diagnosis of ID requires the administration of individual tests of intelligence and adaptive functioning.

The Bayley Scales of Infant and Toddler Development (BSID-III), the most commonly used infant intelligence test, provides an assessment of cognitive, language, motor, behavior, social-emotional, and general adaptive abilities between 1 mo and 42 mo of age. Mental Developmental Index (MDI) and Psychomotor Development Index (PDI, a measure of motor competence) scores are derived from the results. The BSID-III permits the differentiation of infants with severe ID from typically developing infants, but it is less helpful in distinguishing between a typical child and one with mild ID.

The most commonly used psychologic tests for children older than 3 yr are the Wechsler Scales. The Wechsler Preschool and Primary Scale of Intelligence, Fourth Edition (WPPSI-IV) is used for children with mental ages of 2.5-7.6 yr. The Wechsler Intelligence Scale for Children, Fifth Edition (WISC-V) is used for children who function above a 6 yr mental age. Both scales contain numerous subtests in the areas of verbal and performance skills. Although children with ID usually score below average on all subscale scores, they occasionally score in the average range in one or more performance areas.

Several normed scales are used in practice to evaluate adaptive functioning. For example, the Vineland Adaptive Behavior Scale (VABS-3) uses semistructured interviews with parents and caregivers/teachers to assess adaptive behavior in 4 domains: communication, daily living skills, socialization, and motor skills. Other tests of adaptive behavior include the Woodcock-Johnson Scales of Independent Behavior–Revised, the AAIDD Diagnostic Adaptive Behavior Scale (DABS), and the Adaptive Behavior Assessment System (ABAS-3). There is usually (but not always) a good correlation between scores on the intelligence and adaptive scales. However, it is important to recognize that adaptive behavior can be influenced by environmentally based opportunities as
well as family or cultural expectations. Basic practical adaptive skills (feeding, dressing, hygiene) are more responsive to remedial efforts than is the IQ score. Adaptive abilities are also more variable over time, which may be related to the underlying condition and environmental expectations.

**Complications**

Children with ID have higher rates of vision, hearing, neurologic, orthopedic, and behavioral or emotional disorders than typically developing children. These other problems are often detected later in children with ID. If untreated, the associated impairments can adversely affect the individual's outcome more than the ID itself.

The more severe the ID, the greater are the number and severity of associated impairments. Knowing the cause of the ID can help predict which associated impairments are most likely to occur. Fragile X syndrome and fetal alcohol syndrome (see Chapter 126.3) are associated with a high rate of behavioral disorders; Down syndrome has many medical complications (hypothyroidism, obstructive sleep apnea, congenital heart disease, atlantoaxial subluxation). Associated impairments can require ongoing physical therapy, occupational therapy, speech-language therapy, behavioral therapy, adaptive and mobility equipment, glasses, hearing aids, and medication. Failure to identify and treat these impairments adequately can hinder successful habilitation and result in difficulties in the school, home, and neighborhood environment.

**Prevention**

Examples of primary programs to prevent ID include the following:

◆ Increasing the public's awareness of the adverse effects of alcohol and other drugs of abuse on the fetus (the most common preventable cause of ID in the Western world is fetal alcohol exposure).

◆ Encouraging safe sexual practices, preventing teen pregnancy, and promoting early prenatal care with a
focus on preventive programs to limit transmission of
diseases that may cause congenital infection (syphilis,
toxoplasmosis, cytomegalovirus, HIV).
◆ Preventing traumatic injury by encouraging the use
of guards, railings, and window locks to prevent falls
and other avoidable injuries in the home; using
appropriate seat restraints when driving; wearing a
safety helmet when biking or skateboarding; limiting
exposure to firearms.
◆ Preventing poisonings by teaching parents about
locking up medications and potential poisons.
◆ Implementing immunization programs to reduce
the risk of ID caused by encephalitis, meningitis, and
congenital infection.

**Presymptomatic detection** of certain disorders can result in treatment that
prevents adverse consequences. State newborn screening by tandem mass
spectrometry (now including >50 rare genetic disorders in most states), newborn
hearing screening, and preschool lead poisoning prevention programs are
examples. Additionally, screening for comorbid conditions can help to limit the
extent of disability and maximize level of functioning in certain populations.
Annual thyroid, vision, and hearing screening in a child with Down syndrome is
an example of presymptomatic testing in a disorder associated with ID.

**Treatment**
Although the core symptoms of ID itself are generally not treatable, many
associated impairments are amenable to intervention and therefore benefit from
early identification. Most children with an ID do not have a behavioral or
emotional disorder as an associated impairment, but challenging behaviors
(aggression, self-injury, oppositional defiant behavior) and mental illness (mood
and anxiety disorders) occur with greater frequency in this population than among children with typical intelligence. These behavioral and emotional disorders are the primary cause for out-of-home placements, increased family stress, reduced employment prospects, and decreased opportunities for social integration. Some behavioral and emotional disorders are difficult to diagnose in children with more severe ID because of the child's limited abilities to understand, communicate, interpret, or generalize. Other disorders are masked by the ID. The detection of ADHD (see Chapter 49) in the presence of moderate to severe ID may be difficult, as may be discerning a thought disorder (psychosis) in someone with autism and ID.

Although mental illness is generally of biologic origin and responds to medication, behavioral disorders can result from a mismatch between the child's abilities and the demands of the situation, organic problems, and family difficulties. These behaviors may represent attempts by the child to communicate, gain attention, or avoid frustration. In assessing the challenging behavior, one must also consider whether it is inappropriate for the child's mental age, rather than the chronological age. When intervention is needed, an environmental change, such as a more appropriate classroom setting, may improve certain behavior problems. Behavior management techniques are useful; psychopharmacologic agents may be appropriate in certain situations.

No medication has been found that improves the core symptoms of ID. However, several agents are being tested in specific disorders with known biologic mechanisms (e.g., mGluR5 inhibitors in fragile X syndrome, mTOR inhibitors in tuberous sclerosis), with the hope for future pharmacologic options that could alter the natural course of cognitive impairment seen in patients with these disorders. Currently, medication is most useful in the treatment of associated behavioral and psychiatric disorders. Psychopharmacology is generally directed at specific symptom complexes, including ADHD (stimulant medication), self-injurious behavior and aggression (antipsychotics), and anxiety, obsessive-compulsive disorder, and depression (selective serotonin reuptake inhibitors). Even if a medication proves successful, its use should be reevaluated at least yearly to assess the need for continued treatment.

**Supportive Care and Management**

Each child with ID needs a medical home with a pediatrician who is readily accessible to the family to answer questions, help coordinate care, and discuss
concerns. Pediatricians can have effects on patients and their families that are still felt decades later. The role of the pediatrician includes involvement in prevention efforts, early diagnosis, identification of associated deficits, referral for appropriate diagnostic and therapeutic services, interdisciplinary management, provision of primary care, and advocacy for the child and family. The management strategies for children with an ID should be multimodal, with efforts directed at all aspects of the child's life: health, education, social and recreational activities, behavior problems, and associated impairments. Support for parents and siblings should also be provided.

**Primary Care**

For children with an ID, primary care has the following important components:

- **Provision of the same primary care received by all other children of similar chronological age.**
- **Anticipatory guidance relevant to the child's level of function:** feeding, toileting, school, accident prevention, sexuality education.
- **Assessment of issues that are relevant to that child's disorder,** such as dental examination in children who exhibit bruxism, thyroid function in children with Down syndrome, and cardiac function in Williams syndrome (see Chapter 454.5).

The AAP has published a series of guidelines for children with specific genetic disorders associated with ID (Down syndrome, fragile X syndrome, and Williams syndrome). Goals should be considered and programs adjusted as needed during the primary care visit. Decisions should also be made about what additional information is required for future planning or to explain why the child is not meeting expectations. Other evaluations, such as formal psychologic or educational testing, may need to be scheduled.
Interdisciplinary Management

The pediatrician has the responsibility for consulting with other disciplines to make the diagnosis of ID and coordinate treatment services. Consultant services may include psychology, speech-language pathology, physical therapy, occupational therapy, audiology, nutrition, nursing, and social work, as well as medical specialties such as neurodevelopmental disabilities, neurology, genetics, physical medicine and rehabilitation, psychiatry, developmental-behavioral pediatricians, and surgical specialties. Contact with early intervention and school personnel is equally important to help prepare and assess the adequacy of the child's individual family service plan or individual educational plan. The family should be an integral part of the planning and direction of this process. Care should be family centered and culturally sensitive; for older children, their participation in planning and decision-making should be promoted to whatever extent possible.

Periodic Reevaluation

The child's abilities and the family's needs change over time. As the child grows, more information must be provided to the child and family, goals must be reassessed, and programming needs should be adjusted. A periodic review should include information about the child's health status as well as the child's functioning at home, at school, and in other community settings. Other information, such as formal psychologic or educational testing, may be helpful. Reevaluation should be undertaken at routine intervals (every 6-12 mo during early childhood), at any time the child is not meeting expectations, or when the child is moving from one service delivery system to another. This is especially true during the transition to adulthood, beginning at age 16, as mandated by the IDEA Amendments of 2004, and lasting through age 21, when care should be transitioned to adult-based systems and providers.

Federal and Education Services

Education is the single most important discipline involved in the treatment of children with an ID. The educational program must be relevant to the child's needs and address the child's individual strengths and weaknesses. The child's developmental level, requirements for support, and goals for independence provide a basis for establishing an individualized education program (IEP) for
school-age children, as mandated by federal legislation.

Beyond education services, families of children with ID are often in great need of federal or state-provided social services. All states offer developmental disabilities programs that provide home and community-based services to eligible children and adults, potentially including in-home supports, care coordination services, residential living arrangements, and additional therapeutic options. A variety of Medicaid waiver programs are also offered for children with disabilities within each state. Children with ID who live in low socioeconomic status households should qualify to receive supplemental security income (SSI). Of note, in 2012, an estimated >40% of children with ID did not receive SSI benefits for which they would have been eligible, indicating an untapped potential resource for many families.

**Leisure and Recreational Activities**

The child's social and recreational needs should be addressed. Although young children with ID are generally included in play activities with children who have typical development, adolescents with ID often do not have opportunities for appropriate social interactions. Community participation among adults with ID is much lower than that of the typical population, stressing the importance of promoting involvement in social activities such as dances, trips, dating, extracurricular sports, and other social-recreational events at an early age. Participation in sports should be encouraged (even if the child is not competitive) because it offers many benefits, including weight management, development of physical coordination, maintenance of cardiovascular fitness, and improvement of self-image.

**Family Counseling**

Many families adapt well to having a child with ID, but some have emotional or social difficulties. The risks of parental depression and child abuse and neglect are higher in this group of children than in the general population. The factors associated with good family coping and parenting skills include stability of the marriage, good parental self-esteem, limited number of siblings, higher socioeconomic status, lower degree of disability or associated impairments (especially behavioral), parents' appropriate expectations and acceptance of the diagnosis, supportive extended family members, and availability of community
programs and respite care services. In families in whom the emotional burden of having a child with ID is great, family counseling, parent support groups, respite care, and home health services should be an integral part of the treatment plan.

Transition to Adulthood

Transition to adulthood in adolescents with intellectual disabilities can present a stressful and chaotic time for both the individual and the family, just as it does among young adults of typical intelligence. A successful transition strongly correlates to later improved quality of life but requires significant advanced planning. In moving from child to adult care, families tend to find that policies, systems, and services are more fragmented, less readily available, and more difficult to navigate. Several domains of transition must be addressed, such as education and employment, health and living, finances and independence, and social and community life. Specific issues to manage include transitioning to an adult healthcare provider, determining the need for decision-making assistance (e.g., guardianship, medical power of attorney), securing government benefits after aging out of youth-based programs (e.g., SSI, medical assistance), agreeing on the optimal housing situation, applying for state disability assistance programs, and addressing caretaker estate planning as it applies to the individual with ID (e.g., special needs trusts).

Following graduation from high school, options for continued education or entry into the workforce should be thoroughly considered, with the greater goal of ultimate community-based employment. Although employment is a critical element of life adaptation for persons with ID, only 15% are estimated to have jobs, with significant gaps in pay and compensation compared to workers without disability. Early planning and expansion of opportunities can help to reduce barriers to employment. Post–secondary education possibilities might involve community college or vocational training. Employment selection should be “customized” to the individual's interests and abilities. Options may include participation in competitive employment, supported employment, high school–to–work transition programs, job-coaching programs, and consumer-directed voucher programs.

Prognosis

In children with severe ID, the prognosis is often evident by early childhood.
Mild ID might not always be a lifelong disorder. Children might meet criteria for GDD at an early age, but later the disability can evolve into a more specific developmental disorder (communication disorder, autism, specific learning disability, or borderline normal intelligence). Others with a diagnosis of mild ID during their school years may develop sufficient adaptive behavior skills that they no longer fit the diagnosis as adolescents or young adults, or the effects of maturation and plasticity may result in children moving from one diagnostic category to another (from moderate to mild ID). Conversely, some children who have a diagnosis of a specific learning disability or communication disorder might not maintain their rate of cognitive growth and may fall into the range of ID over time.

The apparent higher prevalence of ID in low- and middle-income countries is of concern given the limitations in available resources. **Community-based rehabilitation (CBR)** is an effort promoted by WHO over the past 4 decades as a means of making use of existing community resources for persons with disabilities in low-income countries with the goal of increasing inclusion and participation within the community. CBR is now being implemented in >90 countries, although the efficacy of such programs has not been established.

The long-term outcome of persons with ID depends on the underlying cause, degree of cognitive and adaptive deficits, presence of associated medical and developmental impairments, capabilities of the families, and school and community supports, services, and training provided to the child and family (Table 53.7). As adults, many persons with mild ID are capable of gaining economic and social independence with functional literacy, but they may need periodic supervision (especially when under social or economic stress). Most live successfully in the community, either independently or in supervised settings.

### Table 53.7

**Severity of Intellectual Disability and Adult-Age Functioning**

<table>
<thead>
<tr>
<th>LEVEL</th>
<th>MENTAL AGE AS ADULT</th>
<th>ADULT ADAPTATION</th>
</tr>
</thead>
<tbody>
<tr>
<td>Mild</td>
<td>9-11 yr</td>
<td>Reads at 4th-5th grade level; simple multiplication and division; writes simple letter, lists; completes job application; basic independent job skills (arrive on time, stay at task, interact with coworkers); uses public transportation, might qualify for driver’s license; keeps house, cooks using recipes</td>
</tr>
<tr>
<td>Moderate</td>
<td>6-8 yr</td>
<td>Sight-word reading; copies information (e.g., address from card to job application);</td>
</tr>
</tbody>
</table>
matches written number to number of items; recognizes time on clock; communicates; some independence in self-care; housekeeping with supervision or cue cards; meal preparation, can follow picture recipe cards; job skills learned with much repetition; uses public transportation with some supervision

| Severe | 3-5 yr | Needs continuous support and supervision; might communicate wants and needs, sometimes with augmentative communication techniques |
| Profound | <3 yr | Limitations of self-care, continence, communication, and mobility; might need complete custodial or nursing care |

For persons with moderate ID, the goals of education are to enhance adaptive abilities and “survival” academic and vocational skills so they are better able to live and function in the adult world (Table 53.7). The concept of supported employment has been very beneficial to these individuals; the person is trained by a coach to do a specific job in the setting where the person is to work, bypassing the need for a “sheltered workshop” experience and resulting in successful work adaptation in the community. These persons generally live at home or in a supervised setting in the community.

As adults, people with severe to profound ID usually require extensive to pervasive supports (Table 53.7). These individuals may have associated impairments, such as cerebral palsy, behavioral disorders, epilepsy, or sensory impairments, that further limit their adaptive functioning. They can perform simple tasks in supervised settings. Most people with this level of ID can live in the community with appropriate supports.

The life expectancy of people with mild ID is similar to the general population, with a mean age at death in the early 70s. However, persons with severe and profound ID have a decreased life expectancy at all ages, presumably from associated serious neurologic or medical disorders, with a mean age at death in the mid-50s. Given that persons with ID are living longer and have high rates of comorbid health conditions in adulthood (e.g., obesity, hypertension, diabetes), ID is now one of the costliest ICD-10 diagnoses, with an average lifetime cost of 1-2 million dollars per person. Thus the priorities for pediatricians are to improve healthcare delivery systems during childhood, facilitate the transition of care to adult providers, and ensure high-quality, integrated community-based services for all persons with ID.
Intellectual Disability With Regression

Bruce K. Shapiro, Meghan E. O’Neill

The patients discussed in Chapter 53 with intellectual disability (ID) usually have a static and nonprogressive disease course. They may acquire new developmental milestones, although at a slower rate than unaffected children, or they may remain fixed at a particular developmental stage. Regression of milestones in these children may be caused by increasing spasticity or contractures, new-onset seizures or a movement disorder, or the progression of hydrocephalus.

Nonetheless, regression or loss of milestones should suggest a progressive encephalopathy caused by an inborn error of metabolism, including disorders of energy metabolism and storage disorders, or a neurodegenerative disorder, including disorders of the whole brain (diffuse encephalopathies), white matter (leukodystrophies), cerebral cortex, and basal ganglia as well as spinocerebellar disorders (Table 53.8) (see Chapters 616 and 617).

Table 53.8

Causes of Progressive Encephalopathy

Onset Before Age 2 Years

Acquired Immunodeficiency Syndrome Encephalopathy *

Disorders of Amino Acid Metabolism

- Guanidinoacetate methyltransferase deficiency*
- Homocystinuria (21q22)*
- Maple syrup urine disease (intermediate and thiamine response forms)*
- Phenylketonuria
- Guanidinoacetate methyltransferase deficiency*
- Hyperammononemic disorders
Disorders of Lysosomal Enzymes

Ganglioside storage disorders
  GM$_1$ gangliosidosis
  GM$_2$ gangliosidosis (Tay-Sachs disease, Sandhoff disease)
Gaucher disease type II (glucosylceramide lipidosis)*
Globoid cell leukodystrophy (Krabbe disease)
Glycoprotein degradation disorders
I-cell disease
  Mucopolysaccharidoses*
  Type I (Hurler Syndrome)*
  Type III (Sanfilippo disease)
Niemann-Pick disease type A (sphingomyelin lipidosis)
Sulfatase deficiency disorders
Metachromatic leukodystrophy (sulfatide lipidoses)
Multiple sulfatase deficiency

Carbohydrate-Deficient Glycoprotein Syndromes

Hypothyroidism *

Mitochondrial Disorders

Alexander disease
Mitochondrial myopathy, encephalopathy, lactic acidosis, stroke
Progressive infantile poliodystrophy (Alpers disease)
Subacute necrotizing encephalomyelopathy (Leigh disease)
Trichopoliodystrophy (Menkes disease)

Neurocutaneous Syndromes

Chediak-Higashi syndrome
Neurofibromatosis*
Tuberous sclerosis*

Other Disorders of Gray Matter
Infantile ceroid lipofuscinosis (Santavuori-Haltia disease)
Infantile neuroaxonal dystrophy
Lesch-Nyhan disease*
Progressive neuronal degeneration with liver disease
Rett syndrome

**Progressive Hydrocephalus** *

**Other Disorders of White Matter**

- Aspartoacylase deficiency (Canavan disease)
- Galactosemia: Transferase deficiency*
- Neonatal adrenoleukodystrophy
- Pelizaeus-Merzbacher disease
- Progressive cavitating leukoencephalopathy

**Onset After Age 2 Years**

**Disorders of Lysosomal Enzymes**

- Gaucher disease type III (glucosylceramide lipidosis)
- Globoid cell leukodystrophy (late-onset Krabbe disease)
- Glycoprotein degradation disorders
- Aspartylglycosaminuria
- Mannosidosis type II
- GM₂ gangliosidosis (juvenile Tay-Sachs disease)
- Metachromatic leukodystrophy (late-onset sulfatide lipidoses)
- Mucopolysaccharidoses types II and VII
- Niemann-Pick type C (sphingomyelin lipidosis)

**Infectious Disease**

- Acquired immunodeficiency syndrome encephalopathy*
- Congenital syphilis*
- Subacute sclerosing panencephalitis

**Other Disorders of Gray Matter**
Ceroid lipofuscinosis
  Juvenile
  Late infantile (Bielschowsky-Jansky disease)
Huntington disease
Mitochondrial disorders
  Late-onset poliodystrophy
  Myoclonic epilepsy and ragged-red fibers
Progressive neuronal degeneration with liver disease
Xeroderma pigmentosum

Other Disorders of White Matter

  Adrenoleukodystrophy
  Alexander disease
  Cerebrotendinous xanthomatosis
  Progressive cavitating leukoencephalopathy

Other Diseases

  Wilson disease
  Friedreich ataxia
  Pantothenate kinase neurodegeneration
  Neurodegeneration with brain iron accumulation

American Academy of Pediatrics, Committee on Children with Disabilities. Pediatrician's role in the development and

Van Karnebeek CD, Stockler S. Treatable inborn errors of metabolism causing intellectual disability: a systematic
Definition

Autism spectrum disorder (ASD) is a neurobiologic disorder with onset in early childhood. The key features are impairment in social communication and social interaction accompanied by restricted and repetitive behaviors. The presentation of ASD can vary significantly from one individual to another, as well as over the course of development for a particular child. There is currently no diagnostic biomarker for ASD. Accurate diagnosis therefore requires careful review of the history and direct observation of the child's behavior.

Diagnostic Criteria and Symptoms

The diagnostic criteria in the Diagnostic and Statistical Manual, Fifth Edition (DSM-5) focus on symptoms in two primary domains (Table 54.1). To meet criteria for ASD, the symptoms need to have been present since the early developmental period, significantly impact functioning, and not be better explained by the diagnoses of intellectual disability (ID) or global developmental delay (GDD; Chapter 53). Table 54.2 provides associated features not included in DSM-5 criteria.

Table 54.1

**DSM-5 Diagnostic Criteria for Autism Spectrum Disorder**

A. Persistent deficits in social communication and social interaction across
multiple contexts, as manifested by the following, currently or by history:

1. Deficits in social-emotional reciprocity.
2. Deficits in nonverbal communicative behaviors used for social interaction.
3. Deficits in developing, maintaining, and understanding relationships.

B. Restricted, repetitive patterns of behavior, interests, or activities, as manifested by at least 2 of the following, currently or by history:

1. Stereotyped or repetitive motor movements, use of objects, or speech.
2. Insistence on sameness, inflexible adherence to routines, or ritualized patterns of verbal or nonverbal behavior.
3. Highly restricted, fixated interests that are abnormal in intensity or focus.
4. Hyper- or hyporeactivity to sensory input or unusual interest in sensory aspects of the environment.

C. Symptoms must be present in the early developmental period (may not become fully manifest until social demands exceed limited capacities, or may be masked by learned strategies in later life).

D. Symptoms cause clinically significant impairment in social, occupational, or other important areas of current functioning.

E. These disturbances are not better explained by intellectual disability (intellectual developmental disorder) or global developmental delay.

**Table 54.2**

**Associated Features of Autism Not in DSM-5 Criteria**

Atypical language development and abilities

- Age <6 yr: frequently disordered and delayed in comprehension; two-thirds have difficulty with expressive phonology and grammar
- Age ≥6 yr: disordered pragmatics, semantics, and morphology,
with relatively intact articulation and syntax (i.e., early difficulties are resolved)

Motor abnormalities: motor delay; hypotonia; catatonia; deficits in coordination, movement preparation and planning, praxis, gait, and balance

Previously, ASD was grouped under the heading of *pervasive developmental disorders* (PDDs) and included a variety of subdiagnoses, including autistic disorder, PDD not otherwise specified (PDD-NOS), and Asperger disorder. Research did not support these as distinct conditions; in the current diagnostic framework, any individual previously diagnosed with 1 of these conditions should be diagnosed with ASD.

Symptoms can present early in infancy, with reduced response to name and unusual use of objects being strong predictors for risk of ASD. However, symptoms before age 12 mo are not as reliably predictive of later diagnosis. Individuals with milder severity may not present until preschool or school age, when the social demands for peer interaction and group participation are higher.

**Social Communication and Social Interaction**

Individuals with ASD have difficulty understanding and engaging in social relationships. The problems are pervasive and impact 3 major areas: reciprocal social interactions (social-emotional reciprocity), nonverbal communication, and understanding of social relationships. The presentation can vary with severity and developmental functioning. Diagnosis of ASD requires the presence of symptoms from all 3 categories (*Table 54.3*).

**Table 54.3**

**Signs and Symptoms of Possible Autism in Preschool Children (or Equivalent Mental Age)**
Social Interaction and Reciprocal Communication Behaviors

Spoken Language

Language delay (in babbling or using words; e.g., using <10 words by age 2 yr).
Regression in, or loss of, use of speech.
Spoken language (if present) may include unusual features, such as vocalizations that are not speech-like; odd or flat intonation; frequent repetition of set words and phrases (echolalia); reference to self by name or “you” or “she” or “he” beyond age 3 yr.
Reduced and/or infrequent use of language for communication; e.g., use of single words, although able to speak in sentences.

Responding to Others

Absent or delayed response to name being called, despite normal hearing.
Reduced or absent responsive social smiling.
Reduced or absent responsiveness to other people's facial expressions or feelings.
Unusually negative response to the requests of others (“demand avoidance” behavior).
Rejection of cuddles initiated by parent or caregiver, although the child may initiate cuddles.

Interacting With Others

Reduced or absent awareness of personal space, or unusually intolerant of people entering their personal space.
Reduced or absent social interest in others, including children of own age —may reject others; if interested in others, child may approach others inappropriately, seeming to be aggressive or disruptive.
Reduced or absent imitation of others' actions.
Reduced or absent initiation of social play with others; plays alone.
Reduced or absent enjoyment of situations that most children like; e.g., birthday parties.
Reduced or absent sharing of enjoyment.
Eye Contact, Pointing, and Other Gestures

Reduced or absent use of gestures and facial expressions to communicate (although may place an adult's hand on objects).
Reduced and poorly integrated gestures, facial expressions, body orientation, eye contact (looking at people's eyes when speaking), and speech used in social communication.
Reduced or absent social use of eye contact (assuming adequate vision).
Reduced or absent “joint attention” (when 1 person alerts another to something by means of gazing, finger pointing, or other verbal or nonverbal indication for the purpose of sharing interest). This would be evident in the child from lack of:
  Gaze switching
  Following a point (looking where the other person points to—may look at hand)
  Using pointing at or showing objects to share interest

Ideas and Imagination

Reduced or absent imagination and variety of pretend play.

Unusual or Restricted Interests and/or Rigid and Repetitive Behaviors

Repetitive “stereotypic” movements such as hand flapping, body rocking while standing, spinning, and finger flicking.
Repetitive or stereotyped play; e.g., opening and closing doors.
Over focused or unusual interests.
Excessive insistence on following own agenda.
Extremes of emotional reactivity to change or new situations; insistence on things being “the same.”
Overreaction or underreaction to sensory stimuli, such as textures, sounds, or smells.
Excessive reaction to the taste, smell, texture, or appearance of food, or having extreme food fads.

Adapted from Baird G, Douglas HR, Murphy MS: Recognizing and diagnosing
Social-Emotional Reciprocity

Reduced social interactions in ASD may range from active avoidance or reduced social response to having an interest in, but lacking ability to initiate or sustain, an interaction with peers or adults. A young child with ASD may not respond when his name is called, may exhibit limited showing and sharing behaviors, and may prefer solitary play. In addition, the child may avoid attempts by others to play and may not participate in activities that require taking turns, such as peek-a-boo and ball play. An older child with ASD may have an interest in peers but may not know how to initiate or join in play. The child may have trouble with the rules of conversation and may either talk at length about an area of interest or abruptly exit the interaction. Younger children often have limited capacity for imaginative or pretend play skills. Older children may engage in play but lack flexibility and may be highly directive to peers. Some children with ASD interact well with adults but struggle to interact with same-age peers.

Nonverbal Communicative Behavior

Difficulties with nonverbal communication may manifest as reduced use of eye contact and gestures such as pointing. Children may also show reduced awareness or response to the eye gaze or pointing of others. They may use eye contact only when communicating a highly preferred request or may have difficulty coordinating the use of nonverbal with verbal communication. Children with ASD may have limited range of facial expression or expressed emotion.

Developing, Maintaining, and Understanding Relationships

Children with ASD have limited insight regarding social relationships. They have difficulty understanding the difference between a true friend and a casual acquaintance. They have trouble picking up on the nuances of social interactions and understanding social expectations for polite behavior. They may have reduced understanding of personal boundaries and may stand too close to others. In addition, they can have trouble understanding and inferring others' emotions.
and are less likely to share emotion or enjoyment with others. Adolescents and young adults have difficulty engaging in group interactions and navigating romantic relationships.

**Restrictive and Repetitive Behavior**

Diagnosis of ASD requires the presence of 2 of the 4 symptoms of restrictive and repetitive patterns of behavior discussed next.

**Stereotyped Motor Movements or Speech**

Stereotyped (or stereotypic) movements and repetitive behaviors may include hand flapping, finger movements, body rocking and lunging, jumping, running and spinning, and repetitive speech such as echoing words immediately after they are said. Repetitive patterns of play may be present, such as lining up objects, repetitively turning light switches on and off or opening and closing doors, spinning objects, or arranging toys in a specific manner. These repetitive patterns may not be seen in very young toddlers but may develop as they get older. Stereotyped movements can change over time and in older children are seen more often in individuals with lower cognitive functioning.

**Insistence on Sameness**

Children with ASD have difficulty tolerating transitions or change. They may insist on certain routines or schedules and can become very distressed with unexpected events or new situations. They may repeat scripts from shows or movies or watch the same portion of a video repeatedly. Intolerance for change causes significant impairment and impact on child and family function.

**Restricted Interests**

This symptom may manifest as intense interests that seem out of the norm in comparison to same-age peers. Younger children may play with a limited range of toys or may insist on retaining a small object in each hand. Older children may have a strong preference for a particular story or movie. The area of interest may be shared by peers (e.g., Disney movies, Legos, Thomas the Train) but unusual in its intensity. Other affected children may have interests that are both intense and odd, such as an interest in brands of vehicles, license plate numbers, or fans and heating systems. These interests interfere with social interactions; a
child may only want to talk about her area of interest or may insist that peers act out a particular story in a rigid and inflexible manner.

**Hypo- or Hyperreactivity to Sensory Input**

Children with ASD may be overly sensitive to sensory input, such as noise, smells, or texture. Children may scream when they hear a siren or vacuum and may gag and choke with certain foods or odors. They may refuse to wear certain clothing or may become very distressed with bathing or with cutting nails and hair. Conversely, some affected children seem to crave sensory input. They may engage in repetitive jumping or hugging and may smell or lick objects or people. Young children may inappropriately touch the face or hair of others.

Diagnosing ASD with DSM-5 criteria can be challenging in very young children because of reduced expression of repetitive behaviors, particularly stereotyped behavior and intense interests. Studies monitoring development in high-risk young children who have an older sibling with ASD indicate these additional symptoms may emerge over time. This creates a dilemma for specialty clinicians evaluating very young children for ASD, because they may not be able to endorse sufficient symptoms to make an early diagnosis and access specialized intervention services.

**Severity Levels Defined in DSM-5**

Severity level in ASD is based on the level of support the individual requires in each of the major domains impacted—social communication and restricted and repetitive behavior. Levels range from –“needing support” (level 1), to –“needing substantial support” (level 2), to –“needing very substantial support” (level 3) (Table 54.4).

**Table 54.4**

<table>
<thead>
<tr>
<th>SEVERITY LEVEL</th>
<th>SOCIAL COMMUNICATION</th>
<th>RESTRICTED, REPETITIVE BEHAVIORS</th>
</tr>
</thead>
<tbody>
<tr>
<td>Level 3 “Requiring very substantial support”</td>
<td>Severe deficits in verbal and nonverbal social communication skills cause severe impairments in functioning, very limited initiation of social interactions, and minimal response to social overtures from others. For example, a person with few words of intelligible speech who rarely initiates interaction and, when he or she does, makes unusual approaches to meet needs</td>
<td>Inflexibility of behavior, extreme difficulty coping with change, or other restricted/repetitive behaviors markedly interfere with functioning in all spheres. Great</td>
</tr>
</tbody>
</table>
only and responds to only very direct social approaches

| Level 2 “Requiring substantial support” | Marked deficits in verbal and nonverbal social communication skills; social impairments apparent even with supports in place; limited initiation of social interactions; and reduced or abnormal responses to social overtures from others. For example, a person who speaks simple sentences, whose interaction is limited to narrow special interests, and who has markedly odd nonverbal communication | Inflexibility of behavior, difficulty coping with change, or other restricted/repetitive behaviors appear frequently enough to be obvious to the casual observer and interfere with functioning in a variety of contexts. Distress and/or difficulty changing focus or action. |
| Level 1 “Requiring support” | Without supports in place, deficits in social communication cause noticeable impairments. Difficulty initiating social interactions, and clear examples of atypical or unsuccessful responses to social overtures of others. May appear to have decreased interest in social interactions. For example, a person who is able to speak in full sentences and engages in communication but whose to-and-fro conversation with others fails, and whose attempts to make friends are odd and typically unsuccessful | Inflexibility of behavior causes significant interference with functioning in one or more contexts. Difficulty switching between activities. Problems of organization and planning hamper independence. |

Specifiers Defined in DSM-5

Formal diagnosis of ASD also includes documenting associated conditions including whether the individual has cognitive and/or language impairment, any related medical, genetic or environmental factors and any other neurodevelopmental or behavioral health conditions, including catatonia (Table 54.5). This process helps to better characterize the presentation in an individual child and ensures that the diagnosis has been made by considering the symptoms in the context of the child's current cognitive and language abilities.

**GENERAL MEDICAL DISORDERS**

| Epilepsy | 8–35% | Increased frequency in individuals with intellectual disability or genetic syndromes. Two peaks of onset: early childhood and adolescence. Increases risk of poor outcome. |
| Gastrointestinal problems | 9–70% | Common symptoms include chronic constipation, abdominal pain, chronic diarrhea, and gastroesophageal reflux. Associated disorders include gastritis, esophagitis, gastroesophageal reflux disease, inflammatory bowel disease, celiac disease, Crohn disease, and colitis. |
| Immune dysregulation | ≤38% | Associated with allergic and autoimmune disorders. |
| Genetic disorders | 10–20% | Collectively called syndromic autism. Examples include fragile X syndrome (21–50% of individuals affected have autism), Rett syndrome (most have autistic features but with profiles different from idiopathic autism), tuberous sclerosis complex (24–60%), Down syndrome (5–39%), phenylketonuria (5–20%), CHARGE syndrome* (15–50%), Angelman syndrome (50–81%), Timothy syndrome (60–70%), and Joubert syndrome (~40%). |

| Sleep disorders | 50–80% | Insomnia is the most common. |

**PSYCHIATRIC DISORDERS**

| Anxiety | ~40% | Common across all age-groups. Most common are social anxiety disorder (13–29% of individuals with autism) and generalized anxiety disorder (13–22%). High-functioning individuals are more susceptible (or symptoms are more detectable). |
| Depression | 12–70% | Common in adults, less common in children. High-functioning adults who are less socially impaired are more susceptible (or symptoms are more detectable). |
| Obsessive-compulsive disorder (OCD) | 7–24% | Shares the repetitive behavior domain with autism that could cut across nosologic categories. Important to distinguish between repetitive behaviors that do not involve intrusive, anxiety-causing thoughts or obsessions (part of autism) and those that do (and are part of OCD). |
| Psychotic disorders | 12–17% | Mainly in adults. Most commonly recurrent hallucinosis. High frequency of autism-like features (even a diagnosis of ASD) preceding adult-onset (52%) and childhood-onset schizophrenia (30–50%). |
| Substance use disorders | ≤16% | Potentially because individual is using substances as self-medication to relieve anxiety. |
| Oppositional defiant disorder | 16–28% | Oppositional behaviors could be a manifestation of anxiety, resistance to change, stubborn belief in the correctness of own point of view, difficulty seeing another's point of view, poor awareness of the effect of own behavior on others, or no interest in social compliance. |
Eating disorders 4–5%
Could be a misdiagnosis of autism, particularly in females, because both involve rigid behavior, inflexible cognition, self-focus, and focus on details.

* Coloboma of the eye; heart defects; atresia of the choanae; retardation of growth and development, or both; genital and urinary abnormalities, or both; and ear abnormalities and deafness.
† Particularly in high-functioning adults.

DSM-IV, *Diagnostic and Statistical Manual of Mental Disorders, 4th edition*; DSM-5, *Diagnostic and Statistical Manual of Mental Disorders, Fifth edition*.

**Epidemiology**

The prevalence of ASD is estimated at 1 in 59 persons by the U.S. Centers for Disease Control and Prevention (CDC). The prevalence increased significantly over the past 25 years, primarily because of improved diagnosis and case finding.
as well as inclusion of less severe presentations within the *autism* spectrum. There is a 4:1 male predominance. The prevalence is increased in siblings (up to 10% recurrence rate) and particularly in identical twins. There are no racial or ethnic differences in prevalence. Individuals from racial minorities and lower socioeconomic status are at risk for later diagnosis.

**Etiology**

The etiology of ASD is thought to result from disrupted neural connectivity and is primarily impacted by genetic variations affecting early brain development. Animal models and studies of individuals with ASD indicate changes in brain volume and neural cell density in the limbic system, cerebellum, and frontotemporal regions. One study documented changes in early brain development, characterized as “hyperexpansion of cortical surface area,” at age 6-12 mo on brain MRI, which correlated with later development of impaired social skills. Functional studies show abnormalities of processing information, particularly related to foundational social skills such as facial recognition. The disruptions in early brain development likely are responsive the treatment. Early developmental therapies in young children with ASD have demonstrated the capacity for normalization of electrophysiologic response to visual stimuli, including faces.

Numerous genes involved in brain development and synaptic function have been associated with ASD. Mutations that include large genetic deletions or duplications and small sequencing changes have been implicated; these can be inherited or occur de novo. Heterozygous mutations in genes, such as present in deletion or duplication of 15q11.2 or 16p11.2, may have variable expression within a family. Rare recessive mutations have been implicated in some populations with high levels of consanguinity. Patients with a number of genetic syndromes (e.g., fragile X, Down, Smith-Lemli-Opitz, Rett, Angelman, Timothy, Joubert) as well as disorders of metabolism and mitochondrial function have higher rates of ASD than the general population (Table 54.5).

There is also evidence for environmental contributions to ASD. Older maternal or paternal age may increase the risk of ASD. In addition, factors influencing the intrauterine environment, such as maternal obesity or overweight, short interval from prior pregnancy, premature birth, and certain prenatal infections (e.g., rubella, cytomegalovirus) are associated with ASD. An epigenetic model is considered one explanation for the etiology; individuals with
genetic vulnerability may be more sensitive to environmental factors influencing early brain development.

Despite frequent concerns from families that vaccines or the preservatives in vaccines lead to ASD, there is no evidence to support this claim. Multiple research studies and meta-analyses have failed to show an association of vaccines with ASD.

Differential Diagnosis

The differential diagnosis of ASD is complex because many conditions in the differential can also occur with ASD. The most important conditions to consider in young children are language disorder (see Chapter 52), intellectual disability or global developmental delay (Chapter 53), and hearing loss (Chapter 655). Children with language disorder may have impairments in social communication and play; their social and play skills, however, are typically on par with their language level. In addition, they do not have associated restricted and repetitive behavior or atypical use of language, such as scripting. The diagnosis of social communication disorder is also distinguished from ASD by the lack of restrictive and repetitive behaviors. Children with intellectual disability (ID) or global developmental delay (GDD) may have delays in social and communication skills as well as stereotyped behavior. However, social and communication skills are typically commensurate with their cognitive and adaptive functioning. Children with hearing loss may present with some “red flags” for ASD, such as poor response to name. However, they typically develop nonverbal communication and play skills as expected and do not have stereotyped or restricted behavior patterns.

In older children, disorders of attention, learning, and mood regulation must be considered in the differential diagnosis of ASD. Children with attention-deficit/hyperactivity disorder (ADHD) may present with reduced eye contact and response to name caused by poor attention rather than lack of social awareness. Children with ADHD, however, do not have associated impairments in shared enjoyment and social reciprocity or repetitive behaviors. Children with social anxiety or other anxiety disorders may present with some symptoms suggestive of ASD. Shy children may have reduced eye contact and social initiation. Anxious children can be resistant to change and prefer familiar routines. Children with anxiety, however, typically will have preserved social interest and insight and will not exhibit high levels of stereotyped behaviors.
**Reactive attachment disorder** can be difficult to distinguish from ASD, particularly in younger children with history of trauma. However, social behaviors in these children generally improve with positive caretaking.

The differentiation of ASD from **obsessive-compulsive disorder (OCD)**, tics, and stereotyped behaviors can sometimes be challenging. In general, stereotyped behaviors may be calming or preferred, whereas tics and compulsive routines are distressing to the individual. Children with OCD have intense interests as well as repetitive behaviors and rituals but do not have impairment in social communication or interaction. Children with **stereotypic movement disorder** will not have impaired social skills or other types of restricted and repetitive behaviors. Children with **Landau Kleffner syndrome (LKS)** present with loss of skills in language comprehension (auditory verbal agnosia) and verbal expression (aphasia) associated with onset of epileptic seizures during sleep (see Chapter 52). In contrast to ASD, children with LKS present with typical early development followed by loss of language function at age 3-6 yr.

**Comorbid Conditions**

Up to 50% of individuals with ASD have intellectual disability, ranging in severity from mild to severe (**Table 54.5**). Intellectual disability is associated with higher rates of both identified genetic conditions and epilepsy. Children with ASD often have associated language impairments, including delays in expressive, receptive, and pragmatic (social) language skills. Language function can range widely from nonverbal status to age appropriate. Gastrointestinal (GI) problems such as constipation, esophagitis, and gastroesophageal reflux disease (GERD) are reported in up to 70% of children with ASD. Epilepsy occurs in up to 35% of children with ASD and presents in 2 peaks, in early childhood and in adolescence. Epilepsy or electrical seizures without motor manifestations may be a cause of regression in young children with ASD.

Children with ASD are at higher risk for disorders of attention, including reduced attention for nonpreferred activities and excessive attention for preferred activities. A subset of children will also meet full criteria for a diagnosis of ADHD. There are higher rates of anxiety (~40%) and mood disorders in ASD, particularly during adolescence. Children with ASD are also at increased risk for being bullied and may present with secondary irritability, anxiety, or depression.

Sleep problems, including delayed sleep onset, frequent night waking, and abnormal sleep architecture, are reported in 50–80% of children with ASD.
There is some evidence for baseline abnormalities in melatonin secretion. The use of screen-based activities such as television, computers, or tablets before bedtime can inhibit melatonin secretion. Children with ASD also have higher rates of feeding and toileting problems resulting from resistance to change, sensory sensitivity, and repetitive behavior patterns. Many children with ASD have restrictive feeding patterns and food selectivity. They also have higher rates of overweight, possibly because of diets higher in carbohydrates, reduced physical activity, use of food rewards to regulate behavior, and side effects from medications used for managing mood and behavior.

Disruptive behaviors such as self-injury and aggression are common in ASD patients, but most common in individuals with lower cognitive function and limited language. Sleep deprivation, nutritional deficits, pain, epilepsy, and medication side effects may contribute to disruptive behaviors.

**Screening**

The American Academy of Pediatrics recommends screening for ASD for all children at age 18 mo and 24 mo (see Chapter 28). Screening should also occur when there is increased risk for ASD, such as a child with an older sibling who has ASD, or concern for possible ASD. Screening can be done by parent checklist or direct assessment. The most frequently used screening tool is the Modified Checklist for Autism, Revised/Follow-Up Interview (MCHAT-R/FU), a 20-item parent report measure, with additional parent interview completed for intermediate scores. The MCHAT-R/FU can be used from age 16-30 mo.

**Assessment**

Diagnostic assessment should include medical evaluation and assessment of the child's cognitive, language, and adaptive function. Assessment may occur in a single multidisciplinary visit or through a series of visits with different developmental specialists. Multidisciplinary evaluation with clinicians who have expertise with ASD is optimal for diagnostic accuracy and treatment planning. Developmental-behavioral pediatricians, neurodevelopmental disability specialists, neurologists, psychiatrists, and psychologists are qualified to make a formal diagnosis of ASD. Other specialists, including speech-language pathologists and occupational therapists, should also be included depending on
the child's age and the presenting concerns.

Assessment of ASD includes direct observation of the child to evaluate social skills and behavior. Informal observation can be supplemented with structured diagnostic tools such as the *Autism Diagnostic Observation Schedule, Second Edition* (ADOS-2) and *Autism Diagnostic Observation Schedule, Toddler module* (ADOS-T). These structured play-based assessments provide social prompts and opportunities to evaluate the frequency and quality of a child's social responsiveness to, initiation, and maintenance of social interactions; the capacity for joint attention and shared enjoyment; the child's behavioral flexibility; and presence of repetitive patterns of behavior. The ADOS-2 and ADOS-T are not required for accurate diagnosis and do not stand alone, but rather can be used to augment a careful history and observation. The *Childhood Autism Rating Scale, Second Edition* (CARS-2) is a 15-item direct clinical observation instrument that can assist clinicians in the diagnosis of ASD. The *Autism Diagnostic Interview-Revised* (ADI-R) is a lengthy clinical interview tool that is used primarily in research settings since it takes several hours to administer. Other tools include standardized rating scales that parents and teachers can complete to report on the child's social skills and behaviors.

Medical evaluation should include a thorough history and detailed physical examination of the child, including direct behavioral observations of communication and play. In addition, the examination should include measurement of head circumference, careful evaluation for dysmorphic features, and screening for tuberous sclerosis with Wood lamp exam. Children with ASD should have genetic testing (described later), an audiology examination to rule out hearing loss, and in children with pica, a lead test (*Table 54.6*).

**Table 54.6**

**Medical and Genetic Evaluation of Children With Autism Spectrum Disorder**

**Physical Examination**

- Dysmorphic physical features
- Muscle tone and reflexes
- Head circumference
- Wood lamp examination for tuberous sclerosis
**Diagnostic Testing**

- Chromosomal microarray (CMA) in all individuals
- Fragile X DNA test in males
- Audiology evaluation
- Lead test in children with pica

**Additional Targeted Genetic Testing**

- Fragile X DNA test in females with symptoms suggestive of fragile X, family history of X-linked intellectual disability, tremor, ataxia, or premature ovarian failure
- MeCP2 sequencing in females
- PTEN mutation testing if head circumference $>2.5$ SD above the mean
- MeCP2 deletion/duplication testing in males with significant developmental regression, drooling, respiratory infections, and hypotonia
- Karyotype if unable to obtain CMA or if balanced translocation suspected

**Additional Targeted Diagnostic Testing**

- EEG in children with seizures, staring spells, or developmental regression
- Brain MRI in children with microcephaly, focal neurologic findings, or developmental regression
- Metabolic testing in children with developmental regression, hypotonia, seizures, food intolerance, hearing loss, ataxia, or course facial features

There are currently several specialty-specific clinical guidelines for genetic evaluation of children diagnosed with ASD. Genetic testing is shown to impact clinical decision-making, but no studies have evaluated the impact of genetic testing on the outcome for the child. The American College of Medical Genetics recommends a tiered approach to genetic testing.
First Tier

All children with ASD should have a chromosomal microarray (CMA). CMA will be positive in 10–15% of individuals with ASD. The rate is increased to almost 30% in individuals who have complex presentations, such as associated microcephaly, dysmorphic features, congenital anomalies, or seizures. CMA technology will identify copy number variants but not DNA sequencing errors, balanced translocations, or abnormalities in trinucleotide repeat length. *Fragile X DNA testing is therefore recommended for all boys with ASD.* Fragile X testing should also be considered in girls with physical features suggestive of fragile X syndrome or with a family history of fragile X, X-linked pattern of intellectual disability, tremor/ataxia, or premature ovarian failure.

Second Tier

Girls with ASD should have testing for mutation in the *MeCP2* gene if CMA is normal. Boys who have hypotonia, drooling, and frequent respiratory infections should have *MeCP2* deletion/duplication testing. All individuals with ASD and a head circumference greater than 2.5 standard deviations (SD) above the mean should have testing for mutation in the *PTEN* gene because there is a risk for hamartoma tumor disorders (Cowden, Proteus-like, Bannayan-Riley-Ruvalkaba syndromes) in these individuals. Cytogenetic testing (karyotype) has a lower yield than CMA. Karyotype is recommended if microarray is not available and in children with suspected balanced translocation, such as history of multiple prior miscarriages.

Further medical diagnostic testing is indicated by the child's history and presentation. Brain imaging is indicated in cases of microcephaly, significant developmental regression, or focal findings on neurologic examination. Because of the high rate (up to 25%) of macrocephaly in ASD, imaging is not indicated for macrocephaly alone. MRI is not recommended for minor language regression (loss of a few words) during the 2nd year of life that is often described in toddlers with ASD. Children with concern for seizures, spells, or developmental regression should have an electroencephalogram (EEG). Metabolic screening is indicated for children with signs of a metabolic or mitochondrial disorder, such as developmental regression, weakness, fatigue, lethargy, cyclic vomiting, or seizures (see Chapters 53 and 102).
Treatment and Management

Educational

The primary treatment for ASD is done outside the medical setting and includes developmental and educational programming. Numerous resources have been developed that can help families in the complex process of treatment planning (Table 54.7). Intensive behavioral therapies have the strongest evidence to date. Earlier age at initiation of treatment and higher intensity of treatment are associated with better outcomes. Programming must be individualized, and no approach is successful for all children. In addition, research treatments are often conducted with a high level of intensity and fidelity that are difficult to scale up or reproduce in community settings. Higher cognitive, play, and joint attention skills and lower symptom severity at baseline are predictors for better outcomes in core symptoms, intellectual function, and language function.

</table>

Behavioral approaches based on the principles of applied behavioral analysis (ABA) involve direct incremental teaching of skills within a traditional behavioral framework using reinforcement of desired behavior, careful data collection, and analysis and adjustment of the treatment program based on review of data. Comprehensive models integrating behavioral and developmental approaches that build on key foundational skills, such as joint attention, shared enjoyment, and reciprocal communication, show strong evidence of efficacy for young children, particularly toddlers, with ASD.
Examples include the Early Start Denver Model (ESDM), Joint Attention Symbolic Play Engagement and Regulation (JASPER), and Social Communication/Emotional Regulation/Transactional Support (SCERTS). Parent training models also show promise for younger children.

Educational approaches such as the Treatment and Education of Autistic and Communication Handicapped Children (TEACCH) incorporate structured teaching, visual supports, and adjustment of the environment to the individual needs of students with ASD, such as difficulty with communication, understanding time, and need for routine. These approaches have demonstrated efficacy for improved cognitive and adaptive skills. For older children with more severe symptoms, approaches that use behavioral principles in addition to adjusting the environment may be most effective.

Speech and language therapy can help build vocabulary, comprehension, and pragmatic skills. Children with ASD benefit from visual supports for comprehension, understanding expectations, and communicating their needs. **Augmentative communication** approaches using photographs or picture icons can improve comprehension and ability to communicate. There are a range of options with varying levels of complexity, flexibility, and technology. Using augmentative communication does not inhibit acquisition of verbal language. On the contrary, supporting a child's language development with augmentative supports can facilitate the development of spoken language, even in older children.

Additional strategies to build social skills are used for school age children and adolescents and may be administered in the school or community setting by a variety of specialists, including speech therapists, psychologists, and counselors. **Social skills programs** that include training peer mentors have higher rates of efficacy. Occupational and physical therapy may be indicated for individuals with motor delay and difficulty acquiring adaptive skills such as dressing and toileting.

For some high school students with ASD, training in life skills and vocational skills is critical for maximizing independence in adulthood. Training may focus on basic self-care (e.g., dressing, hygiene), functional academics (e.g., money management, banking skills), learning to fill out a job application, and understanding how to behave with strangers and in work settings. Social skills and job coaching may be needed even for adolescents with strong cognitive and academic function, because they may struggle with social perception and may be vulnerable to exploitation by others.
Co-occurring Conditions

Additional medical or behavioral health treatment is often required for management of co-occurring conditions in ASD. Seizures occur in up to 35% of children with ASD and should be managed with appropriate antiepileptic therapy (see Chapter 611). GI problems (e.g., constipation, esophagitis, GERD) may present with nonspecific irritability, sleep disturbance, self-injury, aggression, and signs of pain or discomfort, such as crying, and can be managed with the same approaches used in typically developing children.

Management of co-occurring attention and mood disorders is similar to that for typically developing children. Strategies to increase structure and organization in the environment and use of visual supports (e.g., schedules) can improve attention and reduce anxiety. Some children with ASD benefit from modified cognitive-behavioral therapy to address anxiety and OCD.

Strategies to promote sleep hygiene and use of behavioral approaches, such as structured bedtime routines, can address delayed sleep onset. Other medical problems, such as epilepsy or GERD, can also contribute to poor sleep and should be treated directly. In cases refractory to behavioral approaches, medications may be used. (For further discussion of management of sleep problems, see Chapter 31.)

Structured behavioral approaches for delayed toilet training in concert with treatment to prevent constipation are often needed for children with ASD. For children with highly restrictive diets, nutrition counseling and behaviorally based feeding therapy may be needed to address poor caloric intake or lack of nutritional quality. Because of limited diets, children with ASD may be at risk for low levels of calcium, vitamin D, and iron. Children who are overweight may have poor nutrition as a result of restrictive diets.

Irritability is a nonspecific symptom and can be a reflection of pain, anxiety, distress, or lack of sleep. Children with ASD are prone to irritability because of their difficulty tolerating change and their limited communication skills. Management of irritability includes evaluating carefully for medical problems that may be causing pain, as well as for any factors in the child's home or school environment that may be causing distress. Possible causes of distress range from common experiences such as changes in the routine to undisclosed abuse or bullying. Treatment should be targeted first at any underlying cause. Medications are often used to treat irritability in ASD but should only be used after appropriate behavioral and communication supports have been implemented.
Pharmacology

There are currently no medications that treat the core symptoms of ASD. Medications can be used to target specific co-occurring conditions or symptoms (Table 54.8; see also Table 54.5). Families should be cautioned, however, that the effect size may be lower and the rate of medication side effects higher in children with ASD.

* Specific medications names are provided in parentheses when there is a FDA-approved indication for the use of the medication to treat the symptom in children with ASD. Further information about these medications is available in Chapter 33.

BP, Blood pressure; HR, heart rate; CBC, complete blood count; ALT, alanine transaminase; AST, aspartate transaminase.
Preliminary data suggest that intranasal therapy with neuropeptide oxytocin may improve social functioning in children with ASD, particularly those with low pretreatment oxytocin levels.

There is evidence to support use of stimulant medication, **atomoxetine** and α-agonists for ADHD in ASD. Selective serotonin reuptake inhibitors (SSRI) can be used for anxiety and OCD and in adolescents may also be useful for depression. Benzodiazepines may be useful for situational anxiety, for example, triggered by dental and medical procedures or air travel. Medications used to treat ADHD and anxiety may result in activation or irritability in ASD and require careful monitoring.

Melatonin can be used to improve sleep onset but will not address night waking. **Clonidine** or **trazodone** may be used for sleep onset and maintenance. No medications are specifically labeled for treatment of insomnia in ASD.

The α-adrenergic agonists may be helpful in children who present with significant behavioral dysregulation. There are two atypical antipsychotic medications that have U.S. Food and Drug Administration (FDA) recommendation for irritability and aggression in children with ASD. Both **risperidone** and **aripiprazole** have several studies documenting efficacy for reducing irritability, aggression, and self-injury. Secondary improvements in attention and repetitive behavior were also noted. Side effects include weight gain and metabolic syndrome as well as tardive dyskinesia and extrapyramidal movements. Careful laboratory monitoring is recommended. Mood-stabilizing antiepileptic medications have also been used to treat irritability.

### Complementary and Alternative Medicine

Families of children with ASD often use complementary and alternative medicine (CAM) approaches. These treatments can include supplements, dietary changes, and body or physical treatments. There is a limited evidence to inform families, who often learn about these treatments from friends and family members, alternative medicine providers, or the internet. For most therapies, evidence is insufficient to show benefit. There is strong evidence that secretin and facilitated communication are not effective. Some therapies, such as hyperbaric oxygen, chelation, and high-dose vitamins, are potentially harmful. For children with restrictive diets, taking a daily multivitamin and 400 IU vitamin D may be indicated, although there is no evidence to support megadoses of vitamins. Similarly, for children with evidence of gluten sensitivity, a trial of
gluten-free diet may be indicated. However, current evidence does not support this as a treatment for all children with ASD.

When discussing CAM with a family, it is best to use open and collaborative communication, encouraging them to share their current practices and any questions. Specifically ask if they use any herbal treatments, supplements, or other therapies, such as acupuncture, massage, or chiropractic treatment, and what they have observed since trying the treatment. Provide accurate information regarding potential benefit and risk for any treatment. Educate about “red flags” such as treatments that are marketed as a cure for multiple conditions, that report no risk of side effects, or that are marketed by the clinician recommending the treatment. Encourage families to identify a target symptom, “try one thing at a time,” and monitor response carefully.

**Transition**

Navigating a successful transition to adult care is a key role for the pediatric provider. This process should ideally start as early as age 12-13 yr. Parents are faced with a complex and disconnected system of diverse agencies that they need to navigate. Use of structured-visit templates and care coordinators can help ensure that families and their youth with ASD are able to make appropriate decisions about secondary and postsecondary educational programming, vocational training, guardianship, finances, housing, and medical care. High school educational programming should include individualized and meaningful vocational training, as well as instruction regarding sexuality, relationships, safety and abuse prevention, finances, travel training, and general self-advocacy. Individuals with ASD who are higher functioning will need help accessing supports for college or postsecondary skills training and may benefit from referral to their state vocational rehabilitative services as well as personal life coaches or counselors. Families who have adult children with more significant cognitive disability need information about the range of adult disability services, how to apply for supplemental security income (SSI), and the process for considering guardianship or medical and financial conservatorship for their adult child. These decisions are complex and must be individualized for the adult with ASD and the family.

**Outcome**
Autism spectrum disorder is a lifelong condition. Although a minority of individuals respond so well to therapy that they no longer meet criteria for the diagnosis, most will make progress but continue to have some impairment in social and behavioral function as adults. Adult outcome studies are sobering, indicating that many adults with ASD are socially isolated, lack gainful employment or independent living, and have higher rates of depression and anxiety. It is not clear if these data can be extrapolated to younger children currently receiving intensive educational therapies. There is a growing network of adult self-advocates who promote the unique strengths in individuals with ASD. Outcome as measured by developmental progress and functional independence is better for individuals who have higher cognitive and language skills and lower ASD severity at initial diagnosis.

Nutritional Requirements

Asim Maqbool, Elizabeth Prout Parks, Ala Shaikhkhalil, Jennifer Panganiban, Jonathan A. Mitchell, Virginia A. Stallings

Nutrition for infants, children, and adolescents should maintain current weight and support normal growth and development. Growth during infancy is rapid, critical for neurocognitive development, and has the highest energy and nutrient requirements relative to body size than any other period of growth. It is followed by growth during childhood, when 60% of total growth occurs, and finally by puberty. Nutrition and growth during the 1st 3 yr of life predict adult stature and some health outcomes. The major risk period for growth stunting (impaired linear growth) is between 4 and 24 mo of age. Therefore, it is critical to identify nutrient deficiencies promptly and to address them aggressively early in life, because missing them can impart lasting adverse effects on later growth and development.

Dietary intake should provide energy requirements as well as the essential macronutrient and micronutrient needs for sustaining the function of multiple vital processes. Nutrient deficiencies can limit growth, impair immune function, affect neurodevelopment, and increase morbidity and mortality. Worldwide, malnutrition and undernutrition are the leading causes of acquired immunodeficiency, and a major factor underlying morbidity and mortality in children <5 yr of age.

The transition in food supply and type of nutrition chosen in many developing countries, coincident with population change, from traditional to Western diet has resulted in increased life expectancy and adult stature. Unfortunately, the Western diet in these populations is also frequently accompanied by decreased physical activity and, in parallel, decreases in the incidence and prevalence of communicable (infectious) diseases along with increases in the incidence and prevalence of noncommunicable diseases such as type 2 diabetes, cardiovascular...
(CV) disease, obesity, inflammatory bowel disease (IBD), and certain cancers. Consequently, it is important to view the impact of nutrition on health from various perspectives: to prevent deficiency, to promote adequacy, and to prevent or reduce the risk for acquiring diseases associated with excess intakes, such as obesity, diabetes, and CV disease.

Advances in our understanding of the roles of some nutrients such as vitamin D, polyunsaturated fatty acids (PUFAs), and fiber have changed our focus from recommendations about preventing deficiency to recommendations about nutritional intake associated with optimal health. The 2006 World Health Organization (WHO) growth charts, which now are recommended for all children until age 2 yr, are not only descriptive but also proscriptive on how children with adequate nutrition and health care should grow. Therefore, identifying and providing appropriate and adequate nutrition in infancy and childhood are critical to supporting normal growth and development as well as providing the foundation for lifelong health and well-being.

**Dietary Reference Intakes**

The dietary reference intake (DRI) established by the Food and Nutrition Board of the U.S. Institutes of Medicine (IOM) provides guidance on the nutrient needs for individuals and groups across different life stages and by gender (see Tables 55.1 to 55.4).

Key concepts on DRI concepts include the estimated average requirement (EAR), the recommended dietary allowance (RDA), and the tolerable upper limit of intake (UL) (Fig. 55.1). The EAR is the average level of daily nutrient intake that is estimated to meet the requirements for 50% of the population, assuming normal distribution. The RDA is an estimate of the daily average nutrient intake that meets the nutritional needs of >97% of the individuals in a population, and it can be used as a guideline for individuals to avoid deficiency. When an EAR cannot be derived, an RDA cannot be calculated; therefore, an adequate intake (AI) is developed as a guideline for individuals based on the best available data and scientific consensus. The UL denotes the highest average daily intake with no associated adverse health effects for almost all individuals in a particular group. Fig. 55.2 shows the relationships among EAR, RDA, and UL.
Energy

Energy includes both food intake and metabolic expenditure. Deficits and excesses of energy intake yield undesirable health consequences. Inadequate energy intake can lead to growth faltering, catabolism of body tissues, and
inability to provide adequate energy substrate. Excess energy intakes can increase the risk for obesity. Adequacy of energy intake in adults is associated with maintenance of a healthy weight. The three components of energy expenditure in adults are the basal metabolic rate (BMR), thermal effect of food (e.g., energy required for digestion and absorption), and energy for physical activity. In children, additional energy intake is required to support growth and development.

Estimated energy requirement (EER) is the average dietary energy intake predicted to maintain energy balance in a healthy individual and takes into account age, gender, weight, stature, and level of physical activity (Table 55.1). The 2015–2020 Dietary Guidelines for Americans refer to the 2008 Physical Activity Guidelines for Americans. These guidelines recommend ≥60 min of moderate- or vigorous-intensity aerobic physical daily for children and adolescents. This activity should include vigorous intensity physical activity at least 3 days per week. In addition, as part of their ≥60 min of daily physical activity, children and adolescents are advised to incorporate muscle- and bone-strengthening activity for ≥3 days a week, to maintain a healthy weight and to prevent or delay progression of chronic noncommunicable diseases such as obesity and CV disease.

</tr>
<tr>
<td>9-18 yr</td>
</tr>
</tbody>
</table>

EER, Estimated energy requirement; TEE, total energy expenditure; ED, energy deposition (energy required for growth /new tissue accretion).

PA indicates the physical activity coefficient:

For boys:

\( \text{PA} = 1.00 \) (sedentary, estimated physical activity level 1.0-1.4)
PA = 1.13 (low active, estimated physical activity level 1.4-1.6)
PA = 1.26 (active, estimated physical activity level 1.6-1.9)
PA = 1.42 (very active, estimated physical activity level 1.9-2.5)

For girls:
PA = 1.00 (sedentary, estimated physical activity level 1.0-1.4)
PA = 1.16 (low active, estimated physical activity level 1.4-1.6)
PA = 1.31 (active, estimated physical activity level 1.6-1.9)
PA = 1.56 (very active, estimated physical activity level 1.9-2.5)

The EER was determined based on empirical research in healthy persons at different levels of physical activity, including levels different from recommended levels. They do not necessarily apply to children with acute or chronic diseases. EER is estimated by equations that account for total energy expenditure (TEE) and energy deposition (ED) for healthy growth. EERs for infants, relative to body weight, are approximately twice those for adults because of the increased metabolic rate and requirements for weight maintenance and tissue accretion (growth).

Dietary nutrients that provide energy include fats (approximately 9 kcal/g), carbohydrates (4 kcal/g), and protein (4 kcal/g). These nutrients are called macronutrients. If alcohol is consumed, it also contributes to energy intake (7 kcal/g). The EER does not specify the relative energy contributions of macronutrients. Once the minimal intake of each macronutrient is attained (e.g., sufficient protein intake to meet specific amino acid requirements, sufficient fat intake to meet linoleic acid and α-linolenic acid needs for brain development), the remainder of the intake is used to meet energy requirements, with some degree of freedom and interchangeability among fat, carbohydrate, and protein. This argument forms the basis for the acceptable macronutrient distribution ranges (AMDRs), expressed as a function of total energy intake (Table 55.2).

Fat

Fat is the most calorically dense macronutrient, providing approximately 9 kcal/g. For infants, human milk and formula are the main dietary sources of fat, whereas older children obtain fat from animal products, vegetable oils, and margarine. The AMDR for fats is 30–40% of total energy intake for children 1-3 yr and 25–35% for children 4-18 yr of age. In addition to being energy dense, fats provide essential fatty acids that have body structural and functional roles (e.g., cholesterol moieties are precursors for cell membranes, hormones, and bile acids). Fat intake facilitates absorption of fat-soluble vitamins (vitamins A, D, E, and K). Both roles are relevant to neurologic and ocular development (Table 55.3).

PUFAs, Polyunsaturated fatty acids.

TOTAL FIBER

| Improves laxation, reduces risk of coronary artery (heart) disease, assists in maintaining normal blood glucose levels | **Infants** | **Includes dietary fiber naturally present in grains (e.g., oats, wheat, unmilled rice) and functional fiber synthesized or isolated from plants or animals and shown to be of benefit to health** | **Dietary fiber can have variable compositions; therefore it is difficult to link a specific source of fiber with a particular adverse effect, especially when phytate is also present in the natural fiber source.**
As part of an overall healthy diet, a high intake of dietary fiber will not produce deleterious effects in healthy persons. Occasional adverse GI symptoms are observed when consuming some isolated or synthetic fibers, but serious chronic adverse effects have not been observed because of the bulky nature of fibers. Excess consumption is likely to be self-limiting; therefore, UL was not set for individual functional fibers. |

Involving with neurologic development and growth
Precursor of eicosanoids

Vegetable oils, e.g., soybean, canola, flax seed oil; fish oils, fatty fish, walnuts; † smaller amounts in meats and eggs

No defined intake levels for potential adverse effects of ω3 PUFAs are identified.
Upper end of AMDR is based on maintaining appropriate balance with ω6 fatty acids and the lack of evidence that demonstrates long-term safety, along with human in vitro studies that show increased free radical formation and lipid peroxidation with higher amounts of PUFAs.

Because the longer-chain n-3 fatty acids, eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA), are biologically more potent than their precursor, linolenic acid, much of the work on adverse effects of this group of fatty acids has been on DHA and EPA.
Lipid peroxidation is thought to be a component in the development of atherosclerotic plaques.

SATURATED AND TRANS FATTY ACIDS

The body can synthesize its needs for saturated fatty acids from other sources.

No dietary requirement

Saturated fatty acids are present in animal fats (meat fats and butter fat), and coconut and palm kernel oils.

Trans fat: stick margarines, foods containing hydrogenated or partially hydrogenated vegetable shortenings

There is an incremental increase in plasma total and LDL cholesterol concentrations with increased intake of saturated or trans fatty acids; therefore, saturated fat intake should be limited to <10% with no trans fat. † ‡

No defined intake levels for potential adverse effects of protein are identified. Upper end of AMDR was based on complementing AMDR for carbohydrate and fat for the various age-groups. Lower end of AMDR is set at approximately the RDA.

* Adequate intake.

‡ Based on 1.5 g/kg/day for infants, 1.1 g/kg/day for 1-3 yr, 0.95 g/kg/day for 4-13 yr, 0.85 g/kg/day for 14-18 yr, 0.8 g/kg/day for adults, and 1.1 g/kg/day for pregnant (using pre-pregnancy weight) and lactating women.

Note: Starred (*) numbers are AI; bold numbers are RDA. RDAs and AIs may both be used as goals for individual intake. RDAs are set to meet the needs of 97-98% of members in a group. For healthy breastfed infants, the AI is the mean intake. The AI for other life stage and gender groups is believed to cover the needs of all members of the group, but lack of data prevents specifying...
with confidence the percentage covered by this intake.

AMDR is the range of intake for a particular energy source that is associated with reduced risk of chronic disease while providing intakes of essential nutrients. With consumption in excess of the AMDR, there is a potential for increasing the risk of chronic diseases and/or insufficient intakes of essential nutrients.

ND amounts are not determinable because of a lack of data regarding adverse effects in this age-group and concern with regard to a lack of ability to handle excess amounts. Source of intake should be from food only to prevent high levels of intake.

AI, Adequate intake; AMDR, acceptable macronutrient distribution range; EAR, estimated average requirement; GI, gastrointestinal; HDL, high-density lipoprotein; LDL, low-density lipoprotein; ND, not determinable; PUFAs, polyunsaturated fatty acids; RDA, recommended dietary allowance; UL, upper limit of normal.

Adapted from Food and Nutrition Board, Institute of Medicine: Dietary reference intakes for, energy, carbohydrate fiber, fat, fatty acids, cholesterol, protein, and amino acids. https://www.nap.edu/read/10490/chapter/32.

**Triglycerides** are the most common form of dietary fat and are composed of 1 glycerol molecule with 3 fatty acids. Triglycerides are found in animal and vegetable fats. Simple sugars (i.e., refined grains and high sugar drinks) are converted to triglycerides in the liver. Elevated serum triglycerides are a risk factor for CV disease and metabolic syndrome. Decreasing simple sugars and increasing complex carbohydrate intake reduces serum triglyceride levels.

Dietary saturated fatty acids (found primarily in animal fat and dairy products), *trans* fats (found in hydrogenated margarines and oils), and **cholesterol** increase the low-density lipoprotein (LDL) fraction of serum cholesterol, which is a risk factor for the development of atherosclerosis (Fig. 55.3). Autopsy studies demonstrate that atherosclerosis begins early in childhood, even in infancy. Therefore, dietary advice to optimize CV health should be given starting from age 2 yr, when sufficient fat intake to sustain growth and brain development is less of a concern.
Because saturated and monounsaturated fats can be synthesized endogenously to support adequate structural and physiologic requirements, there is no AI or RDA set for these dietary components. Trans fats, a by-product of the hydrogenation of vegetable oils to form margarine, have no known health benefits in humans. Trans fats do not have an AI or RDA defined. In fact, trans
fats behave like saturated fats. An UL has not been set for cholesterol, saturated, or *trans* fats because there is a continuous positive linear association between intake of these fats and increased risk for CV disease, without a threshold level. Diets low in saturated fats and cholesterol without *trans* fats are therefore preferred.

Efforts continue to reduce or eliminate *trans* fats from the diet. For optimal CV health in the general population, rather than limiting fat intake, advice should focus in most cases on changing the type of fat consumed. With respect to preventing obesity, all types of fatty acids have the same energy content and can contribute to increasing the risk for obesity. The current 2015–2020 Dietary Guidelines for Americans no longer restrict how much energy should come from fat intake, but continue to recommend that <10% of total daily calories come from saturated fat, with no *trans* fat intake. Furthermore, these guidelines do not specify limits on dietary cholesterol intake, because there is no clear strong evidence of the relationship between dietary and blood cholesterol.

Humans are incapable of synthesizing the precursor omega (ω) 3 (α-linolenic acid; ALA) and ω6 (linoleic acid; LA) PUFAs and depend on diet for these 2 essential fatty acids (EFAs). Safflower and sunflower oil are good sources of linoleic acid. Walnut and flaxseed oil are good sources of ALA. Essential fatty acid deficiency with LA is associated with desquamating skin rashes, alopecia, thrombocytopenia, impaired immunity, and growth deficits but is rare in the general population. EFAs are enzymatically elongated and desaturated into longer-chain fatty acids; ALA can be converted to eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA) ω3 PUFAs. LA is converted to arachidonic acid (ARA). Long-chain PUFAs such as DHA and ARA have a variety of cellular structural and functional roles; they influence membrane fluidity and function in gene expression and modulate the inflammatory response. ARA and DHA are present in breast milk, often supplemented in infant formulas, and are required for normal growth and development. DHA is present in the retina and is involved in the visual evoked response in infants.

The conversion of ALA to EPA and DHA and of LA to ARA is influenced by many factors, including type and amounts of dietary fats, and by enzymatic substrate affinity among competing ω3, ω6, ω9, saturated, and *trans* fatty acids. Approximately 0.5% of dietary ALA is converted to DHA, and 5% of ALA intake is converted to EPA; therefore, dietary intake of longer-chain PUFAs is an important determinant of serum and tissue long-chain PUFA status. The biologic activity and health benefits of ALA are thought to be derived from the longer-
chain PUFA products EPA and DHA. Consistent with these findings of limited conversion of ALA to EPA and DHA, and that EPA and DHA appear to confer the biologic role and health benefits, the dietary reference intake (DRI) stipulates that up to 10% of the AI for ω3 PUFA (ALA being the major dietary constituent) can be replaced by DHA and EPA to support normal neural development and growth.

The ratio of dietary intake of each type of PUFA influences their relative amounts in different tissue compartments. A dietary ω6:ω3 PUFA ratio of 4-5 : 1 may be beneficial in reducing risk of disease and may be associated with improved health outcomes, compared with the current 15-30 : 1 ratio observed in U.S. diets.

**Protein**

Protein and amino acids have structural and functional roles in every cell in the body. Dietary protein intake is required to replenish the turnover of protein and to meet amino acid needs for growth. Dietary protein also provides approximately 4 kcal/g as an energy substrate when intake is in excess of needs, or during periods of catabolism. Inadequate energy intake or inadequate protein intake increases catabolism of body protein reservoirs (i.e., lean body mass) for energy and free amino acids required to support normal physiologic function. Nitrogen from protein turnover is excreted in urine, stool, and other bodily excretions. Increased protein intake may be required for rare hypermetabolic states, such as extensive burn injury. Protein-energy malnutrition, although relatively rare in the noninstitutionalized U.S. population, is more common in the developing world. Protein-energy malnutrition impairs brain, immune system, and intestinal mucosal functions (see Chapter 59).

The DRI for protein is provided in Table 55.3. According to the 2015–2020 Dietary Guidelines for Americans, the average intake of protein from poultry, meat, eggs, nuts, seeds, and soy products are close to the recommended amounts for all ages. Protein intake is higher than recommended amounts in adolescent males (mostly from meats, poultry, and eggs). Intake of seafood protein is low across all age and sex groups. An UL for protein has not been set. Some athletes may have increased protein needs, of approximately 2 g/kg/day, to prevent loss of fat-free mass or lean body mass. Certain conditions may require a modest increase in protein intake, including conditions with high protein turnover, inflammatory conditions, or postsurgical states, as well as with cystic fibrosis,
critical illnesses, burn injuries, compensated liver disease, and bariatric surgery (e.g., laparoscopic sleeve gastrectomy and Roux-en-Y gastric bypass). Intake of protein or specific amino acids needs to be limited in some health conditions, such as renal disease and decompensated liver disease, and metabolic diseases such as phenylketonuria and maple syrup urine disease, in which specific amino acids can be toxic.

The amino acid content of dietary protein is also important. Certain amino acids are **indispensable**, and humans depend on dietary sources to meet adequacy and prevent deficiency. Certain amino acids are termed **conditional essential/indispensable**, meaning they become essential in patients affected by some diseases or during a certain life stage, such as with cysteine, tyrosine, and arginine in newborns because of enzyme immaturity (Table 55.4). Human milk contains both the indispensable and conditionally indispensable amino acids and therefore meets the protein requirements for infants. Breast milk is considered the optimal protein source for infants and is the reference amino acid composition by which biologic quality is determined for infants. If a single amino acid in a food protein source is low or absent but is required to support normal metabolism, that specific amino acid becomes the limiting nutrient in that food. For soy-based infant formula, supplementing the formula with the limiting amino acid (methionine) is necessary. Certain amino acid–like substances, such as creatinine, are used by some athletes and may enhance performance. Such supplementation should be monitored for potential side effects.

*Conditionally indispensable is defined as requiring a dietary source when endogenous synthesis
cannot meet metabolic need.

† Although histidine is considered indispensable, unlike the other 8 indispensable amino acids, it does not fulfill the criteria of reducing protein deposition and inducing negative nitrogen balance promptly on removal from the diet.

To ensure appropriate growth and to promote satiety, children should consume the recommended amount of protein. Specific recommendations for appropriate dietary protein sources to meet indispensable amino acid requirements are available for groups adopting specific diets, such as vegetarians and vegans. Inclusion of legumes and corn, as well as the use of a variety of food sources to provide all of the required amino acids is a strategy advocated for vegetarians and vegans (see Chapter 56).

Carbohydrates

Carbohydrates are abundant in many foods, including cereals, grains, fruits, and vegetables, and provide approximately 4 kcal/g. Dietary carbohydrates include monosaccharides, which contain 1 sugar molecule (glucose, fructose); disaccharides, which contain 2 sugar molecules (sucrose, lactose); oligosaccharides or polysaccharides, which contain multiple sugar molecules in a chain or complex configuration (e.g., starch); and sugar alcohols. Glucose serves as the essential energy source for erythrocytes and the central nervous system and a major energy source for all other cells. The requirements for carbohydrates are based on the average minimum amount of glucose utilized by the brain. Chronic low carbohydrate intake results in ketosis. Although an UL for carbohydrates has not been set, a maximal intake of <10% of total energy intake from added sugars has been proposed in the 2015–2020 Dietary Guidelines for Americans. Added sugars include syrups and other caloric sweeteners (Fig. 55.4). These added sugars do not contribute essential nutrients and function to sweeten foods and beverages to which they are added. Naturally occurring sugars, such as in milk (lactose) or fruits, are not included. Higher intakes of added sugar can displace other macro- and micronutrients and increase risk for nutrient deficiency and excessive energy intake. There is no advantage or benefit from discretionary calorie intake such as consuming added sugars. In fact, the excess calories from added sugars may make it difficult to meet nutrient needs...
while remaining within recommended total calorie intake.

The recommended AMDR for carbohydrates is based on data suggesting a risk for coronary artery disease (CAD) with diets high in carbohydrates and low in fat (see Table 55.2). These diets, compared to diets with higher fat intake, result in high triglyceride levels, low high-density lipoprotein (HDL) cholesterol, and small LDL cholesterol particles, and are associated with a high risk of CAD, especially in sedentary overweight individuals. Diets within the AMDR for carbohydrates and fats minimize the risks of diabetes, obesity, and CAD. Diets with less than the minimum AMDR for carbohydrate most likely do not meet the AI for fiber (see Table 55.3).

Most carbohydrates are present as starches or sugars in food. Simple sugars (monosaccharides and disaccharides) are often added to foods and beverages during food preparation, processing, and packaging to enhance their palatability, as well as acting as preservatives. Nondiet soft drinks, juice drinks, iced tea, and sport drinks are among the major contributors to added sugars in the diet of U.S. children and adolescents. Added sugars increase the risk for obesity, diabetes, and dental caries. Fructose is one such added sugar in the form of high-fructose corn syrup, which is ubiquitous in the U.S. diet. Fructose increases HDL and triglyceride production in the liver and serum uric acid, which increases systolic blood pressure and is associated with nonalcoholic fatty liver disease and metabolic syndrome. Excessive fructose intake, such as in the form of fruit juices, is associated with diarrhea, abdominal pain, and failure to thrive in children.

The glycemic index is a measure of peak blood glucose concentration 2 hr after ingestion of a given food compared with a reference standard (slice of white bread). The glycemic index has predictable effects on blood glucose, hemoglobin A1c, insulin, triglycerides, and HDL cholesterol. Lower–glycemic index foods are recommended and may reduce the risk of insulin resistance and CV disease (e.g., oat bran, muesli, barley carrots, nonstarchy vegetables, most fruits).

**Fiber**

Fiber consists of *nondigestible* carbohydrates mostly derived from plant sources, such as whole grains, fruits, and vegetables, that escape digestion and reach the colon almost 100% intact. These compounds were previously classified as being *water soluble vs insoluble*, which may be a less meaningful health distinction
but still commonly used. The DRI classification lists **dietary fiber** (nondigestible carbohydrates and lignin that are intrinsic and intact in plants), **functional fiber** (fiber with known physiologic benefits in humans), and **total fiber** (dietary plus functional).

Although fiber intake does not contribute significantly to energy intake, it does have several important roles. The metabolic fate of fiber is influenced primarily by colonic bacteria, which render it susceptible to fermentation, depending on the structure of the fiber (e.g., pectin, oat bran). Common by-products of colonic fermentation include carbon dioxide, methane (in addition to other gases), **oligofructose** (also known as a prebiotic, a substrate that nourishes beneficial commensurate gastrointestinal microbiota), and **short-chain fatty acids (SCFAs)**. The common SCFAs produced by fermentation include acetate, butyrate, and propionate. There is dynamic interplay between the colonic bacterial milieu and the diet. SCFAs influence colonic physiology by stimulating colonic blood flow and fluid and electrolyte uptake. Butyrate is the preferred fuel for the colonocyte and may have a role in maintaining the normal phenotype in these cells.

Dietary fiber may have an important role in reducing dysplasia risk by diluting toxins, carcinogens, and tumor promoters; decreasing transit time, thereby decreasing colonic mucosal exposure; and promoting toxin expulsion in the fecal stream. Dietary fiber that is resistant to colonic degradation may also play a role in maintaining and promoting stool bulk and in regulating intraluminal pressure and colonic wall resistance, disordered colonic motility, or both. Lack of certain types of dietary fiber is associated with constipation and diverticulosis.

All types of dietary fiber slow gastric emptying and promote satiety, and thus may help to regulate appetite. Dietary fiber may decrease the rate of release and absorption of simple sugars and may help regulate blood sugar concentration, with lower postprandial level. Dietary fiber has a low glycemic index and may have a beneficial effect on insulin sensitivity. Fiber also binds luminal cholesterol and reduces absorption and enterohepatic circulation of the cholesterol in bile salts (with the intake of more viscous forms of dietary fiber, such as pectin). Guar gum, oat products, and pectin (previously categorized as soluble fiber) lower serum cholesterol, whereas insoluble fiber (e.g., flax, wheat bran) may reduce serum triglycerides. However, fiber such as psyllium, resistant dextrins, and resistant starch may lower both serum LDL cholesterol and triglycerides. The older classifications of the benefits of soluble vs insoluble fiber types are thus not always consistent. Decreased fiber intake in Western
society has been associated with the increasing incidence and prevalence of diabetes, obesity, CV disease, colon cancer, and IBD.

Data are insufficient to establish an EAR for dietary fiber. AI for dietary fiber has been established based on the intake levels associated with reducing risk for CV disease and in lowering or normalizing serum cholesterol (see Table 55.3). A UL has not been established for fiber, which is not thought to be harmful to human health. Several recommendations address dietary fiber intake in children based on body weight or as a proportion of daily calories consumed. The prevailing approach, however, is based on expert consensus and uses a rule of thumb guided by safety considerations, with improved laxation and reduced risk of future chronic diseases as goals. The equation for fiber intake in children follows:

\[
\text{Range of grams of fiber per day} = \text{Age [yr]} + 5 \text{ to } \text{Age [yr]} + 10.
\]

It is noteworthy that the recommendation does not specify type of fiber, and it predates the newer definition of fiber. Difficulties in making better recommendations for fiber intake goals in children include the lack of consensus on defining fiber and inadequate randomized double-blinded placebo-controlled trials with well-defined, clinically meaningful end-points.

Certain types of fiber intake are associated with increased risk for gastrointestinal (GI) symptoms along the functional abdominal pain, functional GI disorders, and IBD spectrum. Some fiber types may exert symptoms on the basis of their digestibility, by-product formation, and interactions with GI microbiota. Restriction of fermentable (i.e., to produce methane, \(\text{CO}_2\), and hydrogen) \textit{oligosaccharides} (e.g., fructooligosaccharides such as onions), \textit{disaccharides} (e.g., lactose), \textit{monosaccharides} (e.g., fructose), and \textit{polyols} (e.g., sorbitol) \textbf{(FODMAP)} or substitution with lower-FODMAP foods may be beneficial. Substitutions within the same food groups can shift from a high-FODMAP diet to a low-FODMAP diet, which may provide GI symptom relief. For example, substituting cucumber for celery would be exchanging a high-FODMAP food for a low-FODMAP food.

Lastly, dietary management in certain diseases may put such children at risk of low fiber intake. For example, children with celiac disease are advised gluten-free diets. As such, these children are at risk of inadequate fiber intake, for which alternative, gluten-free sources of fiber should be recommended, such as
tapioca, flax, corn, rice, sorghum, and quinoa.

**Micronutrients**

(See Chapters 61-67.)

Vitamins and trace minerals, the dietary micronutrients, are essential for growth and development and contribute to a host of physiologic functions. Many U.S. children have suboptimal intake of iron, zinc, potassium, calcium, vitamin D, and vitamin K, and excess intake of sodium. Dietary recommendations for micronutrients were originally established to prevent deficiency and currently also include the impact of micronutrients on long-term health outcomes (Table 55.5). Food fortification is an effective strategy to prevent some nutrient deficiencies and has been successfully implemented to prevent iodine and folate deficiency.

**Coenzyme in metabolism of nucleic and amino acids Prevents megaloblastic anemia**

**Enriched cereal, grains, dark leafy vegetables, enriched and whole-grain breads and bread products, fortified ready-to-eat cereals**

**Masks neurologic complications in people with vitamin B<sub>12</sub> deficiency.**

No adverse effects associated with folate from food or supplements have been reported; this does not mean that there is no potential for adverse effects resulting from high intakes. Because data on adverse effects of folate are limited, caution may be warranted. UL for folate applies to synthetic forms obtained from food folate addition to in.

In view of evidence linking poor folate intake with neural tube defects, all women who can become pregnant should consume 400 µg/day from supplements or fortified foods in addition to intake of food folate from a varied diet.
Niacin (vitamin B₃)
Includes nicotinic acid amide, nicotinic acid (pyridine-3 carboxylic acid), and derivatives that exhibit biologic activity of nicotinamide
Given as niacin equivalents (NE)
1 mg niacin = 60 mg tryptophan
Age 0-6 mo: preformed niacin (not NE).

Green vegetables (collards, spinach, salad greens, broccoli), Brussels sprouts, cabbage, plant oil, margarine. No adverse effects associated with vitamin K consumption from food or supplements have been reported in humans or animals; this does not mean there is no potential for adverse effects resulting from high intake. Because data on adverse effects of vitamin K are limited, caution may be warranted. Patients receiving anticoagulant therapy should monitor vitamin K intake.

Adverse effects from vitamin E-containing supplements may include hemorrhagic toxicity. UL for vitamin E applies to any form of α-tocopherol obtained from supplements, fortified foods, or a combination of these.
Adequate intake. *RDA for vitamin D in IU/day: 400 if <1 yr age, 600 if >1 yr, lactating, or pregnant.

Note: Starred (*) numbers are AI, and bold numbers are RDA. RDAs and AIs may both be used as goals for individual intake. RDAs are set to meet the needs of 97–98% of members in a group. For healthy breastfed infants, the AI is the mean intake. The AI for other life stage and gender groups is believed to cover the needs of all members of the group, but lack of data prevents specifying with confidence the percentage covered by this intake.

UL is the maximum level of daily nutrient intake that is likely to pose no risk of adverse effects. Unless otherwise specified, the UL represents total intake from food, water, and supplements. Because of a lack of suitable data, ULs could not be established for potassium, water, or inorganic sulfate. In the absence of ULs, extra caution may be warranted in consuming levels above recommended intakes.

ND amounts are not determinable because of a lack of data of adverse effects in this age-group and concern with regard to lack of ability to handle excess amounts. Source of intake should be from food only to prevent high levels of intake.

AI, Adequate intake; GI, gastrointestinal; ND, not determinable; PLP, pyridoxal phosphate; PMP, pyridoxamine phosphate; PNP, pyridoxine phosphate; RDA, recommended dietary allowance; UL, upper limit of normal.

Breast milk provides optimal intake of most nutrients, including iron and zinc. Although present in lower amounts compared with infant formula, iron and zinc are more bioavailable and are sufficient to meet infant needs until approximately 4-6 mo of age. After 4-6 mo, iron and zinc are required from complementary foods, such as iron-fortified cereal and pureed meats.

Iron

Iron requirements are relatively higher during infancy and childhood than later in life and are higher for menstruating females than for males of similar age-groups (see Chapter 67). Iron present in animal protein is more bioavailable than that found in vegetables and other foods because it is already incorporated into heme moieties in blood and muscle. Iron deficiency is the most common micronutrient deficiency in the world and is associated with iron-deficiency anemia and neurocognitive deficits in some children. Zinc deficiency affects
millions of children and is associated with increased risk for impaired linear growth (stunting), impaired immune function, and increased risk for respiratory and diarrheal diseases.

**Vitamin D**

Breast milk is a poor source of vitamin D. Vitamin D insufficiency is more common than previously thought in infants and children. Vitamin D is central to calcium and bone metabolism but is also an important determinant of various nonosseous health outcomes (see Chapter 64 ). Children of all ages with darker skin and those who do not consume fortified dairy products should be screened for vitamin D deficiency. The DRI for vitamin D is based on its effects on calcium status and bone health. The goal is to achieve serum 25-hydroxyvitamin D levels $>50$ nmol/L (30 ng/dL). The American Academy of Pediatrics (AAP) recommends total vitamin D intake of 400 IU/day for infants and children. A supplement is recommended for all breastfed infants to ensure sufficient intake. In 2010, IOM increased the RDA of vitamin D to 600 units daily for healthy children 1-18 yr of age.

**Calcium**

Calcium is key to bone health. Adequacy is determined in part by bone mineral content and bone mineral density (BMD). The main storage organs for calcium are the bones and teeth. Bone mineral accretion occurs primarily during childhood, with peak bone mass being achieved by the 2nd to 3rd decade of life. Calcium recommendations vary by age and were updated in 2011. These changes include a change from an AI to RDA, in terms of strength of evidence for recommendations, and increased UL in 9-18 yr olds (Table 55.6 ). There are no adequate biomarkers to assess calcium status in healthy children, because serum calcium is tightly regulated (regardless of intake and total body calcium) by changes in parathyroid hormone and calcitriol levels. Maintaining adequate serum calcium level despite inadequate intake could come at the expense of BMD. Therefore, in the long term, reduced BMD could serve as a surrogate marker of calcium intake and status. It is important to note that other variables influence BMD. Assessments of calcium status should include calcium intake in the diet. It is also important to educate families on additional and alternative sources of calcium (including calcium supplementation) if calcium intake is
determined to be low.

All beverages, including water, moisture in foods, high-moisture foods, include watermelon, meats, and soups. No UL because normally functioning kidneys can handle >0.7 L (24 oz) of fluid per hour. Symptoms of water intoxication include hyponatremia, which can result in heart failure, and rhabdomyolysis (skeletal muscle tissue injury), which can lead to kidney failure.

Maintains homeostasis in the body. Allows transport of nutrients to cells and removal and excretion of waste products of metabolism.

- Infants: 0-6 mo 0.7 L, 7-12 mo 0.8 L
- Children: 1-3 yr 1.3 L, 4-8 yr 1.7 L
- Males: 9-13 yr 2.4 L, 14-18 yr 3.3 L, ≥19 yr 3.7 L
- Females: 9-13 yr 2.1 L, 14-18 yr 2.3 L, ≥19 yr 2.7 L
- Pregnancy: ≥14 yr 3.0 L
- Lactation: ≥14 yr 3.8 L

* Vitamin D RDA in IU/day: 40 if <1 yr, 600 if >1 yr of age or pregnant or lactating.
Note: **Bold** numbers are RDA. RDAs and AIs may both be used as goals for individual intake. RDAs are set to meet the needs of 97–98% of members in a group. For healthy breastfed infants, the AI is the mean intake. The AI for other life stage and gender groups is believed to cover the needs of all members of a group, but lack of data prevents specifying with confidence the percentage covered by this intake.

UL is the maximum level of daily nutrient intake that is likely to pose no risk of adverse effects. Unless otherwise specified, the UL represents total intake from food, water, and supplements. Because of a lack of suitable data, ULs could not be established for potassium, water, or inorganic sulfate. In the absence of ULs, extra caution may be warranted in consuming levels above recommended intakes.

ND amounts are not determinable because of a lack of data on adverse effects in this age-group and concern with regard to lack of ability to handle excess amounts. Source of intake should be from food only to prevent high levels of intake.

ACE, Angiotensin-converting enzyme; AI, adequate intake; ARB, angiotensin receptor blocker; GI, gastrointestinal; ND, not determinable; RDA, recommended dietary allowance; UL, upper limit of normal.

**Vitamin K**

Vitamin K is an important determinant of bone health and an important cofactor for coagulation factors (factors II, VII, IX, and X; protein C and S) (see Chapter **66**).

**Electrolytes**

Potassium (K⁺) and sodium (Na⁺) are the main intra- and extracellular cations, respectively, and are involved in transport of fluids and nutrients across the cellular membrane. The AI for potassium is related to its effects in maintaining a healthy blood pressure, reducing risk for nephrolithiasis, and supporting bone health. Moderate potassium deficiency occurs even in the absence of hypokalemia and can result in increased blood pressure, stroke, and other CV disease.

Most American children have potassium intake below the current recommendations, and blacks have lower potassium intake than whites. For people at increased risk of hypertension and who are salt sensitive, reducing sodium intake and increasing potassium intake is advised. Leafy green
vegetables, vine fruit (e.g., tomatoes, eggplant, zucchini, pumpkin) and root vegetables (e.g., yams, beets) are good sources of potassium (see Table 55.6).

People with impaired renal function may need to reduce potassium intake, because hyperkalemia can increase risk for fatal cardiac arrhythmias among these patients.

Most dietary sodium (as sodium chloride, or table salt) in the United States is found in processed foods, breads, and condiments (Fig. 55.5). Sodium salt is added to foods to serve as a food preservative and enhance palatability. Sodium has an AI, but given the risk of table salt–related hypertension, an UL has also been set. The UL threshold may be even lower in blacks, who on average are more sodium salt sensitive, and for those with hypertension or preexisting renal disease. Dietary sodium intake also displaces potassium intake. Elevated sodium:potassium ratios can increase the risk for nephrolithiasis. Intakes of <2,300 mg (approximately 1 tsp) per day are recommended. The average daily salt intake for most people in the United States and Canada exceeds both the AI and UL. For populations with or at risk for hypertension and renal disease, sodium intake should be decreased to <1,500 mg/day and potassium intake increased to >4,700 mg/day. For persons with hypertension, additional dietary guidelines are available from the Dietary Approaches to Stop Hypertension (DASH) eating plan.

### Water

The daily water requirement and water content as a proportion of body weight are highest in infants and decrease with age. Water intake is achieved with liquid and food intake, and losses include excretion in the urine and stool as well as
insensible and evaporative losses through the skin and respiratory tract. An AI has been established for water (see Table 55.6). Special considerations are required by life stages and by BMR, physical activity, body proportions (surface area to volume), environment, and underlying medical conditions. Breast milk and infant formula provide adequate water, and additional water or other fluid intake is not required until complementary foods are introduced. Water contains no calories; the concern is that water intake will decrease breast milk intake and displace the intake of essential nutrients during this phase of rapid rate of growth and metabolically very active life stage. The relatively higher fluid needs of infants and young children can be explained in part by the high ratio of body surface area to volume in infancy, high respiratory rate, and period of rapid growth.

The consequences of inadequate fluid intake include impaired thermoregulation and heat dissipation, reduced activity tolerance and performance, and reduced intravascular fluid and dehydration. This inadequate fluid intake may be reflected by decreased urine input. These deficits can result in an increased compensatory heart rate, hypotension, and syncope, and if uncorrected, renal injury or nephrolithiasis. “Free water” is defined as water in the body that can be removed by ultrafiltration and in which substances can be dissolved. Excess free water intake is usually better tolerated by healthy adults than by younger children, who are at increased risk for water intoxication. Hyponatremia can result from excess free water intake coupled with inadequate sodium intake. Fluid intake requirements and restrictions are also influenced by any underlying renal and hormonal disorders, including diabetes, the syndrome of inappropriate antidiuretic hormone secretion, and diabetes insipidus.

**Measuring Nutritional Adequacy**

The U.S. Centers for Disease Control and Prevention (CDC) and AAP recommend the use of the WHO charts to monitor growth of all infants and children (breastfed and bottle-fed or infant formula–fed) from birth to 2 yr, and the use of the CDC 2000 growth charts for children 2-20 yr (see Chapters 18 and 27). The WHO growth charts are derived from longitudinal and cross-sectional data obtained from a sample of healthy breastfed infants and children (0-5 yr) who were receiving adequate nutritional intake and medical care in Brazil, Ghana, India, Norway, Oman, and the United States. Consequently, the WHO growth charts are not only descriptive of population average and distribution, but
also describe growth of adequately nourished healthy children under best-care practices.

In the clinical setting, the 2.3rd and 97.7th percentiles on the WHO growth charts are used to identify insufficient and excessive growth from birth to 2 yr, respectively. In contrast, the 5th and 95th percentiles are recommended for the equivalent identification in the CDC growth charts from 2-20 yr (Table 55.7). Note that length, weight, and weight-for-length are used in the WHO growth charts from birth to 2 yr. Body mass index (BMI) can be calculated but is not recommended for use in children <2 yr. Stature, weight, and BMI are used in the CDC 2000 growth charts from 2-20 yr of age. These charts can be used to categorize children 2-20 yr as underweight (<5th BMI percentile), normal weight (5–85th), overweight (85–95th), and obese (≥95th BMI percentile). Severe obesity is defined as BMI ≥120% of the 95th percentile, or BMI ≥35 kg/m² (whichever is lower). This assessment corresponds to approximately the 99th percentile or a BMI z score ≥2.33. Severe obesity that exceeds the 99th percentile is tracked on a specialized percentile curve for obesity. Furthermore, adult classification is used for BMI ≥27 kg/m² in adolescents over age 18 for consideration of medication and bariatric surgery.

Bibliography

Grummer-Strawn LM, Reinold C, Krebs NF. Use of World

Skinner AC, Skelton JA. Prevalence and trends in obesity and

Early feeding and nutrition are of importance in the origin of adult diseases such as type 2 diabetes, hypertension, obesity, and the metabolic syndrome. Therefore, appropriate feeding practices should be established in the neonatal period and continued throughout childhood and adolescence to adulthood. Healthful feeding in children requires partnerships between family members, the healthcare system, schools, the community, and the government.

Feeding During the First Year of Life

Breastfeeding

The American Academy of Pediatrics (AAP) and World Health Organization (WHO) have declared breastfeeding and the administration of human milk to be the normative practice for infant feeding and nutrition. Breastfeeding has documented short- and long-term medical and neurodevelopmental advantages and rare contraindications (Tables 56.1 and 56.2 and Table 56.3). Thus the decision to breastfeed should be considered a public health issue and not only a lifestyle choice. The AAP and the WHO recommend that infants should be exclusively breastfed or given breast milk for 6 mo. Breastfeeding should be continued with the introduction of complementary foods for 1 yr or longer, as mutually desired by mother and infant. The success of breastfeeding initiation and continuation depends on multiple factors, such as education about breastfeeding, hospital breastfeeding practices and policies, routine and timely follow-up care, and family and societal support (Table 56.4 and Table 56.5).

Absolute and Relative Contraindications to Breastfeeding Because of Maternal Health Conditions

<table>
<thead>
<tr>
<th>MATERNAL HEALTH CONDITION</th>
<th>DEGREE OF RISK</th>
</tr>
</thead>
<tbody>
<tr>
<td>HIV and HTLV infection</td>
<td>In the United States, breastfeeding is contraindicated. In other settings, health risks of not breastfeeding must be weighed against the risk of transmitting virus to the infant.</td>
</tr>
<tr>
<td>Tuberculosis infection</td>
<td>Breastfeeding is contraindicated until completion of approximately 2 wk of appropriate maternal therapy.</td>
</tr>
<tr>
<td>Varicella-zoster infection</td>
<td>Infant should not have direct contact to active lesions. Infant should receive immune globulin.</td>
</tr>
<tr>
<td>Herpes simplex infection</td>
<td>Breastfeeding is contraindicated with active herpetic lesions of the breast.</td>
</tr>
<tr>
<td>CMV infection</td>
<td>May be found in milk of mothers who are CMV seropositive. Transmission through human milk causing symptomatic illness in term infants is uncommon.</td>
</tr>
<tr>
<td>Hepatitis B infection</td>
<td>Infants routinely receive hepatitis B immune globulin and hepatitis B vaccine if mother is HBsAg positive. No delay in initiation of breastfeeding is required.</td>
</tr>
<tr>
<td>Hepatitis C infection</td>
<td>Breastfeeding is not contraindicated.</td>
</tr>
</tbody>
</table>

Alcohol intake  Limit maternal alcohol intake to <0.5 g/kg/day (for a woman of average weight, this is the equivalent of 2 cans of beer, 2 glasses of wine, or 2 oz of liquor).

Cigarette smoking  Discourage cigarette smoking, but smoking is not a contraindication to breastfeeding.

Chemotherapy, radiopharmaceuticals  Breastfeeding is generally contraindicated.

CMV, Cytomegalovirus; HBsAg, hepatitis B surface antigen; HIV, human immunodeficiency virus; HTLV, human T-lymphotropic virus.

### Table 56.4

**Ten Hospital Practices to Encourage and Support Breastfeeding**

1. Have a written breastfeeding policy that is routinely communicated to all health care staff.
2. Train all health care staff in the skills necessary to implement this policy.
3. Inform all pregnant women about the benefits and management of breastfeeding.
4. Help women initiate breastfeeding within 1 hour of birth.
5. Show women how to breastfeed and how to maintain lactation, even if they are separated from their newborns.
6. Give newborns no food or drink other than breast milk unless medically indicated.
7. Practice rooming-in; allow mothers and newborns to remain together 24 hours a day.
8. Encourage breastfeeding on demand.
9. Give no pacifiers or artificial nipples to breastfeeding infants. †
10. Foster the establishment of breastfeeding support groups and refer to them on discharge from the hospital or birth center.

### COMPONENTS OF SAFE POSITIONING FOR THE NEWBORN WHILE SKIN-TO-SKIN **

| 1. Infant’s face can be seen. |
| 2. Infant’s head is in “sniffing” position. |
| 3. Infant’s nose and mouth are not covered. |
| 4. Infant’s head is turned to one side. |
| 5. Infant’s neck is straight, not bent. |
| 6. Infant’s shoulders and chest face mother. |
| 7. Infant’s legs are flexed. |
| 8. Infant’s back is covered with blankets. |
| 9. Mother-infant dyad is monitored continuously by staff in the delivery environment and regularly on the postpartum unit. |
| 10. When mother wants to sleep, infant is placed in bassinet or with another support person who is awake and alert. |

* The 1994 report of the Healthy Mothers, Health Babies National Coalition Expert Work Group recommend that the UNICEF-WHO Baby Friendly Hospital Initiative be adapted for use in the United States as the United States Breastfeeding Health Initiative, using the adapted ten hospital practices above.

† The American Academy of Pediatrics endorsed the UNICEF-WHO Ten Steps to Successful Breastfeeding, but does not support a categorical ban on pacifiers because of their role in reducing the risk of sudden infant death syndrome and their analgesic benefit during painful procedures when breastfeeding cannot provide the analgesia.

### Table 56.5

**Recommendations on Breastfeeding Management for Healthy Term Infants**

| 1. Exclusive breastfeeding for about 6 months |
| • Breastfeeding preferred; alternatively expressed mother's milk, or donor breast milk |
• To continue for at least the first year and beyond as long as mutually desired by mother and child
• Complementary foods rich in iron and other micronutrients should be introduced at about 6 mo of age

2. Peripartum policies and practices that optimize breastfeeding initiation and maintenance should be compatible with the AAP and Academy of Breastfeeding Medicine Model Hospital Policy and include the following:
  • Direct skin-to-skin contact with mothers immediately after delivery until the first feeding is accomplished and encouraged throughout the postpartum period
  • Delay in routine procedures (weighing, measuring, bathing, blood tests, vaccines, and eye prophylaxis) until after the first feeding is completed
  • Delay in administration of intramuscular vitamin K until after the first feeding is completed but within 6 hr of birth
  • Ensure 8-12 feedings at the breast every 24 hr
  • Ensure formal evaluation and documentation of breastfeeding by trained caregivers (including position, latch, milk transfer, examination) at least once for each nursing shift
  • Give no supplements (water, glucose water, commercial infant formula, or other fluids) to breastfeeding newborn infants unless medically indicated using standard evidence-based guidelines for the management of hyperbilirubinemia and hypoglycemia
  • Avoid routine pacifier use in the postpartum period
  • Begin daily oral vitamin D drops (400 IU) at hospital discharge

3. All breastfeeding infants should be seen by a pediatrician within 48 to 72 hr after discharge from the hospital
  • Evaluate hydration and elimination patterns
  • Evaluate body weight gain (body weight loss no more than 7% from birth and no further weight loss by day 5: assess feeding and consider more frequent follow-up)
  • Discuss maternal/infant issues
  • Observe feeding

4. Mother and infant should sleep in proximity to each other to facilitate breastfeeding

5. Pacifier should be offered, while placing infant in back-to-sleep-position,
no earlier than 3 to 4 weeks of age and after breastfeeding has been established

Feedings should be initiated soon after birth unless medical conditions preclude them. Mothers should be encouraged to nurse at each breast at each feeding starting with the breast offered second at the last feeding. It is not unusual for an infant to fall asleep after the 1st breast and refuse the 2nd. It is preferable to empty the 1st breast before offering the 2nd to allow complete emptying of both breasts and therefore better milk production. Table 56.6 summarizes patterns of milk supply in the 1st week.

**Table 56.6**

**Patterns of Milk Supply**

<table>
<thead>
<tr>
<th>DAY OF LIFE</th>
<th>MILK SUPPLY</th>
</tr>
</thead>
<tbody>
<tr>
<td>Day 1</td>
<td>Some milk (~5 mL) may be expressed.</td>
</tr>
<tr>
<td>Days 2-4</td>
<td>Lactogenesis; milk production increases.</td>
</tr>
<tr>
<td>Day 5</td>
<td>Milk present; fullness and leaking are felt.</td>
</tr>
<tr>
<td>Day 6 onward</td>
<td>Breasts should feel “empty” after feeding.</td>
</tr>
</tbody>
</table>

New mothers should be instructed about infant hunger cues, correct nipple latch, positioning of the infant on the breast, and feeding frequency. It is also suggested that someone trained in lactation observe a feeding to evaluate positioning, latch, milk transfer, maternal responses, and infant satiety. Attention to these issues during the birth hospitalization allows dialog with the mother and family and can prevent problems that could occur with improper technique or knowledge of breastfeeding. As part of the discharge teaching process, issues on infant feeding, elimination patterns, breast engorgement, breast care, and maternal nutrition should be discussed. A follow-up appointment is recommended within 24-48 hr after hospital discharge.

**Nipple Pain**

Nipple pain is one of the most common complaints of breastfeeding mothers in
the immediate postpartum period. Poor infant positioning and improper latch are the most common reasons for nipple pain beyond the mild discomfort felt early in breastfeeding. If the problem persists and the infant refuses to feed, evaluation for nipple candidiasis is indicated. If candidiasis is present, the mother should be treated with an antifungal cream that is wiped off of the breast before feeding, and the infant treated with an oral antifungal medication.

**Tongue-tie (ankyloglossia)** has been associated with nipple pain, poor latching, and poor weight gain in breastfed and bottle-fed infants. **Frenotomy** is a minor surgical procedure with few complications and has been suggested as a treatment option for ankyloglossia. Nonetheless, there is considerable disagreement about the significance of ankyloglossia and the value of frenotomy. It is often difficult to assess the severity of ankyloglossia on physical examination; a combination of physical assessment and functional feeding difficulty is more useful. Nonetheless, about 50% of infants with ankyloglossia have no feeding problems, and most infants with nursing problems do not have ankyloglossia. Lactation consultants often recommend frenotomy, whereas pediatricians provide lactation management approaches and wait at least 2-3 wk before considering frenotomy. During that time many feeding issues resolve, thus avoiding frenotomy.

**Engorgement**

In the 2nd stage of lactogenesis, physiologic fullness of the breast occurs. Breasts may become engorged: firm, overfilled, and painful as the pattern and volume of milk production adjusts to the infant's feeding schedule. Incomplete removal of milk as a result of poor breastfeeding technique or infant illness can cause engorgement. Breastfeeding immediately at signs of infant hunger will eventually prevent this from occurring. To reduce engorgement, breasts should be softened before infant feeding with a combination of hot compresses and expression of milk. To reduce inflammation and pain, between feedings a supportive bra should be worn, cold compresses applied, and oral nonsteroidal antiinflammatory drugs (NSAIDs) administered.

**Mastitis**

Mastitis occurs in 2–3% of lactating women and is usually unilateral, manifesting with localized warmth, tenderness, edema, and erythema after the
2nd postdelivery week. Sudden onset of breast pain, myalgia, and fever with fatigue, nausea, vomiting, and headache can also occur. Organisms implicated in mastitis include *Staphylococcus aureus, Escherichia coli*, group A streptococcus, *Haemophilus influenzae, Klebsiella pneumoniae*, and *Bacteroides* species. Diagnosis is confirmed by physical examination. Oral antibiotics and analgesics, while promoting breastfeeding or emptying of the affected breast, usually resolve the infection. A breast abscess is a less common complication of mastitis, but it is a more serious infection that requires intravenous antibiotics and incision and drainage, along with temporary cessation of feeding from that breast.

**Inadequate Milk Intake**

Insufficient milk intake, dehydration, and jaundice in the infant can occur within the 1st week of life. Signs include lethargy, delayed stoolsing, decreased urine output, weight loss >7–10% of birth weight, hypernatremic dehydration, inconsolable crying, and increased hunger. Insufficient milk intake may be caused by insufficient milk production, failure of established breastfeeding, and health conditions in the infant that prevent proper breast stimulation. Parents should be counseled that breastfed neonates feed 8-12 times/day with a minimum of 8 times/day. Careful attention to prenatal history can identify maternal factors associated with this problem (failure of breasts to enlarge during pregnancy or within the 1st few days after delivery). Direct observation of breastfeeding can help identify improper technique. If a large volume of milk is expressed manually after breastfeeding, the infant might not be extracting enough milk, eventually leading to decreased milk output. Late preterm infants (34-36 wk) are at risk for insufficient milk syndrome because of poor suck and swallow patterns or medical issues.

**Jaundice**

Breastfeeding jaundice is related to insufficient fluid intake during the 1st week of life and is a common reason for hospital readmission of healthy breastfed infants (see Chapter 123.3). Breastfeeding jaundice is associated with dehydration and hypernatremia. Breast milk jaundice is a different disorder that causes persistently high serum indirect bilirubin in thriving healthy well-fed infants. Breast milk contains inhibitors of glucuronyl transferase and causes
enhanced absorption of bilirubin from the gut. Breast milk jaundice becomes evident later than breastfeeding jaundice and generally declines in the 2nd to 3rd wk of life. Infants with severe or persistent jaundice should be evaluated for other medical causes. Persistently high bilirubin levels may require changing from breast milk to infant formula for 24-48 hr and/or treatment with phototherapy without cessation of breastfeeding. Breastfeeding should resume after the decline in serum bilirubin. Parents should be reassured and encouraged to continue collecting breast milk during the period the infant is taking formula.

**Breast Milk Collection**

The pumping of breast milk is a common practice when the mother and baby are separated. Good handwashing and hygiene should be emphasized. Electric breast pumps are generally more efficient and better tolerated by mothers than mechanical pumps or manual expression. Collection kits should be cleaned with hot soapy water, rinsed, and air-dried after each use. Glass or plastic containers should be used to collect the milk, and milk should be refrigerated and then used within 48 hr. Expressed breast milk can be frozen and used for up to 6 mo. Milk should be thawed rapidly by holding under running tepid water and used completely within 24 hr after thawing. *Milk should never be microwaved.*

**Growth of the Breastfed Infant**

The rate of weight gain of the breastfed infant differs from that of the formula-fed infant; the infant's risk for excess weight gain during late infancy may be associated with bottle feeding. The WHO growth charts are based on growth patterns of healthy breastfed infants through the 1st year of life. These standards ([http://www.who.int/childgrowth](http://www.who.int/childgrowth)) are the result of a study in which >8,000 children were selected from 6 countries. The infants were selected based on being breastfed, having good health care, high socioeconomic status, and nonsmoking mothers, so that they reflect the growth pattern of breastfed infants in optimal conditions and can be used as prescriptive rather than normative curves. Charts are available for growth monitoring. The U.S. Centers for Disease Control and Prevention (CDC) recommend use of the WHO growth charts for infants 0–23 mo of age and CDC growth charts for ages 24 mo to 20 yr (see Chapter 27).
Formula Feeding (Fig. 56.1)

Despite efforts to promote exclusive breastfeeding through 6 mo, <50% of women continue to breastfeed at 6 mo. Most women make their infant feeding choices early in pregnancy. Parental preference is the most common reason for using infant formula. However, infant formula is also indicated for infants whose intake of breast milk is contraindicated for infant factors (e.g., inborn errors of metabolism) and maternal factors (see Table 56.2). In addition, infant formula is used as a supplement to support inadequate weight gain in breastfed infants.

Infant formulas marketed in the United States are safe and nutritionally adequate as the sole source of nutrition for healthy infants for the 1st 6 mo of
life. Infant formulas are available in ready-to-feed, concentrated liquid or powder forms. Ready-to-feed products generally provide 19-20 kcal/30 mL (1 oz) and approximately 64-67 kcal/dL. Concentrated liquid products, when diluted according to instructions, provide a preparation with the same concentration. Powder formulas come in single or multiple servings and when mixed according to instructions will result in similar caloric density.

Although infant formulas are manufactured in adherence to good manufacturing practices and are regulated by the U.S. Food and Drug Administration (FDA), there are potential safety issues. Ready-to-feed and concentrated liquid formulas are commercially sterile, but powder preparations are not. Although the number of bacterial colony-forming units per gram (CFU/g) of powder formula is generally lower than allowable limits, outbreaks of infections with *Cronobacter sakazakii* (previously *Enterobacter sakazakii*) have been documented, especially in premature infants. The powder preparations can contain other coliform bacteria but have not been linked to disease in healthy term infants. Care must be taken in following the mixing instructions to avoid over- or underdilution, to use boiled or sterilized water, and to use the specific scoops provided by the manufacturer because scoop sizes vary. Water that has been boiled should be allowed to cool fully to prevent degradation of heat-labile nutrients, specifically vitamin C. Well water should be tested regularly for bacteria and toxin contamination. Municipal water can contain variable concentrations of fluoride, and if the concentrations are high, bottled water that is defluoridated should be used to avoid toxicity.

Parents should be instructed to use proper handwashing techniques when preparing formula and feedings for the infant. Guidance on formula storage should also be given. Once opened, ready-to-feed and concentrated liquid containers can be covered with aluminum foil or plastic wrap and stored in the refrigerator for no longer than 48 hr. Powder formula should be stored in a cool, dry place; once opened, cans should be covered with the original plastic cap or aluminum foil, and the powdered product can be used within 4 wk. Once prepared, all bottles, regardless of type of formula, should be used within 24 hr. Formula should be warmed by placing the container in warm water for about 5 min. Formula should not be heated in a microwave because it can heat unevenly and result in burns, despite appearing to be at the right temperature when tested.
Formula feedings should be ad libitum, with the goal of achieving growth and development to the child's genetic potential. The usual intake to allow a weight gain of 25-30 g/day will be 140-200 mL/kg/day in the 1st 3 mo of life. The rate of weight gain declines from 3-12 mo of age.

**Cow's Milk Protein–Based Formulas**

Intact cow's milk protein–based formulas in the United States contain a protein concentration varying from 1.8-3 g/100 kcal (or 1.4-1.8 g/dL), considerably higher than in mature breast milk (1.2-1.3 g/100 kcal; 0.9-1.0 g/dL). This increased concentration is designed to meet the needs of the youngest infants, but leads to excess protein intake for older infants. In contrast, breast milk content varies over time to match protein needs at various ages. The whey:casein ratio varies in infant formula from 18 : 82 to 60 : 40; one manufacturer markets a formula that is 100% whey. The predominant whey protein is β-globulin in cow's milk and α-lactalbumin in human milk. This and other differences between human milk and cow's milk–based formulas result in different plasma amino acid profiles in infants on different feeding patterns, but clinical significance has not been demonstrated.

The primary source of fat in cow's milk protein–based infant formulas is plant or a mixture of plant and animal oils. Fat provides 40–50% of the energy in cow's milk–based formulas. Fat blends are better absorbed than dairy fat and provide saturated, monounsaturated, and polyunsaturated fatty acids (PUFAs). All infant formulas are supplemented with long-chain PUFAs, docosahexaenoic acid (DHA), and arachidonic acid (ARA) at varying concentrations. ARA and DHA are found at varying concentrations in human milk and vary by geographic region and maternal diet. DHA and ARA are derived from single-cell microfungi and microalgae and are classified as “generally recognized as safe” (GRAS) for use in infant formulas at approved concentrations and ratios. The routine supplementation of milk formula with long-chain PUFAs to improve the physical, neurodevelopmental, or visual outcomes of term infants cannot be recommended based on the current evidence.

**Lactose** is the major carbohydrate in breast milk and in standard cow's milk–based formulas for term infants. Formulas for term infants may also contain modified starch or other complex carbohydrates. Carbohydrates constitute 67-75 g/L of cow's milk–based formula.
Soy Formulas

Soy protein–based formulas on the market are all free of cow’s milk–based protein and lactose. Carbohydrates are provided by sucrose, corn syrup solids, and maltodextrins to provide 67 kcal/dL. They meet the vitamin, mineral, and electrolyte guidelines from the AAP and the FDA for feeding term infants. The protein is a soy isolate supplemented with \( \text{L} \)-methionine, \( \text{L} \)-carnitine, and taurine to provide a protein content of 2.45-2.8 g/100 kcal, or 1.7-1.9 g/dL.

The quantity of specific fats varies by manufacturer and is usually similar to the manufacturer’s corresponding cow’s milk–based formula. The fat content is 5.0-5.5 g/100 kcal, or 3.4-3.6 g/dL. The oils used in both cow’s milk and soy formula include soy, palm, sunflower, olein, safflower, and coconut. DHA and ARA are also added.

In term infants, although soy protein–based formulas have been used to provide nutrition resulting in normal growth patterns, there are few indications for use in place of cow’s milk–based formula. Indications for soy formula include galactosemia, preference for a vegetarian diet, and hereditary lactase deficiency, because soy-based formulas are lactose free. Most healthy infants with acute gastroenteritis can be managed after rehydration with continued use of breast milk or cow’s milk–based formulas and do not require a lactose-free formula, such as soy-based formula. However, soy protein–based formulas may be indicated when documented secondary lactose intolerance occurs. Soy protein–based formulas have no advantage over cow’s milk protein–based formulas as a supplement for the breastfed infant, unless the infant has one of the indications noted previously, and are not recommended for preterm infants. The routine use of soy protein–based formula has no proven value in the prevention or management of infantile colic, fussiness, or atopic disease. Infants with documented cow’s milk protein–induced enteropathy or enterocolitis often are also sensitive to soy protein. They should be provided formula derived from extensively hydrolyzed protein or synthetic amino acids. Soy formulas contain phytoestrogens, which have been shown to have physiologic activity in rodent models, but there is no conclusive evidence of adverse developmental effects in infants fed soy formula.

Protein Hydrolysate Formulas

Protein hydrolysate formulas may be partially hydrolyzed, containing
oligopeptides with a molecular weight of <5000 daltons (range 3,000-10,000 Da), or **extensively hydrolyzed**, containing peptides with a molecular weight <3000 Da. Partially hydrolyzed proteins formulas have fat blends similar to cow's milk–based formulas, and carbohydrates are supplied by corn maltodextrin or corn syrup solids. Because the protein is not extensively hydrolyzed, these formulas should not be fed to infants who are allergic to cow's milk protein. In studies of formula-fed infants who are at high risk of developing atopic disease, there is modest evidence that childhood atopic dermatitis may be delayed or prevented by the use of extensively or partially hydrolyzed formulas, compared with cow's milk–based formula. Comparative studies of the various hydrolyzed formulas have also indicated that not all formulas have the same protective benefit. Extensively hydrolyzed formulas may be more effective than partially hydrolyzed in preventing atopic disease. Extensively hydrolyzed formulas are recommended for infants intolerant to cow's milk or soy proteins. These formulas are lactose free and can include medium-chain triglycerides, making them useful in infants with gastrointestinal malabsorption as a consequence of cystic fibrosis, short gut syndrome, prolonged diarrhea, and hepatobiliary disease.

### Amino Acid Formulas

Amino acid formulas are peptide-free formulas that contain mixtures of essential and nonessential amino acids. They are designed for infants with cow's milk–based protein allergy who failed to thrive on extensively hydrolyzed protein formulas. The effectiveness of amino acid formulas to prevent atopic disease has not been studied.

### Milk and Other Fluids in Infants and Toddlers

Neither breastfed nor formula-fed infants require additional water unless dictated by a specific condition involving excess water loss, such as diabetes insipidus. Vomiting and spitting up are common in infants. When weight gain and general well-being are noted, no change in formula is necessary.

Whole cow's milk should not be introduced until 12 mo of age. In children 12-24 mo of age for whom overweight or obesity is a concern or who have a family
history of obesity, dyslipidemia, or cardiovascular disease, the use of reduced-fat milk is appropriate. Otherwise, whole milk is recommended until age 24 mo, changing to 1% milk at 24 mo for healthy children. Regardless of the type, all animal milk consumed should be pasteurized. Infants and young children are particularly susceptible to infections such as *E. coli*, *Campylobacter*, and *Salmonella* found in raw or unpasteurized milk. For cultural and other reasons, such as parental preference, goat's milk is sometimes given in place of formula, although this is not recommended. Goat's milk has been shown to cause significant electrolyte disturbances and anemia because it has low folic acid concentrations.

**Nondairy alternatives** to milk from plant-based (e.g., soy, hemp, pea, rice) and nut-based (e.g., almond, cashew, peanut) sources have become popular. When counseling parents, it is important to emphasize that the overall nutritional content of plant-based milk alternatives is not equivalent to cow’s milk. Although most are fortified with vitamin D and calcium, with the exception of some soy-, hemp-, and pea-based milk alternatives, most products have a lower protein content. Concurrently, plant-based products such as soy and rice milk tend to have added oils and sugars, giving them a higher energy content than cow's milk. Secondary to a lower protein content, these alternative milks should not be given to infants. Nut-based milks may be suitable to toddlers ≥24 mo of age without allergies who have an otherwise adequate diet.

**Complementary Feeding**

The timely introduction of **complementary foods** (solid and liquid foods other than breast milk or formula, also called **weaning foods**) during infancy is important for nutritional and developmental reasons (Table 56.7). The ability of exclusive breastfeeding to meet macronutrient and micronutrient requirements becomes limited with increasing age of the infant. The recommendation for timing of complementary food initiation is based on the benefits on neurodevelopment and prevention of future comorbidities from exclusive breastfeeding after 6 mo. The AAP, WHO, and European Society for Pediatric Gastroenterology, Hepatology, and Nutrition Committee on Nutrition all recommend exclusive breastfeeding for the 1st 6 mo. Similar data on the benefits of the exclusive use of formula for 6 mo have not been published.

**Table 56.7**
Important Principles for Weaning

Begin at 6 mo of age.
At the proper age, encourage a cup rather than a bottle.
Introduce 1 new food at a time.
Energy density should exceed that of breast milk.
Iron-containing foods (meat, iron-supplemented cereals) are required.
Zinc intake should be encouraged with foods such as meat, dairy products, wheat, and rice.
Phytate intake should be low to enhance mineral absorption.
Breast milk should continue to 12 mo of age; formula or cow's milk is then substituted.

**Give no more than 24 oz/day of cow's milk.**
Fluids other than breast milk, formula, and water should be discouraged.

**Give no more than 4-6 oz/day of 100% fruit juice; no sugar-sweetened beverages.**

Some foods are more nutritionally appropriate than others to complement breast milk or infant formula. The food consumption patterns of U.S. infants and toddlers demonstrate that almost all infants ≤12 mo consumed some form of milk every day; infants >4 mo consumed more formula than human milk, and by 9-11 mo, 20% consumed whole cow's milk and 25% consumed nonfat or reduced-fat milk.

The most common complementary foods between 4 and 11 mo of age are infant cereals. Almost 45% of infants between 9 and 11 mo of age consumed noninfant cereals. Infant eating patterns also vary, with up to 61% of infants 4-11 mo of age consuming no vegetables. French fries were the most frequently consumed vegetables in toddlers. Positive changes in the last decade include increased duration of breastfeeding, delayed introduction of complementary foods, and decreased juice consumption. Continuing concerns include lack of fruits and vegetables; diets low in iron, essential fatty acids, fiber, and whole grains; and diets high in saturated fat and sodium. Table 56.7 summarizes the AAP recommendations for initiating complementary foods.
The complementary foods should be varied to ensure adequate macro- and micronutrient intake. In addition to complementary foods introduced at 6 mo of age, continued breastfeeding or the use of infant formula for the entire 1st year of life should be encouraged. Overconsumption of energy-dense complementary foods can lead to excessive weight gain in infancy, resulting in an increased risk of obesity in childhood.

Feeding Toddlers and Preschool-Age Children

Toddlerhood is a period when eating behavior and healthful habits can be established and is often a confusing and anxiety-generating period for parents. Growth after the 1st year slows, motor activity increases, and appetite decreases. Birth weight triples during the 1st year of life and quadruples by the 2nd year, reflecting this slowing in growth velocity. Eating behavior is erratic, and the child appears distracted from eating as he explores the environment. Children consume a limited variety of foods and often only “like” a particular food for a period and then reject the favored food. The use of growth charts to demonstrate adequate growth and provide guidance about typical behavior and eating habits will help allay parents' concerns. Important goals of early childhood nutrition are to foster healthful eating habits and offer foods that are developmentally appropriate.

Feeding Practices

The period starting after 6 mo until 15 mo is characterized by the acquisition of self-feeding skills because the infant can grasp finger foods, learn to use a spoon, and eat soft foods (Table 56.8). Around 12 mo of age, the child learns to drink from a cup and may still breastfeed or desire formula bottle feeding. Bottle weaning should begin around 12-15 mo, and bedtime bottles should be discouraged because of the association with dental carries. Unless being used at mealtime, the sippy cup should only contain water to prevent caries. Sugar-sweetened beverages and 100% fruit juice should also be discouraged from being used in bottles in all infants at all times. Cups without a lid can be used for no more than 4-6 oz/day of 100% fruit juice for toddlers.

</tr>
</tbody>
</table>

Adapted from Arvedson JC: Swallowing and feeding in infants and young children. *GI Motility online*, 2006. doi:10.1038/gimo17.

Juices should not be given before 12 mo of age. The volume of juices should be limited to 4 oz/day in children 1-3 yr old, to 4-6 oz/day for 4-6 yr olds, and to 8 oz/day for 7-18 yr olds. Children taking medications metabolized by CYP3A4 must avoid grapefruit juices.

In the 2nd year of life, self-feeding becomes a norm and provides the opportunity for the family to eat together with less stress. Self-feeding allows the child to limit her intake. Child feeding is an interactive process. Children receive cues regarding appropriate feeding behaviors from parents. Parents should praise positive and ignore negative eating behaviors unless the behavior jeopardizes the health and safety of the child. In addition, parents should eat with their toddlers and not simply feed them, in order to model positive eating behaviors.

The 2 yr old child should progress from small pieces of soft food to prepared
table foods with precautions. At this stage, the child is not capable of completely chewing and swallowing foods, and particular attention should be paid to foods with a choking risk. Hard candies, nuts, and raw carrots should be avoided. Hot dogs, sausages, and grapes should be sliced lengthwise. Caregivers should always be vigilant and present during feeding, and the child should be placed in a high chair or booster seat. The AAP discourages eating in the presence of distractions such as television, tablets, mobile devices, and other screens, or eating in a car where an adult cannot adequately observe the child.

Young children have a natural preference for sweetened foods and beverages that begin in infancy. Reluctance to accept new foods is a common developmental phase. A new food should be offered multiple times (8-15) over a period of months for acceptance by the child.

Toddlers need to eat 3 healthy meals and 2 snacks daily. Milk continues to be an important source of nutrition. Guidelines for vitamin D supplementation recommend a daily vitamin D intake of 600 IU/day for children and adolescents who are ingesting <1000 mL/day of vitamin D–fortified milk or formula. Toddlers and preschool children often fail to meet the recommended servings of fruits, vegetables, and fiber, whereas intakes of food with fat and added sugar are high. Giving vegetables at the beginning of the meal and increasing the portion size of vegetables served during meals can be an effective strategy for increasing vegetable consumption in preschool children.

**Eating in the Daycare Setting**

Many U.S. toddlers and preschool children attend daycare and receive meals and snacks in this setting. There is a wide variation in the quality of the food offered and the level of supervision during meals. Parents are encouraged to assess the quality of the food served at daycare by asking questions, visiting the center, and taking part in parent committees. Free or reduced-price snacks and meals are provided in daycare centers for low- and medium-income communities through the U.S. Department of Agriculture (USDA) **Child and Adult Care Food Program**. Participating programs are required to provide meals and snacks that meet the meal regulations set by the USDA, guaranteeing a certain level of food quality. However, often for monetary reasons, many daycare centers still struggle to provide high-quality meals and snacks.
Feeding School-Age Children and Adolescents

MyPlate

The USDA MyPlate (www.choosemyplate.gov) is a basis for building an optimal diet for children and adults (Fig. 56.2). MyPlate is based on the 2010 Dietary Guidelines for Americans and replaced MyPyramid. MyPlate provides a visual representation of the different food groups and portion sizes designed for the general public. In addition to food group information, the website provides discretionary calorie information, weight management strategies, and tools to track calories and physical activity goals. A personalized eating plan based on these guidelines provides, on average over a few days, all the essential nutrients necessary for health and growth, while limiting nutrients associated with chronic disease development. MyPlate can also be used as an interactive tool that allows customization of recommendations, based on age, sex, physical activity, and for some populations, weight and height. Print materials from the USDA are also available for families without internet access.
Recommendations based on MyPlate emphasize making half the plate vegetables and fruits and half the plate protein and grains, with protein having the smallest section. Protein replaces the meat category since many protein sources are not from animals. A separate dairy section is included. Physical activity recommendations to achieve a healthful energy balance are not visually displayed but are provided on the website. MyPlate has removed foods that have low nutritional value, such as sweetened sugar beverages and sweetened bakery products.

In the United States and an increasing number of other countries, the vast majority of children and adolescents do not consume a diet that follows the recommendations of MyPlate. The intake of discretionary calories is much higher than recommended, with frequent consumption of sweetened sugar beverages (soda, juice drinks, iced tea, sport drinks), snack foods, high-fat meat (bacon, sausage), and high-fat dairy products (cheese, ice cream). Intake of dark-green and orange vegetables (vs fried white potatoes), whole fruits, reduced-fat dairy products, and whole grains is typically lower than recommended. Furthermore, unhealthful eating habits, such as larger-than-recommended portion sizes; food preparation that adds fat, sugar, or salt; skipping breakfast and/or lunch; grazing; or following fad diets are prevalent and associated with a poorer diet quality. MyPlate offers a helpful and customer-friendly tool to assist pediatricians counseling families on optimal eating plans for short- and long-term health.

Eating at Home

At home, much of what children and adolescents eat is under the control of their parents. Typically, parents shop for groceries and control, to some extent, what food is available in the house. Modeling of healthful eating behavior by parents is a critical determinant of the food choices of children and adolescents. Counseling to improve diet should include guiding parents in using their influence to make healthier food choices available and attractive at home.

Regular family meals sitting at a table, as opposed to eating alone or watching a TV or other screen, are associated with improved diet quality, perhaps because of increased opportunities for positive parenting during meals. Many families with busy schedules and other stressors are unable to provide the ideal meal.
setting. Another parenting challenge is to control the excess appetite of some children and adolescents. Children should be supported to eat at a slower pace and to chew their food properly. Conversation at the dinner table should be encouraged to prolong eating to at least 15 min. Offering vegetables while children are hungry at the beginning of the meal has been shown to increase vegetable consumption. Useful strategies, when the child is still hungry after a meal, include a 15-20 min pause (allow child to engage in another activity) before a 2nd serving or offering foods that are insufficiently consumed, such as vegetables, whole grains, or fruits.

Eating at School

The **National School Lunch Program** and the **School Breakfast Program** provide low-cost meals to more than 5 billion children nationwide. Guidelines for meals are taken from the Dietary Guidelines for Americans and the 2005 Dietary Reference. Recommendations include the use of age-grade portion sizes and the amounts of vegetables and fruits, grains, and fats (Table 56.9). The training and equipment for school food service staff, school community engagement, parent education, and food industry involvement are among the necessary components. The target year is 2020 for achieving recommendations for sodium. In the meantime, while schools are working on implementing changes, parents should be encouraged to examine the weekly menu with their child and assist with their choices. If children bring their lunch from home, recommendations for what constitutes a healthful lunch should be provided by the pediatrician. Parents can be directed to [www.choosemyplate.org](http://www.choosemyplate.org) for healthful lunch ideas. In addition, parties within classrooms should be limited to once a month.

**Table 56.9**

**Revised National School Lunch Program and School Breakfast Program Recommendations**

- Portion sizes of food are to be based on age-grade groups.
- School lunches and breakfasts will have a minimum and maximum calorie level, maximum saturated fat content, and a maximum sodium content.
- Foods must contain zero grams of *trans* fat per serving.
• The inclusion of unsaturated vegetable oils is encouraged within calorie limits.
• Vegetables and fruits are not interchangeable.
• Vegetable offerings at lunch must include \( \frac{1}{2} \) cup equivalent of the following: dark-green vegetables, bright-orange vegetables, and legumes.
• No more than half of fruit servings may be in the form of juice.
• At least one half of bread/grain offered must be whole grain.
• Milk must be fat free if flavored and either fat free or 1% fat if plain.
• Students must select a fruit option at breakfast with their meal, and either a fruit or a vegetable at lunch, for the meal to be reimbursable.

**Eating Out**

The number of meals eaten outside the home or brought home from takeout restaurants has increased in all age-groups of the U.S. population. The increased convenience of this meal pattern is undermined by the generally lower nutritional value of the meals, compared to home-cooked meals. Typically, meals consumed or purchased in fast-food or casual restaurants are of large portion size, are dense in calories, and contain large amounts of saturated fat, salt, and sugar and low amounts of whole grains, fruits, and vegetables. Although still a problem currently, *trans* fat is being phased out of most commercial restaurants and prepared foods. Although an increasing number of restaurants offer healthier alternatives, the vast majority of what is consumed at restaurants does not fit MyPlate recommendations.

With increasing age, an increasing number of meals and snacks are also consumed during peer social gatherings at friends' houses and parties. When a large part of a child's or adolescent's diet is consumed on these occasions, the diet quality can suffer, because food offerings are typically of low nutritional value. Parents and pediatricians need to guide teens in navigating these occasions while maintaining a healthful diet and enjoying meaningful social interactions. These occasions often are also opportunities for teens to consume alcohol; consequently, adult supervision is important.
Nutrition Issues of Importance Across Pediatric Ages

Food Environment

Most families have some knowledge of nutrition and intend to provide their children with a healthful diet. The discrepancy between this fact and the actual quality of the diet consumed by U.S. children is often explained by challenges in the environment for families to make healthful food choices. Because the final food choice is made by individual children or their parents, interventions to improve diet have focused on individual knowledge and behavior changes, but these have had limited success (Fig. 56.3). Understanding the context of food and lifestyle choices helps in understanding lack of changes or “poor compliance” and can decrease the frustration often experienced by the pediatricians who might “blame the victim” for behavior that is not entirely under their control. In recent time, national initiatives have been launched to increase access to vegetables and fruits and increase public awareness of healthful eating (e.g., Let’s Move!).
While **taste** is the main determinant of food choice, many other complex determinants influence that choice including **cost** and marketing strategies. **Marketing** includes strategies as diverse as shelf placements, association of cartoon characters with food products, coupons, and special offers or pricing, all of which influence food purchase choices. Television advertising is an important part of how children and adolescents hear about food, with an estimated 40,000 TV commercials per year, as seen by the average U.S. child, many of which are for food, compared to the few hours of nutrition education they receive in school. Additional food advertisement increasingly occurs as brand placement in movies and TV shows, on websites, and even video games.

**Using Food as Reward**

It is a prevalent habit to use food as a reward or sometimes withdraw food as punishment. Most parents use this practice occasionally, and some use it almost
systematically, starting at a young age. The practice is also commonly used in other settings where children spend time, such as daycare, school, or even athletic settings. Although it might be a good idea to limit some unhealthful but desirable food categories to special occasions, using food as a reward is problematic. Limiting access to some foods and making its access contingent on a particular accomplishment increases the desirability of that type of food. Conversely, encouraging the consumption of some foods renders them less desirable. Therefore, phrases such as, “Finish your vegetables, and you will get ice cream for dessert,” can result in establishing unhealthful eating habits once the child has more autonomy in food choices. Parents should be counseled on such issues and encouraged to choose items other than food as reward, such as inexpensive toys or sporting equipment, family time, special family events, or collectible items. Similar types of behavior are also seen in schools and extracurricular events. Instead of rewards of food (e.g., pizza, candy), daycare providers, teachers, and counselors should be encouraged to use alternative rewards, such as minutes of free time, sitting in the teacher's chair, being the teacher's helper, and homework-free nights.

Cultural Considerations in Nutrition and Feeding

Food choices, food preparation, eating patterns, and infant feeding practices all have very deep cultural roots. In fact, beliefs, attitudes, and practices surrounding food and eating are some of the most important components of cultural identity. Therefore, it is not surprising that in multicultural societies, great variability exists in the cultural characteristics of the diet. Even in a world where global marketing forces tend to reduce geographic differences in the types of food, or even brands, that are available, most families, especially during family meals at home, are still much influenced by their cultural background. Therefore, pediatricians should become familiar with the dietary characteristics of various cultures in their community, so that they can identify and address, in a nonjudgmental way and avoiding stereotypes, the potential nutritional issues related to the diet of their patients.

Vegetarianism

Vegetarianism is the practice of following a diet that excludes animal flesh foods, including beef, pork, poultry, fish, and shellfish. There are several variants
of the diet, some of which also exclude eggs and/or some products produced from animal labor, such as dairy products and honey. It is important to understand different variations in vegetarianism, as follows:

- **Veganism:** excludes all animal products. It may be part of a larger practice of abstaining from the use of animal products for any purpose.
- **Ovovegetarianism:** includes eggs but not dairy products.
- **Lactovegetarianism:** includes dairy products but excludes eggs.
- **Lactoovovegetarianism:** includes eggs and dairy products.
- **Flexitarian:** a vegetarian who will occasionally eat meat.
- **Pescatarian:** consumes fish, but often self-labeled a vegetarian.

Another expression used for vegetarianism and veganism is “plant-based diets.”

Other dietary practices commonly associated with vegetarianism include *fruitarian* diet (fruits, nuts, seeds, and other plant matter gathered without harm to the plant), *Su vegetarian* diet (excludes all animal products as well as onion, garlic, scallions, leeks, or shallots), *macrobiotic* diet (includes whole grains and beans and, in some cases, fish), and *raw vegan* diet (includes fresh and uncooked fruits, nuts, seeds, and vegetables). The safety of these restrictive diets has not been studied in children. These diets can be very limited in macro- and micronutrients and are not recommended for children. While being on a vegetarian or vegan diet does not appear to increase the risk of an eating disorder, some teenagers with disordered eating may choose such diets to aid in limiting their caloric intake.

Vegetarianism is considered a healthful and viable diet; both the U.S.
Academy of Nutrition and Dietetics and the Dietitians of Canada have found that a properly planned and well-balanced vegetarian diet can satisfy the nutritional goals for all stages of life. Compared with nonvegetarian diets, vegetarian diets have lower intakes of saturated fat, cholesterol, and animal protein and relatively higher levels of complex carbohydrates, fiber, magnesium, potassium, folate, vitamins C and E, and phytochemicals. Vegetarians have a lower body mass index, cholesterol level, and blood pressure and are at decreased risk for cancer and ischemic heart disease. Specific nutrients of concern in vegetarian diets include the following:

◆ **Iron** (see Chapter 55): Vegetarian diets may have similar levels of iron as nonvegetarian diets, but iron from vegetable sources has lower bioavailability than iron from meat sources, and iron absorption may be inhibited by other dietary constituents, such as phytate (found in leafy green vegetables and whole grains). Iron stores are lower in vegetarians and vegans than in nonvegetarians; and iron deficiency is more common in vegetarian and vegan women and children. Foods rich in iron include iron-fortified cereals, black beans, cashews, kidney beans, lentils, oatmeal, raisins, black-eyed peas, soybeans, sunflower seeds, chickpeas, molasses, chocolate, and tempeh. Iron absorption can be increased by eating food containing ascorbic acid (vitamin C) along with foods containing iron.

◆ **Vitamin B₁₂**: Plants are not a good source of B₁₂ (see Chapter 62.7). Vitamin B₁₂ can be obtained through dairy products and eggs; vegans need
fortified foods or supplements. Breastfeeding by vegan mothers can place an infant at risk for vitamin 
$B_{12}$ deficiency.

◆ **Fatty acids:** Vegetarians and vegans may be at risk for insufficient eicosapentaenoic acid (EPA) and 
DHA. The inclusion of sources of linolenic acid (precursor of EPA and DHA), such as walnuts, soy 
products, flaxseed oil, and canola oil, is recommended.

◆ **Calcium and vitamin D:** Without 
supplementation, vegan diets are low in calcium and 
vitamin D, putting vegans at risk for impaired bone 
mineralization (see Chapter 64). Serum 
hydroxyvitamin D levels should be monitored in 
vegans and supplemented for levels <30 dL. Calcium 
sources include leafy greens with low oxalate, such as 
broccoli, kale, and Chinese cabbage. Calcium and 
vitamin D are found in fortified almond, soy milk, 
and orange juice.

◆ **Zinc:** The bioavailability of zinc in plant sources 
tends to be low because of the presence of phytates 
and fiber that inhibit zinc absorption (see Chapter 67 
). Zinc is found in soy products, legumes, grains, 
cheese, and nuts.

◆ **Iodine:** Plant-based diets can be low in iodine, and 
therefore vegetarians and vegans who do not consume 
iodized salt or sea vegetables (which have variable
iodine content) may be at risk of iodine deficiency. The exclusive use of sea salt or kosher salt could further increase that risk, because these are typically not iodized, and iodized salt is not used in processed foods.

**Organic Foods**

Parents may prefer organic foods to feed children secondary to concerns regarding chemical and hormonal content of animals and produce. **Organic food** is defined as produce and ingredients that are grown without the use of pesticides, synthetic fertilizers, sewage sludge, genetically modified organisms, or ionizing radiation. Animals that produce meat, poultry, eggs, and dairy products are not given antibiotics or growth hormones. In the United States, certification must be obtained, and USDA regulations must be followed to market food as “organic.” The nutritional differences between organic and conventional foods may not be clinically relevant. Children consuming organic foods have lower or no detectable levels of pesticides in their urine compared to those consuming nonorganic foods. It remains unclear whether such a reduction in exposure to chemicals is clinically significant. Organic foods have higher levels of PUFAs (α-linolenic acid, very-long-chain n-3 fatty acids), α-tocopherol, and iron and lower levels of cadmium, selenium, and iodine. Similarly, despite concerns of parents, the amount of bovine growth hormone in conventional milk is thought to be neither significant nor biologically active in humans. Additionally, milk consumption from estrogen-treated cows does not result in endocrine disruptions in infants. However, other chemicals in the environment, such as bisphenol-A (found in plastics), nitrates, endocrine disruptors, and phthalates, should be avoided. Organic certification of a food also suggests the food source is not from a genetically modified nutrient.

**Genetically modified organisms (GMOs)** in themselves may not be harmful. However, GMOs are modified to be resistant to the effects of herbicides, including glyphosate and 2,4-dichlorophenoxyacetic acid (2,4-D), which give GMOs a selective growth advantage. Nonetheless, glyphosate and 2,4-D have been designated by the International Agency for Research on Cancer as probable and possible human carcinogens, respectively.
Because the cost of organic foods is generally higher than that of other foods, a prudent approach is to explain to families that the scientific basis for choosing organic foods is uncertain, and that large-scale human studies to evaluate these issues will be difficult to carry out. If it is their preference, however, and they can afford the added cost, there is no reason not to eat organic foods.

**Nutrition as Part of Complementary and Alternative Medicine, Functional Foods, Dietary Supplements, Vitamin Supplements, and Botanical and Herbal Products**

The use of nutrition or nutritional supplements as complementary or alternative medicine is increasing, despite limited data on safety and efficacy, especially in children. Many parents assume that if a food or supplement is “natural” or “organic,” there is no potential for risk and some potential for benefit. However, adverse effects of some dietary supplements have been documented, and some supplements have been discovered to contain common allergens. Dietary supplements, including botanical and herbal products, are regulated differently than medication in the United States. Manufacturers do not have to prove safety or efficacy before marketing the supplement; the potential for adverse effects or simply for ineffectiveness is therefore high. It is difficult for pediatricians to compete against the aggressive marketing through multimedia sources of food supplements to families of healthy and chronically ill children. Pediatricians must also compete against word of mouth, the internet, and advice from people without a scientific background and those with significant conflicts of interest.

Pediatricians are often asked by parents if their children need to receive a **daily multivitamin**. Unless the child follows a particular diet that may be poor in one or more nutrients for health, cultural, or religious reasons, or if the child has a chronic health condition that puts the child at risk for deficiency in one or more nutrients, multivitamins are not indicated. Many children do not follow all the guidelines of MyPlate, and parents and pediatricians may be tempted to use multivitamin supplements to ensure nutrient deficiencies are avoided. Use of a daily multivitamin supplement can result in a false impression that the child's diet is complete and in decreased efforts to meet dietary recommendations with food rather than the intake of supplements (see Chapter 55). The average U.S. diet provides more than a sufficient amount of most nutrients, including most
vitamins. Therefore, multivitamins should not be routinely recommended.

**Food Safety**

Constantly keeping food safety issues in mind is an important aspect of feeding infants, children, and adolescents. In addition to choking hazards and food allergies, pediatricians and parents should be aware of food safety issues related to infectious agents and environmental contaminants. **Food poisoning** with bacteria, viruses, or their toxins is most common with raw or undercooked food, such as oysters, beef, and eggs, or cooked foods that have not been handled or stored properly. The specific bacteria and viruses involved in food poisoning are described in Chapter 740. Many chemical contaminants, such as heavy metals, pesticides, and organic compounds, are present in various foods, usually in small amounts. Because of concerns regarding their child's neurologic development and cancer risk, many questions arise from parents, especially after media coverage of isolated incidents. A recurring debate is the balance between the benefits of seafood for the growing brain and cardiovascular health and the risk of mercury contamination from consuming large, predatory fish species. Pediatricians need to become familiar with reliable sources of information, such as the websites of the U.S. Environmental Protection Agency (EPA), FDA, and CDC. The **Food Safety Modernization Act** provides the FDA with authority to have stricter control over food production and distribution. The FDA can require that manufacturers develop food safety plans. A good source of information for patients and parents can be found at www.foodsafety.gov.

**Preventive Nutrition Counseling in Pediatric Primary Care**

An important part of the primary care well child visit focuses on nutrition and growth because most families turn to pediatricians for guidance on child nutrition. Preventive nutrition is one of the cornerstones of preventive pediatrics and a critical aspect of anticipatory guidance. The first steps of nutrition counseling are nutritional status assessments, primarily done through growth monitoring and dietary intake assessment. Although **dietary assessment** is somewhat simple in infants who have a relatively monotonous diet, it is more challenging at older ages. The goals of dietary assessment in the primary care setting need to include an idea of the eating patterns (time, location, and
environment) and usual diet by asking the parent to describe the child's dietary intake on a typical day or in the last 24 hr. Alternatively, a basic assessment of the child's consumption of vegetables, fruits, whole grains, low-fat or nonfat dairy products, 100% fruit juice, and sugar-sweetened beverages should be assessed. Pediatricians should encourage regularly scheduled meals and 1 or 2 healthy snacks (depending on the child's age). For more ambitious goals of dietary assessment, referral to a registered dietician with pediatric experience is recommended.

After understanding the child's usual diet, existing or anticipated nutritional problems should be addressed, such as diet quality, dietary habits, and portion size. For a few nutritional problems, a lack of knowledge can be addressed with nutrition education, but key nutritional issues, such as overeating or poor food choices, are not solely the result of lack of parents' knowledge. Therefore, nutrition education alone is insufficient in these situations, and pediatricians need to acquire training in behavior-modification techniques or refer to specialists to assist their patients in engaging in healthful feeding and eating behaviors. The physical, cultural, and family environment in which the child lives should always be considered so that nutrition counseling is relevant and changes are feasible.

One important aspect of nutrition counseling is providing families with sources of additional information and behavioral change tools. Although some handouts are available from government agencies, the AAP, and other professional organizations for families without internet access, an increasing number of families rely on the internet to find nutrition information. Therefore, pediatricians need to become familiar with common websites so that they can point families to reliable and unbiased sources of information. Perhaps the most useful websites for children are the AAP and USDA MyPlate sites and those of the CDC, FDA, National Institutes of Health, The National Academies, and Food and Nutrition Board for government sources. Other professional resources include the American Heart Association and Academy of Nutrition and Dietetics. Pediatricians should also be aware of sites that provide biased or even dangerous information so that they can warn families accordingly. Examples include dieting sites, sites that openly promote dietary supplements or other food products, and the sites of “nonprofit” organizations that are mainly sponsored by food companies or that have other social or political agendas.
U.S. Food Assistance Programs

Several programs exist in the United States to ensure sufficient and high-quality nutrition for children of families who cannot always afford optimal nutrition. One of the most utilized federal programs is the **Special Supplemental Nutrition Program for Women, Infants, and Children (WIC)**. This program provides nutrition supplements to a large proportion of pregnant women, postpartum women, and children up to their 5th birthday. One of its strengths is that in order to qualify, families need to regularly visit a WIC nutritionist, who can be a useful resource for nutritional counseling. For older children, federal programs provide school lunches, breakfasts, and after-school meals, as well as daycare and summer nutrition. Lower-income families are also eligible for the **Supplemental Nutrition Assistance Program (SNAP)**, formerly known as the Food Stamp Program. This program provides funds directly to families to purchase various food items in regular food stores.

Nutrition, Food Security, and Health

Ann Ashworth
Malnutrition as the Intersection of Food Insecurity and Health Insecurity

Undernutrition is usually an outcome of three factors, often in combination: household food supply, childcare practices, and access to health and water/sanitation services. In famine and emergency settings, food shortage is the foremost factor, but in many countries with widespread undernutrition, food production or access to food might not be the most limiting factor. More important causes might be repeated childhood infections, especially diarrheal diseases associated with an unsafe environment and lack of exclusive breastfeeding, or inadequate complementary feeding practices, or the lack of time families have available for appropriate infant or maternal care. Fig. 57.1 shows some of the many causal factors on the pathway to undernutrition and how they extend from household and community levels to national/international levels. Inequitable distribution of resources because of political, economic, and agricultural policies often denies families their right to adequate land, water, food, healthcare, education, and a safe environment, all of which can influence nutritional status.

**FIG. 57.1** Basic, underlying, and immediate causes of undernutrition.

Families with few economic resources who know how to care for their
children and are enabled to do so can often use available food and health services to produce well-nourished children. If food resources and health services are not available in a community, not utilized, or not accessible to some families, children might become undernourished. Undernutrition is not confined to low-income countries. It has been noted in chronically ill patients in neonatal and pediatric intensive care units in high-income countries and among patients with burns, human immunodeficiency virus (HIV) infection, tuberculosis, cystic fibrosis, chronic diarrhea syndromes, malignancies, bone marrow transplantation, and inborn errors of metabolism. Severe malnutrition has been reported in affluent communities in infants whose families believe in fad diets, as well as in infants with food allergies fed nutritionally inadequate foods such as rice “milk,” which has a very low protein and micronutrient content (Figs. 57.2 and 57.3).

Food Security

Food security exists when all people, at all times, have access to sufficient, safe, nutritious food to maintain a healthy and active life. Four main dimensions of food security can be identified: availability, access, utilization, and stability. **Availability** refers to the supply of food, reflecting the level of food production, food stocks, and net trade. **Access** is at the household level, reflecting purchasing power, household food production, and food/cash transfers received through social “safety net” programs. The **utilization** dimension recognizes that even when a household has access to food, it is not necessarily shared equitably within a household. **Stability** refers to being “food secure” at all times: Examples of situations that affect stability are the “lean seasons” before a harvest, natural disasters, political unrest, and rising food prices. To be food secure, all four dimensions must be met simultaneously.

Measuring Food Insecurity

The most commonly used measurement of food insecurity is **undernourishment** (chronic hunger), which is the proportion of the population who are unable to
meet daily energy requirements for light activities. It is an estimate calculated by the **Food and Agriculture Organization (FAO)** based on country-level food balance sheets. It does not take nutrient adequacy into account, but has the advantage of being available for almost all countries annually (although with a time lag) and assists in monitoring global trends. In addition, FAO measures food access by asking individuals about their experiences over the last 12 mo, such as whether they ran out of food or skipped meals. The responses are graded from mild to severe food insecurity. This relatively simple monitoring tool, the **Food Insecurity Experience Scale**, provides timely information to guide decision-making at national and local levels.

In 2017, FAO estimated that about 821 million people, or 10.9% of the world's population, were undernourished, 98% of whom were in developing countries. The majority are rural poor people subsisting on small plots of land or hired as laborers, and urban poor people who lack the means to grow or buy food. Alongside the 0.82 billion people who are underfed are 1.9 billion who are overfed, reflecting global inequalities and the “double burden of malnutrition” in low- and middle-income countries.

**Nutrition, Food Security, and Poverty**

Household food security tracks income closely. With rising incomes, very poor households first increase their dietary energy intake to avert hunger. If incomes rise further, there is a shift to more expensive staple foods and then to a more varied diet with a greater proportion of energy from animal sources, fruits/vegetables, and fats/sugars, and less from cereals, roots, and tubers. National economic growth tends to be accompanied by reductions in stunting, but economic growth can pass by poor persons if they work in unaffected sectors, or are unable to take advantage of new opportunities because of lack of education, access to credit, or transportation, or if governments do not channel resources accruing from economic growth to healthcare, education, social protection, and other public services and infrastructure. There is good evidence that economic growth reduces poverty but does not necessarily reduce undernutrition.

**Food Security and Nutrition Targets**

The period of Millennium Development Goals (MDGs) ended in 2015. All
developing regions except sub-Saharan Africa achieved the target to halve the proportion of people living in extreme poverty, with the proportion falling from 47% in 1990 to 14% in 2015. Reductions in hunger were broadly consistent with those of poverty reduction, and rates of undernourishment in developing regions fell from 23% in 1990 to 13% in 2015. The prevalence of underweight children (another MDG indicator of “hunger”) fell from 29% in 1990 to 15% in 2015 for the developing regions combined. Rural children are almost twice as likely to be underweight as urban children, and the poorest quintile is almost 3 times as likely to be underweight as the richest quintile.

Eradicating poverty and hunger continue to be core targets of the Sustainable Development Goals, as agreed by 193 countries of the United Nations General Assembly in September 2015, and are to be achieved by 2030. In addition, in 2012 the World Health Assembly agreed to 6 global nutrition targets to be reached by 2025, measured against a 2010 baseline, and the United Nations Secretary-General launched the Zero Hunger Challenge with 5 objectives that “would boost economic growth, reduce poverty and safeguard the environment” and “would foster peace and stability” (Table 57.1).

### Future Food Security

Between now and 2050 the world's population is expected to exceed 9 billion, and an increase in food supply of 70–100% will be needed to feed this larger, more urban, and more affluent populace. Over this same period, the world's food supply is expected to diminish unless action is taken. Accelerating the decline in fertility rates and reducing overconsumption are basic but difficult actions to
bridge the gap between increasing demand and diminishing supply. Equally challenging actions include limiting climate disruption, increasing the efficiency of food production, reducing waste, and reducing the demand for meat and dairy foods.

◆ **Limit climate disruption.** Drought, floods, and other extreme weather events are becoming more prevalent and destroy crops and livestock, often on a huge scale. Rising sea levels will lead to loss of productive land through inundation and salinization. Acidification of oceans will reduce marine harvests. Because curbing greenhouse gas emissions is essential to minimize climate disruption, the goals are (1) to cut fossil fuel use by at least half of present levels by 2050 so as to reduce carbon dioxide ($CO_2$) emissions and (2) change livestock husbandry and agronomic practices to reduce methane and nitrous oxide ($N_2O$) emissions.

◆ **Increase efficiency of food production.** Expanding the area of agricultural land to any large extent (e.g., by deforestation) is not a sustainable option because of adverse consequences on ecosystems and biodiversity, although some expansion of food production could be achieved by switching good-quality land away from first-generation biofuels. For example, almost 40% of the U.S. corn harvest in 2016–2017 went to biofuels. Efforts to increase the intensity of production need to be environmentally
sustainable. These include optimizing yields by soil and water conservation, removal of technical and financial constraints faced by farmers, and breeding resource-efficient crops and livestock that are also climate resilient and pest/disease resistant.

◆ *Reduce waste.* From 30–40% of food is wasted, between harvesting and the market, during retail, at home, and in the food service industry. Better transport and storage facilities in developing countries, less stringent sell-by dates, lower cosmetic standards for fruits and vegetables, and ending supersized portions would help reduce waste.

◆ *Change diets.* As wealth increases, so does the demand for processed foods, meat, dairy products, and fish. About one third of global cereal production is fed to animals, so reducing consumption of meat from grain-fed livestock and increasing the proportion derived from the most efficient sources (pigs and poultry) would allow more people to be fed from the same amount of land.

**Undernutrition**

The greatest risk of undernutrition (underweight, stunting, wasting, and micronutrient deficiencies) occurs in the first 1000 days, from conception to 24 mo of age, and this early damage to growth and development can have adverse consequences in later life on health, intellectual ability, school achievement, work productivity, and earnings. Governments and agencies are therefore advised to focus interventions on this critical window of opportunity. For folate
deficiency, which increases the risk of birth defects, this particular window is before conception.

**Measurement of Undernutrition**

The term *malnutrition* encompasses both ends of the nutrition spectrum, from undernutrition to overweight. Many poor nutritional outcomes begin in utero and are manifest as low birthweight (LBW, <2,500 g). Preterm delivery and fetal growth restriction are the 2 main causes of LBW, with prematurity relatively more common in richer countries and fetal growth restriction relatively more common in poorer countries.

Nutritional status is often assessed in terms of anthropometry (Table 57.2). International standards of normal child growth under optimum conditions from birth to 5 yr have been established by the World Health Organization (WHO). To compile the standards, longitudinal data from birth to 24 mo of healthy, breastfed, term infants were combined with cross-sectional measurements of children ages 18-71 mo. The standards allow normalization of anthropometric measures in terms of *z* scores (standard deviation [SD] scores). A *z*-score is the child's height (weight) minus the median height (weight) for the child's age and sex divided by the relevant SD. The standards are applicable to all children everywhere, having been derived from a large, multicountry study reflecting diverse ethnic backgrounds and cultural settings.

**Table 57.2**

**Classification of Undernutrition**

SD, Standard deviation; WHO, World Health Organization.

**Height-for-age** (or length-for-age for children <2 yr) is a measure of linear growth, and a deficit represents the cumulative impact of adverse events, usually in the first 1000 days from conception, that result in *stunting*, or chronic malnutrition. A low height-for-age typically reflects socioeconomic disadvantage. A low **weight-for-height**, or *wasting*, usually indicates acute malnutrition. Conversely, a high weight-for-height indicates *overweight*.

**Weight-for-age** is the most commonly used index of nutritional status, although a low value has limited clinical significance because it does not differentiate between wasting and stunting. Weight-for-age has the advantage of being somewhat easier to measure than indices that require height measurements. In humanitarian emergencies and some community or outpatient settings, **mid-upper arm circumference** is used for screening wasted children (**Fig. 57.4**).

**Body mass index (BMI)** is calculated by dividing weight in kilograms by the square of height in meters. For children, BMI is age and gender specific. **BMI-for-age** can be used from birth to 20 yr and is a screening tool for *thinness* (less than −2 SD), *overweight* (between +1 SD and +2 SD), and *obesity* (greater than +2 SD). To diagnose obesity, additional measures of adiposity are desirable because a high BMI can result from high muscularity, and not only from excess
Micronutrient deficiencies are another dimension of undernutrition. Those of particular public health significance are vitamin A, iodine, iron, and zinc deficiencies.

Vitamin A deficiency is caused by a low intake of retinol (in animal foods) or its carotenoid precursors, mainly beta carotene (in orange-colored fruits and vegetables and dark-green leaves) (see Chapter 61). The prevalence of clinical deficiency is assessed from symptoms and signs of xerophthalmia (principally night blindness and Bitot spots). Subclinical deficiency is defined as serum retinol concentration ≤0.70 µmol/L. Vitamin A deficiency is the leading cause of preventable blindness in children. It is also associated with a higher morbidity and mortality among young children.

Iodine deficiency is the main cause of preventable intellectual impairment (see Chapter 67). An enlarged thyroid (goiter) is a sign of deficiency. Severe deficiency in pregnancy causes fetal loss and permanent damage to the brain and central nervous system in surviving offspring (cretinism). It can be prevented by iodine supplementation before conception or during the 1st trimester of pregnancy. Postnatal iodine deficiency is associated with impaired mental function and growth retardation. The median urinary iodine concentration in children age 6-12 yr is used to assess the prevalence of deficiency in the general population, and a median of <100 µg/L indicates insufficient iodine intake.

Iron-deficiency anemia is common in childhood either from low iron intakes or poor absorption, or as a result of illness or parasite infestation (see Chapter 67). Women also have relatively high rates of anemia as a result of menstrual blood loss, pregnancy, low iron intake, poor absorption, and illness. Hemoglobin cutoffs to define anemia are 110 g/L for children 6-59 mo, 115 g/L for children 5-11 yr, and 120 g/L for children 12-14 yr. Cutoffs to define anemia for nonpregnant women are 120 g/L, 110 g/L for pregnant women, and 130 g/L for men.

Zinc deficiency increases the risk of morbidity and mortality from diarrhea, pneumonia, and possibly other infectious diseases (see Chapter 67). Zinc deficiency also has an adverse effect on linear growth. Deficiency at the population level is assessed from dietary zinc intakes or serum zinc concentrations.

Prevalence of Undernutrition
It is estimated that approximately 16% of births worldwide in 2013 were LBW. Rates of LBW are highest (28%) in southern Asia, which are twice those of sub-Saharan Africa. Globally, in 2015, 14% of children <5 yr of age were underweight (weight-for-age < −2 SD). The global prevalence of stunting (height-for-age < −2 SD) has declined from 33% in 2000 to 22% in 2017, with the greatest reductions occurring in Asia. Stunting prevalence is highest in the African region (30%). Wasting (weight-for-height < −2 SD) affects 7% of children <5 yr, with minimal change in prevalence over the past 2 decades. These figures represent 151 million stunted children, and 51 million wasted children.

Asia carries most of the global burden of underweight children because of the combination of large population size and high prevalence. In 2017, 55% of all stunted children and 69% of all wasted children lived in Asia. Africa carries most of the remaining global burden. For children <5 yr, the global prevalence is estimated to be 33% for vitamin A deficiency, 29% for iodine deficiency, 17% for zinc deficiency, and 18% for iron-deficiency anemia. Prevalence of micronutrient deficiencies tends to be highest in Africa. For pregnant women, the estimated prevalence of vitamin A deficiency is 15% and for iron-deficiency anemia, 19%.

Rates of clinical deficiency of vitamin A in children <5 yr have been declining, probably as a result of high-dose vitamin A supplementation programs and measles vaccination (because measles leads to sizable urinary loss of vitamin A), but subclinical deficiency remains widespread (>90 million children). Large-scale availability of iodized salt has reduced rates of iodine deficiency substantially, and iodized salt reaches an estimated 75% of households. In contrast, progress in reducing rates of iron-deficiency anemia is slow, and rates remain largely static.

Consequences of Undernutrition

The most profound consequence of undernutrition is premature death (Table 57.3). Fetal growth restriction together with suboptimal breastfeeding in the 1st month of life contribute to 19% of all deaths in children <5 yr (1.3 million deaths/yr). When the effects of stunting, wasting, and deficiencies of vitamin A and zinc are also considered, these 6 items jointly contribute to 45% of global child deaths (3.1 million deaths/yr), and many more are disabled or stunted for life. Anemia contributes to over one quarter of maternal deaths.

The risk of child death from infectious diseases increases even with mild undernutrition, and as the severity of undernutrition increases, the risk increases exponentially (Table 57.4). Undernutrition impairs immune function and other host defenses; consequently, childhood infections are more severe and longer-lasting in undernourished children and more likely to be fatal than the same illnesses in well-nourished children. Infections can adversely affect nutritional status, and young children can quickly enter a cycle of repeated infections and ever-worsening malnutrition. Even for the survivors, physical and cognitive damage as a result of undernutrition can impact their future health and economic well-being. For girls, the cycle of undernutrition is passed on to the next generation when undernourished women give birth to LBW babies.

</table>
Fetal growth restriction and early childhood undernutrition have consequences for adult chronic illness. LBW is associated with an increased risk of hypertension, stroke, and type 2 diabetes in adults. The increased risk is thought to reflect “fetal programming,” a process by which fetal undernutrition leads to permanent changes in the structure and metabolism of organs and systems that manifest as disease in later life. The risk is exacerbated by low weight gain during the first 2 yr of life. The increased risk of adult chronic disease from undernutrition early in life is a particular challenge to low-income countries with rapid economic growth.

Stunting before age 3 yr is associated with poorer motor and cognitive development and altered behavior in later years. The effect is 6-13 DQ (developmental quotient) points. Iodine and iron deficiencies also lead to loss of cognitive potential. Indications are that children living in areas of chronic iodine deficiency have an average reduction in IQ (intelligence quotient) of 12-13.5 points compared with children in iodine-sufficient areas. Iron deficiency has a detrimental effect on the motor development of children <4 yr and on cognition of school-age children. The estimated deficit is 1.73 IQ points for each 10 g/L decrease in hemoglobin concentration.

Undernutrition can have substantial economic consequences for survivors and their families. The consequences can be quantified in 5 categories: (1) increased costs of healthcare, either neonatal care for LBW babies or treatment of illness for infants and young children; (2) productivity losses (and thus reduced earnings) associated with smaller stature and muscle mass; (3) productivity losses from reduced cognitive ability and poorer school performance; (4) increased costs of chronic diseases associated with fetal and early child malnutrition; and (5) consequences of maternal undernutrition on future generations. The impact of nutrition on earnings appears to be independent of the effects of childhood deprivation.
Key Interventions

Interventions to address child undernutrition can be divided into those that address immediate causes (nutrition-specific interventions) and those that address underlying causes (nutrition-sensitive interventions) (Table 57.5). In the short-term, nutrition-specific interventions (e.g., salt iodization) can have substantial impact even in the absence of economic growth, and micronutrient interventions (supplementation and fortification) are consistently ranked as the most cost-effective investment. There is increased attention to nutrition-sensitive interventions as the best means of sustainably eliminating malnutrition, and to multisectoral policies that harness the synergism between the two types of intervention (e.g., cross-sectoral linkages among agriculture, nutrition, and health).

</tr>
<tr>
<td>• Reduced heavy physical activity in pregnancy</td>
<td>• Birth spacing; delaying pregnancy until after 18 yr of age</td>
</tr>
</tbody>
</table>

To reduce the adverse consequences of undernutrition on mortality, morbidity, and cognitive development, interventions must encompass both fetal and postnatal periods. Preventing LBW is essential, with emphasis on prevention of low maternal BMI and anemia, and in the longer term, prevention of low maternal stature. Other measures include smoking cessation, birth spacing, delaying pregnancy until after 18 yr of age, and intermittent preventive treatment of malaria. In the postnatal period, promotion and support of exclusive breastfeeding is a high priority. Although the Baby Friendly Hospital Initiative
has a marked benefit on rates of exclusive breastfeeding in hospital, postnatal counseling from community workers or volunteers is needed to facilitate continuation of exclusive breastfeeding at home for 6 mo (see Chapter 56). Most studies show a lower risk of HIV transmission with exclusive breastfeeding than with mixed breastfeeding. The risk of HIV transmission by breastfeeding is approximately 5–20%, depending on duration, but can be reduced to <2% with antiretroviral drugs. Even without antiretroviral drugs, exclusively breastfed children of HIV-infected mothers in low-income countries have lower mortality than non-breastfed children, because the latter are at increased risk of death from diarrhea and pneumonia.

Interventions to improve infant feeding must be designed for the local setting and thus require careful formative research during their development. Messages should be few, feasible, and culturally appropriate. For complementary feeding, nutrient-rich energy-dense mixtures of foods and responsive feeding are often emphasized. Where adequate complementary feeding is difficult to achieve and subclinical deficiencies are common, high-dose vitamin A supplementation every 6 mo in children 6-59 mo of age reduces all-cause mortality and death due to diarrhea by 12%, and zinc supplementation can reduce 1-4 yr mortality by 18%, diarrhea incidence by 13%, and pneumonia by 19%. Monitoring of child growth provides an early alert to a nutrition or health problem but is only worthwhile if accompanied by good counseling and growth promotion activities. The impact of growth monitoring and promotion will depend on coverage, intensity of contact, health worker performance and communication skills, adequacy of resources, and the motivation and ability of families to follow agreed actions.

**Clinical Manifestations and Treatment of Undernutrition**

Treatment of vitamin and mineral deficiencies is discussed in Chapters 61-67. Treatment of LBW and intrauterine growth restriction is discussed in Chapter 117.

**Severe Acute Malnutrition**

Severe acute malnutrition is defined as severe wasting and/or bilateral edema.
Severe wasting is extreme thinness diagnosed by a weight-for-length (or height) < −3 SD of the WHO Child Growth Standards. In children ages 6-59 mo, a mid-upper arm circumference <115 mm also denotes extreme thinness: a color-banded tape (see Fig. 57.4) is a convenient way of screening children in need of treatment.

Bilateral edema is diagnosed by grasping both feet, placing a thumb on top of each, and pressing gently but firmly for 10 sec. A pit (dent) remaining under each thumb indicates bilateral edema.

This definition of severe acute malnutrition distinguishes wasted/edematous children from those who are stunted, since stunted children (although underweight) are not a priority for acute clinical care because their deficits in height and weight cannot be corrected in the short term. The previous name protein-energy malnutrition is avoided because it oversimplifies the complex, multideficiency etiology. Other terms are marasmus (severe wasting), kwashiorkor (characterized by edema), and marasmic-kwashiorkor (severe wasting and edema).

Children with severe acute malnutrition have had a diet insufficient in energy and nutrients relative to their needs. The magnitude of the deficits will differ depending on the duration of inadequacy, quantity and diversity of food consumed, presence of antinutrients (e.g., phytate), individual variation in requirements, and number and severity of coexisting infections and their duration. Infections can lead to profound nutrient deficits and imbalances: For example, amino acids are diverted to form acute-phase proteins, and potassium, magnesium, vitamin A, and zinc are lost through diarrhea, and losses of glycine and taurine are linked to small bowel bacterial overgrowth. Ingested microbes can cause villous atrophy and loss of nutrients from maldigestion and malabsorption, as well as disruption of gut barrier function leading to microbial translocation, chronic immune activation, and altered gut microbiome (environmental enteric dysfunction). Deficits can also arise from increased nutrient utilization in response to noxae (e.g., cysteine and methionine to detoxify dietary cyanogens).

Heterogeneity in the extent and nature of the deficits and imbalances, reflecting the diverse pathways to severe acute malnutrition, helps explain why affected children differ in their clinical presentation and degree of metabolic disturbance. Children who develop edematous malnutrition are more likely than nonedematous children to have been exposed to noxae that generate oxidative stress and/or to have greater deficits in free radical–scavenging antioxidants.
(glutathione, vitamins A, C, and E, and essential fatty acids) or cofactors (zinc, copper, selenium).

**Clinical Manifestations of Severe Acute Malnutrition (Table 57.6)**

**Severe wasting** is most visible on the thighs, buttocks, and upper arms, as well as over the ribs and scapulae, where loss of fat and skeletal muscle is greatest (Fig. 57.5). Wasting is preceded by failure to gain weight and then by weight loss. The skin loses turgor and becomes loose as subcutaneous tissues are broken down to provide energy. The face may retain a relatively normal appearance, but eventually becomes wasted and wizened. The eyes may be sunken from loss of retroorbital fat, and lacrimal and salivary glands may atrophy, leading to lack of tears and a dry mouth. Weakened abdominal muscles and gas from bacterial overgrowth of the upper gut may lead to a distended abdomen. Severely wasted children are often fretful and irritable.

</tbody>
</table>

In edematous malnutrition the edema is most likely to appear first in the feet and then in the lower legs. It can quickly develop into generalized edema affecting also the hands, arms, and face (Fig. 57.6). Skin changes typically occur over the swollen limbs and include dark, crackled peeling patches (“flaky paint” dermatosis) with pale skin underneath that is easily infected (see Figs. 57.2 and 57.6). The hair is sparse and easily pulled out and may lose its curl. In dark-haired children the hair may turn pale or reddish. The liver is often enlarged with fat. Children with edema are miserable and apathetic, and often refuse to eat.
Pathophysiology

When a child's intake is insufficient to meet daily needs, physiologic and metabolic changes take place in an orderly progression to conserve energy and prolong life. This process is called reductive adaptation. Fat stores are mobilized to provide energy. Later, protein in muscle, skin, and the gastrointestinal tract is mobilized. Energy is conserved by reducing physical activity and growth, reducing basal metabolism and the functional reserve of organs, and reducing inflammatory and immune responses. These changes have important consequences:

◆ The liver makes glucose less readily, making the
child more prone to hypoglycemia. It produces less albumin, transferrin, and other transport proteins. It is less able to cope with excess dietary protein and to excrete toxins.

◆ Heat production is less, making the child more vulnerable to hypothermia.
◆ The kidneys are less able to excrete excess fluid and sodium, and fluid easily accumulates in the circulation, increasing the risk of fluid overload.
◆ The heart is smaller and weaker and has a reduced output, and fluid overload readily leads to death from cardiac failure.
◆ Sodium builds up inside cells due to leaky cell membranes and reduced activity of the sodium-potassium pump, leading to excess body sodium, fluid retention, and edema.
◆ Potassium leaks out of cells and is excreted in urine, contributing to electrolyte imbalance, fluid retention, edema, and anorexia.
◆ Loss of muscle protein is accompanied by loss of potassium, magnesium, zinc, and copper.
◆ The gut produces less gastric acid and enzymes. Motility is reduced, and bacteria may colonize the stomach and small intestine, damaging the mucosa and deconjugating bile salts. Digestion and absorption are impaired.
◆ Cell replication and repair are reduced, increasing
the risk of bacterial translocation through the gut mucosa.

◆ Immune function is impaired, especially cell-mediated immunity. The usual responses to infection may be absent, even in severe illness, increasing the risk of undiagnosed infection.

◆ Red blood cell mass is reduced, releasing iron, which requires glucose and amino acids to be converted to ferritin, increasing the risk of hypoglycemia and amino acid imbalances. If conversion to ferritin is incomplete, unbound iron promotes pathogen growth and formation of free radicals.

◆ Micronutrient deficiencies limit the body's ability to deactivate free radicals, which cause cell damage. Edema and hair/skin changes are outward signs of cell damage.

When prescribing treatment, it is essential to take these changes in function into account. Otherwise, organs and systems will be overwhelmed, and death will rapidly ensue.

**Principles of Treatment**

Fig. 57.7 shows the 10 steps of treatment, which are separated into 2 phases, stabilization and rehabilitation. These steps apply to all clinical forms and all geographic locations, including North America and Europe. The aim of the *stabilization* phase is to repair cellular function, correct fluid and electrolyte imbalance, restore homeostasis, and prevent death from the interlinked triad of hypoglycemia, hypothermia, and infection. The aim of the *rehabilitation* phase is to restore wasted tissues (i.e., catch-up growth). It is essential that treatment
proceeds in an ordered progression and that the metabolic machinery is repaired before any attempt is made to promote weight gain. Pushing ahead too quickly risks inducing the potentially fatal “refeeding syndrome” (see Chapter 58).

**Fig. 57.7** The 10 steps of treatment for severe acute malnutrition and their approximate time frames.

Caregivers bring children to health facilities because of illness, rarely because of their malnutrition. A common mistake among healthcare providers is to focus on the illness and treat as for a well-nourished child. This approach ignores the deranged metabolism in malnourished children and can be fatal. Such children should be considered as severely malnourished with a complication, and treatment should follow the 10 steps. Two other potentially fatal mistakes are to treat edema with a diuretic and to give a high-protein diet in the early phase of treatment.

**Emergency Treatment**

Table 57.7 summarizes the therapeutic directives for malnourished children with shock and other emergency conditions. Note that treatment of shock in these children is different (less rapid, smaller volume, different fluid) from treatment of shock in well-nourished children, because shock from dehydration and shock from sepsis often coexist and are difficult to differentiate on clinical grounds. Thus the physician must be guided by the response to treatment: children with dehydration respond to intravenous (IV) fluid, whereas those with septic shock will not respond. Since severely malnourished children can quickly succumb to
fluid overload, they must be monitored closely.

<td>If there are signs of improvement (pulse and respiration rates fall) repeat IV drip, 15 mL/kg for 1 more hr. Then switch to oral or nasogastric rehydration with ReSoMal, 5-10 mL/kg in alternate hr (see Table 57.8 step 3). If there are no signs of improvement, assume septic shock and:</td>
</tr>
<tr>
<td></td>
<td>1. Give maintenance fluid IV (4 mL/kg/hr) while waiting for blood.</td>
</tr>
<tr>
<td></td>
<td>2. Order 10 mL/kg fresh whole blood and transfuse slowly over 3 hr. If signs of heart failure, give 5-7 mL/kg packed cells rather than whole blood.</td>
</tr>
<tr>
<td></td>
<td>3. Give furosemide, 1 mL/kg IV at start of transfusion.</td>
</tr>
</tbody>
</table>

Hypoglycemia
Blood glucose <3 mmol/L

See Table 57.8 step 1 for treatment.

Severe dehydration

Do not give IV fluids except in shock. See Table 57.8 step 3 for treatment.

Very severe anemia
Hgb <4 g/dL

If very severe anemia (or Hgb 4-6 g/dL and respiratory distress):
1. Give whole blood 10 mL/kg slowly over 3 hr. If signs of heart failure, give 5-7 mL/kg packed cells rather than whole blood. |
2. Give furosemide 1 mL/kg IV at the start of the transfusion.

Emergency eye care
Corneal ulceration

If corneal ulceration:
1. Give vitamin A immediately (age <6 mo: 50,000 IU; 6-12 mo: 100,000 IU; >12 mo: 200,000 IU) |
2. Instill 1 drop atropine (1%) into affected eye to relax the eye and prevent the lens from pushing out.

* Some would recommend 5% dextrose in normal saline.

Hgb, Hemoglobin; IV, intravenous(ly).

Stabilization

Table 57.8 summarizes the therapeutic directives for stabilization steps 1-7 (Fig. 57.7). Giving broad-spectrum antibiotics (Table 57.9) and feeding frequent small amounts of F75 (a specially formulated low-lactose milk with 75 kcal and 0.9 g protein per 100 mL to which potassium, magnesium, and micronutrients are added), will reestablish metabolic control, treat edema, and restore appetite.
The parenteral route should be avoided; children who lack appetite should be fed by nasogastric tube, because nutrients delivered within the gut lumen help in its repair. Table 57.10 provides recipes for preparing the special feeds and their nutrient composition. Of the 2 recipes for F75, one requires no cooking, and the other is cereal based and has a lower osmolality, which may benefit children with persistent diarrhea. F75 is also available commercially; maltodextrins replace some of the sugar, and potassium, magnesium, minerals, and vitamins are already added.

**Table 57.8**

**Therapeutic Directives for Stabilization of Malnourished Children**

<table>
<thead>
<tr>
<th>STEP</th>
<th>PREVENTION</th>
<th>TREATMENT</th>
</tr>
</thead>
<tbody>
<tr>
<td>1. Prevent/treat hypoglycemia blood glucose &lt;3 mmol/L.</td>
<td>Avoid long gaps without food and minimize need for glucose: 1. Feed immediately. 2. Feed every 3 hr day and night (2 hr if ill). 3. Feed on time. 4. Keep warm. 5. Treat infections (they compete for glucose). Note: Hypoglycemia and hypothermia often coexist and are signs of severe infection.</td>
<td>If conscious: 1. Give 10% glucose (50 mL), or a feed (see step 7), or 1 tsp sugar under tongue, whichever is quickest. 2. Feed every 2 hr for at least 1st day. Initially give ( \frac{1}{4} ) of feed every 30 min. 3. Keep warm. 4. Start broad-spectrum antibiotics.</td>
</tr>
<tr>
<td>2. Prevent/treat hypothermia axillary &lt;35°C (95°F); rectal &lt;35.5°C (95.9°F).</td>
<td>Keep warm and dry and feed frequently. 1. Avoid exposure. 2. Dress warmly, including head and cover with blanket. 3. Keep room hot; avoid drafts. 4. Change wet clothes and bedding. 5. Do not bathe if very ill. 6. Feed frequently day and night. 7. Treat infections.</td>
<td>Actively rewarm. 1. Feed. 2. Skin-to-skin contact with caregiver (“kangaroo technique”) or dress in warmed clothes, cover head, wrap in warmed blanket and provide indirect heat (e.g., heater; transwarmer mattress; incandescent lamp). 3. Monitor temperature hourly (or every 30 min if using heater). 4. Stop rewarming when rectal temperature is 36.5°C (97.7°F).</td>
</tr>
<tr>
<td>3. Prevent/treat dehydration.</td>
<td>Replace stool losses. 1. Give ReSoMal after each watery stool. ReSoMal (37.5 mmol Na/L) is a low-osmolar electrolyte solution. 2. Give ReSoMal 5 mL/kg every 30 min for 1st 2 hr orally or NG tube. 3. Then give 5-10 mL/kg in alternate hours for up to</td>
<td>Do not give IV fluids unless the child is in shock. 1. Give ReSoMal 5 mL/kg every 30 min for 1st 2 hr orally or NG tube. 2. Then give 5-10 mL/kg in alternate hours for up to</td>
</tr>
</tbody>
</table>
sodium rehydration solution for malnutrition. 10 hr. Amount depends on stool loss and eagerness to drink. Feed in the other alternate hour. 3. Monitor hourly and stop if signs of overload develop (pulse rate increases by 25 beats/min and respiratory rate by 5 breaths/min; increasing edema; engorged jugular veins). 4. Stop when rehydrated (≥3 signs of hydration: less thirsty, passing urine, skin pinch less slow, eyes less sunken, moist mouth, tears, less lethargic, improved pulse and respiratory rate).

4. Correct electrolyte imbalance—deficit of potassium and magnesium, excess sodium. 1. Give extra potassium (4 mmol/kg/day) and magnesium (0.6 mmol/kg/day) for at least 2 wk (see Table 57.12). Note: Potassium and magnesium are already added in Nutriset F75 and F100 packets.

5. Prevent/treat infections. Minimize risk of cross-infection. 1. Avoid overcrowding. 2. Wash hands. 3. Give measles vaccine to unimmunized children age >6 mo. Infections are often silent. Starting on 1st day, give broad-spectrum antibiotics to all children. 1. For antibiotic choices/schedule, see Table 57.9. 2. Ensure all doses are given, and given on time. 3. Cover skin lesions so that they do not become infected. Note: Avoid steroids because they depress immune function.

6. Correct micronutrient deficiencies. Note: Folic acid, multivitamins, zinc, copper, and other trace minerals are already added in Nutriset F75 and F100 packets. Do not give iron in the stabilization phase. 1. Give vitamin A on day 1 (<6 mo 50,000 units; 6-12 mo 100,000 units; >12 mo 200,000 units) if child has any eye signs of vitamin A deficiency or has had recent measles. Repeat this dose on days 2 and 14. 2. Give folic acid, 1 mg (5 mg on day 1). 3. Give zinc (2 mg/kg/day) and copper (0.3 mg/kg/day). These are in the electrolyte/mineral solution and Combined Mineral Vitamin mix (CMV) and can be added to feeds and ReSoMal. 4. Give multivitamin syrup or CMV.

7. Start cautious feeding. 1. Give 8-12 small feeds of F75 to provide 130 mL/kg/day, 100 kcal/kg/day, and 1-1.5 g protein/kg/day. 2. If gross edema, reduce volume to 100 mL/kg/day. 3. Keep a 24-hr intake chart. Measure feeds carefully. Record leftovers. 4. If child has poor appetite, coax and encourage to finish the feed. If unfinished, reoffer later. Use NG tube if eating ≤80% of the amount offered. 5. If breastfed, encourage continued breastfeeding but also give F75. 6. Transfer to F100 when appetite returns (usually within 1 wk) and edema has been lost or is reduced. 7. Weigh daily and plot weight.

a See Table 57.12 for recipe, or use commercially available therapeutic Combined Mineral Vitamin mix (CMV).

b A comparable F75 can be made from 35 g dried whole milk, 100 g sugar, 20 g oil, 20 mL electrolyte/mineral solution, and water to 1000 mL; or from 300 mL full-cream cow's milk, 100 g sugar, 20 g oil, 20 mL electrolyte/mineral solution, and water to 1000 mL.
This lower-osmolality formula may be helpful for children with dysentery or persistent diarrhea. Cook for 4 min.

A comparable F100 can be made from 110 g dried whole milk, 50 g sugar, 30 g oil, 20 mL electrolyte/mineral solution, and water to 1000 mL; or from 880 mL full-cream cow's milk, 75 g sugar, 20 g oil, 20 mL electrolyte/mineral solution, and water to 1000 mL. Whisk at high speed to prevent oil from separating out.

Dehydration status is easily misdiagnosed in severely wasted children, because the usual signs (e.g., slow skin pinch, sunken eyes) may be present even without dehydration. Rehydration must therefore be closely monitored for signs of fluid overload. Serum electrolyte levels can be misleading because of sodium leaking from the blood into cells and potassium leaking out of cells. Keeping the intake of electrolytes and nutrients constant (see Table 57.8) allows systems to stabilize more quickly than adjusting intake in response to laboratory results.

Table 57.11 provides a recipe for the special rehydration solution used in severe malnutrition (ReSoMal). Therapeutic Combined Mineral Vitamin mix (CMV) contains electrolytes, minerals, and vitamins and is added to ReSoMal and feeds. If unavailable, potassium, magnesium, zinc, and copper can be added as an electrolyte/mineral stock solution (Table 57.12 provides a recipe), and a multivitamin supplement can be given separately.

Add 20 mL when preparing 1 L of feed or ReSoMal.

**Rehabilitation**

The signals for entry to the rehabilitation phase are reduced or minimal edema and return of appetite.

A controlled transition over 3 days is recommended to prevent refeeding syndrome (see Chapter 58). After the transition, unlimited amounts should be given of a high-energy, high-protein milk formula such as F100 (100 kcal and 3 g protein per 100 mL), or a ready-to-use therapeutic food (RUTF), or family foods modified to have comparable energy and protein contents.

To make the transition, for 2 days replace F75 with an equal volume of F100, then increase each successive feed by 10 mL until some feed remains uneaten (usually at about 200 mL/kg/day). After this transition, give 150-220 kcal/kg/day and 4-6 g protein/kg/day, and continue to give potassium, magnesium, and micronutrients. Add iron (3 mg/kg/day). If breastfed, encourage continued breastfeeding. Children with severe malnutrition have developmental delays, so loving care, structured play, and sensory stimulation during and after treatment are essential to aid recovery of brain function.

**Community-Based Treatment**

Many children with severe acute malnutrition can be identified in their communities before medical complications arise. If these children have a good appetite and are clinically well, they can be rehabilitated at home through community-based therapeutic care, which has the added benefit of reducing their exposure to nosocomial infections and providing continuity of care after recovery. It also reduces the time caregivers spend away from home and their opportunity costs and can be cost-effective for health services.

Fig. 57.8 shows the criteria for inpatient and outpatient care. To maximize coverage and compliance, community-based therapeutic care has 4 main
elements: community mobilization and sensitization, active case finding, therapeutic care, and follow-up after discharge.

Community-based therapeutic care comprises steps 8-10 (Fig. 57.7), plus a broad-spectrum antibiotic (step 5). RUTF is usually provided, especially in times of food shortage. RUTF is specially designed for rehabilitating children with severe acute malnutrition at home. It is high in energy and protein and has electrolytes and micronutrients added. The most widely used RUTF is a thick paste that contains milk powder, peanuts, vegetable oil, and sugar. Pathogens cannot grow in it because of its low moisture content. Hospitalized children who have completed steps 1-7 and the transition can be transferred to community-based care for completion of their rehabilitation, thereby reducing their hospital stay to about 7-10 days.

The refeeding syndrome may occur if high-energy feeding is started too soon or too vigorously, and it may lead to sudden death with signs of heart failure. Early accounts of the syndrome were among starved survivors of wartime sieges and concentration camps and among prisoners of war when given sudden access to unlimited food. The refeeding syndrome occurs in malnourished individuals as a result of untimely, overzealous oral, enteral, or parenteral (highest risk) feeding, and the risk is not widely recognized. Refeeding syndrome has also been seen among malnourished patients with anorexia nervosa with a body mass index (BMI) <70% median values. Onset is usually 24-48 hr after the start of high-energy feeding and is characterized by breathlessness, rapid pulse, increased venous pressure, rapid enlargement of the liver, and watery diarrhea. Other features are noted in Table 58.1.

</table>

An increase in the supply of energy (usually carbohydrates) is accompanied by an increase in sodium pump activity, and too sudden a supply risks causing a rapid release of accumulated sodium from cells, causing expansion of extracellular and plasma volumes. At the same time there is increased uptake by cells of glucose, potassium, magnesium, and phosphate. A sudden lowering of serum potassium, magnesium, and phosphate concentrations is an important feature of the refeeding syndrome.

The key to preventing the syndrome is to minimize the risk of its occurrence. It can be avoided by following the World Health Organization (WHO) guidelines for the treatment of malnutrition (see Chapter 57). Of particular relevance to minimizing the risk is the initial stabilization phase, which includes providing maintenance amounts of energy and protein and correcting electrolyte imbalances and micronutrient deficiencies, followed by a controlled transition to high-energy feeding. Milk-based diets are desirable because milk is a good source of phosphate. No or minimal edema and return of appetite are signs of readiness for the transition. Monitoring for sudden increases in pulse and respiration rates during the transition to high-energy feeding is advisable to detect these early warning signs. Should refeeding syndrome occur, prompt treatment with a single parenteral dose of digoxin and furosemide has been useful.

**Bibliography**

Malnutrition

Failure to thrive (FTT) has classically been the term used to describe children who are not growing as expected. Studies have advocated using the term malnutrition to describe this cohort of children with specifically defined classification based on anthropometric measurements. In this chapter, malnutrition refers to undernutrition and is defined as an imbalance between nutrient requirements and intake or delivery that then results in deficits—of energy, protein, or micronutrients—that may negatively affect growth and development. Malnutrition may be illness related or non–illness related, or both. Illness-related malnutrition may be caused by one or more diseases, infections, or congenital anomalies, as well as by injury or surgery. Non–illness-related causes include environmental, psychosocial, or behavioral factors. Often, one cause may be primary and exacerbated by another. Patients with malnutrition may present with growth deceleration, faltering growth, or even weight loss, as measured by anthropometric parameters, including weight, height/length, skinfolds, and mid-upper arm circumference (see Chapter 57).

Clinical Manifestations

Inadequate weight-for–corrected age, failure to gain adequate weight over a period of time (weight gain velocity), height velocity, weight-for-height, body mass index (BMI), and developmental outcomes help define malnutrition (see Chapter 57). These growth and anthropometric parameters should be measured serially and plotted on growth charts appropriate for the child's sex, age (corrected if premature), and, if known, genetic disorders, such as trisomy 21. The American Academy of Pediatrics (AAP) and U.S. Centers for Disease Control and Prevention (CDC) recommend the 2006 World Health Organization
(WHO) charts for children up to 2 yr of age who are measured supine for length. The CDC 2000 growth charts are recommended for children and adolescents (age 2-20 yr) when measured with a standing height. The severity of malnutrition (mild, moderate, or severe) may be determined by plotting the z score (standard deviation [SD] from the mean) for each of these anthropometric values (Table 59.1).

* It is recommended that when a child meets more than one malnutrition acuity level, the provider should document the severity of the malnutrition at the highest acuity level to ensure that an appropriate treatment plan and appropriate intervention, monitoring, and evaluation are provided.

† Needs additional positive diagnostic criteria to make a malnutrition diagnosis.

BMI, Body mass index; UBW, usual body weight.

Use clinical judgment when applying these diagnostic criteria.

### Etiology and Diagnosis

The most common mechanisms for illness-related causes of insufficient growth include (1) failure to ingest sufficient calories, or starvation (e.g., cardiac failure, fluid restriction), (2) increased nutrient losses (e.g., protein-losing enteropathy,
A complete history should include a detailed nutritional, family, and prenatal history; the quantity, quality, and frequency of meals; and further information regarding the onset of the growth failure (Table 59.2). A comprehensive physical examination is necessary to elicit underlying etiologies (Table 59.3). Puberty is often delayed or stalled in malnutrition, so Tanner stage should be carefully noted during the initial evaluation of preteens and adolescents. Tanner staging cannot be used as a marker for nutritional status, but it is influenced by malnourishment. Puberty will usually resume progression when the malnourished state improves. Laboratory evaluation of children with malnutrition should be judicious and based on findings from the history and physical examination. Obtaining the state's newborn screening results, a
complete blood count, and urinalysis represent a reasonable initial screen.

Additional measurements that are useful for following the progress of the acutely malnourished child are mid-upper arm circumference (MUAC) and hand-grip strength. MUAC is a particularly useful anthropometric measure when weight may be distorted by use of corticosteroids or fluid status (e.g., ascites, edema).

For children 6 yr and older, **hand-grip strength** may be a more acute
measurement of response to nutritional intervention than MUAC, because muscle function reacts earlier to changes in nutritional status than does muscle mass. The dynamometer is a simple, noninvasive, and low-cost instrument for measuring baseline functional status and tracking progress throughout the therapeutic course. Hand-grip strength can help to identify the presence of malnutrition, but the current lack of reference ranges for mild, moderate, and severe malnutrition in large populations limit the ability to use hand-grip strength to quantify the degree of malnutrition.

**Treatment**

While an illness-related etiology of mild malnutrition is being investigated, caloric supplementation should occur simultaneously. Both the medical workup and the initiation of supplemental oral feeds should occur in the outpatient setting with close follow-up. Consider including a speech therapist for a suck-and-swallow evaluation if the history suggests difficulty with oral feeds. If a child has not responded after 2-3 mo of outpatient management, consider hospitalization for potential initiation of nasogastric tube feeds, further diagnostic and laboratory evaluation, assessment and observed implementation of adequate nutrition, and evaluation of the parent–child feeding interaction. Additional indications for hospitalization include moderate or severe malnutrition, since the potential for refeeding syndrome requires close monitoring (see Chapter 58). The type of caloric supplementation is based on the severity of malnutrition and the underlying medical condition. The response to feeding depends on the specific diagnosis, medical treatment, and severity of malnutrition.

The same anthropometric measures used to diagnosis malnutrition should be used to measure progress and recovery from the malnourished state. Multivitamin supplementation should be given to all children with malnutrition to meet the recommended dietary allowance, because these children usually have iron, zinc, and vitamin D deficiencies, as well as increased micronutrient demands with catch-up growth.

Therapy for the psychosocial factors should be specific for the underlying issue, such as maternal depression or insufficient funds for food. In addition, parent education should focus on what is normal infant development and on correcting any parental misconceptions about feeding and temperament, as well as learning the infant cues for hunger, satiety, and sleep. Some children who
develop feeding aversion behaviors will require treatment by a specialized feeding team. If abuse or purposeful neglect is a concern, the family should be referred to the child protective services team.

**Prognosis**

Malnutrition, regardless of cause, is concerning because of the detrimental effect on physical and intellectual growth and development. Early diagnosis and treatment of acute malnutrition allow children to catch up to and sometimes even surpass their peers who were not malnourished. The long-term sequelae of malnutrition in young infants and children have been conflicting, and there is no clear consensus regarding the long-term emotional, cognitive, and metabolic effects. Despite inconclusive long-term outcomes in children who have malnutrition, investigators support early nutritional interventions for children who have poor growth.

Overweight and Obesity

Sheila Gahagan

Epidemiology

Obesity is an important pediatric public health problem associated with risk of complications in childhood and increased morbidity and mortality throughout adult life. Obesity is now linked to more deaths than underweight. In 2014, according to the World Health Organization (WHO), more than 1.9 billion persons ≥20 yr old were overweight or obese.

In the United States, 37% of adults are obese, and 35% are overweight. In children the prevalence of obesity increased 300% over approximately 40 yr. According to the National Health and Nutrition Examination Survey (NHANES), 2013–2014, 34% of children 2-19 yr old were overweight or obese, with 17% in the obese range. Risk for obesity in children 2-19 yr old varies significantly by race/ethnicity, with >20% for minority children compared with 15% for white children. Across all racial groups, higher maternal education confers protection against childhood obesity.

The first 1000 days, the period from conception to age 2 yr, are increasingly recognized as a modifiable period related to risk for childhood obesity. Parental obesity correlates with a higher risk for obesity in the children. Prenatal factors, including high preconceptual weight, gestational weight gain, high birthweight, and maternal smoking, are associated with increased risk for later obesity. Paradoxically, intrauterine growth restriction with early infant catch-up growth is associated with the development of central adiposity and adult-onset cardiovascular (CV) risk. Breastfeeding is modestly protective for obesity based on dose and duration. Infants with high levels of negative reactivity (temperament) are more at risk for obesity than those with better self-regulation.
Body Mass Index

Obesity or increased adiposity is defined using the **body mass index (BMI)**, an excellent proxy for more direct measurement of body fat. BMI = weight in kg/(height in meters)$^2$. Adults with a BMI ≥30 meet the criterion for obesity, and those with a BMI 25-30 fall in the overweight range. During childhood, levels of body fat change beginning with high adiposity during infancy. Body fat levels decrease for approximately 5.5 yr until the period called *adiposity rebound*, when body fat is typically at the lowest level. Adiposity then increases until early adulthood (Fig. 60.1). Consequently, obesity and overweight are defined using BMI percentiles for children ≥2 yr old and weight/length percentiles for infants <2 yr old. The criterion for **obesity** is BMI ≥95th percentile and for **overweight** is BMI between 85th and 95th percentiles.
A, Body mass index (BMI)-for-age profiles for boys and men. (Developed by the National Center for Health Statistics in collaboration with the National Center for Chronic Disease Prevention and Health Promotion,
B, BMI-for-age profiles for girls and women.
Etiology

Humans have the capacity to store energy in adipose tissue, allowing improved survival in times of famine. Simplistically, obesity results from an imbalance of caloric intake and energy expenditure. Even incremental but sustained caloric excess results in excess adiposity. Individual adiposity is the result of a complex interplay among genetically determined body habitus, appetite, nutritional intake, physical activity (PA), and energy expenditure. Environmental factors determine levels of available food, preferences for types of foods, levels of PA, and preferences for types of activities. Food preferences play a role in consumption of energy-dense foods. Humans innately prefer sweet and salty foods and tend initially to reject bitter flavors, common to many vegetables. Repeated exposure to healthy foods promotes their acceptance and liking, especially in early life. This human characteristic to adapt to novel foods can be used to promote healthy food selection.

Environmental Changes

Over the last 4 decades, the food environment has changed dramatically related to urbanization and the food industry. As fewer families routinely prepare meals, foods prepared by a food industry have higher levels of calories, simple carbohydrates, and fat. The price of many foods has declined relative to the family budget. These changes, in combination with marketing pressure, have resulted in larger portion sizes and increased snacking between meals. The increased consumption of high-carbohydrate beverages, including sodas, sport drinks, fruit punch, and juice, adds to these factors.

Fast food is consumed by one third of U.S. children each day and by two thirds of children every week. A typical fast food meal can contain 2000 kcal and 84 g of fat. Many children consume 4 servings of high-carbohydrate beverages per day, resulting in an additional 560 kcal of low nutritional value. Sweetened beverages have been linked to increased risk for obesity. The dramatic increase in the use of high-fructose corn syrup to sweeten beverages
and prepared foods is another important environmental change, leading to availability of inexpensive calories.

Since World War II, levels of PA in children and adults have declined. According to the 2012 NHANES survey, 25% of 12-15 yr olds met PA guidelines of 60 min of PA per day. Decline in PA is related to many factors, including changes in the built environment, more reliance on cars, lower levels of active transportation, safety issues, and increasingly sedentary lifestyles. Many sectors of society do not engage in PA during leisure time. For children, budgetary constraints and pressure for academic performance have led to less time devoted to physical education in schools. Perception of poor neighborhood safety also leads to lower levels of PA. Furthermore, screens (televisions, tablets, smartphones, computers) offer compelling sedentary activities that do not burn calories.

**Sleep** plays a role in risk for obesity. Over the last 4 decades, children and adults have decreased the amount of time spent sleeping. Reasons for these changes may relate to increased time at work, increased time watching television, and a generally faster pace of life. Chronic partial sleep loss can increase risk for weight gain and obesity, with the impact possibly greater in children than in adults. In studies of young, healthy, lean men, short sleep duration was associated with decreased leptin levels and increased ghrelin levels, along with increased hunger and appetite. **Sleep debt** also results in decreased glucose tolerance and insulin sensitivity related to alterations in glucocorticoids and sympathetic activity. Some effects of sleep debt might relate to *orexins*, peptides synthesized in the lateral hypothalamus that can increase feeding, arousal, sympathetic activity, and neuropeptide Y activity.

**Genetics**

Genetic determinants also have a role in individual susceptibility to obesity ([Table 60.1](#)). Findings from genome-wide association studies explain a very small portion of interindividual variability in obesity. One important example, the *FTO* gene at 16q12, is associated with adiposity in childhood, probably explained by increased energy intake. Monogenic forms of obesity have also been identified, including **melanocortin-4 receptor (MC4R)** deficiency, associated with early-onset obesity and food-seeking behavior. Mutations in *MC4R* are a common cause of monogenetic obesity but a rare cause of obesity in general. Deficient activation of *MC4R* is seen in patients with
proopiomelanocortin (POMC) deficiency, a prohormone precursor of adrenocorticotropic hormone (ACTH) and melanocyte-stimulating hormone (MSH), resulting in adrenal insufficiency, light skin, hyperphagia, and obesity.

</table>
In addition, evidence suggests that appetitive traits are moderately heritable. For example, some genes associated with appetite also relate to weight, and vice-versa. In addition, there are genetic conditions associated with obesity, such as **Prader-Willi syndrome**, which results from absence of paternally expressed imprinted genes in the 15q11.2–q13 region. Prader-Willi syndrome is characterized by insatiable appetite and food seeking. In the era of genomic medicine, it will be increasingly possible to identify risks according to specific genes and consider gene-environment interactions. Epigenetic environmental modification of genes may have a role in the development of obesity, especially during fetal and early life.
Microbiome

It is increasingly recognized the human gut microbiota play a role in regulating metabolism. This novel area of research raises questions about the role of antibiotics in the pathway to obesity and the possibility that probiotics could be therapeutic for certain individuals.

Endocrine and Neural Physiology

Monitoring of “stored fuels” and short-term control of food intake (appetite and satiety) occurs through neuroendocrine feedback loops linking adipose tissue, the gastrointestinal (GI) tract, and the central nervous system (CNS) (Figs. 60.2 and 60.3). GI hormones, including cholecystokinin, glucagon-like peptide 1, peptide YY, and vagal neuronal feedback promote satiety. Ghrelin stimulates appetite. Adipose tissue provides feedback regarding energy storage levels to the brain through hormonal release of adiponectin and leptin. These hormones act on the arcuate nucleus in the hypothalamus and on the solitary tract nucleus in the brainstem and in turn activate distinct neuronal networks. Adipocytes secrete adiponectin into the blood, with reduced levels in response to obesity and increased levels in response to fasting. Reduced adiponectin levels are associated with lower insulin sensitivity and adverse CV outcomes. Leptin is directly involved in satiety; low leptin levels stimulate food intake, and high leptin levels inhibit hunger in animal models and in healthy human volunteers. However, the negative feedback loop from leptin to appetite may be more adapted to preventing starvation than excess intake.
FIG. 60.2 Regulation of energy homeostasis by the brain-gut-adipose axis. CCK, Cholecystokinin; GLP-1, glucagon-like peptide 1; PYY, peptide YY. (From Melmed S, Polonsky KS, Larsen PR, Kronenberg HM, editors: Williams textbook of endocrinology,
Numerous neuropeptides in the brain, including peptide YY (PYY), agouti-related peptide, and orexin, appear to affect appetite stimulation, whereas melanocortins and α-melanocortin–stimulating hormone are involved in satiety (Fig. 60.3). The neuroendocrine control of appetite and weight involves a negative-feedback system, balanced between short-term control of appetite and long-term control of adiposity (including leptin). PYY reduces food intake via the vagal-brainstem-hypothalamic pathway. Developmental changes in PYY are evident as infants have higher PYY levels than school-age children and adults. Obese children have lower fasting levels of PYY than adults. Weight loss may
restore PYY levels in children, even though this does not happen in adults. In addition, patients homozygous for the FTO obesity-risk allele demonstrate poor regulation of the orexigenic hormone acyl-ghrelin and have poor postprandial appetite suppression.

## Comorbidities

Complications of pediatric obesity occur during childhood and adolescence and persist into adulthood. An important reason to prevent and treat pediatric obesity is the increased risk for morbidity and mortality later in life. The Harvard Growth Study found that boys who were overweight during adolescence were twice as likely to die from CV disease as those who had normal weight. More immediate comorbidities include type 2 diabetes, hypertension, hyperlipidemia, and nonalcoholic fatty liver disease (NAFLD) (Table 60.2). Insulin resistance increases with increasing adiposity and independently affects lipid metabolism and CV health. The metabolic syndrome (central obesity, hypertension, glucose intolerance, and hyperlipidemia) increases risk for CV morbidity and mortality. NAFLD has been reported in 34% of patients treated in pediatric obesity clinic. NAFLD is now the most common chronic liver disease in U.S. children and adolescents. It can present with advanced fibrosis or nonalcoholic steatohepatitis and may result in cirrhosis and hepatocellular carcinoma. Insulin resistance is often associated. Furthermore, NAFLD is independently associated with increased risk of CV disease.

Obesity may also be associated with chronic inflammation. Adiponectin, a peptide with antiinflammatory properties, occurs in reduced levels in obese patients compared to insulin-sensitive, lean persons. Low adiponectin levels correlate with elevated levels of free fatty acids and plasma triglycerides as well as a high BMI, and high adiponectin levels correlate with peripheral insulin sensitivity. Adipocytes secrete peptides and cytokines into the circulation, and proinflammatory peptides such interleukin (IL)-6 and tumor necrosis factor (TNF)-α occur in higher levels in obese patients. Specifically, IL-6 stimulates production of C-reactive protein (CRP) in the liver. CRP is a marker of inflammation and might link obesity, coronary disease, and subclinical inflammation.
Some complications of obesity are mechanical, including obstructive sleep apnea and orthopedic complications. Orthopedic complications include Blount disease and slipped femoral capital epiphysis (see Chapters 697 and 698.4).

Mental health problems can coexist with obesity, with the possibility of bidirectional effects. These associations are modified by gender, ethnicity, and socioeconomic status. Self-esteem may be lower in obese adolescent girls than in nonobese peers. Some studies have found an association between obesity and adolescent depression. There is considerable interest in the co-occurrence of eating disorders and obesity. Obese youth are also at risk for bullying based on their appearance.

**Identification**

Overweight and obese children are often identified as part of routine medical care. The child and family may be unaware that the child has increased adiposity. They may be unhappy with the medical provider for raising this issue and may respond with denial or apparent lack of concern. It is often necessary to begin by helping the family understand the importance of healthy weight for current and future health. Forging a good therapeutic relationship is important because obesity intervention requires a chronic disease management approach. Intervention and successful resolution of this problem require considerable effort by the family and the child over an extended period in order to change eating and activity behaviors.

**Evaluation**

The evaluation of the overweight or obese child begins with examination of the growth chart for weight, height, and BMI trajectories; consideration of possible medical causes of obesity; and detailed exploration of family eating, nutritional, and activity patterns. A complete pediatric history is used to uncover comorbid disorders. The family history focuses on the adiposity of other family members and the family history of obesity-associated disorders. The physical examination adds data that can lead to important diagnoses. Laboratory testing is guided by the need to identify comorbidities.

Examination of the *growth chart* reveals the severity, duration, and timing of obesity onset. Children who are overweight (BMI in 85–95th percentile) are less
likely to have developed comorbid conditions than those who are obese (BMI ≥95th percentile). Those with a BMI ≥99th percentile are more likely to have coexisting medical problems. Once obesity severity is determined, the BMI trajectory is examined to elucidate when the child became obese. Several periods during childhood are considered sensitive periods, or times of increased risk for developing obesity, including infancy, adiposity rebound (when body fat is lowest at approximately age 5.5 yr), and adolescence. An abrupt change in BMI might signal the onset of a medical problem or a period of family or personal stress for the child. Examination of the weight trajectory can further reveal how the problem developed. A young child might exhibit high weight and high height because linear growth can increase early in childhood if a child consumes excess energy. At some point the weight percentile exceeds the height percentile, and the child's BMI climbs into the obese range. Another example is a child whose weight rapidly increases when she reduces her activity level and consumes more meals away from home. Examination of the height trajectory can reveal endocrine problems, which often occur with slowing of linear growth.

Consideration of possible medical causes of obesity is essential, even though endocrine and genetic causes are rare (see Table 60.1 ). Growth hormone deficiency, hypothyroidism, and Cushing syndrome are examples of endocrine disorders that can lead to obesity. In general, these disorders manifest with slow linear growth. Because children who consume excessive amounts of calories tend to experience accelerated linear growth, short stature warrants further evaluation. Genetic disorders associated with obesity may manifest extreme hyperphagia, or they can have coexisting dysmorphic features, cognitive impairment, vision and hearing abnormalities, or short stature. In some children with congenital disorders such as myelodysplasia or muscular dystrophy, lower levels of PA can lead to secondary obesity. Some medications, such as atypical antipsychotics, can cause excessive appetite and hyperphagia, resulting in obesity (Table 60.3 ). Rapid weight gain in a child or adolescent taking one of these medications might require its discontinuation. Poor linear growth and rapid changes in weight gain are indications for evaluation of possible medical causes.

### Table 60.3

#### Medications Associated With Obesity

<table>

</tr>
</tbody>
</table>
Exploration of family eating, nutritional, and activity patterns begins with a description of regular meal and snack times and family habits for walking, bicycle riding, active recreation, and screen time (TV, computer, video games). It is useful to request a 24-hr dietary recall with special attention to intake of fruits, vegetables, and water, as well as high-calorie foods and high-carbohydrate beverages. When possible, evaluation by a nutritionist is extremely helpful. This information will form the basis for incremental changes in eating behavior, caloric intake, and PA during the intervention.

Initial assessment of the overweight or obese child includes a complete review of bodily systems focusing on the possibility of comorbid conditions (see Table 60.2 ). Developmental delay and visual and hearing impairment can be associated with genetic disorders. Difficulty sleeping, snoring, or daytime sleepiness suggests sleep apnea. Abdominal pain might suggest NAFLD. Symptoms of polyuria, nocturia, or polydipsia may be the result of type 2 diabetes. Hip or knee pain can be caused by secondary orthopedic problems, including Blount disease and slipped capital femoral epiphysis. Irregular menses may be associated with polycystic ovary syndrome. Acanthosis nigricans can suggest insulin resistance and type 2 diabetes (Fig. 60.4 ).
The family history begins with identifying other obese family members. Parental obesity is an important risk for child obesity. If all family members are obese, focusing the intervention on the entire family is reasonable. The child may be at increased risk for developing type 2 diabetes if a family history exists. Patients of African American, Hispanic, or Native American heritage are also at increased risk for developing type 2 diabetes. Identification of a family history of hypertension, CV disease, or metabolic syndrome indicates increased risk for developing these obesity-associated conditions. If the clinician helps the family to understand that childhood obesity increases risk for developing these chronic diseases, this educational intervention might serve as motivation to improve their nutrition and PA.

Physical examination should be thorough, focusing on possible comorbidities (see Table 60.2). Careful screening for hypertension using an appropriately sized blood pressure cuff is important. Systematic examination of the skin can reveal acanthosis nigricans, suggesting insulin resistance, or hirsutism, suggesting polycystic ovary syndrome. Tanner staging can reveal premature adrenarche secondary to advanced sexual maturation in overweight and obese girls.

Laboratory testing for fasting plasma glucose, triglycerides, low-density lipoprotein and high-density lipoprotein cholesterol, and liver function tests are recommended as part of the initial evaluation for newly identified pediatric obesity (Table 60.4). Overweight children (BMI 85–95th percentile) who have a family history of diabetes mellitus or signs of insulin resistance should also be evaluated with a fasting plasma glucose test. Other laboratory testing should be
guided by history or physical examination findings. Fig. 60.5 provides a recommended approach to categorization, evaluation, and treatment.

Intervention

Evidence shows that some interventions result in modest but significant and sustained improvement in body mass. Based on behavior change theories, treatment includes specifying target behaviors, self-monitoring, goal setting, stimulus control, and promotion of self-efficacy and self-management skills. Behavior changes associated with improving BMI include drinking lower quantities of sugar-sweetened beverages, consuming higher-quality diets, increasing exercise, decreasing screen time, and self-weighing. Most successful interventions have been family based and consider the child's developmental age. “Parent-only” treatment can be as effective as “parent–child” treatment. Because obesity is multifactorial, not all children and adolescents will respond to the same approach. For example, loss-of-control eating, associated with weight gain and obesity, predicts poor outcome in response to family-based treatment. Furthermore, clinical treatment programs are expensive and not widely available. Therefore, interest has grown in novel approaches such as internet-based treatments and guided self-help.

It is important to begin with clear recommendations about appropriate caloric intake for the obese child (Table 60.5). Working with a dietitian is essential. Meals should be based on fruits, vegetables, whole grains, lean meat, fish, and poultry. Prepared foods should be chosen for their nutritional value, with attention to calories and fat. Foods that provide excessive calories and low nutritional value should be reserved for infrequent treats.

### Table 60.5

<table>
<thead>
<tr>
<th>LIFE-STAGE</th>
<th>AGE</th>
<th>RELATIVELY SEDENTARY LEVEL</th>
<th>MODERATE LEVEL OF</th>
<th>ACTIVE</th>
</tr>
</thead>
</table>

Weight reduction diets in adults generally do not lead to sustained weight loss. Therefore the focus should be on changes that can be maintained for life. Attention to eating patterns is helpful. Families should be encouraged to plan family meals, including breakfast. It is almost impossible for a child to make changes in nutritional intake and eating patterns if other family members do not make the same changes. Dietary needs also change developmentally; adolescents require greatly increased calories during their growth spurts, and adults who lead inactive lives need fewer calories than active, growing children.

Psychologic strategies are helpful. The “traffic light” diet groups foods into those that can be consumed without any limitations (green), in moderation (yellow), or reserved for infrequent treats (red) (Table 60.6). The concrete categories are very helpful to children and families. This approach can be adapted to any ethnic group or regional cuisine. Motivational interviewing begins with assessing how ready the patient is to make important behavioral changes. The professional then engages the patient in developing a strategy to take the next step toward the ultimate goal of healthy nutritional intake. This method allows the professional to take the role of a coach, helping the child and family reach their goals. Other behavioral approaches include family rules about where food may be consumed (e.g., “not in the bedroom”).

Increasing PA without decreasing caloric intake is unlikely to result in weight loss. However, aerobic exercise training has been shown to improve metabolic profiles in obese children and adolescents. Furthermore, it can increase aerobic fitness and decrease percent body fat even without weight loss. Therefore, increasing PA can decrease risk for CV disease, improve well-being, and contribute to weight loss. Increased PA can be accomplished by walking to school, engaging in PA during leisure time with family and friends, or enrolling in organized sports. Children are more likely to be active if their parents are active. As with family meals, family PA is recommended. When adults lose significant weight, they may regain that weight despite eating fewer calories. The body may adapt to weight loss by reducing the basal metabolic rate (BMR), thus requiring fewer calories. One approach to this phenomenon is to increase PA.

Active pursuits can replace more sedentary activities. The American Academy of Pediatrics recommends that screen time be restricted to no more than 2 hr/day for children >2 yr old and that children <2 yr old not watch television. TV watching is often associated with eating, and many highly caloric food products are marketed directly to children during child-oriented television programs.

Pediatric healthcare providers should assist families to develop goals to change nutritional intake and PA. They can also provide the child and family with needed information. The family should not expect immediate lowering of BMI percentile related to behavioral changes, but can instead count on a gradual decrease in the rate of BMI percentile increase until it stabilizes, followed by a gradual decrease. Referral to multidisciplinary, comprehensive pediatric weight management programs is ideal for obese children whenever possible.

Pharmacotherapy for weight loss in the pediatric population is understudied. Randomized controlled trials (RCTs) have evaluated many medications, including metformin, orlistat, sibutramine, and exanatide (Table 60.7). Available medications result in modest weight loss or BMI improvement, even when combined with behavioral interventions. Various classes of drugs are of interest, including those that decrease energy intake or act centrally as anorexiants, those that affect the availability of nutrients through intestinal or renal tubular reabsorption, and those that affect metabolism. The only U.S. Food and Drug

Administration (FDA)–approved medication for obesity in children <16 yr old is orlistat, which decreases absorption of fat, resulting in modest weight loss. Complications include flatulence, oily stools, and spotting. This agent offers little benefit to severely obese adolescents. Because multiple redundant neural mechanisms act to protect body weight, promoting weight loss is extremely difficult. Thus there is considerable interest in combining therapies that simultaneously target multiple weight-regulating pathways. One example, approved for adults, combines phentermine, a noradrenergic agent, with topiramate, a γ-aminobutyric acid (GABA)–ergic medication. This combination resulted in a mean 10.2-kg weight loss vs 1.4 kg in the placebo group. Side effects are common and include dry mouth, constipation, paresthesias, insomnia, and cognitive dysfunction. Another promising example is the combination of amylin (decreases food intake and slows gastric emptying) with leptin, which has no anorexigenic effects when given alone. This combination requires injection and is in clinical trials in adults. Another FDA-approved drug for adults is lorcaserin, a selective serotonin 2C receptor agonist. Establishing long-term safety and tolerability in children is a challenge because medications of interest have CNS effects or interfere with absorption of nutrients. Teratologic effects must be considered for use in adolescent girls.

**Hormone replacement therapy** is available for patients with leptin deficiency and may become available for patients with POMC deficiency. Setmelanotide binds to and activates MC4R and may be useful for patients with POMC deficiency–associated obesity.

In some cases it is reasonable to refer adolescents for **bariatric surgery** evaluation. The American Pediatric Surgical Association guidelines recommends that surgery be considered only in children with complete or near-complete skeletal maturity, a BMI ≥40, and a medical complication resulting from obesity, after they have failed 6 mo of a multidisciplinary weight management program. Surgical approaches include the Roux-en-Y and the adjustable gastric band (Fig. 60.6). In obese adults, bariatric surgery reduces the risk of developing type 2 diabetes mellitus. In obese adult patients with existing type 2 diabetes, bariatric surgery improves diabetic control. Nutritional complications of bariatric surgery include malabsorption and vitamin (A, B₁, B₂, B₆, B₁₂, D, E, K) and mineral (copper, iron) deficiencies that require supplementation.

**Prevention**

Prevention of child and adolescent obesity is essential for public health in the United States and most other countries (Tables 60.8 and 60.9). Efforts by pediatric providers can supplement national and community public health programs. The National Institutes of Health (NIH) and U.S. Centers for Disease Control and Prevention (CDC) recommend a variety of initiatives to combat the current obesogenic environment, including promotion of breastfeeding, access to fruits and vegetables, walkable communities, and 60 min/day of activity for children. The U.S. Department of Agriculture (USDA) sponsors programs promoting 5.5 cups of fruits and vegetables per day. Incentives for the food industry to promote consumption of healthier foods should be considered. Marketing of unhealthy foods to children is now being regulated. Changes in federal food programs are expected, including commodity foods, the Women,
Infant, and Children Supplemental Food Program (WIC), and school lunch programs, to meet the needs of today's children.

### Table 60.8

**Proposed Suggestions for Preventing Obesity**

#### Pregnancy

- Normalize body mass index (BMI) before pregnancy.
- Do not smoke.
- Maintain moderate exercise as tolerated.
- In women with gestational diabetes, provide meticulous glucose control.
- Monitor gestational weight gain within Institute of Medicine (IOM) recommendations.

#### Postpartum and Infancy

- Breastfeeding: exclusive for 4-6 mo; continue with other foods for 12 mo.
- Postpone introduction of baby foods to 4-6 mo and juices to 12 mo.

#### Families

- Eat meals as a family in a fixed place and time.
- Do not skip meals, especially breakfast.
- Do not allow television during meals.
- Use small plates, and keep serving dishes away from the table.
- Avoid unnecessary sweet or fatty foods and sugar-sweetened drinks.
- Remove televisions from children's bedrooms; restrict times for TV viewing and video games.
- Do not use food as a reward.

#### Schools

- Eliminate candy and cookie sales as fundraisers.
- Review the contents of vending machines, and replace with healthier choices; eliminate sodas.
Avoid financial support for sports teams from beverage and food industries. Install water fountains and hydration stations. Educate teachers, especially physical education and science faculty, about basic nutrition and the benefits of physical activity (PA). Educate children from preschool through high school on appropriate diet and lifestyle. Mandate minimum standards for physical education, including 60 min of strenuous exercise 5 times weekly. Encourage “the walking school bus”: groups of children walking to school with adult supervision.

**Communities**

Increase family-friendly exercise and safe play facilities for children of all ages. Develop more mixed residential-commercial developments for walkable and bicyclable communities. Discourage the use of elevators and moving walkways. Provide information on how to shop and prepare healthier versions of culture-specific foods.

**Healthcare Providers**

Explain the biologic and genetic contributions to obesity. Give age-appropriate expectations for body weight in children. Work toward classifying obesity as a disease to promote recognition, reimbursement for care, and willingness and ability to provide treatment.

**Industry**

Mandate age-appropriate nutrition labeling for products aimed at children (e.g., “red light/green light” foods, with portion sizes). Encourage marketing of interactive video games in which children must exercise to play. Use celebrity advertising directed at children for healthful foods to promote breakfast and regular meals.
Reduce portion size (drinks and meals).

**Government and Regulatory Agencies**

Classify childhood obesity as a legitimate disease.
Find novel ways to fund healthy lifestyle programs (e.g., with revenues from food and drink taxes).
Subsidize government-sponsored programs to promote the consumption of fresh fruits and vegetables.
Provide financial incentives to industry to develop more healthful products and to educate the consumer on product content.
Provide financial incentives to schools that initiate innovative PA and nutrition programs.
Allow tax deductions for the cost of weight loss and exercise programs.
Provide urban planners with funding to establish bicycle, jogging, and walking paths.
Ban advertising of fast foods, non-nutritious foods, and sugar-sweetened beverages directed at preschool children, and restrict advertising to school-age children.
Ban toys as gifts to children for purchasing fast foods.

**Table 60.9**

**Anticipatory Guidance: Establishing Healthy Eating Habits in Children**

Do not punish a child during mealtimes with regard to eating. The emotional atmosphere of a meal is very important. Interactions during meals should be pleasant and happy.
Do not use foods as rewards.
Parents, siblings, and peers should model healthy eating, tasting new foods, and eating a well-balanced meal.
Children should be exposed to a wide range of foods, tastes, and textures. New foods should be offered multiple times. Repeated exposure leads to
acceptance and liking.
Forcing a child to eat a certain food will decrease the child's preference for that food. Children's wariness of new foods is normal and should be expected. Offering a variety of foods with low-energy density helps children balance energy intake.
Parents should control what foods are in the home. Restricting access to foods in the home will increase rather than decrease a child's desire for that food.
Children tend to be more aware of satiety than adults, so allow children to respond to satiety, and stop eating. Do not force children to “clean their plate.”

Pediatric prevention efforts begin with careful monitoring of weight and BMI percentiles at healthcare maintenance visits. Attention to changes in BMI percentiles can alert the pediatric provider to increasing adiposity before the child becomes overweight or obese. All families should be counseled about healthy nutrition for their children, because the current prevalence of overweight and obesity in adults is 65%. Therefore, approximately two thirds of all children can be considered at risk for becoming overweight or obese at some time in their lives. Those who have an obese parent are at increased risk. Prevention efforts begin with promotion of *exclusive breastfeeding for 6 mo* and total breastfeeding for 12 mo. Introduction of infant foods at 6 mo should focus on cereals, fruits, and vegetables. Lean meats, poultry, and fish may be introduced later in the 1st year of life. Parents should be specifically counseled to *avoid introducing highly sugared beverages and foods in the 1st year of life.* Instead, they should expose their infants and young children to a rich variety of fruits, vegetables, grains, lean meats, poultry, and fish to facilitate acceptance of a diverse and healthy diet. Parenting matters, and *authoritative* parents are more likely to have children with a healthy weight than those who are authoritarian or permissive. Families who eat regularly scheduled meals together are less likely to have overweight or obese children. Child health professionals can address a child's nutritional status and provide expertise in child growth and development.
Child health professionals can also promote PA during regular healthcare maintenance visits. Parents who spend some of their leisure time in PA promote healthy weight in their children. Beginning in infancy, parents should be cognizant of their child’s developmental capability and need for PA. Because TV, computer, and video game time can replace health-promoting PA, physicians should counsel parents to limit screen time for their children. Snacking during TV watching should be discouraged. Parents can help their children to understand that television commercials intend to sell a product. Children can learn that their parents will help them by responsibly choosing healthy foods.

Because obesity is determined by complex multifactorial conditions, prevention will take efforts at multiple levels of social organization. Successful programs include EPODE (Ensemble Prévenons l’Obésité Des Enfants), a multilevel prevention strategy that began in France and has been adopted by more than 500 communities in 6 countries. Shape Up Somerville is a citywide campaign to increase daily PA and healthy eating in Somerville, MA, since 2002. The “Let’s Move” campaign was championed by former First Lady Michelle Obama. Since community and environmental factors are related to pediatric obesity risk, changes in local environments, daycare centers, schools, and recreational settings can have a public health impact. Programs can empower families to adopt practices that promote healthy lifestyles for children and adolescents. The most successful programs are comprehensive and rely on 4 strategies: political commitment to change, resources to support social marketing and changes, support services, and evidence-based practices. Community-wide programs are important because neighborhood environmental factors (e.g., poverty) have been associated with obesity in its residents. There is considerable interest in focusing these efforts early in the life cycle. Beginning obesity prevention during pregnancy and engaging health systems, early childhood programs, and community systems to support healthier life cycles is an approach with great promise.

Rapid-Onset Obesity With Hypothalamic Dysfunction,
Hypoventilation, and Autonomic Dysregulation (ROHHAD)

Sarah F. Barclay, Amy Zhou, Casey M. Rand, Debra E. Weese-Mayer

Keywords

ROHHAD
obesity
hypothalamic dysfunction
hypoventilation
autonomic nervous system dysregulation
artificial ventilation
sleep-disordered breathing

ROHHAD—rapid-onset obesity with hypothalamic dysfunction, hypoventilation, and autonomic dysregulation—is a rare, poorly understood disease of childhood onset, the first sign of which is sudden, rapid, and extreme weight gain in a previously healthy child. The acronym describes the presenting symptoms and the typical order in which they will manifest or unfold, as the condition evolves over months to years. Despite its rarity, ROHHAD must be considered whenever rapid-onset obesity is observed in a child, because in the absence of appropriate treatment, a high mortality rate is associated with the severe central hypoventilation that will invariably develop.

The diagnosis is initially considered after the observation of rapid-onset obesity (15-20 lb gain) after age 1.5 yr, accompanied by at least 1 additional sign of hypothalamic dysfunction. Central hypoventilation may not be present at diagnosis but will develop over time, and artificial ventilatory support will be required at least during sleep, if not 24 hr/day. Signs of autonomic nervous system dysregulation typically occur after the weight gain, hypothalamic dysfunction, and hypoventilation have been identified. Additionally,
approximately 40% of ROHHAD patients will have a tumor of neural crest origin, typically ganglioneuroma or ganglioneuroblastoma.

ROHHAD is distinct from late-onset congenital central hypoventilation syndrome (LO-CCHS ; see later and Chapter 446.2 ). ROHHAD is primarily distinguished from LO-CCHS by the presence of obesity and other signs of hypothalamic dysfunction and by the absence of CCHS-related PHOX2B mutation. Approximately 100 cases of ROHHAD have been described in the literature to date.

**Clinical Manifestations**

Children with ROHHAD initially appear healthy, with an unremarkable history. The initial symptoms present between ages 18 mo and 7 yr. Typically, the 1st symptom observed is rapid-onset obesity , with weight gain of 15-20 lb in 6-12 mo. This is a sign of hypothalamic dysfunction (HD) in these patients. The 2nd common sign of HD, seen in most ROHHAD patients, is disordered water balance , including hyper- and hyponatremia and both adipsia and polydipsia. Growth hormone (GH) deficiency is also observed in most patients. In some this manifests clinically as slowed growth rate and short stature, whereas in others a failed GH stimulation test is the only evidence. Other symptoms of HD, occurring in >25–50% of ROHHAD patients, include hyperprolactinemia, poor thermoregulation, central hypothyroidism, adrenal insufficiency, and delayed or precocious puberty. The number of hypothalamic abnormalities that will be observed and the sequential order in which they will appear are variable, and some symptoms may not manifest for months to 1-2 yr after the initial diagnosis. However, all ROHHAD patients will present with at least 1 of these signs of HD.

Sleep-disordered breathing (SDB) is one of the key symptoms of ROHHAD, often manifesting as one of the most severe features of the phenotype, with the greatest potential for fatal complications. More than half of ROHHAD patients have initial obstructive sleep apnea (OSA) ; although SDB is known to be associated with obesity, and OSA is often seen in obese individuals, the extent that SDB is tied to obesity in ROHHAD patients is not yet well defined. However, over time, as the ROHHAD phenotype unfolds, SDB will evolve beyond what could potentially be explained as obesity related. All ROHHAD patients will eventually develop central alveolar hypoventilation , requiring artificial ventilatory support, even when the upper airway obstruction is relieved as an intervention for OSA. About half of ROHHAD patients will
require artificial ventilation only during sleep, while half will require continuous artificial ventilation (during sleep and wakefulness). More than 40% of children with ROHHAD will have a cardiorespiratory arrest before their hypoventilation is identified and treated. Unfortunately, many ROHHAD patients die from cardiorespiratory arrest because of unrecognized or inadequately managed hypoventilation. Thus, if a ROHHAD diagnosis is suspected, it is crucial that a comprehensive respiratory physiology evaluation is performed, including overnight polysomnography and awake physiologic recording in activities of daily living (ADLs).

All ROHHAD patients have symptoms of **autonomic nervous system (ANS) dysregulation**, but as described for signs of HD, the exact symptoms and the order and timing of their appearance will vary between patients. The most common manifestations of ANS dysregulation in ROHHAD are ophthalmologic, including pupillary dysfunction, strabismus, and alacrima. Many ROHHAD patients will have gastrointestinal dysmotility, presenting as either chronic constipation or chronic diarrhea. Other signs of ANS dysregulation include altered sweating, decreased body temperature, decreased sensitivity to pain, and cold hands and feet indicating altered vasomotor tone. Bradycardia is seen in some ROHHAD patients, typically related to extreme hypothermia.

**Neural crest tumors** are observed in at least 40% of ROHHAD patients, most frequently ganglioneuromas and ganglioneuroblastosomas of the chest or abdomen; rarely a neuroblastoma has been reported. These tumors can occur at any age, so proactive imaging evaluation to identify the tumors is essential.

Most patients do not have **behavioral or psychologic disorders**. For those who do, however, the disorders can be quite severe, including anxiety, depression, rage, lethargy, irritability, aggressiveness, psychosis, and obsessive-compulsive disorder. Developmental disorders described include neurocognitive delay, developmental regression, attention-deficit/hyperactivity disorder, and pervasive developmental disorder. These disorders are most likely caused by poorly managed hypoventilation because the majority of ROHHAD patients have no behavioral issues and a normal IQ.

**Seizures** have been reported in some ROHHAD patients, likely caused by episodes of hypoxemia, when hypoventilation either has not yet been diagnosed or has been inadequately managed.

**Diagnosis**
The diagnostic criteria for ROHHAD include rapid-onset obesity after 1.5 years of age, central hypoventilation beginning after age 1.5 yr, and ≥1 of the following signs of HD: disordered water balance, hyperprolactinemia, failed GH stimulation test, central hypothyroidism, corticotropin deficiency, and altered onset of puberty. Additionally, it should be confirmed that no CCHS-related PHOX2B gene mutation is present, to rule out a diagnosis of CCHS or LO-CCHS.

Since no single diagnostic test is currently available for ROHHAD, diagnosis must be based on observation of the clinical presentation and therefore requires expert consultation in several specialties, including respiratory physiology, endocrinology, autonomic medicine, cardiology, oncology, nutrition, critical care, and psychiatry. When a child with rapid-onset obesity is seen by a general pediatrician or family physician, the trajectory of weight gain should signal prompt consideration of a ROHHAD diagnosis, with immediate referral to a center with expertise in this unique constellation of symptoms. Early recognition is critical for a positive outcome in children with ROHHAD. If alveolar hypoventilation is not identified and aggressively managed, cardiorespiratory arrest can occur and has proved fatal in many cases.

Initial evaluations should include overnight polysomnography to identify OSA or central hypoventilation, awake comprehensive physiologic recording in activities of daily living, cardiac evaluation to evaluate for cor pulmonale, endocrine function evaluation, screening for neural crest tumors (chest radiograph, abdominopelvic ultrasound), and a psychiatric evaluation, especially if any behavioral, psychologic, or developmental disorders are seen or suspected. Brain imaging should be performed to rule out intracranial lesions that may account for the observed hypothalamic-pituitary abnormalities. If the criteria are met, and a ROHHAD diagnosis is made, successful management requires ongoing cooperation among the various specialists, with a team leader to orchestrate all testing, to provide integrated care for the child.

Management

There is currently no cure for ROHHAD. Rather, treatment consists of early identification, meticulous monitoring, and symptomatic management of the various symptoms as they develop. Comprehensive initial evaluations should determine the nature and severity of hypoventilation, HD, and ANS dysregulation, and appropriate interventions should be implemented. Obesity is
very difficult to control, but in consultation with a nutritionist and endocrinologist, the trajectory of advancing weight gain can be diminished with moderate exercise and calorie restriction, leading to improved body mass index (BMI) with advancing age. Specific signs of HD and ANS dysregulation should be evaluated by a pediatric endocrinologist and expert in pediatric autonomic medicine, respectively, and treated as necessary. Such treatments or management strategies may include hormone replacement; regimented fluid intake; ophthalmologic assessment and treatment; longitudinal monitoring of peripheral, core, and ambient temperature; and management of constipation with stool softeners. Disordered water balance to prevent dehydration should be addressed, as well as regulation of heart rate, since bradycardia is seen in some patients (usually with decreased core temperature).

Neural crest tumors should be assessed and resected by a pediatric surgeon together with a pediatric oncologist, because the sheer size of these benign tumors creates serious compromise to surrounding tissues. If no tumor is identified initially, screening should continue every 6 mo until age 7 yr and thereafter annually.

Most critical is the management of hypoventilation. Initial intervention for OSA will likely involve surgical relief of the upper airway obstruction. This will usually unveil central hypoventilation, and initiation of supported ventilation will be required. If no central hypoventilation is identified, the patient should continue to be vigilantly monitored by a respiratory physiologist because all ROHHAD patients will eventually develop central hypoventilation requiring artificial ventilation. Optimal oxygenation and ventilation can then be maintained using a mechanical ventilator with mask or tracheostomy. This should be accompanied by highly trained home nursing and continuous monitoring with oximetry and capnography during sleep, with spot checks during wakefulness. The goal should be to maintain hemoglobin saturation values of ≥95% and end-tidal CO₂ values of 35-45 mm Hg, with vigilant evaluation for awake hypoventilation necessitating artificial ventilation up to 24 hr/day as necessary.

Given that the ROHHAD phenotype evolves with advancing age, ongoing care requires regularly scheduled evaluation of all the systems involved to identify and treat further symptoms as they appear. Comprehensive evaluation should ideally occur at a Center of Excellence for ROHHAD and should include respiratory physiology assessment both asleep and awake (in ADLs including varied levels of exertion, concentrational tasks, quiet play, and eating),
screening of chest and abdomen for neural crest tumors in the adrenals or along the sympathetic chain, evaluation of the hypothalamic-pituitary axis with hormonal replacement as necessary, age-appropriate noninvasive evaluation of ANS dysregulation, comprehensive cardiac evaluation for evidence of recurrent hypoxemia, and neurocognitive testing. These evaluations should initially occur at 3-6 mo intervals, but this schedule may be altered with advancing age, depending on each patient's clinical condition.

Without proper management, oxygen deprivation can lead to irreversible deterioration in patients. However, with prompt diagnosis and aggressive management, including careful attention to the child's airway, breathing, and circulation, complications can be minimized and the prognosis can be quite favorable, although long-term outcome remains unknown but the focus of an international registry (https://clinicaltrials.gov/show/NCT03135730).

**Etiology: Studies and Hypotheses**

Despite advances made in the characterization of the ROHHAD phenotype and early identification, the cause of the disease is unknown. The interrelationships among the observed symptoms, as well as the mechanisms that underlie them, remain to be elucidated.

**Genetic Studies**

Because the related but seemingly distinct disorder CCHS has a genetic basis (PHOX2B mutation), ROHHAD may be genetic as well. ROHHAD patients do not have CCHS-related PHOX2B mutations, however, and no numerical or structural chromosomal rearrangements have been described. The sporadic occurrence of ROHHAD, without familial recurrence, is consistent with de novo mutations. Exome-sequencing analysis of 7 ROHHAD family trios did not identify any causative de novo protein-altering mutations, or any candidates under autosomal recessive or autosomal dominant inheritance models, even when a replication cohort of 28 additional ROHHAD probands was included.

Another genetic mutation model that can account for sporadic occurrence of a phenotype is a *somatic mutation* model, in which mutations occur postzygotically and are thus only present in a subset of an individual's cells. Consistent with a somatic mutation hypothesis, 2 pairs of monozygotic twins discordant for the ROHHAD phenotype have been reported. The exomes (from
blood samples) of 1 twin pair were compared, but no discordant coding mutations were identified. The challenge is that the “correct” tissue needs to be sampled for the somatic mutation to be identified. In other phenotypes caused by somatic mutations, such as Proteus syndrome, the mutation causes overgrowth, so the affected (mutated) tissue is visible and can be sampled and sequenced. In ROHHAD, presumably the affected (mutated) cells are in the hypothalamus and/or ANS, which cannot be sampled and sequenced from living individuals. The neural crest tumors in many ROHHAD patients might represent an additional affected tissue. The exomes of neural crest tumors from 4 ROHHAD patients were compared to the exomes of blood samples from the same patients, but no tumor-specific mutations were identified.

The observation of monozygotic twins discordant for the ROHHAD phenotype could be consistent with a somatic genetic mutation, but could also suggest an alternative, nongenetic etiology. For example, epigenetic variation can account for some discordance between monozygotic twins and also can play a role in diseases involving respiratory and autonomic function, such as Prader-Willi syndrome (see later) and Rett syndrome.

**Paraneoplastic/Autoimmune Hypothesis**

*Paraneoplastic syndromes* are rare disorders caused by a neoplasm triggering an altered immune response that aberrantly attacks and destroys neurons, leading to the nervous system symptoms. An autoimmune or paraneoplastic basis for ROHHAD has been suggested based on neural crest tumors occurring in 40% of ROHHAD patients and 2 early cases with autopsies revealing low-density lesions in the basal ganglia and neuronal loss from lymphocytic infiltration of the hypothalamus, thalamus, midbrain, and pons. Autopsy of another ROHHAD patient revealed similar findings of hypothalamic inflammation with lymphocytic infiltrates and gliosis, although other autopsies have found no such pathology. Some cerebrospinal fluid (CSF) analyses have revealed pleocytosis, elevated neopterins, and oligoclonal bands consistent with intrathecal synthesis of oligoclonal immunoglobulin G. However, other studies report a lack of oligoclonal IgG and antineuronal antibodies, as well as clear CSF microscopies and cultures. Thus the evidence so far is conflicting, with some reports supporting the autoimmune hypothesis, while others do not. Further, the onset of ROHHAD symptoms often precedes the diagnosis of a neural crest tumor in ROHHAD patients, and in many cases, neural crest tumors have not been
discovered with MRI or even an autopsy, although these tumors are often difficult to detect. However, this is also seen in other paraneoplastic syndromes, such as opsoclonus-myoclonus, where only some cases are associated with a neoplasm, the remainder being idiopathic.

After a patient with idiopathic HD was treated with immune globulin therapy, several other studies pursued similar treatments with immunoglobulins and corticosteroids in ROHHAD patients. After high-dose cyclophosphamide treatment, some ROHHAD patients reported symptomatic and neurophysiologic improvements while others had poor clinical results. Notably, reports indicate that immunotherapy has not consistently halted unfolding and advancing of the unique constellation of symptoms described in ROHHAD. Even with complete tumor resection and immunoablation, only partial recovery has been reported. The lack of return to baseline has been attributed to late treatment, where early rapid progressive disease left residual damage. This would be consistent with an immune-mediated hypothesis, in which an autoimmune process is initiated by a neural crest tumor but maintained in its absence, resulting in irreversible injury that prevents complete symptom resolution.

**Neurocristopathy**

Neurocristopathies are disorders caused by abnormal development of any of the tissues or systems that develop from the embryonic neural crest cell lineage. Given that the systems involved in the ROHHAD phenotype (hypothalamus, ANS, endocrine system) share a neural crest origin, ROHHAD fits into this class. One could then hypothesize that the observed symptoms are caused by abnormal development of neural crest cells at an early embryonic stage. This is indeed the case for the related disorder, CCHS, caused by mutations in the gene *PHOX2B*, which is important for the development of the ANS from neural crest cells. Under this hypothesis, the neural crest tumors seen in ROHHAD patients, rather than being the trigger for the rest of the phenotype (as proposed by the paraneoplastic theory), would be a result of the same abnormal development that caused the rest of the phenotype.

**Differential Diagnosis**

As noted earlier, **congenital central hypoventilation syndrome** is a rare pediatric disorder of the ANS and respiratory control. CCHS is caused by
mutations in the PHOX2B gene, which plays an important role in the
differentiation and development of the ANS from neural crest progenitor cells.
The hallmark feature of CCHS is life-threatening hypoventilation while sleeping
(and in some cases, also while awake). As with ROHHAD patients, CCHS
patients require artificial ventilatory support, typically by tracheostomy and
mechanical ventilator. Unlike ROHHAD, however, CCHS usually presents in the
newborn period, although late-onset CCHS has been diagnosed in later
childhood, adolescence, and even adulthood. CCHS also presents with other
symptoms of ANS dysregulation, including altered heart rate regulation and
altered vasomotor tone, altered temperature regulation, ophthalmologic
manifestations, and reduced gastrointestinal motility. However, CCHS patients
are not obese and do not typically have HD. When hypoventilation is observed, a
simple blood test can confirm a CCHS diagnosis by looking for PHOX2B
mutations. If PHOX2B mutations are not identified and the other features of the
ROHHAD phenotype are identified, a ROHHAD diagnosis must be considered.

**Prader-Willi syndrome** (PWS) is similar to ROHHAD in that childhood
obesity is one of the most prominent features; however, many important
differences set these two conditions apart. PWS is caused by chromosomal
abnormalities at chromosome 15q11-q13, specifically by a lack of the paternal
contribution at this region (from genomic deletion, uniparental disomy, or
imprinting error). Infants with PWS present with neonatal hypotonia and failure
to thrive (malnutrition). Later, children with PWS develop extreme hyperphagia
and obesity. Other major symptoms include mild intellectual impairment,
maladaptive behaviors, short stature caused by GH insufficiency, hypogonadism,
and SDB. In addition, many PWS patients show signs of ANS dysregulation,
including altered temperature perception and regulation, strabismus, and high
pain threshold. Although there are several apparently overlapping symptoms
(pediatric obesity, SDB, ANS dysregulation), ROHHAD patients do not have the
characteristic PWS genomic abnormality, hypogonadism, or consistent
neurocognitive impairment. ROHHAD patients also are healthy in the neonatal
period, showing none of the early PWS symptoms.

Overview of Vitamin A

Vitamin A is a fat-soluble micronutrient that cannot be synthesized de novo by mammals; thus it is an obligatory dietary factor. The term vitamin A is generally used to refer to a group of compounds that possess the biologic activity of all-trans retinol (Fig. 61.1). As a fat-soluble micronutrient, vitamin A is recognized as being essential for all vertebrates for normal vision, reproduction, cell and tissue differentiation, and functions of the immune system. Vitamin A plays critical roles in neonatal development. It is required for normal embryonic development, hematopoiesis, immune response, metabolism, and growth and differentiation of many types of cells.
Vitamin A can be obtained from the diet from preformed vitamin A (retinyl esters, such as retinyl palmitate) primarily in foods of animal origin. Organ meats (especially liver, kidney) are very rich in vitamin A, whereas other meats, milk, and cheese contain moderate levels. Other sources of vitamin A include several provitamin A carotenoids, which are found naturally in many fruits and vegetables, especially yellow-orange vegetables (pumpkin, squash, sweet potato), and leafy green vegetables (chard, spinach, broccoli). One of the most abundant carotenoids is β-carotene. Several cultivars or biofortified forms of sweet potatoes have been introduced to elevate carotene intake in areas of the world where vitamin A deficiency still is prevalent. α-Carotene and oxygenated carotenoids, such as β-cryptoxanthin, found in oranges, also possess vitamin A activity, at a lower bioactivity. In the body, these precursors are used for the synthesis of 2 essential metabolites of vitamin A. All-trans retinoic acid is the form required for cell differentiation and regulation of gene transcription and is the most bioactive form of vitamin A; 11-cis retinal is the form required for vision as the light-absorbing chromophore of the visual pigments rhodopsin and iodopsin.
Metabolism of Vitamin A

Vitamin A compounds in foods must first be released through normal digestive processes. Retinyl esters must first be hydrolyzed in the intestinal lumen to liberate unesterified retinol for absorption across the mucosal barrier. Once in the enterocyte, most of the retinol is reesterified, forming new retinyl esters for inclusion in chylomicrons. Approximately 70–90% of dietary preformed vitamin A is absorbed provided there is ≥10 g fat in the meal; otherwise the absorption efficiency is lower. Chronic intestinal disorders or lipid malabsorption can result in vitamin A deficiency. Provitamin-A carotenoids are transported from the intestinal lumen into the enterocytes by specific transporters, then either incorporated intact into chylomicrons or cleaved to form retinal, a precursor for retinol; β-carotene becomes retinol through this process. The estimated efficiency of absorption of carotenoids is 20–50%, lower than for preformed vitamin A. Moreover, the efficiency is reduced when the body's vitamin A status is high, and because vitamin A status may vary, there is significant interindividual variability in absorption efficiency. The carotene cleavage enzyme β-carotene monooxygenase, present in the enterocyte and in other tissues at lower levels, exhibits certain single nucleotide polymorphisms (SNPs) that, at least in vitro, reduce the efficiency of conversion of β-carotene to retinol. Clinical studies suggest a similar effect in vivo.

Once retinol is esterified in the enterocyte, retinyl ester is then packaged into nascent chylomicrons, which are secreted into the lymphatic vessels, enter the systemic circulation, and are then transported to and taken up by various tissues. When vitamin A status is adequate, in most mammals, including humans, the liver is the major site of chylomicron vitamin A uptake and storage, with potentially high levels of retinyl esters within hepatic stellate cells (HSCs). As vitamin A status deteriorates into the deficient range, vitamin A stores are mobilized from the HSCs, such that the released retinol can be taken up and utilized by extrahepatic tissues. Circulating retinol is bound to a specific transport protein, retinol-binding protein (RBP), which in turn binds to the thyroid hormone transport protein, transthyretin (TTR); this complex delivers plasma retinol (as well as the thyroid hormone) to a large number of vitamin A target tissues. The major physiologic mediator of retinol uptake by cells in many tissues is Stra6, a widely expressed multitransmembrane domain protein that functions as a cell surface receptor for retinol bound to RBP. Stra6 is not significantly expressed in the liver, but a homologous receptor may perform the
similar function. Within target tissues, retinol is either esterified into retinyl esters for storage or oxidized into retinoic acid for function. In the eye, 11-cis-retinal is formed, bound to the protein rhodopsin (rods) or iodopsin (cones), where it functions as a light-sensing receptor.

**Vitamin A Status in Neonates**

Neonates begin life with low levels of vitamin A, in plasma, liver, and extrahepatic tissues, compared with those in adults. Normal plasma levels of retinol are 20-50 µg/dL in infants and increase gradually as children become older. Median serum retinol values are 1.19 µmol/L in both boys and girls ages 4-8 yr; 1.4 and 1.33 µmol/L in boys and girls, respectively, ages 9-13; and 1.71 and 1.57 µmol/L in boys and girls, ages 14-18 (for conversion, 1 µmol/L = 28.6 µg/dL). Values of 1.96 and 1.85 µmol/L are found in 19-30 yr old adult men and women, respectively. **Fig. 61.2** shows the distribution of serum retinol concentrations in U.S. children.

![FIG. 61.2 Distribution of serum retinol concentrations in U.S. children and adults by age and sex in the National Health and Nutrition Examination Survey (NHANES).](image-url)
Retinol levels are even lower in neonates in developing countries, where vitamin A intakes may be low and vitamin A deficiency is a common and significant nutritional problem. Lower vitamin A stores and plasma retinol concentrations are seen in low-birthweight infants and in preterm newborns. Malnutrition, particularly protein deficiency, can cause vitamin A deficiency because of the impaired synthesis of RBP.

Inflammation Causing Low Plasma Retinol

Inflammation is a cause of reduced levels of plasma retinol as a result of reduced synthesis of RBP and TTR. This condition may mimic a lack of vitamin A, but will not be corrected by supplementation. In U.S. adults, those with moderately elevated levels of C-reactive protein (CRP), indicative of mild inflammation, had lower average plasma retinol levels. The extent to which inflammation is a factor in low plasma retinol in children is uncertain but likely significant in acute infectious diseases such as measles, and possibly in chronic inflammatory conditions such as cystic fibrosis.

Functions of Vitamin A and Mechanisms of Action

Except for its role in vision, the pleiotropic actions of this micronutrient are mediated by all-trans-retinoic acid (RA), which is a ligand for specific nuclear transcription factors, the retinoid receptors; RARs and RXRs regulate the expression of several hundred genes. When an RAR is activated by RA, an RAR-RXR complex is formed, which binds to and activates specific DNA sequences present in retinoid-responsive genes, RAREs and RXREs. Genes can be either induced or repressed, depending on additional co-activators or co-repressors recruited to the RAR-RXR complex. Retinoid-regulated genes are involved in several fundamental biologic activities, including regulation of cell division, death, and differentiation. The term retinoids applies to both natural and synthetic compounds with vitamin A activity and is most often used in the context of vitamin A acting at the gene level. Numerous synthetic retinoids have gained clinical acceptance in the treatment of skin disorders and certain cancers.

During embryonic development, retinoic acid is among the most important signaling molecules that determine body patterning (morphogenesis). Many
Physiologic processes are sensitive to a deficiency or excess of vitamin A or RA, including reproduction, growth, bone development, and the functions of the respiratory, gastrointestinal, hematopoietic, and immune systems. Vitamin A, presumably by enhancing immune function and host defense, is particularly important in developing countries; studies show that vitamin A supplementation or therapy reduces morbidity and mortality from various infectious diseases, including measles (see Chapter 273).

Vitamin A plays a critical role in vision, mediated by 11-cis retinal. The human retina contains 2 distinct photoreceptor systems: the rods, in which rhodopsin senses light of low-intensity, and the cones, in which iodopsins detect different colors; 11-cis-retinal is the prosthetic group on both these visual proteins. The mechanism of vitamin A action is similar for rods and cones, based on photoisomerization of 11-cis to all-trans retinal (change shape when exposed to light), which initiates signal transduction via the optic nerve to the brain, resulting in visual sensation. After isomerization (also known as photobleaching), a series of reactions serves to regenerate the 11-cis retinal for resynthesis of rhodopsin and iodopsin; accessory cells, including retinal pigment epithelium and Müller cells, are involved in this recycling process.

**Vitamin A Deficiency**

If the growing child has a well-balanced diet and obtains vitamin A from foods rich in vitamin A or provitamin A (Table 61.1), the risk of vitamin A deficiency is small. However, even subclinical vitamin A deficiency can have serious consequences.

Deficiency states in developed countries are rare, except in some impoverished populations (see Chapter 57), or after mistakes in food preparation or with fad diets, but are common in many developing countries and often associated with global malnutrition. In the clinical setting, vitamin deficiencies can also occur as complications in children with various chronic disorders or diseases. Information obtained in the medical history related to dietary habits can be important in identifying the risk of such nutritional problems. Except for vitamin A, toxicity from excess intake of vitamins is rare. Table 61.1 summarizes the food sources, functions, and deficiency and excess symptoms of the vitamins.

### Clinical Manifestations of Vitamin A Deficiency

The most obvious symptoms of vitamin A deficiency are associated with changes in epithelial cell morphology and functions. In the intestines, mucus-secreting goblet cells are affected, and loss of an effective barrier against pathogens can cause diarrhea or impairment of epithelial barrier function. Similarly, mucus secretion by the epithelium is essential in the respiratory tract for the disposal of inhaled pathogens and toxicants. Characteristic epithelial changes result from vitamin A deficiency, including proliferation of basal cells, hyperkeratosis, and formation of stratified cornified squamous epithelium. Squamous metaplasia of the renal pelves, ureters, vaginal epithelium, and the
pancreatic and salivary ducts can lead to increased infections in these areas. In the urinary bladder, loss of epithelial integrity can result in pyuria and hematuria. In the skin, vitamin A deficiency manifests as dry, scaly, hyperkeratotic patches, typically on the arms, legs, shoulders, and buttocks. The combination of defective epithelial barriers to infection, low immune response, and lowered response to inflammatory stress, all from insufficient vitamin A, can cause poor growth and serious health problems in children.

The most characteristic and specific signs of vitamin A deficiency are eye lesions, but these may manifest rather late in the progression of vitamin A deficiency, develop insidiously, and rarely occur before age 2 yr. An earlier symptom of vitamin A deficiency is delayed dark adaptation, as a result of reduced resynthesis of rhodopsin; this may progress to night blindness. Photophobia is a common symptom. The retinal pigment epithelium (RPE), the structural element of the retina, undergoes keratinization. When the RPE degenerates, the rods and cones have no support and eventually break down, resulting in blindness.

As vitamin A deficiency progresses, the corneal and conjunctival epithelial tissues of the eye become severely altered because of a lack of sufficient RA for normal epithelial cell differentiation. The cornea protects the eye from the environment and is also important in light refraction. Stages in vitamin A deficiency include corneal keratinization and opacity, susceptibility to infection, and formation of dry, scaly layers of cells (xerophthalmia) (Figs. 61.3 and 61.4). The conjunctival membrane undergoes keratinization and may develop foamy-appearing plaques (Bitôt spots; Fig. 61.5). When lymphocytes infiltrate the cornea in later stages of infection, it degenerates irreversibly (keratomalacia and corneal ulceration), resulting in irreversible blindness. These eye lesions are primarily diseases of the young and are a major cause of blindness in developing countries. Although rates of xerophthalmia have fallen, the number of affected children is still too high. Treatment with vitamin A, up to the stage of keratomalacia, is effective in rapidly repleting the individual and saving vision.
FIG. 61.3 Advanced xerophthalmia with an opaque, dull cornea and some damage to the iris in a 1 yr old boy. (From Oomen HAPC: Vitamin A deficiency, xerophthalmia and blindness, Nutr Rev 6:161–166, 1974.)

FIG. 61.4 Recovery from xerophthalmia, showing a permanent eye lesion. (From Bloch CE: Blindness and other disease arising from deficient nutrition [lack of fat soluble A factor], Am J Dis Child 27:139, 1924.)
Other clinical signs of vitamin A deficiency include poor overall growth, diarrhea, susceptibility to infections, anemia, apathy, intellectual impairment, and increased intracranial pressure, with wide separation of the cranial bones at the sutures. There may be vision problems as a consequence of bone overgrowth causing pressure on the optic nerve.

**Malnutrition**, particularly protein deficiency, can cause vitamin A deficiency through impaired synthesis of retinol transport protein. In developing countries, subclinical or clinical zinc deficiency can increase the risk of vitamin A deficiency. There is also some evidence of marginal zinc intakes in U.S. children.

## Diagnosis

Dark adaptation tests can be used to assess early-stage vitamin A deficiency. Although Bitôt spots develop relatively early, those related to active vitamin A deficiency are usually confined to preschool-age children. Xerophthalmia is a very characteristic lesion of vitamin A deficiency. For detection of less severe deficiency (marginal vitamin A status), methods include conjunctival impression cytology, relative dose response, and modified relative dose response tests. A diet history is useful in suggesting or ruling out low intake as a cause of symptoms. Marginal vitamin A status is relatively prevalent among pregnant and lactating women in low-resource (and therefore poor dietary intake) areas of the world. Although plasma retinol level is not a completely accurate indicator of vitamin A status, various guidelines have been proposed for categorizing vitamin
A status based on serum retinol. In children, plasma retinol <0.35 µmol/L is considered very deficient, 0.35-0.7 µmol/L deficient, 0.7-1.05 µmol/L marginal, and >1.05 µmol/L adequate. It has long been thought that a liver vitamin A concentration >20 µg/g is needed to support a normal rate of secretion of retinol-RBP into plasma, and therefore normal delivery of retinol to peripheral tissues.

Epidemiology and Public Health Issues

Vitamin A deficiency and xerophthalmia still occur throughout much of the developing, income-poor world and are linked to undernourishment and complicated by illness. Various public health programs to provide large doses of vitamin A periodically have been instituted. Vitamin A supplementation is considered part of the strategy of the World Health Organization (WHO) Millennium Development Goals to reduce <5 yr mortality. Neonatal supplementation may be most effective in populations with a high incidence of maternal vitamin A deficiency. Other strategies being tested include improving the content of β-carotene in staple foods through plant breeding (biofortification).

Dietary Reference Intakes for the Healthy Population

Table 61.2 summarizes the dietary reference intakes for infants and children. Dietary reference intake values include the estimated average requirement (EAR), which is the mean biologic requirement for the nutrient for the age-sex group of interest; the recommended dietary allowance (RDA), which is set to cover the physiological needs of >97% of the population (thus the needs of many people are more than met by consuming the RDA); and the upper level of normal (UL), an intake level above which risk of adverse effects may increase; the UL pertains only to chronic consumption of preformed vitamin A. The RDA is expressed as retinol activity equivalents (RAEs; 1 RAE = 1 µg all-trans retinol; equivalents for provitamin-A in foods = 12 µg β-carotene, 24 µg α-carotene, or 24 µg β-cryptoxanthin). From infancy to age 18 yr, the RDA increases as a result of increased body size, becoming higher for boys than girls during adolescence. During pregnancy the RDA is 750-770 µg, and during lactation it increases to 1,200-1,300 µg to ensure sufficient vitamin A content during breastfeeding.

It is noteworthy that, especially for young children, the UL is only about 2 times higher than the RDA. This suggests that for children whose diet is good, care should be taken not to overuse dietary supplements (vitamin-mineral supplements) containing preformed vitamin A, and/or to avoid excessive consumption of foods that are very rich in vitamin A, such as liver.

### Vitamin A for Treatment of Deficiency

A daily supplement of 1,500 µg of vitamin A is sufficient for treating latent vitamin A deficiency, after which intake at the RDA level should be the goal. In children without overt signs of vitamin A deficiency but suspected low reserves of vitamin A, rates of morbidity and mortality, as from viral infections such as measles, have been reduced by a weekly doses of vitamin A at the RDA level. More often, higher doses of 30-60 mg of retinol (100,000-200,000 IU/child) are given once or twice, under careful monitoring to avoid toxicity associated with excess vitamin A. Xerophthalmia is treated by giving 1,500 µg/kg body weight orally for 5 days, followed by intramuscular injection of 7,500 µg of vitamin A in oil, until recovery. In neonatal rats, vitamin A given as a supplemental dose only transiently increased retinol levels in most tissues, although liver vitamin A remained higher more persistently.

Vitamin A is also used in preterm infants to improve respiratory function and prevent development of chronic lung disease. An analysis of 9 randomized controlled trials found that vitamin A appears to be beneficial in reducing death or oxygen requirement with no difference in neurodevelopmental outcomes.
Hypervitaminosis A

Chronic hypervitaminosis A results from excessive ingestion of preformed vitamin A (retinol or retinyl ester), generally for several weeks or months. Hypervitaminosis A is most often caused by vitamin A–containing supplements or food faddism, including high intakes of organ meats. Chronic daily intakes of 15,000 µg and 6,000 µg can be toxic in adults and children, respectively. Because there is no antidote for hypervitaminosis A, and vitamin A is readily stored in liver and other tissues, it is most important to prevent toxicity. Symptoms may subside rapidly on withdrawal of the vitamin, but the rate of improvement depends on the amount of vitamin A stored in tissues. Extreme hypervitaminosis A is fatal. Signs of subacute or chronic toxicity can include headache, vomiting (early signs), anorexia, dry itchy desquamating skin, and seborrheic cutaneous lesions. With chronic hypervitaminosis A, one may observe fissuring at the corners of the mouth, alopecia and coarsening of the hair, bone abnormalities and swelling, enlargement of the liver and spleen, diplopia, increased intracranial pressure, irritability, stupor, limited motion, dryness of the mucous membranes, and desquamation of the palms and the soles of the feet. Radiographs may show hyperostosis affecting several long bones, especially in the middle of the shafts (Fig. 61.6). Serum levels of vitamin A are elevated, mostly as retinyl esters carried in lipoproteins, which may result in tissue damage and release of liver enzymes into plasma. Hypercalcemia and/or liver cirrhosis may be present. Hypervitaminosis A is distinct from cortical hyperostosis (see Chapter 720).
FIG. 61.6 Hyperostosis of the ulna and tibia in 21 mo old infant, resulting from vitamin A positioning. A, Long, wavy cortical hyperostosis of the ulna (arrow). B, Long, wavy cortical hyperostosis of the right tibia (arrow), with a striking absence of metaphyseal changes. (From Caffey J: Pediatric x-ray diagnosis, ed 5, Chicago, 1967, Year Book, p 994.)

In young children, signs of vitamin A toxicity include vomiting and bulging fontanels, neither of which is specific. Combined with anorexia, pruritus, and a lack of weight gain, vitamin A toxicity should be considered. Less common symptoms include diplopia, papilledema, cranial nerve palsies, and other symptoms suggesting pseudotumor cerebri.

If high levels of vitamin A or synthetic retinoids are taken early in pregnancy, severe congenital malformations may occur in the fetus. Teratogenicity has been associated with therapeutic doses (0.5-1.5 mg/kg) of oral 13-cis-retinoic acid (e.g., Accutane), generally taken for the treatment of acne or cancer, during the 1st trimester of pregnancy. A high incidence (>20%) of spontaneous abortions and birth defects, including characteristic craniofacial abnormalities, has prompted the U.S. Food and Drug Administration (FDA) to enact more
stringent prescription regulations for such drugs in women of childbearing age, to attempt to reduce these birth defects.

Carotenoids, even in high doses, are not associated with toxicity but can cause yellowing of the skin (*carotenodermia*), including palms of the hands, and high levels in serum (carotenemia); this relatively benign state disappears slowly when carotene intake is reduced. Children with liver disease, diabetes mellitus, or hypothyroidism are more susceptible. Food faddism, such as excessive consumption of carotene-rich foods and juices, may be a cause of carotenodermia.

**Bibliography**

Grune T, Lietz G, Palou A, et al. Beta-carotene is an important

Vitamin B complex includes a number of water-soluble nutrients, including thiamine (vitamin B₁), riboflavin (B₂), niacin (B₃), pyridoxine (B₆), folate, cobalamin (B₁₂), biotin, and pantothenic acid. Choline and inositol are also considered part of the B complex and are important for normal body functions, but specific deficiency syndromes have not been attributed to a lack of these factors in the diet.

B-complex vitamins serve as coenzymes in many metabolic pathways that are functionally closely related. Consequently, a lack of one of the vitamins has the potential to interrupt a chain of chemical processes, including reactions that are dependent on other vitamins, and ultimately can produce diverse clinical manifestations. Because diets deficient in any one of the B-complex vitamins are often poor sources of other B vitamins, manifestations of several vitamin B deficiencies usually can be observed in the same person. It is therefore a general practice in a patient who has evidence of deficiency of a specific B vitamin to treat with the entire B-complex group of vitamins.

62.1
Thiamine (Vitamin B₁)
Thiamine diphosphate, the active form of thiamine, serves as a cofactor for several enzymes involved in carbohydrate catabolism such as pyruvate dehydrogenase, transketolase, and α-ketoglutarate. These enzymes also play a role in the hexose monophosphate shunt that generates nicotinamide adenine dinucleotide phosphate (NADP) and pentose for nucleic acid synthesis. Thiamine is also required for the synthesis of acetylcholine (ACh) and γ-aminobutyric acid (GABA), which have important roles in nerve conduction. Thiamine is absorbed efficiently in the gastrointestinal (GI) tract and may be deficient in persons with GI or liver disease. The requirement of thiamine is increased when carbohydrates are taken in large amounts and during periods of increased metabolism, such as fever, muscular activity, hyperthyroidism, pregnancy, and lactation. Alcohol affects various aspects of thiamine transport and uptake, contributing to the deficiency in alcoholics.

Pork (especially lean), fish, and poultry are good nonvegetarian dietary sources of thiamine. Main sources of thiamine for vegetarians are rice, oat, wheat, and legumes. Most ready-to-eat breakfast cereals are enriched with thiamine. Thiamine is water soluble and heat labile; most of the vitamin is lost when the rice is repeatedly washed and the cooking water is discarded. The breast milk of a well-nourished mother provides adequate thiamine; breastfed infants of thiamine-deficient mothers are at risk for deficiency. Thiamine antagonists (coffee, tea) and thiaminases (fermented fish) may contribute to thiamine deficiency. Most infants and older children consuming a balanced diet obtain an adequate intake of thiamine from food and do not require supplements.

**Thiamine Deficiency**

Deficiency of thiamine is associated with severely malnourished states, including malignancy and following surgery. The disorder (or spectrum of
disorders) is classically associated with a diet consisting largely of polished rice (oriental beriberi); it can also arise if highly refined wheat flour forms a major part of the diet, in alcoholic persons, and in food faddists (occidental beriberi). Thiamine deficiency has often been reported from inhabitants of refugee camps consuming the polished rice–based monotonous diets. Low thiamine concentrations are also noted during critical illnesses.

**Thiamine-responsive megaloblastic anemia (TRMA) syndrome** is a rare autosomal recessive disorder characterized by megaloblastic anemia, diabetes mellitus, and sensorineural hearing loss, responding in varying degrees to thiamine treatment. The syndrome occurs because of mutations in the SLC19A2 gene, encoding a thiamine transporter protein, leading to abnormal thiamine transportation and cellular vitamin deficiency. Another dependency state, **biotin and thiamine–responsive basal ganglia disease**, results from mutations in the SLC19A3 gene; presents with lethargy, poor contact, and poor feeding in early infancy; and responds to combined treatment with biotin and thiamine. Thiamine and related vitamins may improve the outcome in children with Leigh encephalomyelopathy and type 1 diabetes mellitus.

**Clinical Manifestations**

Thiamine deficiency can develop within 2-3 mo of a deficient intake. Early symptoms of thiamine deficiency are nonspecific, such as fatigue, apathy, irritability, depression, drowsiness, poor mental concentration, anorexia, nausea, and abdominal discomfort. As the condition progresses, more-specific manifestations of **beriberi** develop, such as peripheral neuritis (manifesting as tingling, burning, paresthesias of the toes and feet), decreased deep tendon reflexes, loss of vibration sense, tenderness and cramping of the leg muscles, heart failure, and psychologic disturbances. Patients can have ptosis of the eyelids and atrophy of the optic nerve. Hoarseness or aphonia caused by paralysis of the laryngeal nerve is a characteristic sign. Muscle atrophy and tenderness of the nerve trunks are followed by ataxia, loss of coordination, and loss of deep sensation. Later signs include increased intracranial pressure, meningismus, and coma. The clinical picture of thiamine deficiency is usually divided into a dry (neuritic) type and a wet (cardiac) type. The disease is wet or dry depending on the amount of fluid that accumulates in the body because of cardiac and renal dysfunction, even though the exact cause for this edema is unknown. Many cases of thiamine deficiency show a mixture of both features.
and are more properly termed thiamine deficiency with cardiopathy and peripheral neuropathy.

The classic clinical triad of Wernicke encephalopathy—mental status changes, ocular signs, and ataxia—is rarely reported in infants and young children with severe deficiency secondary to malignancies or feeding of defective formula. An epidemic of life-threatening thiamine deficiency was seen in infants fed a defective soy-based formula that had undetectable thiamine levels. Manifestations included emesis, lethargy, restlessness, ophthalmoplegia, abdominal distention, developmental delay, failure to thrive (malnutrition), lactic acidosis, nystagmus, diarrhea, apnea, seizures, and auditory neuropathy. An acute presentation with tachycardia, moaning, and severe metabolic acidosis responding to parenteral thiamine has been occasionally reported in infants of mothers consuming polished and frequently washed rice.

Death from thiamine deficiency usually is secondary to cardiac involvement. The initial signs are cyanosis and dyspnea, but tachycardia, enlargement of the liver, loss of consciousness, and convulsions can develop rapidly. The heart, especially the right side, is enlarged. The electrocardiogram (ECG) shows an increased QT interval, inverted T waves, and low voltage. These changes, as well as the cardiomegaly, rapidly revert to normal with treatment, but without prompt treatment, cardiac failure can develop rapidly and result in death. In fatal cases of beriberi, lesions are principally located in the heart, peripheral nerves, subcutaneous tissue, and serous cavities. The heart is dilated, and fatty degeneration of the myocardium is common. Generalized edema or edema of the legs, serous effusions, and venous engorgement are often present. Degeneration of myelin and axon cylinders of the peripheral nerves, with wallerian degeneration beginning in the distal locations, is also common, particularly in the lower extremities. Lesions in the brain include vascular dilation and hemorrhage.

**Diagnosis**

The diagnosis is often suspected based on clinical setting and compatible symptoms. A high index of suspicion in children presenting with unexplained cardiac failure may sometimes be lifesaving. Objective biochemical tests of thiamine status include measurement of erythrocyte transketolase activity and the thiamine pyrophosphate effect. The biochemical diagnostic criteria of thiamine deficiency consist of low erythrocyte transketolase activity and high
thiamine pyrophosphate effect (normal range: 0–14%). Urinary excretion of thiamine or its metabolites (thiazole or pyrimidine) after an oral loading dose of thiamine may also be measured to help identify the deficiency state. MRI changes of thiamine deficiency in infants are characterized by bilateral symmetric hyperintensities of the basal ganglia and frontal lobe, in addition to the lesions in the mammillary bodies, periaqueductal region, and thalami described in adults.

**Prevention**

A maternal diet containing sufficient amounts of thiamine prevents thiamine deficiency in breastfed infants, and infant formulas marketed in all developed countries provide recommended levels of intake. During complementary feeding, adequate thiamine intake can be achieved with a varied diet that includes meat and enriched or whole-grain cereals. When the staple cereal is polished rice, special efforts need to be made to include legumes and/or nuts in the ration. Thiamine and other vitamins can be retained in rice by *parboiling*, a process of steaming the rice in the husk before milling. Improvement in cooking techniques, such as not discarding the water used for cooking, minimal washing of grains, and reduction of cooking time helps to minimize the thiamine losses during the preparation of food. Thiamine supplementation should be ensured during total parenteral nutrition (TPN).

**Treatment**

In the absence of GI disturbances, oral administration of thiamine is effective. Children with cardiac failure, convulsions, or coma should be given 10 mg of thiamine intramuscularly (IM) or intravenously (IV) daily for the 1st wk. This treatment should then be followed by 3-5 mg/day of thiamine orally (PO) for at least 6 wk. The response is dramatic in infants and in those having predominantly cardiovascular manifestations, whereas the neurologic response is slow and often incomplete. Epilepsy, mental disability, and language and auditory problems of varying degree have been reported in survivors of severe infantile thiamine deficiency.

Patients with beriberi often have other B-complex vitamin deficiencies; therefore, all other B-complex vitamins should also be administered. Treatment of TRMA and other dependency states require higher dosages (100-200 mg/day).
The anemia responds well to thiamine administration, and insulin for associated diabetes mellitus can also be discontinued in many patients with TRMA syndrome.

**Thiamine Toxicity**

There are no reports of adverse effects from consumption of excess thiamine by ingestion of food or supplements. A few isolated cases of pruritus and anaphylaxis have been reported in patients after parenteral administration of vitamin B$_1$.

Riboflavin (Vitamin B₂)

H.P.S. Sachdev, Dheeraj Shah

Keywords

- ariboflavinosis
- angular cheilosis
- glossitis
- riboflavin deficiency

Riboflavin is part of the structure of the coenzymes flavin adenine dinucleotide (FAD) and flavin mononucleotide, which participate in oxidation-reduction (redox) reactions in numerous metabolic pathways and in energy production via the mitochondrial respiratory chain. Riboflavin is stable to heat but is destroyed by light. Milk, eggs, organ meats, legumes, and mushrooms are rich dietary sources of riboflavin. Most commercial cereals, flours, and breads are enriched with riboflavin.

Riboflavin Deficiency

The causes of riboflavin deficiency (ariboflavinosis) are mainly related to malnourished and malabsorptive states, including GI infections. Treatment with some drugs, such as probenecid, phenothiazine, or oral contraceptives (OCs), can also cause the deficiency. The side chain of the vitamin is photochemically destroyed during phototherapy for hyperbilirubinemia, since it is involved in the photosensitized oxidation of bilirubin to more polar excretable compounds.
Isolated complex II deficiency, a rare mitochondrial disease manifesting in infancy and childhood, responds favorably to riboflavin supplementation and thus can be termed a dependency state. Brown-Vialetto-Van Laere syndrome (BVVLS), a rare, potentially lethal neurologic disorder characterized by rapidly progressive neurologic deterioration, peripheral neuropathy, hypotonia, ataxia, sensorineural hearing loss, optic atrophy, pontobulbar palsy, and respiratory insufficiency, responds to treatment with high doses of riboflavin if treated early in the disease course. Mutations in SLC52A2 gene (autosomal recessive), encoding riboflavin transporter proteins, have been identified in children with BVVLS.

Clinical Manifestations

Clinical features of nutritional riboflavin deficiency include cheilosis, glossitis, keratitis, conjunctivitis, photophobia, lacrimation, corneal vascularization, and seborrheic dermatitis. Cheilosis begins with pallor at the angles of the mouth and progresses to thinning and maceration of the epithelium, leading to fissures extending radially into the skin (Fig. 62.1). In glossitis the tongue becomes smooth, with loss of papillary structure (Fig. 62.2). Normochromic, normocytic anemia may also be seen because of the impaired erythropoiesis. A low riboflavin content of the maternal diet has been linked to congenital heart defects, but the evidence is weak.

**FIG. 62.1** Angular cheilosis with ulceration and crusting. (Courtesy of National Institute of Nutrition, Indian Council of Medical Research, Hyderabad, India.)

**Diagnosis**

Most often, the diagnosis is based on the clinical features of angular cheilosis in a malnourished child, who responds promptly to riboflavin supplementation. A functional test of riboflavin status is done by measuring the activity of erythrocyte glutathione reductase (EGR), with and without the addition of FAD. An EGR activity coefficient (ratio of EGR activity with added FAD to EGR activity without FAD) of >1.4 is used as an indicator of deficiency. Urinary excretion of riboflavin <30 µg/24 hr also suggests low intakes.

**Prevention**

Table 62.1 lists the recommended daily allowance of riboflavin for infants, children, and adolescents. Adequate consumption of milk, milk products, and eggs prevents riboflavin deficiency. Fortification of cereal products is helpful for those who follow vegan diets or who are consuming inadequate amounts of milk products for other reasons.

</table>

* For healthy breastfed infants, the values represent adequate intakes, that is, the mean intake of apparently “normal” infants.

PO, Orally; IM, intramuscularly; IV, intravenously; INH, isoniazid; NAD, nicotinamide adenine dinucleotide; NADP, nicotinamide adenine dinucleotide phosphate; OCP, oral contraceptive pill; RDA, recommended dietary allowance.

From Dietary reference intakes (DRIs): *Recommended dietary allowances and adequate intakes, vitamins*, Food and Nutrition Board, Institute of Medicine, National Academies. 

**Treatment**

Treatment includes oral administration of 3-10 mg/day of riboflavin, often as an ingredient of a vitamin B–complex mix. The child should also be given a well-balanced diet, including milk and milk products.

**Riboflavin Toxicity**

No adverse effects associated with riboflavin intakes from food or supplements have been reported, and the upper safe limit for consumption has not been established. Although the photosensitizing property of vitamin B\textsubscript{2} suggests some potential risks, limited absorption in high-intake situations precludes such
concerns.

### 62.3

**Niacin (Vitamin B₃ )**

*H.P.S. Sachdev, Dheeraj Shah*

**Keywords**

dermatitis
dementia
niacin deficiency
pellagra
Niacin (nicotinamide or nicotinic acid) forms part of two cofactors, nicotinamide adenine dinucleotide (NAD) and NADP, which are important in several biologic reactions, including the respiratory chain, fatty acid and steroid synthesis, cell differentiation, and DNA processing. Niacin is rapidly absorbed from the stomach and the intestines and can also be synthesized from tryptophan in the diet.

Major dietary sources of niacin are meat, fish, and poultry for nonvegetarians and cereals, legumes, and green leafy vegetables for vegetarians. Enriched and fortified cereal products and legumes also are major contributors to niacin intake. Milk and eggs contain little niacin but are good sources of tryptophan, which can be converted to NAD (60 mg tryptophan = 1 mg niacin).

**Niacin Deficiency**

**Pellagra**, the classic niacin deficiency disease, occurs chiefly in populations where corn (maize), a poor source of tryptophan, is the major foodstuff. A severe dietary imbalance, such as in anorexia nervosa and in war or famine conditions, also can cause pellagra. Pellagra can also develop in conditions associated with disturbed tryptophan metabolism, such as carcinoid syndrome and Hartnup disease.

**Clinical Manifestations**

The early symptoms of pellagra are vague: anorexia, lassitude, weakness, burning sensation, numbness, and dizziness. After a long period of deficiency, the classic triad of dermatitis, diarrhea, and dementia appears. **Dermatitis**, the most characteristic manifestation of pellagra, can develop suddenly or insidiously and may be initiated by irritants, including intense sunlight. The lesions first appear as symmetric areas of erythema on exposed surfaces, resembling sunburn, and might go unrecognized. The lesions are usually sharply demarcated from the surrounding healthy skin, and their distribution can change frequently. The lesions on the hands and feet often have the appearance of a glove or stocking (Fig. 62.3). Similar demarcations can also occur around the neck (Casal necklace) (Fig. 62.3). In some cases, vesicles and bullae develop (wet type). In others there may be suppuration beneath the scaly, crusted epidermis; in still others the swelling can disappear after a short time, followed by desquamation (Fig. 62.4). The healed parts of the skin might remain
pigmented. The cutaneous lesions may be preceded by or accompanied by stomatitis, glossitis, vomiting, and diarrhea. Swelling and redness of the tip of the tongue and its lateral margins is often followed by intense redness, even ulceration, of the entire tongue and the papillae. Nervous symptoms include depression, disorientation, insomnia, and delirium.

**FIG. 62.3** Characteristic skin lesions of pellagra on hands and lesions on the neck (Casal necklace). (Courtesy of Dr. J.D. MacLean, McGill Centre for Tropical Diseases, Montreal.)
The classic symptoms of pellagra usually are not well developed in infants and young children, but anorexia, irritability, anxiety, and apathy are common. Young patients might also have sore tongues and lips and usually have dry scaly skin. Diarrhea and constipation can alternate, and anemia can occur. Children who have pellagra often have evidence of other nutritional deficiency diseases.

**Diagnosis**

Because of lack of a good functional test to evaluate niacin status, the diagnosis of deficiency is usually made from the physical signs of glossitis, GI symptoms, and a symmetric dermatitis. Rapid clinical response to niacin is an important confirmatory test. A decrease in the concentration and/or a change in the proportion of the niacin metabolites N\(^1\)-methyl-nicotinamide and 2-pyridone in the urine provide biochemical evidence of deficiency and can be seen before the appearance of overt signs of deficiency. Histopathologic changes from the
affected skin include dilated blood vessels without significant inflammatory infiltrates, ballooning of the keratinocytes, hyperkeratosis, and epidermal necrosis.

**Prevention**

Adequate intakes of niacin are easily met by consumption of a diet that consists of a variety of foods and includes meat, eggs, milk, and enriched or fortified cereal products. The **dietary reference intake (DRI)** is expressed in milligram niacin equivalents (NE) in which 1 mg NE = 1 mg niacin or 60 mg tryptophan. An intake of 2 mg of niacin is considered adequate for infants 0-6 mo of age, and 4 mg is adequate for infants 7-12 mo. For older children, the recommended intakes are 6 mg for 1-3 yr of age, 8 mg for 4-8 yr, 12 mg for 9-13 yr, and 14-16 mg for 14-18 yr of age.

**Treatment**

Children usually respond rapidly to treatment. A liberal and varied diet should be supplemented with 50-300 mg/day of niacin; in severe cases or in patients with poor intestinal absorption, 100 mg may be given IV. The diet should also be supplemented with other vitamins, especially other B-complex vitamins. Sun exposure should be avoided during the active phase of pellagra, and the skin lesions may be covered with soothing applications. Other coexisting nutrient deficiencies such as iron-deficiency anemia should be treated. Even after successful treatment, the diet should continue to be monitored to prevent recurrence.

**Niacin Toxicity**

No toxic effects are associated with the intake of naturally occurring niacin in foods. Shortly after the ingestion of large doses of nicotinic acid taken as a supplement or a pharmacologic agent, a person often experiences a burning, tingling, and itching sensation as well as flushing on the face, arms, and chest. Large doses of niacin also can have nonspecific GI effects and can cause cholestatic jaundice or hepatotoxicity. Tolerable upper intake levels for children are approximately double the recommended dietary allowance.

62.4

Vitamin B$_6$ (Pyridoxine)

*H.P.S. Sachdev, Dheeraj Shah*

Keywords

pyridoxine deficiency
pyridoxine-dependent epilepsy
vitamin B$_6$

Vitamin B$_6$ includes a group of closely related compounds: pyridoxine, pyridoxal, pyridoxamine, and their phosphorylated derivatives. *Pyridoxal 5’-phosphate (PLP)* and, to a lesser extent, pyridoxamine phosphate function as coenzymes for many enzymes involved in amino acid metabolism,
neurotransmitter synthesis, glycogen metabolism, and steroid action. If vitamin 
B₆ is lacking, glycine metabolism can lead to oxaluria. The major excretory 
product in the urine is 4-pyridoxic acid.

The vitamin B₆ content of human milk and infant formulas is adequate. Good 
food sources of the vitamin include fortified ready-to-eat cereals, meat, fish, 
poultry, liver, bananas, rice, and certain vegetables. Large losses of the vitamin 
can occur during high-temperature processing of foods or milling of cereals, 
whereas parboiling of rice prevents its loss.

**Vitamin B₆ Deficiency**

Because of the importance of vitamin B₆ in amino acid metabolism, high protein 
intakes can increase the requirement for the vitamin; the recommended daily 
allowances are sufficient to cover the expected range of protein intake in the 
population. The risk of deficiency is increased in persons taking medications that 
inhibit the activity of vitamin B₆ (e.g., isoniazid, penicillamine, corticosteroids, 
phenytoin, carbamazepine), in young women taking oral progesterone-estrogen 
OCs, and in patients receiving maintenance dialysis.

**Clinical Manifestations**

The vitamin B₆ deficiency symptoms seen in infants are listlessness, irritability, 
seizures, vomiting, and failure to thrive. Peripheral neuritis is a feature of 
deficiency in adults but is not usually seen in children. Electroencephalogram 
(EEG) abnormalities have been reported in infants as well as in young adults in 
controlled depletion studies. Skin lesions include cheilosis, glossitis, and 
seborrheic dermatitis around the eyes, nose, and mouth. Microcytic anemia can 
occur in infants but is not common. Oxaluria, oxalic acid bladder stones, 
hyperglycinemia, lymphopenia, decreased antibody formation, and infections 
also are associated with vitamin B₆ deficiency.

Several types of vitamin B₆ dependence syndromes, presumably resulting 
from errors in enzyme structure or function, respond to very large amounts of 
pyridoxine. These syndromes include pyridoxine-dependent epilepsy, a vitamin 
B₆ –responsive anemia, xanthurenic aciduria, cystathioninuria, and 
homocystinuria (see Chapter 103 ). Pyridoxine-dependent epilepsy involves
mutations in the ALDH7A1 gene causing deficiency of antiquitin, an enzyme involved in dehydrogenation of L-α-aminoacidic semialdehyde.

**Diagnosis**

The activity of aspartate (glutamic-oxaloacetic) transaminase (AST) and alanine (glutamic-pyruvic) transaminase (ALT) is low in vitamin B$_6$ deficiency; tests measuring the activity of these enzymes before and after the addition of PLP may be useful as indicators of vitamin B$_6$ status. Abnormally high xanthurenic acid excretion after tryptophan ingestion also provides evidence of deficiency. Plasma PLP assays are being used more often, but factors such as inflammation, renal function, and hypoalbuminemia can influence the results. Ratios between substrate-products pairs (e.g., PAr index, 3-hydroxykynurenine/xanthurenic acid ratio, oxoglutarate/glutamate ratio) may attenuate such influence. Quantification of a large number of metabolites, using mass spectrometry–based metabolomics, are being evaluated as functional biomarkers of pyridoxine status.

Vitamin B$_6$ deficiency or dependence should be suspected in all infants with seizures. If more common causes of infantile seizures have been eliminated, 100 mg of pyridoxine can be injected, with EEG monitoring if possible. If the seizure stops, vitamin B$_6$ deficiency should be suspected. In older children, 100 mg of pyridoxine may be injected IM while the EEG is being recorded; a favorable response of the EEG suggests pyridoxine deficiency.

**Prevention**

Deficiency is unlikely in children consuming diets that meet their energy needs and contain a variety of foods. Parboiling of rice prevents the loss of vitamin B$_6$ from the grains. The DRIs for vitamin B$_6$ are 0.1 mg/day for infants up to 6 mo of age; 0.3 mg/day for 6 mo to 1 yr; 0.5 mg/day for 1-3 yr; 0.6 mg/day for 4-8 yr; 1.0 mg/day for 9-13 yr; and 1.2-1.3 mg/day for 14-18 yr. Infants whose mothers have received large doses of pyridoxine during pregnancy are at increased risk for seizures from pyridoxine dependence, and supplements during the 1st few weeks of life should be considered. Any child receiving a pyridoxine antagonist, such as isoniazid, should be carefully observed for neurologic manifestations; if these develop, vitamin B$_6$ should be administered or the dose of the antagonist should be decreased.
Treatment

Intramuscular or intravenous administration of 100 mg of pyridoxine is used to treat convulsions caused by vitamin B₆ deficiency. One dose should be sufficient if adequate dietary intake follows. For pyridoxine-dependent children, daily doses of 2-10 mg IM or 10-100 mg PO may be necessary.

Vitamin B₆ Toxicity

Adverse effects have not been associated with high intakes of vitamin B₆ from food sources. However, ataxia and sensory neuropathy have been reported with dosages as low as 100 mg/day in adults taking vitamin B₆ supplements for several months.

62.5

Biotin
Biotin (vitamin B₇ or vitamin H) functions as a cofactor for enzymes involved in carboxylation reactions within and outside mitochondria. These biotin-dependent carboxylases catalyze key reactions in gluconeogenesis, fatty acid metabolism, and amino acid catabolism.

There is limited information on the biotin content of foods; biotin is believed to be widely distributed, making a deficiency unlikely. Avidin found in raw egg whites acts as a biotin antagonist. Signs of biotin deficiency have been demonstrated in persons who consume large amounts of raw egg whites over long periods. Deficiency also has been described in infants and children receiving enteral and parenteral nutrition formula that lack biotin. Treatment with valproic acid may result in a low biotinidase activity and/or biotin deficiency.

The clinical findings of biotin deficiency include scaly periorificial dermatitis, conjunctivitis, thinning of hair, and alopecia (Fig. 62.5). Central nervous system (CNS) abnormalities seen with biotin deficiency are lethargy, hypotonia, seizures, ataxia, and withdrawn behavior. Biotin deficiency can be successfully treated using 1-10 mg of biotin orally daily. The adequate dietary intake values for biotin are 5 µg/day for ages 0-6 mo, 6 µg/day for 7-12 mo, 8 µg/day for 1-3 yr, 12 µg/day for 4-8 yr, 20 µg/day for 9-13 yr, and 25 µg/day for 14-18 yr. No toxic effects have been reported with very high doses.
Biotin-responsive basal ganglia disease or biotin and thiamine–responsive basal ganglia disease is a rare childhood neurologic disorder characterized by encephalopathy, seizures, extrapyramidal manifestations, altered signals in basal ganglia (bilateral involvement of caudate nuclei and putamen with sparing of globus pallidus) on MRI, and homozygous missense mutation in the SLC19A3 gene. Chapter 103 describes conditions involving deficiencies in the enzymes holocarboxylase synthetase and biotinidase that respond to treatment with biotin.

Bibliography

62.6

**Folate**

*H.P.S. Sachdev, Dheeraj Shah*

**Keywords**

- folic acid deficiency
- megaloblastic anemia
- neural tube defects

Folate exists in a number of different chemical forms. **Folic acid** (pteroylglutamic acid) is the synthetic form used in fortified foods and supplements. Naturally occurring folates in foods retain the core chemical structure of pteroylglutamic acid but vary in their state of reduction, the single-carbon moiety they bear, or the length of the glutamate chain. These polyglutamates are broken down and reduced in the small intestine to dihydro- and tetrahydrofolates, which are involved as coenzymes in amino acid and nucleotide metabolism as acceptors and donors of 1-carbon units. Folate is important for CNS development during embryogenesis.

Rice and cereals are rich dietary sources of folate, especially if enriched. Beans, leafy vegetables, and fruits such as oranges and papaya are good sources as well. The vitamin is readily absorbed from the small intestine and is broken down to monoglutamate derivatives by mucosal polyglutamate hydrolases. A high-affinity proton-coupled folate transporter (PCFT) seems to be essential for absorption of folate in intestine and in various cell types at low pH. The vitamin is also synthesized by colonic bacteria, and its half-life is prolonged by
enterohepatic recirculation.

**Folate Deficiency**

Because of folate's role in protein, DNA, and RNA synthesis, the risk of deficiency is increased during periods of rapid growth or increased cellular metabolism. Folate deficiency can result from poor nutrient content in diet, inadequate absorption (celiac disease, inflammatory bowel disease), increased requirement (sickle cell anemia, psoriasis, malignancies, periods of rapid growth as in infancy and adolescence), or inadequate utilization (long-term treatment with high-dose nonsteroidal antiinflammatory drugs; anticonvulsants such as phenytoin and phenobarbital; methotrexate). Rare causes of deficiency are hereditary folate malabsorption, inborn errors of folate metabolism (methylene tetrahydrofolate reductase, methionine synthase reductase, and glutamate formiminotransferase deficiencies), and cerebral folate deficiency. A loss-of-function mutation in the gene coding for PCFT is the molecular basis for hereditary folate malabsorption. A high-affinity blocking autoantibody against the membrane-bound folate receptor in the choroid plexus preventing its transport across the blood-brain barrier is the likely cause of the infantile cerebral folate deficiency.

**Clinical Manifestations**

Folic acid deficiency results in megaloblastic anemia and hypersegmentation of neutrophils. Nonhematologic manifestations include glossitis, listlessness, and growth retardation not related to anemia. An association exists between low maternal folate status and neural tube defects, primarily spina bifida and anencephaly, and the role of periconceptional folic acid in their prevention is well established (see Chapter 481.1).

**Hereditary folate malabsorption** manifests at 1-3 mo of age with recurrent or chronic diarrhea, failure to thrive (malnutrition), oral ulcerations, neurologic deterioration, megaloblastic anemia, and opportunistic infections. **Cerebral folate deficiency** manifests at 4-6 mo of age with irritability, microcephaly, developmental delay, cerebellar ataxia, pyramidal tract signs, choreoathetosis, ballismus, seizures, and blindness as a result of optic atrophy. 5-Methyltetrahydrofolate levels are normal in serum and red blood cells (RBCs) but greatly depressed in the cerebrospinal fluid (CSF).
Diagnosis

The diagnosis of folic acid deficiency anemia is made in the presence of macrocytosis along with low folate levels in serum or RBCs. Normal serum folic acid levels are 5-20 ng/mL; with deficiency, levels are <3 ng/mL. Levels of RBC folate are a better indicator of chronic deficiency. The normal RBC folate level is 150-600 ng/mL of packed cells. The bone marrow is hypercellular because of erythroid hyperplasia, and megaloblastic changes are prominent. Large, abnormal neutrophilic forms (giant metamyelocytes) with cytoplasmic vacuolation also are seen.

Cerebral folate deficiency is associated with low levels of 5-methyltetrahydrofolate in CSF and normal folate levels in the plasma and RBCs. Mutations in the PCFT gene are demonstrated in the hereditary folate malabsorption.

Prevention

Breastfed infants have better folate nutrition than nonbreastfed infants throughout infancy. Consumption of folate-rich foods and food fortification programs are important to ensure adequate intake in children and in women of childbearing age. The DRIs for folate are 65 µg of dietary folate equivalents (DFE) for infants 0-6 mo of age and 80 µg of DFE for infants 6-12 mo. (1 DFE = 1 µg food folate = 0.6 µg of folate from fortified food or as a supplement consumed with food = 0.5 µg of a supplement taken on an empty stomach.) For older children, the DRIs are 150 µg of DFE for ages 1-3 yr; 200 µg DFE for 4-8 yr; 300 µg DFE for 9-13 yr; and 400 µg DFE for 14-18 yr. All women desirous of becoming pregnant should consume 400-800 µg folic acid daily; the dose is 4 mg/day in those having delivered a child with neural tube defect. To be effective, supplementation should be started at least 1 mo before conception and continued through the 1st 2-3 mo of pregnancy. The benefit of periconceptional folate supplementation in prevention of congenital heart defects, orofacial clefts, and autistic spectrum disorders is unclear. Preconceptional folate supplementation continued throughout pregnancy may marginally reduce the risk of delivering a small-for-gestational-age infant. Providing iron and folic acid tablets for prevention of anemia in children and pregnant women is a routine strategy in at-risk populations. Mandatory fortification of cereal flours with folic acid coupled with health-education programs has been associated with a substantial reduction
in incidence of neural tube defects in many countries.

**Treatment**

When the diagnosis of folate deficiency is established, folic acid may be administered orally or parenterally at 0.5-1.0 mg/day. Folic acid therapy should be continued for 3-4 wk or until a definite hematologic response has occurred. Maintenance therapy with 0.2 mg of folate is adequate. Prolonged treatment with oral folinic acid is required in cerebral folate deficiency, and the response may be incomplete. High-dose intravenous folinic acid may help in refractory cases. Treatment of hereditary folate malabsorption may be possible with intramuscular folinic acid; some patients may respond to high-dose oral folinic acid therapy.

**Folate Toxicity**

No adverse effects have been associated with consumption of the amounts of folate normally found in fortified foods. Excessive intake of folate supplements might obscure and potentially delay the diagnosis of vitamin $B_{12}$ deficiency. Massive doses given by injection have the potential to cause neurotoxicity.

Vitamin B_{12} (Cobalamin)

H.P.S. Sachdev, Dheeraj Shah

Keywords

cyanocobalamin
hydroxocobalamin
intrinsic factor
methyl cobalamin

Vitamin B_{12}, in the form of deoxyadenosylcobalamin, functions as a cofactor for isomerization of methylmalonyl-CoA to succinyl-CoA, an essential reaction in lipid and carbohydrate metabolism. Methylcobalamin is another circulating form of vitamin B_{12} and is essential for methyl group transfer during the conversion of homocysteine to methionine. This reaction also requires a folic acid cofactor and is important for protein and nucleic acid biosynthesis. Vitamin
B$_{12}$ is important for hematopoiesis, CNS myelination, and mental and psychomotor development (Fig. 62.6).

Dietary sources of vitamin B$_{12}$ are almost exclusively from animal foods. Organ meats, muscle meats, seafood (mollusks, oysters, fish), poultry, and egg yolk are rich sources. Fortified ready-to-eat cereals and milk and their products
are the important sources of the vitamin for vegetarians. Human milk is an adequate source for breastfeeding infants if the maternal serum B_{12} levels are adequate. Vitamin B_{12} is absorbed from ileum at alkaline pH after binding with intrinsic factor. Enterohepatic circulation, direct absorption, and synthesis by intestinal bacteria are additional mechanisms helping to maintain the vitamin B_{12} nutriture.

**Vitamin B_{12} Deficiency**

Deficiency of vitamin B_{12} caused by inadequate dietary intake occurs primarily in persons consuming strict vegetarian or vegan diets. Prevalence of vitamin B_{12} deficiency is high in predominantly vegetarian or lactovegetarian populations. Breastfeeding infants of B_{12}-deficient mothers are also at risk for significant deficiency. Malabsorption of B_{12} occurs in celiac disease, ileal resections, Crohn disease, *Helicobacter pylori* infection, and autoimmune atrophic gastritis (pernicious anemia). Use of metformin, proton pump inhibitors, and histamine (H_{2}) receptor antagonists may increase the risk of deficiency. Hereditary intrinsic factor deficiency and Imerslund-Gräsbeck disease are inborn errors of metabolism leading to vitamin B_{12} malabsorption. Mutations in the hereditary intrinsic factor gene cause hereditary intrinsic factor deficiency, whereas mutations in any of the 2 subunits (cubilin and amnionless) of the intrinsic factor receptor cause Imerslund-Gräsbeck disease.

**Clinical Manifestations**

The hematologic manifestations of vitamin B_{12} deficiency are similar to manifestations of folate deficiency and are discussed in Chapter 481.2. Irritability, hypotonia, developmental delay, developmental regression, and involuntary movements (predominantly coarse tremors) are the common neurologic symptoms in infants. Older children with vitamin B_{12} deficiency may show poor growth and poor school performance, whereas sensory deficits, paresthesias, peripheral neuritis, and psychosis are seen in adults. Hyperpigmentation of the knuckles and palms is another common observation with B_{12} deficiency in children (Fig. 62.7). Maternal B_{12} deficiency may also be an independent risk factor for fetal neural tube defects.
FIG. 62.7 Hyperpigmentation of knuckles in an infant with vitamin B$_{12}$ deficiency and megaloblastic anemia.

**Diagnosis**

See Chapter 481.2.

**Treatment**

The hematologic symptoms respond promptly to parenteral administration of 250-1,000 µg vitamin B$_{12}$. Children with severe deficiency and those with neurologic symptoms need repeated doses, daily or on alternate days in first week, followed by weekly for the 1st 1-2 mo and then monthly. Children having only hematologic presentation recover fully within 2-3 mo, whereas those with neurologic disease need at least 6 mo of therapy. Children with a continuing malabsorptive state and those with inborn errors of vitamin B$_{12}$ malabsorption need lifelong treatment. Prolonged daily treatment with high-dose (1,000-2,000 µg) oral vitamin B$_{12}$ preparations is also equally effective in achieving hematologic and neurologic responses in elderly patients, but the data are inadequate in children and young adults.

**Prevention**
Vitamin B<sub>12</sub> DRIs are 0.4 µg/day at age 0-6 mo, 0.5 µg/day at 6-12 mo, 0.9 µg/day at 1-3 yr, 1.2 µg/day at 4-8 yr, 1.8 µg/day at 9-13 yr, 2.4 µg/day at 14-18 yr and in adults, 2.6 µg/day in pregnancy, and 2.8 µg/day in lactation. Pregnant and breastfeeding women should ensure an adequate consumption of animal products to prevent cobalamin deficiency in infants. Strict vegetarians, especially vegans, should ensure regular consumption of vitamin B<sub>12</sub>. Food fortification with the vitamin helps to prevent deficiency in predominantly vegetarian populations.

Vitamin C (Ascorbic Acid) Deficiency and Excess

Dheeraj Shah, H.P.S. Sachdev

Vitamin C is important for synthesis of collagen at the level of hydroxylation of lysine and proline in precollagen. It is also involved in neurotransmitter metabolism (conversion of dopamine to norepinephrine and tryptophan to serotonin), cholesterol metabolism (conversion of cholesterol to steroid hormones and bile acids), and the biosynthesis of carnitine. Vitamin C functions to maintain the iron and copper atoms, cofactors of the metalloenzymes, in a reduced (active) state. Vitamin C is an important antioxidant (electron donor) in the aqueous milieu of the body. Vitamin C enhances nonheme iron absorption, the transfer of iron from transferrin to ferritin, and the formation of tetrahydrofolic acid and thus can affect the cellular and immunologic functions of the hematopoietic system.

Dietary Needs and Sources of Vitamin C

Humans depend on dietary sources for vitamin C. An adequate intake is 40 mg for ages 0-6 mo and 50 mg for 6-12 mo. For older children the recommended dietary allowance is 15 mg for ages 1-3 yr, 25 mg for 4-8 yr, 45 mg for 9-13 yr, and 65-75 mg for 14-18 yr. The recommended dietary allowances during pregnancy and lactation are 85 mg/day and 120 mg/day, respectively. The requirement for vitamin C is increased during infectious and diarrheal diseases. Children exposed to smoking or environmental tobacco smoke also require increased amounts of foods rich in vitamin C. The best food sources of vitamin C are citrus fruits and fruit juices, peppers, berries, melons, guava, kiwifruit, tomatoes, cauliflower, and green leafy vegetables. Vitamin C is easily destroyed
by prolonged storage, overcooking, and processing of foods.

Absorption of vitamin C occurs in the upper small intestine by an active process or by simple diffusion when large amounts are ingested. Vitamin C is not stored in the body but is taken up by all tissues; the highest levels are found in the pituitary and adrenal glands. The brain ascorbate content in the fetus and neonate is markedly higher than the content in the adult brain, a finding probably related to its function in neurotransmitter synthesis.

When a mother's intake of vitamin C during pregnancy and lactation is adequate, the newborn will have adequate tissue levels of vitamin C related to active placental transfer, subsequently maintained by the vitamin C in breast milk or commercial infant formulas. Breast milk contains sufficient vitamin C to prevent deficiency throughout infancy. Infants consuming pasteurized or boiled animal milk are at significant risk of developing deficiency if the other sources of vitamin C are also lacking in the diet. Neonates whose feeding has been delayed because of a clinical condition can also have ascorbic acid deficiency. For patients receiving total parenteral nutrition (TPN), 80 mg/day is recommended for full-term infants and 25 mg/kg/day for preterm infants. Parents and children who choose a limited (selective) diet or those on fad diets are at risk for vitamin C deficiency.

**Vitamin C Deficiency**

A deficiency of vitamin C results in the clinical presentation of *scurvy*. Children fed predominantly heat-treated (ultrahigh-temperature or pasteurized) milk or unfortified formulas and not receiving fruits and fruit juices are at significant risk for symptomatic disease. Infants and children on highly restrictive diets, devoid of most fruits and vegetables, are at risk of acquiring severe vitamin C deficiency. Such diets are occasionally promoted with unsubstantiated claims of benefit in autism and other developmental disorders. In scurvy, there is defective formation of connective tissues and collagen in skin, cartilage, dentine, bone, and blood vessels, leading to their fragility. In the long bones, osteoid is not deposited by osteoblasts, cortex is thin, and the trabeculae become brittle and fracture easily.

**Clinical Features**

The early manifestations of vitamin C deficiency are irritability, loss of appetite,
low-grade fever, musculoskeletal pain, and tenderness in the legs. These signs and symptoms are followed by leg swelling—most marked at the knees and the ankles—and pseudoparalysis. The infant might lie with the hips and knees semiflexed and the feet rotated outward. Subperiosteal hemorrhages in the lower-limb bones sometimes acutely increase the swelling and pain, and the condition might mimic acute osteomyelitis or arthritis. A “rosary” at the costochondral junctions and depression of the sternum are other typical features (Fig. 63.1). The angulation of scorbutic beads is usually sharper than that of a rachitic rosary. Gum changes are seen in older children after teeth have erupted, manifested as bluish purple, spongy swellings of the mucous membrane, especially over the upper incisors (Fig. 63.2). Anemia, a common finding in infants and young children with scurvy, is related to impaired iron absorption and coexistent hematopoietic nutrient deficiencies, including iron, vitamin B₁₂, and folate. Hemorrhagic manifestations of scurvy include petechiae, purpura, and ecchymoses at pressure points; epistaxis; gum bleeding; and the characteristic perifollicular hemorrhages (Fig. 63.3). Other manifestations are poor wound and fracture healing, hyperkeratosis of hair follicles, arthralgia, and muscle weakness.

**FIG. 63.1** Scorbutic “rosary.” (Courtesy of Dr. J.D. MacLean, McGill Centre for Tropical Diseases, Montreal.)
Laboratory Findings and Diagnosis

The diagnosis of vitamin C deficiency is usually based on the characteristic clinical picture, the radiographic appearance of the long bones, and a history of poor vitamin C intake. A high index of suspicion is required in children on restrictive diets, particularly those with autism and other developmental
disorders, and they should be evaluated for scurvy whenever they present with difficulty in walking or bone pains. The typical radiographic changes occur at the distal ends of the long bones and are particularly common at the knees. The shafts of the long bones have a ground-glass appearance because of trabecular atrophy. The cortex is thin and dense, giving the appearance of pencil outlining of the diaphysis and epiphysis. The white line of Fränkel, an irregular but thickened white line at the metaphysis, represents the zone of well-calcified cartilage. The epiphyseal centers of ossification also have a ground-glass appearance and are surrounded by a sclerotic ring (Fig. 63.4). The more specific but late radiologic feature of scurvy is a zone of rarefaction under the white line at the metaphysis. This zone of rarefaction (Trümmerfeld zone), a linear break in the bone that is proximal and parallel to the white line, represents area of debris of broken-down bone trabeculae and connective tissue. A Pelkan spur is a lateral prolongation of the white line and may be present at cortical ends. Epiphyseal separation can occur along the line of destruction, with either linear displacement or compression of the epiphysis against the shaft (Fig. 63.5). Subperiosteal hemorrhages are not visible using plain radiographs during the active phase of scurvy. However, during healing the elevated periosteum becomes calcified and radiopaque (Fig. 63.5), sometimes giving a dumbbell or club shape to the affected bone. MRI can demonstrate acute as well as healing subperiosteal hematomas along with periostitis, metaphyseal changes, and heterogeneous bone marrow signal intensity, even in absence of changes in plain radiographs. Gelatinous transformation of bone marrow, on aspiration, has been reported in children with suspected malignancy.
FIG. 63.4 Radiographs of a leg. A, An early scurvy "white line" is visible on the ends of the shafts of the tibia and fibula; sclerotic rings (Wimberger sign) are shown around the epiphyses of the femur and tibia. B, More advanced scorbutic changes; zones of destruction (ZD) are evident in the femur and tibia. Pelkan spur is also seen at the cortical end.
Biochemical tests are not very useful in the diagnosis of scurvy, because they do not reflect the tissue status. A plasma ascorbate concentration of <0.2 mg/dL usually is considered deficient. Leukocyte concentration of vitamin C is a better indicator of body stores, but this measurement is technically more difficult to perform. Leukocyte concentrations of $\leq 10 \, \mu g/10^8$ white blood cells are considered deficient and indicate latent scurvy, even in the absence of clinical signs of deficiency. Saturation of the tissues with vitamin C can be estimated from the urinary excretion of the vitamin after a test dose of ascorbic acid. In healthy children, 80% of the test dose appears in the urine within 3-5 hr after parenteral administration. Generalized nonspecific aminoaciduria is common in scurvy, whereas plasma amino acid levels remain normal.

**Differential Diagnosis**
Scurvy is often misdiagnosed as arthritis, osteomyelitis, nonaccidental trauma (child abuse), malignancy, or acrodynia. The early irritability and bone pain are sometimes attributed to nonspecific pains or other nutritional deficiencies. Copper deficiency results in a radiographic picture similar to that of scurvy. Henoch-Schönlein purpura, thrombocytopenic purpura, or leukemia is sometimes suspected in children presenting with hemorrhagic manifestations.

**Treatment**

Vitamin C supplements of 100-200 mg/day orally or parenterally ensure rapid and complete cure. The clinical improvement is seen within 1 week in most cases, but the treatment should be continued for up to 3 mo for complete recovery.

**Prevention**

Breastfeeding protects against vitamin C deficiency throughout infancy. In children consuming milk formula, fortification with vitamin C must be ensured. Children consuming heat-treated milk or plant-based beverages (e.g., almond milk, soy milk) should consume adequate vitamin C–rich foods in infancy. Dietary or medicinal supplements are required in children on restrictive diets deficient in vitamin C, severely malnourished children, and those with chronic debilitating conditions (e.g., malignancies, neurologic disorders). Providing antenatal supplements of vitamin C to smoking mothers may mitigate some of the harmful effects of smoking on fetal and infant lung development and function.

**Vitamin C Toxicity**

Daily intake of <2 g of vitamin C is generally without adverse effects in adults. Larger doses can cause gastrointestinal problems, such as abdominal pain and osmotic diarrhea. Hemolysis has rarely been reported after high doses of ascorbic acid. Megadoses of vitamin C should be avoided in patients with a history of urolithiasis or conditions related to excessive iron accumulation, such as thalassemia and hemochromatosis. Data are sparse regarding vitamin C toxicity in children. The following values for tolerable upper intake levels are extrapolated from data for adults based on body weight differences: ages 1-3 yr,
400 mg; 4-8 yr, 650 mg; 9-13 yr, 1,200 mg; and 14-18 yr, 1,800 mg.

CHAPTER 64

Vitamin D Deficiency (Rickets) and Excess

Larry A. Greenbaum

Rickets

Bone consists of a protein matrix called osteoid and a mineral phase, principally composed of calcium and phosphate, mostly in the form of hydroxyapatite. Osteomalacia occurs with inadequate mineralization of bone osteoid in children and adults. Rickets is a disease of growing bone caused by unmineralized matrix at the growth plates in children only before fusion of the epiphyses. Because growth plate cartilage and osteoid continue to expand but mineralization is inadequate, the growth plate thickens. Circumference of the growth plate and metaphysis is also greater, increasing bone width at the growth plates and causing classic clinical manifestations, such as widening of the wrists and ankles. The general softening of the bones causes them to bend easily when subject to forces such as weight bearing or muscle pull. This softening leads to a variety of bone deformities.

Rickets is principally caused by vitamin D deficiency and was rampant in northern Europe and the United States during the early years of the 20th century. Although largely corrected through public health measures that provided children with adequate vitamin D, rickets remains a persistent problem in developed countries, with many cases still secondary to preventable nutritional vitamin D deficiency. It remains a significant problem in developing countries and may be secondary to nutritional vitamin D deficiency and inadequate intake of calcium (Table 64.1).

**Etiology**

There are many causes of rickets, including vitamin D disorders, calcium deficiency, phosphorus deficiency, and distal renal tubular acidosis (Table 64.2).
Causes of Rickets

Vitamin D Disorders

- Nutritional vitamin D deficiency
- Congenital vitamin D deficiency
- Secondary vitamin D deficiency
- Malabsorption
- Increased degradation
- Decreased liver 25-hydroxylase
- Vitamin D–dependent rickets types 1A and 1B
- Vitamin D–dependent rickets types 2A and 2B
- Chronic kidney disease

Calcium Deficiency

- Low intake
- Diet
- Premature infants (rickets of prematurity)
- Malabsorption
- Primary disease
- Dietary inhibitors of calcium absorption

Phosphorus Deficiency

- Inadequate intake
- Premature infants (rickets of prematurity)
- Aluminum-containing antacids

Renal Losses

- X-linked hypophosphatemic rickets*
- Autosomal dominant hypophosphatemic rickets*
- Autosomal recessive hypophosphatemic rickets types 1 and 2*
- Hereditary hypophosphatemic rickets with hypercalciuria
Overproduction of fibroblast growth factor-23
Tumor-induced rickets*
McCune-Albright syndrome*
Epidermal nevus syndrome*
Neurofibromatosis*
Fanconi syndrome
Dent disease
Distal renal tubular acidosis

* Disorders secondary to excess fibroblast growth factor-23.

**Clinical Manifestations**

Most manifestations of rickets are a result of skeletal changes (Table 64.3). **Craniotabes** is a softening of the cranial bones and can be detected by applying pressure at the occiput or over the parietal bones. The sensation is similar to the feel of pressing into a Ping-Pong ball and then releasing. Craniotabes may also be secondary to osteogenesis imperfecta, hydrocephalus, and syphilis. It is a normal finding in many newborns, especially near the suture lines, but typically disappears within a few months of birth. Widening of the costochondral junctions results in a rachitic “rosary,” which feels like the beads of a rosary as the examiner's fingers move along the costochondral junctions from rib to rib (Fig. 64.1). Growth plate widening is also responsible for the enlargement at the wrists and ankles (Fig. 64.2). The horizontal depression along the lower anterior chest known as **Harrison groove** occurs from pulling of the softened ribs by the diaphragm during inspiration. Softening of the ribs also impairs air movement and predisposes patients to atelectasis and pneumonia. Valgus or varus deformities of the legs are common; **windswept deformity** occurs when one leg is in extreme valgus and the other is in extreme varus (Fig. 64.3).

**Table 64.3**

**Clinical Features of Rickets**

**General**

| Failure to thrive (malnutrition) |
Listlessness
Protruding abdomen
Muscle weakness (especially proximal)
Hypocalcemic dilated cardiomyopathy
Fractures (pathologic, minimal trauma)
Increased intracranial pressure

**Head**

Craniotabes
Frontal bossing
Delayed fontanel closure (usually closed by 2 yr)
Delayed dentition
   No incisors by age 10 mo
   No molars by age 18 mo
Caries
Craniosynostosis

**Chest**

Rachitic rosary
Harrison groove
Respiratory infections and atelectasis*

**Back**

Scoliosis
Kyphosis
Lordosis

**Extremities**

Enlargement of wrists and ankles
Valgus or varus deformities
Windswept deformity (valgus deformity of one leg with varus deformity of
other leg
Anterior bowing of tibia and femur
Coxa vara
Leg pain

**Hypocalcemic Symptoms**

Tetany
Seizures
Stridor caused by laryngeal spasm

* These features are most frequently associated with the vitamin D deficiency disorders.

† These symptoms develop only in children with disorders that produce hypocalcemia (see Table 64.4).

**FIG. 64.1** Rachitic “rosary” in a child with rickets. (Courtesy of Dr. Thomas D. Thacher, Rochester, MN.)
FIG. 64.2  Hands and forearms of a young child with rickets show prominence above the wrist, resulting from flaring and poor mineralization of lower end of the radius and ulna. (From Bullough PG: Orthopaedic pathology, ed 5, St Louis, 2010, Mosby, Fig 8-31.)
The clinical presentation of rickets may vary based on the etiology. Changes in the lower extremities tend to be the dominant feature in X-linked hypophosphatemic rickets. Symptoms secondary to hypocalcemia occur only in those forms of rickets associated with decreased serum calcium.

The chief complaint in a child with rickets is quite variable. Many children present because of skeletal deformities, whereas others have difficulty walking owing to a combination of deformity and weakness. Other common presenting complaints include failure to thrive (malnutrition) and symptomatic hypocalcemia (see Chapters 588 to 590).

**Radiology**

Rachitic changes are most easily visualized on posteroanterior radiographs of the
wrist, although characteristic rachitic changes can be seen at other growth plates (Figs. 64.4 and 64.5). Decreased calcification leads to thickening of the growth plate. The edge of the metaphysis loses its sharp border, which is described as fraying. The edge of the metaphysis changes from a convex or flat surface to a more concave surface. This change to a concave surface is termed cupping and is most easily seen at the distal ends of the radius, ulna, and fibula. There is widening of the distal end of the metaphysis, corresponding to the clinical observation of thickened wrists and ankles, as well as the rachitic rosary. Other radiologic features include coarse trabeculation of the diaphysis and generalized rarefaction.

![FIG. 64.4](image) Radiographs of the wrist in A, normal child; and B, child with rickets, who has metaphyseal fraying and cupping of the distal radius and ulna.
FIG. 64.5  Radiographs of the knees in 7 yr old girl with distal renal tubular acidosis and rickets. A, At initial presentation, there is widening of the growth plate and metaphyseal fraying. B, Dramatic improvement after 4 mo of therapy with alkali.

Diagnosis

The diagnosis of rickets is based on the presence of classic radiographic abnormalities. It is supported by physical examination findings, history, and laboratory results consistent with a specific etiology (Table 64.4).

Clinical Evaluation

Because the majority of children with rickets have a nutritional deficiency, the initial evaluation should focus on a **dietary history**, emphasizing intake of both vitamin D and calcium. Most children in industrialized nations receive vitamin D from formula, fortified milk, or vitamin supplements. Along with the amount, the exact composition of the formula or milk is pertinent, because rickets has occurred in children given products that are called “milk” (e.g., soy milk) but are deficient in vitamin D and minerals.

**Cutaneous synthesis** mediated by sunlight exposure is an important source of vitamin D. It is important to ask about time spent outside, sunscreen use, and clothing, especially if there may be a cultural reason for increased covering of the skin. Because winter sunlight is ineffective at stimulating cutaneous synthesis of vitamin D, the season is an additional consideration. Children with increased skin pigmentation are at increased risk for vitamin D deficiency because of decreased cutaneous synthesis.

The presence of **maternal** risk factors for nutritional vitamin D deficiency, including diet and sun exposure, is an important consideration when a neonate or young infant has rachitic findings, especially if the infant is breastfed (Table 64.5...
Determining a child's intake of dairy products, the main dietary source of calcium, provides a general sense of calcium intake. High dietary fiber can interfere with calcium absorption.

### Table 64.5

**Risk Factors for Nutritional Rickets and Osteomalacia and Their Prevention**

#### Maternal Factors

- Vitamin D deficiency
  - Dark skin pigmentation
  - Full body clothing cover
  - High latitude during winter/spring season
  - Other causes of restricted sun (UVB) exposure, e.g., predominant indoor living, disability, pollution, cloud cover
- Low–vitamin D diet
- Low-calcium diet
- Poverty, malnutrition, special diets

#### Infant/Childhood Factors

- Neonatal vitamin D deficiency secondary to maternal deficiency/vitamin D deficiency
  - Lack of infant supplementation with vitamin D
  - Prolonged breastfeeding without appropriate complementary feeding from 6 mo
  - High latitude during winter/spring season
  - Dark skin pigmentation and/or restricted sun (UVB) exposure, e.g., predominant indoor living, disability, pollution, cloud cover
- Low–vitamin D diet
- Low-calcium diet
- Poverty, malnutrition, special diets

#### Preventive Measures
The child's medication use is relevant, because certain medications, such as the anticonvulsants phenobarbital and phenytoin, increase degradation of vitamin D, and phosphate binders or aluminum-containing antacids interfere with the absorption of phosphate.

**Malabsorption** of vitamin D is suggested by a history of liver or intestinal disease. Undiagnosed liver or intestinal disease should be suspected if the child has gastrointestinal (GI) symptoms, although occasionally rickets is the presenting complaint. Fat malabsorption is often associated with diarrhea or oily stools, and there may be signs or symptoms suggesting deficiencies of other fat-soluble vitamins (A, E, and K; see Chapters 61, 65, and 66).

A history of **renal disease** (proteinuria, hematuria, urinary tract infections) is an additional significant consideration, given the importance of chronic kidney disease as a cause of rickets. Polyuria can occur in children with chronic kidney disease or Fanconi syndrome.

Children with rickets might have a history of dental caries, poor growth, delayed walking, waddling gait, pneumonia, and hypocalcemic symptoms.

The family history is critical, given the large number of **genetic causes** of rickets, although most of these causes are rare. Along with bone disease, it is important to inquire about leg deformities, difficulties with walking, or unexplained short stature, because some parents may be unaware of their diagnosis. Undiagnosed disease in the mother is not unusual in X-linked hypophosphatemia. A history of an unexplained sibling death during infancy may be present in the child with cystinosis, the most common cause of Fanconi syndrome in children.

The physical examination focuses on detecting manifestations of rickets (see Table 64.3). It is important to observe the child's gait, auscultate the lungs to detect atelectasis or pneumonia, and plot the patient's growth. Alopecia suggests vitamin D–dependent rickets type 2.
The initial laboratory tests in a child with rickets should include serum calcium, phosphorus, alkaline phosphatase (ALP), parathyroid hormone (PTH), 25-hydroxyvitamin D, 1,25-dihydroxyvitamin D (1,25-D), creatinine, and electrolytes (see Table 64.4 for interpretation). Urinalysis is useful for detecting the glycosuria seen with Fanconi syndrome and low-molecular-weight proteinuria (positive dipstick for protein) in Fanconi syndrome or Dent disease. Evaluation of urinary excretion of calcium (24 hr collection for calcium or calcium:creatinine ratio) is helpful if hereditary hypophosphatemic rickets with hypercalciuria or Dent disease is suspected. Direct measurement of other fat-soluble vitamins (A, E, and K) or indirect assessment of deficiency (prothrombin time for vitamin K deficiency) is appropriate if malabsorption is a consideration.

Vitamin D Disorders

Vitamin D Physiology

Vitamin D can be synthesized in skin epithelial cells and therefore technically is not a vitamin. Cutaneous synthesis is normally the most important source of vitamin D and depends on the conversion of 7-dehydrocholesterol to vitamin D₃ (3-cholecalciferol) by ultraviolet B (UVB) radiation from the sun. The efficiency of this process is decreased by melanin; therefore, more sun exposure is necessary for vitamin D synthesis in people with increased skin pigmentation. Measures to decrease sun exposure, such as covering the skin with clothing or applying sunscreen, also decrease vitamin D synthesis. Children who spend less time outside have reduced vitamin D synthesis. The winter sun away from the equator is ineffective at mediating vitamin D synthesis.

There are few natural dietary sources of vitamin D. Fish liver oils have a high vitamin D content. Other good dietary sources include fatty fish and egg yolks. Most children in industrialized countries receive vitamin D via fortified foods, especially formula and milk (both of which contain 400 IU/L) and some breakfast cereals and breads. Supplemental vitamin D may be vitamin D₂ (which comes from plants or yeast) or vitamin D₃. Breast milk has a low vitamin D content, approximately 12-60 IU/L.

Vitamin D is transported bound to vitamin D–binding protein to the liver, where 25-hydroxylase converts vitamin D into 25-hydroxyvitamin D (25-D), the most abundant circulating form of vitamin D. Because there is little regulation of
this liver hydroxylation step, measurement of 25-D is the standard method for determining a patient's vitamin D status. The final step in activation occurs in the kidney, where the enzyme 1α-hydroxylase adds a second hydroxyl group, resulting in 1,25-D. The 1α-hydroxylase is upregulated by PTH and hypophosphatemia and inhibited by hyperphosphatemia and 1,25-D. Most 1,25-D circulates bound to vitamin D–binding protein.

1,25-Dihydroxyvitamin D acts by binding to an intracellular receptor, and the complex affects gene expression by interacting with vitamin D response elements. In the intestine, this binding results in a marked increase in calcium absorption, which is highly dependent on 1,25-D. There is also an increase in phosphorus absorption, but this effect is less significant because most dietary phosphorus absorption is vitamin D independent. 1,25-D also has direct effects on bone, including mediating resorption. 1,25-D directly suppresses PTH secretion by the parathyroid gland, thus completing a negative feedback loop. PTH secretion is also suppressed by the increase in serum calcium mediated by 1,25-D. 1,25-D inhibits its own synthesis in the kidney and increases the synthesis of inactive metabolites.

**Nutritional Vitamin D Deficiency**

Vitamin D deficiency remains the most common cause of rickets globally and is prevalent, even in industrialized countries. Because vitamin D can be obtained from dietary sources or from cutaneous synthesis, most patients in industrialized countries have a combination of risk factors that lead to vitamin D deficiency.

**Etiology**

Vitamin D deficiency most frequently occurs in infancy because of a combination of poor intake and inadequate cutaneous synthesis. Transplacental transport of vitamin D, mostly 25-D, typically provides enough vitamin D for the 1st 2 mo of life unless there is severe maternal vitamin D deficiency. Infants who receive formula receive adequate vitamin D, even without cutaneous synthesis. Because of the low vitamin D content of breast milk, breastfed infants rely on cutaneous synthesis or vitamin supplements. Cutaneous synthesis can be limited because of the ineffectiveness of the winter sun in stimulating vitamin D synthesis; avoidance of sunlight because of concerns about cancer, neighborhood safety, or cultural practices; and decreased cutaneous synthesis because of increased skin pigmentation.
The effect of skin pigmentation explains why most cases of nutritional rickets in the United States and northern Europe occur in breastfed children of African descent or other dark-pigmented populations. The additional impact of the winter sun is supported by such infants more often presenting in the late winter or spring. In some groups, complete covering of infants or the practice of not taking infants outside has a significant role, explaining the occurrence of rickets in infants living in areas of abundant sunshine, such as the Middle East. Because the mothers of some infants can have the same risk factors, decreased maternal vitamin D can also contribute, both by leading to reduced vitamin D content in breast milk and by lessening transplacental delivery of vitamin D. Rickets caused by vitamin D deficiency can also be secondary to unconventional dietary practices, such as vegan diets that use unfortified soy milk or rice milk.

**Clinical Manifestations**

The clinical features are typical of rickets (see Table 64.3), with a significant minority presenting with symptoms of hypocalcemia. Prolonged laryngospasm is occasionally fatal. These children have an increased risk of pneumonia and muscle weakness leading to a delay in motor development.

**Laboratory Findings**

Table 64.4 summarize the principal laboratory findings. Hypocalcemia is a variable finding because the elevated PTH acts to increase the serum calcium concentration. The hypophosphatemia is caused by PTH-induced renal losses of phosphate, combined with a decrease in intestinal absorption.

The wide variation in 1,25-D levels (low, normal, or high) is secondary to the upregulation of renal 1α-hydroxylase caused by concomitant hypophosphatemia and hyperparathyroidism. Because serum levels of 1,25-D are much lower than the levels of 25-D, even with low levels of 25-D there is often enough 25-D still present to act as a precursor for 1,25-D synthesis in the presence of upregulated 1α-hydroxylase. The level of 1,25-D is only low when there is severe vitamin D deficiency.

Some patients have a metabolic acidosis secondary to PTH-induced renal bicarbonate wasting. There may also be generalized aminoaciduria.

**Diagnosis and Differential Diagnosis**

The diagnosis of nutritional vitamin D deficiency is based on the combination of
a history of poor vitamin D intake and risk factors for decreased cutaneous synthesis, radiographic changes consistent with rickets, and typical laboratory findings (see Table 64.4). A normal PTH level almost never occurs with vitamin D deficiency and suggests a primary phosphate disorder.

**Treatment**

Children with nutritional vitamin D deficiency should receive vitamin D and adequate nutritional intake of calcium and phosphorus. There are 2 strategies for administration of vitamin D. With **stoss therapy**, vitamin D (300,000-600,000 IU) is administered orally (preferred) or intramuscularly as 2-4 doses over 1 day (vitamin D₃ is preferred to D₂ because of longer half-life of D₃). Since the doses are observed, stoss therapy is ideal in patients in whom adherence to therapy is questionable. The alternative strategy is daily vitamin D with a minimum dose of 2,000 IU/day for a minimum of 3 mo. Either strategy should be followed by daily vitamin D intake of 400 IU/day if <1 yr old or 600 IU/day if >1 yr old. It is important to ensure that children receive adequate dietary calcium (minimum of 500 mg/day) and phosphorus; this dietary intake is usually provided by milk, formula, and other dairy products, although calcium supplements may be needed in some patients.

Children who have symptomatic hypocalcemia might need intravenous (IV) calcium acutely, followed by oral calcium supplements, which typically can be tapered over 2-6 wk in children who receive adequate dietary calcium. Transient use of IV or oral 1,25-D (calcitriol) is often helpful in reversing hypocalcemia in the acute phase by providing active vitamin D during the delay as supplemental vitamin D is converted to active vitamin D. Calcitriol doses are typically 0.05 µg/kg/day. IV calcium is initially given as an acute bolus for symptomatic hypocalcemia (20 mg/kg calcium chloride or 100 mg/kg calcium gluconate). Some patients require a continuous IV calcium drip, titrated to maintain the desired serum calcium level. These patients should transition to enteral calcium, and most infants require approximately 1,000 mg of elemental calcium.

**Prognosis**

Most children with nutritional vitamin D deficiency have an excellent response to treatment, with radiologic healing occurring within a few months. Laboratory test results should also normalize rapidly. Many of the bone malformations
improve dramatically, but children with severe disease can have permanent deformities and short stature. Rarely, patients benefit from orthopedic intervention for leg deformities, although this is generally not done until the metabolic bone disease has healed, there is clear evidence that the deformity will not self-resolve, and the deformity is causing functional problems.

**Prevention**

Most cases of nutritional rickets can be prevented by universal administration of 400 IU of vitamin D to infants <1 yr old. Older children with risk factors for inadequate intake should receive 600 IU/day. Vitamin D may be administered as a component of a multivitamin or as a vitamin D supplement.

**Congenital Vitamin D Deficiency**

**Congenital rickets** is quite rare in industrialized countries and occurs when there is severe maternal vitamin D deficiency during pregnancy. Maternal risk factors include poor dietary intake of vitamin D, lack of adequate sun exposure, and closely spaced pregnancies. These newborns can have symptomatic hypocalcemia, intrauterine growth retardation, and decreased bone ossification, along with classic rachitic changes. Subtler maternal vitamin D deficiency can have an adverse effect on neonatal bone density and birthweight, cause a defect in dental enamel, and predispose infants to neonatal hypocalcemic tetany. Treatment of congenital rickets includes vitamin D supplementation and adequate intake of calcium and phosphorus. Use of prenatal vitamins containing vitamin D (600 IU) prevents this entity.

**Secondary Vitamin D Deficiency**

**Etiology**

Along with inadequate intake, vitamin D deficiency can result from inadequate absorption, decreased hydroxylation in the liver, and increased degradation. Because vitamin D is fat soluble, its absorption may be decreased in patients with a variety of liver and GI diseases, including cholestatic liver disease, defects in bile acid metabolism, cystic fibrosis and other causes of pancreatic dysfunction, celiac disease, and Crohn disease. Malabsorption of vitamin D can also occur with intestinal lymphangiectasia and after intestinal resection.

Severe liver disease, which usually is also associated with malabsorption, can
cause a decrease in 25-D formation as a result of insufficient enzyme activity. Because of the large reserve of 25-hydroxylase activity in the liver, vitamin D deficiency caused by liver disease usually requires a loss of >90% of liver function. A variety of medications increase the degradation of vitamin D by inducing the cytochrome P450 (CYP) system. Rickets from vitamin D deficiency can develop in children receiving anticonvulsants (e.g., phenobarbital, phenytoin) or antituberculosis medications (e.g., isoniazid, rifampin).

**Treatment**

Treatment of vitamin D deficiency attributable to malabsorption requires high doses of vitamin D. Because of its better absorption, 25-D (25-50 μg/day or 5-7 μg/kg/day) is superior to vitamin D₃. The dose is adjusted based on monitoring of serum levels of 25-D. Alternatively, patients may be treated with 1,25-D, which also is better absorbed in the presence of fat malabsorption, or with parenteral vitamin D. Children with rickets as a result of increased degradation of vitamin D by the CYP system require the same acute therapy as indicated for nutritional deficiency (discussed earlier), followed by long-term administration of high doses of vitamin D (e.g., 1,000 IU/day), with dosing titrated based on serum levels of 25-D. Some patients require as much as 4,000 IU/day.

**Vitamin D–Dependent Rickets, Type 1**

Children with vitamin D–dependent rickets type 1A, an autosomal recessive disorder, have mutations in the gene encoding renal 1α-hydroxylase, preventing conversion of 25-D into 1,25-D. These patients normally present during the 1st 2 yr of life and can have any of the classic features of rickets (see Table 64.3), including symptomatic hypocalcemia. They have normal levels of 25-D but low levels of 1,25-D (see Table 64.4). Occasionally, 1,25-D levels are at the lower limit of normal, inappropriately low given the high PTH and low serum phosphorus levels, both of which should increase the activity of renal 1α-hydroxylase and cause elevated levels of 1,25-D. As in nutritional vitamin D deficiency, renal tubular dysfunction can cause a metabolic acidosis and generalized aminoaciduria.

Vitamin D–dependent rickets type 1B is secondary to a mutation in the gene for a 25-hydroxylase. Patients have low levels of 25-D but normal levels of 1,25-D (see Table 64.4).
Treatment
Vitamin D–dependent rickets type 1A responds to long-term treatment with 1,25-D (calcitriol). Initial doses are 0.25-2 µg/day, and lower doses are used once the rickets has healed. Especially during initial therapy, it is important to ensure adequate intake of calcium. The dose of calcitriol is adjusted to maintain a low-normal serum calcium level, a normal serum phosphorus level, and a high-normal serum PTH level. Targeting a low-normal calcium concentration and a high-normal PTH level avoids excessive dosing of calcitriol, which can cause hypercalciuria and nephrocalcinosis. Therefore, patient monitoring includes periodic assessment of urinary calcium excretion, with a target of <4 mg/kg/day.

Vitamin D–dependent rickets type 1B may respond to pharmacologic doses of vitamin D$_2$ (3,000 U/day) as a result of alternative enzymes with 25-hydroxylase activity or residual activity of the mutant protein.

Vitamin D–Dependent Rickets, Type 2
Patients with vitamin D–dependent rickets type 2A have mutations in the gene encoding the vitamin D receptor, preventing a normal physiologic response to 1,25-D. Levels of 1,25-D are extremely elevated in this autosomal recessive disorder (see Table 64.4 ). Most patients present during infancy, although rickets in less severely affected patients might not be diagnosed until adulthood. Less severe disease is associated with a partially functional vitamin D receptor. Approximately 50–70% of children have alopecia, which tends to be associated with a more severe form of the disease and can range from alopecia areata to alopecia totalis. Epidermal cysts are a less common manifestation.

Vitamin D–dependent rickets type 2B appears to result from overexpression of a hormone response element–binding protein that interferes with the actions of 1,25-D. Alopecia may be present.

Treatment
Some patients respond to extremely high doses of vitamin D$_2$ (25-D or 1,25-D), especially patients without alopecia. This response is caused by a partially functional vitamin D receptor in patients with vitamin D–dependent rickets type 2A, but may also occur in vitamin D–dependent rickets type 2B. All patients should be given a 3-6 mo trial of high-dose vitamin D and oral calcium. The initial dose of 1,25-D should be 2 µg/day, but some patients require doses as
high as 50-60 µg/day. Calcium doses are 1,000-3,000 mg/day. Patients who do not respond to high-dose vitamin D may be treated with long-term IV calcium, with possible transition to very high dose oral calcium supplements. Treatment of patients who do not respond to vitamin D is difficult.

**Chronic Kidney Disease**

With chronic kidney disease, there is decreased activity of 1α-hydroxylase in the kidney, leading to diminished production of 1,25-D. In chronic kidney disease, unlike the other causes of vitamin D deficiency, patients have hyperphosphatemia as a result of decreased renal excretion (see Table 64.4 and Chapter 550.2).

**Treatment**

Therapy requires the use of a form of vitamin D that can act without 1-hydroxylation by the kidney (calcitriol), which both permits adequate absorption of calcium and directly suppresses the parathyroid gland. Because hyperphosphatemia is a stimulus for PTH secretion, normalization of the serum phosphorus level through a combination of dietary phosphorus restriction and use of oral phosphate binders is as important as the use of activated vitamin D.

**Calcium Deficiency**

**Pathophysiology**

Rickets secondary to inadequate dietary calcium is a significant problem in some countries in Africa, although there are cases in other regions of the world, including industrialized countries. Because breast milk and formula are excellent sources of calcium, this form of rickets develops after children have been weaned from breast milk or formula and is more likely to occur in children who are weaned early. Rickets develops because the diet has low calcium content, typically <200 mg/day if <12 mo old or <300 mg/day if >12 mo old. The child has minimal intake of dairy products or other sources of calcium. In addition, because of reliance on grains and green leafy vegetables, the diet may be high in phytate, oxalate, and phosphate, which decrease absorption of dietary calcium. In industrialized countries, rickets caused by calcium deficiency can occur in children who consume an unconventional diet. Examples include children with
milk allergy who have low dietary calcium and children who transition from formula or breast milk to juice, soda, or a calcium-poor soy drink, without an alternative source of dietary calcium.

This type of rickets can develop in children who receive intravenous nutrition without adequate calcium. Malabsorption of calcium can occur in celiac disease, intestinal abetalipoproteinemia, and after small bowel resection. There may be concurrent malabsorption of vitamin D.

Clinical Manifestations

Children with calcium deficiency have the classic signs and symptoms of rickets (see Table 64.3). Presentation can occur during infancy or early childhood, although some cases are diagnosed in teenagers. Because calcium deficiency occurs after the cessation of breastfeeding, it tends to occur later than the nutritional vitamin D deficiency that is associated with breastfeeding. In Nigeria, nutritional vitamin D deficiency is most common at 4-15 mo of age, whereas calcium deficiency rickets typically occurs at 15-25 mo.

Diagnosis

Laboratory findings include increased levels of ALP, PTH, and 1,25-D (see Table 64.4). Calcium levels may be normal or low, although symptomatic hypocalcemia is uncommon. There is decreased urinary excretion of calcium, and serum phosphorus levels may be low as a result of renal wasting of phosphate from secondary hyperparathyroidism. In some children, there is coexisting nutritional vitamin D deficiency, with low 25-D levels.

Treatment

Treatment focuses on providing adequate calcium, typically as a dietary supplement (doses of 700 [age 1-3 yr], 1,000 [4-8 yr], and 1,300 [9-18 yr] mg/day of elemental calcium are effective). Vitamin D supplementation is necessary if there is concurrent vitamin D deficiency (discussed earlier). Prevention strategies include discouraging early cessation of breastfeeding and increasing dietary sources of calcium. In countries such as Kenya, where many children have diets high in cereal with negligible intake of cow’s milk, school-based milk programs have been effective in reducing the prevalence of rickets.
Phosphorus Deficiency

Inadequate Intake
With the exception of starvation or severe anorexia, it is almost impossible to have a diet that is deficient in phosphorus, because phosphorus is present in most foods. Decreased phosphorus absorption can occur in diseases associated with malabsorption (celiac disease, cystic fibrosis, cholestatic liver disease), but if rickets develops, the primary problem is usually malabsorption of vitamin D and/or calcium.

Isolated malabsorption of phosphorus occurs in patients with long-term use of aluminum-containing antacids. These compounds are very effective at chelating phosphate in the GI tract, leading to decreased absorption. This decreased absorption results in hypophosphatemia with secondary osteomalacia in adults and rickets in children. This entity responds to discontinuation of the antacid and short-term phosphorus supplementation.

Fibroblast Growth Factor-23
Fibroblast growth factor-23 (FGF-23) is a humoral mediator that decreases renal tubular reabsorption of phosphate and therefore decreases serum phosphorus. FGF-23, synthesized by osteocytes, also decreases the activity of renal 1α-hydroxylase, resulting in a decrease in the production of 1,25-D. Increased levels of FGF-23 cause many of the renal phosphate-wasting diseases (see Table 64.2).

X-Linked Hypophosphatemic Rickets
Among the genetic disorders causing rickets because of hypophosphatemia, X-linked hypophosphatemic rickets (XLH) is the most common, with a prevalence of 1/20,000. The defective gene is on the X chromosome, but female carriers are affected, so it is an X-linked dominant disorder.

Pathophysiology
The defective gene is called PHEX because it is a phosphate-regulating gene with homology to endopeptidases on the X chromosome. The product of this gene appears to have an indirect role in inactivating FGF-23. Mutations in PHEX
lead to increased levels of FGF-23. Because the actions of FGF-23 include inhibition of phosphate reabsorption in the proximal tubule, phosphate excretion is increased. FGF-23 also inhibits renal 1α-hydroxylase, leading to decreased production of 1,25-D.

**Clinical Manifestations**

These patients have rickets, but abnormalities of the lower extremities and poor growth are the dominant features. Delayed dentition and tooth abscesses are also common. Some patients have hypophosphatemia and short stature without clinically evident bone disease.

**Laboratory Findings**

Patients have high renal excretion of phosphate, hypophosphatemia, and increased ALP; PTH and serum calcium levels are normal (see Table 64.4). Hypophosphatemia normally upregulates renal 1α-hydroxylase and should lead to an increase in 1,25-D, but these patients have low or inappropriately normal levels of 1,25-D.

**Treatment**

Patients respond well to a combination of oral phosphorus and 1,25-D (calcitriol). The daily need for phosphorus supplementation is 1-3 g of elemental phosphorus divided into 4 or 5 doses. Frequent dosing helps to prevent prolonged decrements in serum phosphorus because there is a rapid decline after each dose. In addition, frequent dosing decreases diarrhea, a complication of high-dose oral phosphorus. Calcitriol is administered at 30-70 ng/kg/day in 2 doses. Burosumab-twza is a monoclonal antibody to FGF-23 that is an approved alternative approach for treating XLH in children >1 yr.

Complications of treatment occur when there is not an adequate balance between phosphorus supplementation and calcitriol. Excess phosphorus, by decreasing enteral calcium absorption, leads to secondary hyperparathyroidism, with worsening of the bone lesions. In contrast, excess calcitriol causes hypercalciuria and nephrocalcinosis and can even cause hypercalcemia. Therefore, laboratory monitoring of treatment includes serum calcium, phosphorus, ALP, PTH, and urinary calcium, as well as periodic renal ultrasound to evaluate patients for nephrocalcinosis. Because of variation in the serum phosphorus level and the importance of avoiding excessive phosphorus dosing,
normalization of ALP levels is a more useful method of assessing the therapeutic response than measuring serum phosphorus. For children with significant short stature, growth hormone is an effective option. Children with severe deformities might need osteotomies, but these procedures should be done only when treatment has led to resolution of the bone disease.

**Prognosis**

The response to therapy is usually good, although frequent dosing can lead to problems with compliance. Girls generally have less severe disease than boys, probably because of the X-linked inheritance. Short stature can persist despite healing of the rickets. Adults generally do well with less aggressive treatment, and some receive calcitriol alone. Adults with bone pain or other symptoms improve with oral phosphorus supplementation and calcitriol.

**Autosomal Dominant Hypophosphatemic Rickets**

Autosomal dominant hypophosphatemic rickets (ADHR) is much less common than XLH. There is incomplete penetrance and variable age of onset. Patients with ADHR have a mutation in the gene encoding FGF-23 (FGF23). The mutation prevents degradation of FGF-23 by proteases, leading its level to increase. The actions of FGF-23 include decreased reabsorption of phosphate in the renal proximal tubule, which results in hypophosphatemia, and inhibition of the 1α-hydroxylase in the kidney, causing a decrease in 1,25-D synthesis.

In ADHR, as in XLH, abnormal laboratory findings are hypophosphatemia, elevated ALP level, and a low or inappropriately normal 1,25-D level (see Table 64.4). Treatment is similar to the approach used in XLH.

**Autosomal Recessive Hypophosphatemic Rickets**

Autosomal recessive hypophosphatemic rickets (ARHR) type 1 is an extremely rare disorder caused by mutations in the gene encoding dentin matrix protein 1 (DMP1). ARHR type 2 occurs in patients with mutations in the ENPP1 gene. Mutations in ENPP1 also cause generalized arterial calcification of infancy. Both types of ARHR are associated with elevated levels of FGF-23, leading to renal
phosphate wasting, hypophosphatemia, and low or inappropriately normal levels of 1,25-D. Treatment is similar to the approach used in XLH, although monitoring for arterial calcification is prudent in patients with ENPP1 mutations.

**Hereditary Hypophosphatemic Rickets With Hypercalciuria**

Hereditary hypophosphatemic rickets with hypercalciuria (HHRH) is a rare disorder that is mainly found in the Middle East.

**Pathophysiology**

This autosomal recessive disorder is caused by mutations in the gene for a sodium-phosphate co-transporter in the proximal tubule (SLC34A3). The renal phosphate leak causes hypophosphatemia, which then stimulates production of 1,25-D. The high level of 1,25-D increases intestinal absorption of calcium, suppressing PTH. Hypercalciuria ensues as a result of the high absorption of calcium and the low level of PTH, which normally decreases renal excretion of calcium.

**Clinical Manifestations**

The dominant symptoms of HHRH are rachitic leg abnormalities (see Table 64.3), muscle weakness, and bone pain. Patients can have short stature, with a disproportionate decrease in the length of the lower extremities. The severity of the disease varies, and some family members have no evidence of rickets but have kidney stones secondary to hypercalciuria.

**Laboratory Findings**

Laboratory findings include hypophosphatemia, renal phosphate wasting, elevated serum ALP levels, and elevated 1,25-D levels. PTH levels are low (see Table 64.4).

**Treatment**

Therapy for HHRH patients relies on oral phosphorus replacement (1-2.5 g/day of elemental phosphorus in 5 divided doses). Treatment of the hypophosphatemia decreases serum levels of 1,25-D and corrects the hypercalciuria. The response to therapy is usually excellent, with resolution of
pain, weakness, and radiographic evidence of rickets.

**Overproduction of FGF-23**

**Tumor-induced osteomalacia** is more common in adults; in children it can produce classic rachitic findings. Most tumors are mesenchymal in origin and are usually benign, small, and located in bone. These tumors secrete FGF-23 and produce a biochemical phenotype similar to XLH, including urinary phosphate wasting, hypophosphatemia, elevated ALP levels, and low or inappropriately normal 1,25-D levels (see Table 64.4). Curative treatment is excision of the tumor. If the tumor cannot be removed, treatment is identical to that for XLH.

Renal phosphate wasting leading to hypophosphatemia and rickets (or osteomalacia in adults) is a potential complication in McCune-Albright syndrome, an entity that includes the triad of polyostotic fibrous dysplasia, hyperpigmented macules, and polyendocrinopathy (see Chapter 578.6). Affected patients have inappropriately low levels of 1,25-D and elevated ALP levels. The renal phosphate wasting and inhibition of 1,25-D synthesis are related to the polyostotic fibrous dysplasia. Patients have elevated FGF-23, presumably caused by the dysplastic bone. Hypophosphatemic rickets can also occur in children with isolated polyostotic fibrous dysplasia. Although it is rarely possible, removal of the abnormal bone can cure this disorder in children with McCune-Albright syndrome. Most patients receive the same treatment as children with XLH. Bisphosphonate treatment decreases the pain and fracture risk associated with the bone lesions.

Rickets is an unusual complication of epidermal nevus syndrome (see Chapter 670). Patients have hypophosphatemic rickets caused by renal phosphate wasting and an inappropriately normal or low level of 1,25-D from excessive production of FGF-23. The timing of presentation with rickets varies from infancy to early adolescence. Hypophosphatemia and rickets have resolved after excision of the epidermal nevi in some patients, but not in others. In most the skin lesions are too extensive to be removed, necessitating treatment with phosphorus supplementation and 1,25-D. Rickets caused by phosphate wasting is an extremely rare complication in children with neurofibromatosis (see Chapter 614.1).

**Raine syndrome**, an autosomal recessive disorder caused by mutations in the FAM20C gene, is an osteosclerotic bone dysplasia that is often fatal in the neonatal period. However, patients who survive into childhood may develop
rickets from increased levels of FGF-23.

**Fanconi Syndrome**

Fanconi syndrome is secondary to generalized dysfunction of the renal proximal tubule (see Chapter 547.1). There are renal losses of phosphate, amino acids, bicarbonate, glucose, urate, and other molecules that are normally reabsorbed in the proximal tubule. Some patients have partial dysfunction, with less generalized losses. The most clinically relevant consequences are hypophosphatemia caused by phosphate losses and proximal renal tubular acidosis caused by bicarbonate losses. Patients have rickets as a result of hypophosphatemia, with exacerbation from the chronic metabolic acidosis, which causes bone dissolution. Failure to thrive (malnutrition) is a consequence of both rickets and renal tubular acidosis. Treatment is dictated by the etiology (see Chapter 547).

**Dent Disease**

Dent disease is an X-linked disorder usually caused by mutations in the gene encoding a chloride channel expressed in the kidney (CLCN5). Some patients have mutations in the OCRL1 gene, which can also cause Lowe syndrome (see Chapter 549.3). Affected males have variable manifestations, including hematuria, nephrolithiasis, nephrocalcinosis, rickets, and chronic kidney disease. Almost all patients have low-molecular-weight proteinuria and hypercalciuria. Other, less universal abnormalities are aminoaciduria, glycosuria, hypophosphatemia, and hypokalemia. Rickets occurs in approximately 25% of patients, and it responds to oral phosphorus supplements. Some patients also need 1,25-D, but this treatment should be used cautiously because it can worsen the hypercalciuria.

**Rickets of Prematurity**

Rickets in very-low-birthweight infants has become a significant problem, as the survival rate for this group of infants has increased (see Chapter 117.2).

**Pathogenesis**
The transfer of calcium and phosphorus from mother to fetus occurs throughout pregnancy, but 80% occurs during the 3rd trimester. Premature birth interrupts this process, with rickets developing when the premature infant does not have an adequate supply of calcium and phosphorus to support mineralization of the growing skeleton.

Most cases of rickets of prematurity occur in infants with a birthweight <1,000 g. It is more likely to develop in infants with lower birthweight and younger gestational age. Rickets occurs because unsupplemented breast milk and standard infant formula do not contain enough calcium and phosphorus to supply the needs of the premature infant. Other risk factors include cholestatic jaundice, a complicated neonatal course, prolonged use of parenteral nutrition, the use of soy formula, and medications such as diuretics and corticosteroids.

**Clinical Manifestations**

Rickets of prematurity occurs 1-4 mo after birth. Infants can have nontraumatic fractures, especially of the legs, arms, and ribs. Most fractures are not suspected clinically. Because fractures and softening of the ribs lead to decreased chest compliance, some infants have respiratory distress from atelectasis and poor ventilation. This rachitic respiratory distress usually develops >5 wk after birth, distinguishing it from the early-onset respiratory disease of premature infants. These infants have poor linear growth, with negative effects on growth persisting beyond 1 yr of age. An additional long-term effect is enamel hypoplasia. Poor bone mineralization can contribute to dolichocephaly. There may be classic rachitic findings, such as frontal bossing, rachitic rosary (see Fig. 64.1), craniotabes, and widened wrists and ankles (see Table 64.3). Most infants with rickets of prematurity have no clinical manifestations, and the diagnosis is based on radiographic and laboratory findings.

**Laboratory Findings**

Because of inadequate intake, the serum phosphorus level is low or low-normal in patients with rickets of prematurity. The renal response is appropriate, with conservation of phosphate leading to a low urine phosphate level; tubular reabsorption of phosphate is >95%. Most patients have normal levels of 25-D, unless there has been inadequate intake or poor absorption (discussed earlier). The hypophosphatemia stimulates renal 1α-hydroxylase, so levels of 1,25-D are
high or high-normal. These high levels can contribute to bone demineralization because 1,25-D stimulates bone resorption. Serum levels of calcium are low, normal, or high, and patients often have hypercalciuria. Elevated serum calcium levels and hypercalciuria are secondary to increased intestinal absorption and bone dissolution caused by elevated 1,25-D levels and inability to deposit calcium in bone because of an inadequate phosphorus supply. The hypercalciuria indicates that phosphorus is the limiting nutrient for bone mineralization, although increased provision of phosphorus alone often cannot correct the mineralization defect; increased calcium is also necessary. Thus there is an inadequate supply of calcium and phosphorus, but the deficiency in phosphorus is greater.

Alkaline phosphatase levels are often elevated, but some affected infants have normal levels. In some cases, normal ALP levels may be secondary to resolution of the bone demineralization because of an adequate mineral supply despite the continued presence of radiologic changes, which take longer to resolve. However, ALP levels may be normal despite active disease. No single blood test is 100% sensitive for the diagnosis of rickets. The diagnosis should be suspected in infants with ALP >5-6 times the upper limit of normal (UL) for adults (unless there is concomitant liver disease) or phosphorus <5.6 mg/dL. The diagnosis is confirmed by radiologic evidence of rickets, which is best seen on x-ray films of the wrists and ankles. Films of the arms and legs might reveal fractures. The rachitic rosary may be visible on chest radiograph. Unfortunately, x-ray films cannot show early demineralization of bone because changes are not evident until there is >20–30% reduction in the bone mineral content.

**Diagnosis**

Because many premature infants have no overt clinical manifestations of rickets, screening tests are recommended. These tests should include weekly measurements of calcium, phosphorus, and ALP. Periodic measurement of the serum bicarbonate concentration is also important, because metabolic acidosis causes dissolution of bone. At least 1 screening radiograph for rickets at 6-8 wk of age is appropriate in infants who are at high risk for rickets; additional films may be indicated in high-risk infants.

**Prevention**
Provision of adequate amounts of calcium, phosphorus, and vitamin D significantly decreases the risk of rickets of prematurity. Parenteral nutrition is often necessary initially in very premature infants. In the past, adequate parenteral calcium and phosphorus delivery was difficult because of limits secondary to insolubility of these ions when their concentrations were increased. Current amino acid preparations allow higher concentrations of calcium and phosphate, decreasing the risk of rickets. Early transition to enteral feedings is also helpful. These infants should receive either human milk fortified with calcium and phosphorus or preterm infant formula, which has higher concentrations of calcium and phosphorus than standard formula. Soy formula should be avoided because there is decreased bioavailability of calcium and phosphorus. Increased mineral feedings should continue until the infant weighs 3-3.5 kg. These infants should also receive approximately 400 IU/day of vitamin D through formula and vitamin supplements.

**Treatment**

Therapy for rickets of prematurity focuses on ensuring adequate delivery of calcium, phosphorus, and vitamin D. If mineral delivery has been good and there is no evidence of healing, it is important to screen for vitamin D deficiency by measuring serum 25-D. Measurement of PTH, 1,25-D, and urinary calcium and phosphorus may be helpful in some cases.

**Distal Renal Tubular Acidosis**

Distal renal tubular acidosis usually manifests with failure to thrive. Patients have a metabolic acidosis with an inability to acidify the urine appropriately. Hypercalciuria and nephrocalcinosis are typically present. The many etiologies include autosomal recessive and autosomal dominant forms. Rickets is variable and responds to alkali therapy (see Fig. 64.5 and Chapter 547.2).

**Hypervitaminosis D**

**Etiology**

Hypervitaminosis D is caused by excessive intake of vitamin D. It can occur with long-term high intake or with a substantial, acute ingestion (see Table 64.1).
Most cases are secondary to misuse of prescribed or nonprescription vitamin D supplements, but other cases have been secondary to accidental overfortification of milk, contamination of table sugar, and inadvertent use of vitamin D supplements as cooking oil. The recommended upper limits for long-term vitamin D intake are 1,000 IU for children <1 yr old and 2,000 IU for older children and adults. Hypervitaminosis D can also result from excessive intake of synthetic vitamin D analogs (25-D, 1,25-D). Vitamin D intoxication is never secondary to excessive exposure to sunlight, probably because ultraviolet irradiation can transform vitamin D₃ and its precursor into inactive metabolites.

Pathogenesis

Although vitamin D increases intestinal absorption of calcium, the dominant mechanism of the hypercalcemia is excessive bone resorption.

Clinical Manifestations

The signs and symptoms of vitamin D intoxication are secondary to hypercalcemia. GI manifestations include nausea, vomiting, poor feeding, constipation, abdominal pain, and pancreatitis. Possible cardiac findings are hypertension, decreased QT interval, and arrhythmias. The central nervous system effects of hypercalcemia include lethargy, hypotonia, confusion, disorientation, depression, psychosis, hallucinations, and coma. Hypercalcemia impairs renal concentrating mechanisms, which can lead to polyuria, dehydration, and hypernatremia. Hypercalcemia can also lead to acute renal failure, nephrolithiasis, and nephrocalcinosis, which can result in chronic renal insufficiency. Deaths are usually associated with arrhythmias or dehydration.

Laboratory Findings

The classic findings in vitamin D intoxication are hypercalcemia, elevated levels of 25-D (>100 ng/mL), hypercalciuria, and suppressed PTH. Hyperphosphatemia is also common. Hypercalciuria can lead to nephrocalcinosis, which is visible on renal ultrasound. Hypercalcemia and nephrocalcinosis can lead to renal insufficiency.

Surprisingly, levels of 1,25-D are usually normal. This may result from downregulation of renal 1α-hydroxylase by the combination of low PTH,
hyperphosphatemia, and a direct effect of 1,25-D. The level of free 1,25-D may be high because of displacement from vitamin D–binding proteins by 25-D. Anemia is sometimes present; the mechanism is unknown.

**Diagnosis and Differential Diagnosis**

The diagnosis is based on the presence of hypercalcemia and an elevated serum 25-D level, although children with excess intake of 1,25-D or another synthetic vitamin D preparation have normal levels of 25-D. With careful sleuthing, there is usually a history of excess intake of vitamin D, although in some situations (overfortification of milk by a dairy) the patient and family may be unaware.

The differential diagnosis of vitamin D intoxication focuses on other causes of hypercalcemia. Hyperparathyroidism produces hypophosphatemia, whereas vitamin D intoxication usually causes hyperphosphatemia. Williams syndrome is often suggested by phenotypic features and accompanying cardiac disease. Idiopathic infantile hypercalcemia occurs in children taking appropriate doses of vitamin D. Subcutaneous fat necrosis is a common cause of hypercalcemia in young infants; skin findings are usually present. The hypercalcemia of familial benign hypocalciuric hypercalcemia is mild, asymptomatic, and associated with hypocalciuria. Hypercalcemia of malignancy is an important consideration. High intake of calcium can also cause hypercalcemia, especially in the presence of renal insufficiency. Questioning about calcium intake should be part of the history in a patient with hypercalcemia. Occasionally, patients are intentionally taking high doses of calcium and vitamin D.

**Treatment**

The treatment of vitamin D intoxication focuses on control of hypercalcemia. Many patients with hypercalcemia are dehydrated as a result of polyuria from nephrogenic diabetes insipidus, poor oral intake, and vomiting. Rehydration lowers the serum calcium level by dilution and corrects prerenal azotemia. The resultant increased urine output increases urinary calcium excretion. Urinary calcium excretion is also increased by high urinary sodium excretion. The mainstay of the initial treatment is aggressive therapy with normal saline, often in conjunction with a loop diuretic to further increase calcium excretion; this is often adequate for treating mild or moderate hypercalcemia. More significant hypercalcemia usually requires other therapies. Glucocorticoids decrease
intestinal absorption of calcium by blocking the action of 1,25-D. There is also a
decrease in the levels of 25-D and 1,25-D. The usual dosage of prednisone is 1-2
mg/kg/24 hr.

Calcitonin, which lowers calcium by inhibiting bone resorption, is a useful
adjunct, but its effect is usually not dramatic. There is an excellent response to
IV or oral bisphosphonates in vitamin D intoxication. Bisphosphonates inhibit
bone resorption through their effects on osteoclasts. Hemodialysis using a low or
0 dialysate calcium can rapidly lower serum calcium in patients with severe
hypercalcemia that is refractory to other measures.

Along with controlling hypercalcemia, it is imperative to eliminate the source
of excess vitamin D. Additional sources of vitamin D such as multivitamins and
fortified foods should be eliminated or reduced. Avoidance of sun exposure,
including the use of sunscreen, is prudent. The patient should also restrict
calcium intake.

**Prognosis**

Most children make a full recovery, but hypervitaminosis D may be fatal or can
lead to chronic kidney disease. Because vitamin D is stored in fat, levels can
remain elevated for months, necessitating regular monitoring of 25-D, serum
calcium, and urine calcium.

Vitamin E is a fat-soluble vitamin and functions as an antioxidant, but its precise biochemical functions are not known. Vitamin E deficiency can cause hemolysis or neurologic manifestations and occurs in premature infants, in patients with malabsorption, and in an autosomal recessive disorder affecting vitamin E transport. Because of its role as an antioxidant, there is considerable research on vitamin E supplementation in chronic illnesses.

Pathogenesis

The term vitamin E denotes a group of 8 compounds with similar structures and antioxidant activity. The most potent member of these compounds is \( \alpha \)-tocopherol, which is also the main form in humans. The best dietary sources of vitamin E are vegetable oils, seeds, nuts, green leafy vegetables, and margarine (see Table 64.1).

The majority of vitamin E is located within cell membranes, where it prevents lipid peroxidation and the formation of free radicals. Other antioxidants, such as ascorbic acid, enhance the antioxidant activity of vitamin E. The importance of other functions of vitamin E is still being delineated.

Premature infants are particularly susceptible to vitamin E deficiency, because there is significant transfer of vitamin E during the last trimester of pregnancy. Vitamin E deficiency in premature infants causes thrombocytosis, edema, and hemolysis, potentially causing anemia. The risk of symptomatic vitamin E deficiency was increased by the use of formulas for premature infants that had a high content of polyunsaturated fatty acids (PUFAs). These formulas led to a high content of PUFAs in red blood cell membranes, making them more susceptible to oxidative stress, which could be ameliorated by vitamin E.
Oxidative stress was augmented by aggressive use of iron supplementation; iron increases the production of oxygen radicals. The incidence of hemolysis as a result of vitamin E deficiency in premature infants decreased secondary to the use of formulas with a lower content of PUFAs, less-aggressive use of iron, and provision of adequate vitamin E.

Because vitamin E is plentiful in common foods, primary dietary deficiency is rare except in premature infants and in severe, generalized malnutrition. Vitamin E deficiency does occur in children with fat malabsorption secondary to the bile acid needed for vitamin E absorption. Although symptomatic disease is most common in children with cholestatic liver disease, it can occur in patients with cystic fibrosis, celiac disease, short bowel syndrome, and Crohn disease. The autosomal recessive disorder abetalipoproteinemia causes fat malabsorption, and vitamin E deficiency is a common complication (see Chapter 104).

In ataxia with isolated vitamin E deficiency (AVED), a rare autosomal recessive disorder, there are mutations in the gene for α-tocopherol transfer protein (TTPA). Patients with this disorder are unable to incorporate vitamin E into lipoproteins before their release from the liver, leading to reduced serum levels of vitamin E. There is no associated fat malabsorption, and absorption of vitamin E from the intestine occurs normally.

**Clinical Manifestations**

A severe, progressive neurologic disorder occurs in patients with prolonged vitamin E deficiency. Clinical manifestations do not appear until after 1 yr of age, even in children with cholestasis since birth. Patients may have cerebellar disease, posterior column dysfunction, and retinal disease. Loss of deep tendon reflexes is usually the initial finding. Subsequent manifestations include limb ataxia (intention tremor, dysdiadochokinesia), truncal ataxia (wide-based, unsteady gait), dysarthria, ophthalmoplegia (limited upward gaze), nystagmus, decreased proprioception (positive Romberg test), decreased vibratory sensation, and dysarthria. Some patients have pigmentary retinopathy. Visual field constriction can progress to blindness. Cognition and behavior can also be affected. Myopathy and cardiac arrhythmias are less common findings.

In premature infants, hemolysis as a result of vitamin E deficiency typically develops during the 2nd mo of life. Edema may also be present.
Laboratory Findings

Serum vitamin E levels increase in the presence of high serum lipid levels, even when vitamin E deficiency is present. Therefore, vitamin E status is best determined by measuring the ratio of vitamin E to serum lipids; a ratio <0.8 mg/g is abnormal in older children and adults; <0.6 mg/g is abnormal in infants <1 yr. Premature infants with hemolysis caused by vitamin E deficiency also often have elevated platelet counts.

Neurologic involvement can cause abnormal somatosensory evoked potentials and nerve conduction studies. Abnormalities on electroretinography can precede physical examination findings in patients with retinal involvement.

Diagnosis and Differential Diagnosis

Premature infants with unexplained hemolytic anemia after the 1st mo of life, especially if thrombocytosis is present, either should be empirically treated with vitamin E or should have serum vitamin E and lipid levels measured. Children with neurologic findings and a disease that causes fat malabsorption should have their vitamin E status evaluated.

Because children with AVED do not have symptoms of malabsorption, a correct diagnosis requires a high index of suspicion. **Friedreich ataxia** has been misdiagnosed in some patients (see Chapter 615.1). Children with unexplained ataxia should be screened for vitamin E deficiency.

Treatment

For correction of deficiency in neonates, the dose of vitamin E is 25-50 units/day for 1 wk, followed by adequate dietary intake. Children with deficiency as a result of malabsorption should receive 1 unit/kg/day, with the dose adjusted based on levels; ongoing treatment is necessary. Children with AVED normalize their serum vitamin E levels with high doses of vitamin E and require ongoing treatment.

Prognosis

The hemolytic anemia in infants resolves with correction of the vitamin E
deficiency. Some neurologic manifestations of vitamin E deficiency may be reversible with early treatment, but many patients have little or no improvement. Importantly, treatment prevents progression.

**Prevention**

Premature infants should receive sufficient vitamin E through formula or breast milk fortifier and formula without a high content of PUFAs. Children at risk for vitamin E deficiency as a result of malabsorption should be screened for deficiency and given adequate vitamin E supplementation. Vitamin preparations with high content of all the fat-soluble vitamins are available.

Qi YJ, Niu QL, Zhu XL, et al. Relationship between deficiencies in vitamin A and E and occurrence of infectious

Vitamin K is necessary for the synthesis of clotting factors II, VII, IX, and X; deficiency of vitamin K can result in clinically significant bleeding. Vitamin K deficiency typically affects infants, who experience a transient deficiency related to inadequate intake, or patients of any age who have decreased vitamin K absorption. Mild vitamin K deficiency can affect long-term bone and vascular health (see Chapters 124.4 and 507).

Pathogenesis

Vitamin K is a group of compounds that have a common naphthoquinone ring structure (see Table 64.1). Phylloquinone, called vitamin K₁, is present in a variety of dietary sources, with green leafy vegetables, liver, and certain legumes and plant oils having the highest content. Vitamin K₁ is the form used to fortify foods and as a medication in the United States. Vitamin K₂ is a group of compounds called menaquinones, which are produced by intestinal bacteria. There is uncertainty regarding the relative importance of intestinally produced vitamin K₂. Menaquinones are also present in meat, especially liver, and cheese. A menaquinone is used pharmacologically in some countries.

Vitamin K is a cofactor for γ-glutamyl carboxylase, an enzyme that performs posttranslational carboxylation, converting glutamate residues in proteins to γ-carboxyglutamate (Gla). The Gla residues, by facilitating calcium binding, are necessary for protein function.

The classic Gla-containing proteins involved in blood coagulation that are decreased in vitamin K deficiency are factors II (prothrombin), VII, IX, and X. Vitamin K deficiency causes a decrease in proteins C and S, which inhibit blood
coagulation, and protein Z, which also has a role in coagulation. All these proteins are made only in the liver, except for protein S, a product of various tissues.

Gla-containing proteins are also involved in bone biology (osteocalcin and protein S) and vascular biology (matrix Gla protein and protein S). Based on the presence of reduced levels of Gla, these proteins appear more sensitive than the coagulation proteins to subtle vitamin K deficiency. Evidence suggests that mild vitamin K deficiency might have a deleterious effect on long-term bone strength and vascular health.

Because it is fat soluble, vitamin K requires the presence of bile salts for its absorption. Unlike other fat-soluble vitamins, there are limited body stores of vitamin K. In addition, there is high turnover of vitamin K, and the vitamin K–dependent clotting factors have a short half-life. Thus, symptomatic vitamin K deficiency can develop within weeks when there is inadequate supply because of low intake or malabsorption.

There are 3 forms of vitamin K deficiency bleeding (VKDB) of the newborn (see Chapter 124.4). Early VKDB was formerly called classic hemorrhagic disease of the newborn and occurs at 1-14 days of age. Early VKDB is secondary to low stores of vitamin K at birth as a result of the poor transfer of vitamin K across the placenta and inadequate intake during the 1st few days of life. In addition, there is no intestinal synthesis of vitamin K₂ because the newborn gut is sterile. Early VKDB occurs mostly in breastfed infants as a consequence of the low vitamin K content of breast milk (formula is fortified). Delayed feeding is an additional risk factor.

Late VKDB most often occurs at 2-12 wk of age, although cases can occur up to 6 mo after birth. Almost all cases are in breastfed infants because of the low vitamin K content of breast milk. An additional risk factor is occult malabsorption of vitamin K, as occurs in children with undiagnosed cystic fibrosis or cholestatic liver disease (e.g., biliary atresia, α₁-antitrypsin deficiency). Without vitamin K prophylaxis, the incidence is 4-10 per 100,000 newborns.

The third form of VKDB of the newborn occurs at birth or shortly thereafter. It is secondary to maternal intake of medications (warfarin, phenobarbital, phenytoin) that cross the placenta and interfere with vitamin K function.

VKDB as a result of fat malabsorption can occur in children of any age. Potential etiologies include cholestatic liver disease, pancreatic disease, and intestinal disorders (celiac sprue, inflammatory bowel disease, short bowel
syndrome). Prolonged diarrhea can cause vitamin K deficiency, especially in breastfed infants. Children with cystic fibrosis are most likely to have vitamin K deficiency if they have pancreatic insufficiency and liver disease.

Beyond infancy, low dietary intake by itself never causes vitamin K deficiency. However, the combination of poor intake and the use of broad-spectrum antibiotics that eliminate the intestine's vitamin K$_2$–producing bacteria can cause vitamin K deficiency. This scenario is especially common in the intensive care unit. Vitamin K deficiency can also occur in patients who receive total parenteral nutrition (TPN) without vitamin K supplementation.

**Clinical Manifestations**

In early VKDB, the most common sites of bleeding are the gastrointestinal (GI) tract, mucosal and cutaneous tissue, umbilical stump, and postcircumcision site; intracranial bleeding is less common. GI blood loss can be severe enough to require a transfusion. In contrast, the most common site of bleeding in late VKDB is intracranial, although cutaneous and GI bleeding may be the initial manifestation. Intracranial bleeding can cause convulsions, permanent neurologic sequelae, or death. In some patients with late VKDB, the presence of an underlying disorder may be suggested by jaundice or failure to thrive (malnutrition). Older children with vitamin K deficiency can present with bruising, mucocutaneous bleeding, or more serious bleeding.

**Laboratory Findings**

In patients with bleeding as a result of vitamin K deficiency, the prothrombin time (PT) is prolonged. The PT must be interpreted based on the patient's age, because it is normally prolonged in newborns (see Chapters 124.4 and 502). The partial thromboplastin time (PTT) is usually prolonged but may be normal in early deficiency. Factor VII has the shortest half-life of the coagulation factors and is the first to be affected by vitamin K deficiency, but isolated factor VII deficiency does not affect PTT. The platelet count and fibrinogen level are normal.

When there is mild vitamin K deficiency, the PT is normal, but there are elevated levels of the undercarboxylated forms of the proteins that are normally carboxylated in the presence of vitamin K. These undercarboxylated proteins are called *proteins induced by vitamin K absence* (PIVKA). Measurement of
undercarboxylated factor II (PIVKA-II) can be used to detect mild vitamin K deficiency. Determination of blood vitamin K levels is less useful because of significant variation based on recent dietary intake; levels do not always reflect tissue stores.

**Diagnosis and Differential Diagnosis**

The diagnosis is established by the presence of a prolonged PT that corrects rapidly after administration of vitamin K, which stops the active bleeding. Other possible causes of bleeding and a prolonged PT include disseminated intravascular coagulation (DIC), liver failure, and rare hereditary deficiencies of clotting factors. DIC, which is usually secondary to sepsis, is associated with thrombocytopenia, low fibrinogen, and elevated D-dimers. Severe liver disease results in decreased production of clotting factors; the PT does not fully correct with administration of vitamin K. Children with a hereditary disorder have a deficiency in a specific clotting factor (I, II, V, VII, X).

**Coumarin** derivatives inhibit the action of vitamin K by preventing its recycling to an active form after it functions as a cofactor for γ-glutamyl carboxylase. Bleeding can occur with overdosage of the common anticoagulant warfarin or with ingestion of rodent poison, which contains a coumarin derivative. High doses of salicylates also inhibit vitamin K regeneration, potentially leading to a prolonged PT and clinical bleeding.

**Treatment**

Infants with VKDB should receive 1 mg of parenteral vitamin K. The PT should decrease within 6 hr and normalize within 24 hr. For rapid correction in adolescents, the parenteral dose is 2.5-10 mg. In addition to vitamin K, a patient with severe, life-threatening bleeding should receive an infusion of fresh-frozen plasma (FFP), which corrects the coagulopathy rapidly. Children with vitamin K deficiency caused by malabsorption require chronic administration of high doses of oral vitamin K (2.5 mg twice/wk to 5 mg/day). Parenteral vitamin K may be necessary if oral vitamin K is ineffective.

**Prevention**
Administration of either oral or parenteral vitamin K soon after birth prevents early VKDB of the newborn. In contrast, a single dose of oral vitamin K does not prevent a substantial number of cases of late VKDB. However, a single intramuscular (IM) injection of vitamin K (1 mg), the current practice in the United States, is almost universally effective, except in children with severe malabsorption. This increased efficacy of the IM form is thought to be the result of a depot effect. Concerns about an association between parenteral vitamin K at birth and the later development of malignancy are unsubstantiated.

Discontinuing the offending medications before delivery can prevent VKDB attributable to maternal medications. If this is not possible, administration of vitamin K to the mother may be helpful. In addition, the neonate should receive parenteral vitamin K immediately after birth. If parenteral vitamin K does not correct the coagulopathy rapidly, the child should receive FFP.

Children who are at high risk for malabsorption of vitamin K should receive supplemental vitamin K and periodic measurement of the PT.

CHAPTER 67

Micronutrient Mineral Deficiencies

Larry A. Greenbaum

Micronutrients include vitamins (see Chapters 61-66) and trace elements. By definition, a trace element is <0.01% of the body weight. Trace elements have a variety of essential functions (Table 67.1). With the exception of iron deficiency, trace element deficiency is uncommon in developed countries, but some deficiencies (iodine, zinc, selenium) are important public health problems in a number of developing countries. Because of low nutritional requirements and plentiful supply, deficiencies of some of the trace elements are extremely rare in humans and typically occur in patients receiving unusual diets or prolonged total parenteral nutrition (TPN) without adequate delivery of a specific trace element. Trace element deficiencies can also occur in children with short bowel syndrome or malabsorption. Excess intake of trace elements is uncommon but can result from environmental exposure or overuse of supplements (Table 67.1).

* These deficiency states have been reported only in case reports associated with parenteral nutrition or highly unusual diets.
For a number of reasons, children are especially susceptible to trace element deficiency. First, growth creates an increased demand for most trace elements. Second, some organs are more likely to sustain permanent damage because of trace element deficiency during childhood. The developing brain is particularly vulnerable to the consequences of certain deficiency states (iron, iodide). Similarly, adequate fluoride is most critical for dental health during childhood. Third, children, especially in the developing world, are more prone to gastrointestinal disorders that can cause trace element deficiencies because of malabsorption.

A normal diet provides adequate intake of most trace elements. However, the intake of certain trace elements varies significantly in different geographic locations. Iodide-containing food is plentiful near the ocean, but inland areas often have inadequate sources, leading to goiter and hypothyroidism. Iodine deficiency is not a problem in the United States because of the widespread use of iodized salt; however, symptomatic iodine deficiency (goiter, hypothyroidism) is common in many developing countries. Selenium content of the soil and consequently of food is also quite variable. Dietary selenium deficiency (associated with cardiomyopathy) occurs in certain locations, such as some parts of China.

The consequences of severe isolated trace mineral deficiency are illustrated in certain genetic disorders. The manifestations of Menkes disease are caused by a mutation in the gene coding for a protein that facilitates intestinal copper absorption (see Chapters 617.5 and 682). This mutation results in severe copper deficiency; subcutaneous copper is an effective treatment. The recessive disorder acrodermatitis enteropathica is secondary to malabsorption of zinc (see Chapter 691). These patients respond dramatically to zinc supplementation.

Children can have apparently asymptomatic deficiencies of certain trace elements but still benefit from supplementation. As an example, zinc is highly effective in treating children before or during diarrheal illnesses in the developing world.

Zinc deficiency is quite common in the developing world and is often associated with malnutrition or other micronutrient deficiencies (iron). Chronic zinc deficiency is associated with dwarfism, hypogonadism, dermatitis, and T-cell immunodeficiency. Diets rich in phytates bind zinc, impairing its absorption. Zinc supplementation in at-risk children reduces the incidence and severity of diarrhea, pneumonia, and possibly malaria. In developing countries, children who have diarrhea may benefit from zinc supplementation, especially if there is

Fluid and Electrolyte Disorders

OUTLINE

Chapter 68 Electrolyte and Acid-Base Disorders
Chapter 69 Maintenance and Replacement Therapy
Chapter 70 Deficit Therapy
Chapter 71 Fluid and Electrolyte Treatment of Specific Disorders
Total Body Water

Total body water (TBW) as a percentage of body weight varies with age (Fig. 68.1). The fetus has very high TBW, which gradually decreases to approximately 75% of birthweight for a term infant. Premature infants have higher TBW than term infants. During the 1st yr of life, TBW decreases to
approximately 60% of body weight and remains at this level until puberty. At puberty, the fat content of females increases more than that in males, who acquire more muscle mass than females. Because fat has very low water content and muscle has high water content, by the end of puberty, TBW in males remains at 60%, but TBW in females decreases to approximately 50% of body weight. The high fat content in overweight children causes a decrease in TBW as a percentage of body weight. During dehydration, TBW decreases and thus is a smaller percentage of body weight.

**FIG. 68.1** Total body water, intracellular fluid, and extracellular fluid as a percentage of body weight as a function of age. (From Winters RW: Water and electrolyte regulation. In Winters RW, editor: The body fluids in pediatrics, Boston, 1973, Little, Brown.)

**Fluid Compartments**

TBW is divided between 2 main compartments: **intracellular fluid (ICF)** and **extracellular fluid (ECF)**. In the fetus and newborn, the ECF volume is larger than the ICF volume (Fig. 68.1). The normal postnatal diuresis causes an immediate decrease in the ECF volume. This is followed by continued expansion of the ICF volume, which results from cellular growth. By 1 yr of age, the ratio of ICF volume to ECF volume approaches adult levels. The ECF volume is
approximately 20–25% of body weight, and the ICF volume is approximately 30–40% of body weight, close to twice the ECF volume (Fig. 68.2). With puberty, the increased muscle mass of males causes them to have a higher ICF volume than females. There is no significant difference in the ECF volume between postpubertal females and males.

The ECF is further divided into the plasma water and the interstitial fluid (see Fig. 68.2). The plasma water is 5% of body weight. The blood volume, given a hematocrit of 40%, is usually 8% of body weight, although it is higher in newborns and young infants; in premature newborns it is approximately 10% of body weight. The volume of plasma water can be altered by pathologic conditions, including dehydration, anemia, polycythemia, heart failure, abnormal
plasma osmolality, and hypoalbuminemia. The interstitial fluid, normally 15% of body weight, can increase dramatically in diseases associated with edema, such as heart failure, protein-losing enteropathy, liver failure, nephrotic syndrome, and sepsis. An increase in interstitial fluid also occurs in patients with ascites or pleural effusions.

There is a delicate equilibrium between the intravascular fluid and the interstitial fluid. The balance between hydrostatic and oncotic forces regulates the intravascular volume, which is critical for proper tissue perfusion. The intravascular fluid has a higher concentration of albumin than the interstitial fluid, and the consequent oncotic force draws water into the intravascular space. The maintenance of this gradient depends on the limited permeability of albumin across the capillaries. The hydrostatic pressure of the intravascular space, which is caused by the pumping action of the heart, drives fluid out of the intravascular space. These forces favor movement into the interstitial space at the arterial ends of the capillaries. The decreased hydrostatic forces and increased oncotic forces, which result from the dilutional increase in albumin concentration, cause movement of fluid into the venous ends of the capillaries. Overall, there is usually a net movement of fluid out of the intravascular space to the interstitial space, but this fluid is returned to the circulation via the lymphatics.

An imbalance in these forces may cause expansion of the interstitial volume at the expense of the intravascular volume. In children with hypoalbuminemia, the decreased oncotic pressure of the intravascular fluid contributes to the development of edema. Loss of fluid from the intravascular space may compromise the intravascular volume, placing the child at risk for inadequate blood flow to vital organs. This is especially likely in diseases in which capillary leak occurs because the loss of albumin from the intravascular space is associated with an increase in the albumin concentration in the interstitial space, further compromising the oncotic forces that normally maintain intravascular volume. In contrast, with heart failure, there is an increase in venous hydrostatic pressure from expansion of the intravascular volume, which is caused by impaired pumping by the heart, and the increase in venous pressure causes fluid to move from the intravascular space to the interstitial space. Expansion of the intravascular volume and increased intravascular pressure also cause the edema that occurs with acute glomerulonephritis.

**Electrolyte Composition**
The composition of the solutes in the ICF and ECF are very different (Fig. 68.3). Sodium (Na\(^+\)) and chloride (Cl\(^-\)) are the dominant cation and anion, respectively, in the ECF. The sodium and chloride concentrations ([Na\(^+\)], [Cl\(^-\)]) in the ICF are much lower. Potassium (K\(^+\)) is the most abundant cation in the ICF, and its concentration ([K\(^+\)]) within the cells is approximately 30 times higher than in the ECF. Proteins, organic anions, and phosphate are the most plentiful anions in the ICF. The dissimilarity between the anions in the ICF and the ECF is largely determined by the presence of intracellular molecules that do not cross the cell membrane, the barrier separating the ECF and the ICF. In contrast, the difference in the distribution of cations—Na\(^+\) and K\(^+\)—relies on activity of the Na\(^+\),K\(^+\)-adenosine triphosphatase (ATPase) pump and membrane ion channels.

![FIG. 68.3](image)

**FIG. 68.3** Concentrations of the major cations and anions in the intracellular space and the plasma, expressed in mEq/L.

The difference in the electrolyte compositions of the ECF and the ICF has important ramifications in the evaluation and treatment of electrolyte disorders. Serum concentrations of electrolytes—[Na\(^+\)], [K\(^+\)], and [Cl\(^-\)]—do not always reflect total body content. Intracellular [K\(^+\)] is much higher than the serum concentration. A shift of K\(^+\) from the **intracellular space (ICS)** can maintain a
normal or even an elevated serum [K⁺] despite massive losses of K⁺ from the ICS. This effect is seen in diabetic ketoacidosis, in which significant K⁺ depletion is masked by transmembrane shift of K⁺ from the ICF to the ECF. Therefore, for K⁺ and phosphorus, electrolytes with a high intracellular concentration, serum level may not reflect total body content. Similarly, the serum calcium concentration ([Ca²⁺]) does not reflect total body content of Ca²⁺, which is largely contained in bone and teeth (see Chapter 64).

**Osmolality**

The ICF and the ECF are in osmotic equilibrium because the cell membrane is permeable to water. If the osmolality in 1 compartment changes, then water movement leads to a rapid equalization of osmolality, with a shift of water between the ICS and extracellular space (ECS). Clinically, the primary process is usually a change in the osmolality of the ECF, with resultant shift of water into the ICF if ECF osmolality decreases, or vice versa if ECF osmolality increases. The ECF osmolality can be determined and usually equals ICF osmolality. **Plasma osmolality**, normally 285-295 mOsm/kg, is measured by the degree of freezing-point depression. The plasma osmolality can also be estimated by a calculation based on the following formula:

\[
\text{Osmolality} = 2 \times [\text{Na}] + [\text{glucose}] / 18 + [\text{BUN}] / 2.8
\]

Glucose and blood urea nitrogen (BUN) are reported in mg/dL. Division of these values by 18 and 2.8, respectively, converts the units into mmol/L. Multiplication of the [Na⁺] value by 2 accounts for its accompanying anions, principally Cl⁻ and bicarbonate. The calculated osmolality is usually slightly lower than measured osmolality.

Urea is not only confined to the ECS because it readily crosses the cell membrane, and its intracellular concentration approximately equals its extracellular concentration. Whereas an elevated [Na⁺] causes a shift of water from the ICS, with uremia there is no osmolar gradient between the two compartments and consequently no movement of water. The only exception is during hemodialysis, when the decrease in extracellular urea is so rapid that intracellular urea does not have time to equilibrate. This disequilibrium
syndrome may result in shift of water into brain cells and leads to severe symptoms. Ethanol, because it freely crosses cell membranes, is another ineffective osmole. In the case of glucose, the effective osmolality can be calculated as follows:

$$\text{Effective osmolality} = 2\times[\text{Na}]+[\text{glucose}]/18$$

The effective osmolality (also called the tonicity) determines the osmotic force that is mediating the shift of water between the ECF and the ICF.

Hyperglycemia causes an increase in the plasma osmolality because it is not in equilibrium with the ICS. During hyperglycemia, there is shift of water from the ICS to the ECS. This shift causes dilution of the $\text{Na}^+$ in the ECS, causing hyponatremia despite elevated plasma osmolality. The magnitude of this effect can be calculated as follows:

$$[\text{Na}]_{\text{corrected}} = [\text{Na}]_{\text{measured}} + 1.6\times([\text{glucose}] - 100 \text{ mg/dL})/100$$

where $[\text{Na}]_{\text{measured}} = \text{Na}^+$ concentration measured by the clinical laboratory and $[\text{Na}]_{\text{corrected}} = \text{corrected Na}^+$ concentration (the $\text{Na}^+$ concentration if the glucose concentration were normal and its accompanying water moved back into the cells). The $[\text{Na}]_{\text{corrected}}$ is the more reliable indicator of the ratio of total body $\text{Na}^+$ to TBW, the usual determinant of the $[\text{Na}^+]$.

Normally, measured osmolality and calculated osmolality are within 10 mOsm/kg. However, there are some clinical situations in which this difference does not occur. The presence of unmeasured osmoles causes measured osmolality to be significantly elevated in comparison with the calculated osmolality. An osmolar gap is present when the difference between measured osmolality exceeds calculated osmolality by $>10$ mOsm/kg. Examples of unmeasured osmoles include ethanol, ethylene glycol, methanol, sucrose, sorbitol, and mannitol. These substances increase measured osmolality but are not part of the equation for calculating osmolality. The presence of an osmolar gap is a clinical clue to the presence of unmeasured osmoles and may be diagnostically useful when there is clinical suspicion of poisoning with methanol or ethylene glycol.
Pseudohyponatremia is a second situation in which there is discordance between measured osmolality and calculated osmolality. Lipids and proteins are the solids of the serum. In patients with elevated serum lipids or proteins, the water content of the serum decreases because water is displaced by the larger amounts of solids. Some instruments measure $[\text{Na}^+]$ by determining the amount of Na$^+$ per liter of serum, including the solid component. When the solid component increases, there is a decrease in $[\text{Na}^+]$ per liter of serum, despite a normal concentration when based on the amount of Na$^+$ per liter of serum water. It is the concentration of Na$^+$ in serum water that is physiologically relevant. A similar problem occurs when using instruments that require dilution of the sample prior to measurement of Na$^+$ (indirect potentiometry). In both situations, the plasma osmolality is normal despite the presence of pseudohyponatremia, because the method for measuring osmolality is not appreciably influenced by the percentage of serum that is composed of lipids and proteins. Pseudohyponatremia is diagnosed by the finding of a normal measured plasma osmolality despite hyponatremia. This laboratory artifact does not occur if the [Na$^+$ ] in water is measured directly with an ion-specific electrode, as with arterial blood gas (ABG) analyzers. Pseudohypernatremia may occur in patients with very low levels of serum proteins by a similar mechanism.

When there are no unmeasured osmoles and pseudohyponatremia is not a concern, the calculated osmolality provides an accurate estimate of the plasma osmolality. Measurement of plasma osmolality is useful for detecting or monitoring unmeasured osmoles and confirming the presence of true hyponatremia. Whereas many children with high plasma osmolality are dehydrated—as seen with hypernatremic dehydration or diabetic ketoacidosis—high osmolality does not always equate with dehydration. A child with salt poisoning or uremia has an elevated plasma osmolality but may be volume-overloaded.

Point-of-Care Testing

Point-of-care (POC) testing offers a number of advantages, including rapid turnaround and usually smaller blood sample volume required. POC devices may provide more accurate results in certain situations, such as pseudohyponatremia (see earlier) and pseudohyperkalemia (see Chapter 68.4 ). However, the agreement between POC and the laboratory is variable, and thus
caution is needed when interpreting results. Because of bias, POC and laboratory results should not be used on an alternating basis when following critical trends (e.g., during correction of hypernatremia or hyponatremia; see Chapter 68.3 ).

The regulation of plasma osmolality and the intravascular volume is controlled by independent systems for water balance, which determines osmolality, and sodium balance, which determines volume status. Maintenance of normal osmolality depends on control of water balance. Control of volume status depends on regulation of sodium balance. When present, volume depletion takes precedence over regulation of osmolality, and retention of water contributes to the maintenance of intravascular volume.

Regulation of Osmolality

The plasma osmolality is tightly regulated and maintained at 285-295 mOsm/kg.
Modification of water intake and excretion maintains normal plasma osmolality. In the steady state the combination of water intake and water produced by the body from oxidation balances water losses from the skin, lungs, urine, and gastrointestinal (GI) tract. Only water intake and urinary losses can be regulated.

Osmoreceptors in the hypothalamus sense plasma osmolality (see Chapter 572). An elevated effective osmolality leads to secretion of **antidiuretic hormone (ADH)** by neurons in the supraoptic and paraventricular nuclei in the hypothalamus. The axons of these neurons terminate in the posterior pituitary. Circulating ADH binds to its V2 receptors in the collecting duct cells of the kidney, and causes insertion of water channels (aquaporin-2) into the renal collecting duct cells. This produces increased permeability to water, permitting resorption of water into the hypertonic renal medulla. Urine concentration increases and water excretion decreases. Urinary water losses cannot be eliminated because there is obligatory excretion of urinary solutes, such as urea and sodium. The regulation of ADH secretion is tightly linked to plasma osmolality, responses being detectable with a 1% change in osmolality. ADH secretion virtually disappears when plasma osmolality is low, allowing excretion of maximally dilute urine. The resulting loss of free water (i.e., water without Na\(^+\)) corrects plasma osmolality. ADH secretion is not an all-or-nothing response; there is a graded adjustment as the osmolality changes.

Water intake is regulated by hypothalamic osmoreceptors, which stimulate thirst when the serum osmolality increases. Thirst occurs with a small increase in the serum osmolality. **Control of osmolality is subordinate to maintenance of an adequate intravascular volume.** When volume depletion is present, both ADH secretion and thirst are stimulated, regardless of the plasma osmolality. The sensation of thirst requires moderate volume depletion but only a 1–2% change in the plasma osmolality.

A number of conditions can limit the kidney's ability to excrete adequate water to correct low plasma osmolality. In the **syndrome of inappropriate antidiuretic hormone (SIADH)**, ADH continues to be produced despite a low plasma osmolality (see Chapters 68.3 and 575).

The glomerular filtration rate (GFR) affects the kidney's ability to eliminate water. With a decrease in the GFR, less water is delivered to the collecting duct, limiting the amount of water that can be excreted. The impairment in the GFR must be quite significant to limit the kidney's ability to respond to an excess of water.

The **minimum urine osmolality** is approximately 30-50 mOsm/kg. This
places an upper limit on the kidney's ability to excrete water; sufficient solute must be present to permit water loss. Massive water intoxication may exceed this limit, whereas a lesser amount of water is necessary in the child with a diet that has very little solute. This can produce severe hyponatremia in children who receive little salt and have minimal urea production as a result of inadequate protein intake. Volume depletion is an extremely important cause of decreased water loss by the kidney despite a low plasma osmolality. This “appropriate” secretion of ADH occurs because volume depletion takes precedence over the osmolality in the regulation of ADH.

The maximum urine osmolality is approximately 1,200 mOsm/kg. The obligatory solute losses dictate the minimum volume of urine that must be produced, even when maximally concentrated. Obligatory water losses increase in patients with high salt intake or high urea losses, as may occur after relief of a urinary obstruction or during recovery from acute kidney injury. An increase in urinary solute and thus water losses occurs with an osmotic diuresis, which occurs classically from glycosuria in diabetes mellitus as well as iatrogenically after mannitol administration. There are developmental changes in the kidney's ability to concentrate the urine. The maximum urine osmolality in a newborn, especially a premature newborn, is less than that in an older infant or child. This limits the ability to conserve water and makes such a patient more vulnerable to hypernatremic dehydration. Very high fluid intake, as seen with psychogenic polydipsia, can dilute the high osmolality in the renal medulla, which is necessary for maximal urinary concentration. If fluid intake is restricted in patients with this condition, the kidney's ability to concentrate the urine may be somewhat impaired, although this defect corrects after a few days without polydipsia. This may also occur during the initial treatment of central diabetes insipidus with desmopressin acetate; the renal medulla takes time to achieve its normal maximum osmolality.

**Regulation of Volume**

An appropriate intravascular volume is critical for survival; both volume depletion and volume overload may cause significant morbidity and mortality. Because sodium is the principal extracellular cation and is restricted to the ECF, adequate body sodium is necessary for maintenance of intravascular volume. The principal extracellular anion, Cl−, is also necessary, but for simplicity, Na+ balance is considered the main regulator of volume status because body content
of sodium and that of chloride usually change proportionally, given the need for equal numbers of cations and anions. In some situations, Cl\(^-\) depletion is considered the dominant derangement causing volume depletion (metabolic alkalosis with volume depletion).

The kidney determines sodium balance because there is little homeostatic control of sodium intake, even though salt craving does occasionally occur, typically in children with chronic renal salt loss. The kidney regulates Na\(^+\) balance by altering the percentage of filtered Na\(^+\) that is resorbed along the nephron. Normally, the kidney excretes <1% of the Na\(^+\) filtered at the glomerulus. In the absence of disease, extrarenal losses and urinary output match intake, with the kidney having the capacity to adapt to large variations in sodium intake. When necessary, urinary sodium excretion can be reduced to virtually undetectable levels or increased dramatically.

The most important determinant of renal Na\(^+\) excretion is the volume status of the child; it is the effective intravascular volume that influences urinary Na\(^+\) excretion. The effective intravascular volume is the volume status that is sensed by the body's regulatory mechanisms. Heart failure is a state of volume overload, but the effective intravascular volume is low because poor cardiac function prevents adequate perfusion of the kidneys and other organs. This explains the avid renal Na\(^+\) retention often present in patients with heart failure.

The renin-angiotensin system is an important regulator of renal Na\(^+\) excretion. The juxtaglomerular apparatus produces renin in response to decreased effective intravascular volume. Specific stimuli for renin release are decreased perfusion pressure in the afferent arteriole of the glomerulus, decreased delivery of sodium to the distal nephron, and \(\beta_1\) -adrenergic agonists, which increase in response to intravascular volume depletion. Renin, a proteolytic enzyme, cleaves angiotensinogen, producing angiotensin I. Angiotensin-converting enzyme (ACE) converts angiotensin I into angiotensin II. The actions of angiotensin II include direct stimulation of the proximal tubule to increase sodium resorption and stimulation of the adrenal gland to increase aldosterone secretion. Through its actions in the distal nephron—specifically, the late distal convoluted tubule and the collecting duct—aldosterone increases sodium resorption. Aldosterone also stimulates potassium excretion, increasing urinary losses. Along with decreasing urinary loss of sodium, angiotensin II acts as a vasoconstrictor, which helps maintain adequate blood pressure in the presence of volume depletion.
Volume expansion stimulates the synthesis of **atrial natriuretic peptide (ANP)**, which is produced by the atria in response to atrial wall distention. Along with increasing the GFR, ANP inhibits Na⁺ resorption in the medullary portion of the collecting duct, facilitating an increase in urinary Na⁺ excretion.

**Volume overload** occurs when Na⁺ intake exceeds output. Children with kidney failure have impaired ability to excrete Na⁺. The GFR is low at birth, limiting a newborn's ability to excrete an Na⁺ load. In other situations, there is a loss of the appropriate regulation of renal Na⁺ excretion. This loss occurs in patients with excessive aldosterone, as seen in primary hyperaldosteronism or renal artery stenosis, where excess renin production leads to high aldosterone levels. In acute glomerulonephritis, even without significantly reduced GFR, the normal intrarenal mechanisms that regulate Na⁺ excretion malfunction, causing excessive renal retention of Na⁺ and volume overload.

Renal retention of Na⁺ occurs during volume depletion, but this appropriate response causes the severe excess in total body Na⁺ that is present in heart failure, liver failure, nephrotic syndrome, and other causes of hypoalbuminemia. In these diseases the effective intravascular volume is decreased, causing the kidney and the various regulatory systems to respond, leading to renal Na⁺ retention and edema formation.

**Volume depletion** usually occurs when Na⁺ losses exceed intake. The most common etiology in children is gastroenteritis. Excessive losses of sodium may also occur from the skin in children with burns, in sweat from patients with cystic fibrosis, or after vigorous exercise. Inadequate intake of Na⁺ is uncommon except in neglect, in famine, or with an inappropriate choice of liquid diet in a child who cannot take solids. Urinary Na⁺ wasting may occur in a range of renal diseases, from renal dysplasia to tubular disorders, such as Bartter syndrome. The neonate, especially if premature, has a mild impairment in the ability to conserve Na⁺. Iatrogenic renal Na⁺ wasting takes place during diuretic therapy. Renal Na⁺ loss occurs as a result of derangement in the normal regulatory systems. An absence of aldosterone, seen most frequently in children with **congenital adrenal hyperplasia** caused by 21-hydroxylase deficiency, causes sodium wasting (see Chapter 594).

Isolated disorders of water balance can affect volume status and Na⁺ balance. Because the cell membrane is permeable to water, changes in TBW influence both the extracellular volume and the intracellular volume. In isolated water loss, as occurs in diabetes insipidus, the impact is greater on the ICS because it has a
greater volume than the ECS. Thus, compared with other types of dehydration, hypernatremic dehydration has less impact on plasma volume; most of the fluid loss comes from the ICS. Yet, significant water loss eventually affects intravascular volume and will stimulate renal $\text{Na}^+$ retention, even if total body $\text{Na}^+$ content is normal. Similarly, with acute water intoxication or SIADH, there is an excess of TBW, but most is in the ICS. However, there is some effect on the intravascular volume, which causes renal excretion of $\text{Na}^+$. Children with SIADH or water intoxication have high urine $\text{Na}^+$ concentration, despite hyponatremia. This finding reinforces the concept of independent control systems for water and $\text{Na}^+$, but the 2 systems interact when pathophysiologic processes dictate, and control of effective intravascular volume always takes precedence over control of osmolality.

Sodium Metabolism

Body Content and Physiologic Function

Sodium is the dominant cation of the ECF (see Fig. 68.3), and it is the principal determinant of extracellular osmolality. Na⁺ is therefore necessary for the maintenance of intravascular volume. Less than 3% of Na⁺ is intracellular. More than 40% of total body Na⁺ is in bone; the remainder is in the interstitial and intravascular spaces. The low intracellular [Na⁺], approximately 10 mEq/L, is maintained by Na⁺,K⁺ -ATPase, which exchanges intracellular Na⁺ for extracellular K⁺.
Sodium Intake

A child's diet determines the amount of Na\(^+\) ingested—a predominantly cultural determination in older children. An occasional child has salt craving because of an underlying salt-wasting renal disease or adrenal insufficiency. Children in the United States tend to have very high salt intakes because their diets include a large amount of “junk” food or fast food. Infants receive sodium from breast milk (approximately 7 mEq/L) and formula (7-13 mEq/L, for 20 calorie/oz formula).

Sodium is readily absorbed throughout the GI tract. Mineralocorticoids increase sodium transport into the body, although this effect has limited clinical significance. The presence of glucose enhances sodium absorption owing to the presence of a co-transport system. This is the rationale for including sodium and glucose in oral rehydration solutions (see Chapter 366).

Sodium Excretion

Sodium excretion occurs in stool and sweat, but the kidney regulates Na\(^+\) balance and is the principal site of Na\(^+\) excretion. There is some Na\(^+\) loss in stool, but it is minimal unless diarrhea is present. Normally, sweat has 5-40 mEq/L of sodium. Sweat Na\(^+\) concentration is increased in children with cystic fibrosis, aldosterone deficiency, or pseudohypoaldosteronism. The higher sweat losses in these conditions may cause or contribute to Na\(^+\) depletion.

Sodium is unique among electrolytes because water balance, not Na\(^+\) balance, usually determines its concentration. When the [Na\(^+\) ] increases, the resultant higher plasma osmolality causes increased thirst and increased secretion of ADH, which leads to renal conservation of water. Both these mechanisms increase the water content of the body, and the [Na\(^+\) ] returns to normal. During hyponatremia, the decrease in plasma osmolality stops ADH secretion, and consequent renal water excretion leads to an increase in the [Na\(^+\) ]. Even though water balance is usually regulated by osmolality, volume depletion does stimulate thirst, ADH secretion, and renal conservation of water. Volume depletion takes precedence over osmolality; volume depletion stimulates ADH secretion, even if a patient has hyponatremia.

The excretion of Na\(^+\) by the kidney is not regulated by the plasma osmolality. The patient's effective plasma volume determines the amount of sodium in the urine. This is mediated by a variety of regulatory systems, including the renin-
angiotensin-aldosterone system and intrarenal mechanisms. In hyponatremia or hypernatremia, the underlying pathophysiology determines the amount of urinary Na⁺, not the serum [Na⁺].

**Hypernatremia**

Hypernatremia is a [Na⁺] >145 mEq/L, although it is sometimes defined as >150 mEq/L. Mild hypernatremia is fairly common in children, especially among infants with gastroenteritis. Hypernatremia in hospitalized patients may be iatrogenic—caused by inadequate water administration or, less often, by excessive Na⁺ administration. Moderate or severe hypernatremia has significant morbidity because of the underlying disease, the effects of hypernatremia on the brain, and the risks of overly rapid correction.

**Etiology and Pathophysiology**

There are 3 basic mechanisms of hypernatremia (Table 68.1). *Sodium intoxication* is frequently iatrogenic in a hospital setting as a result of correction of metabolic acidosis with sodium bicarbonate. Baking soda, a putative home remedy for upset stomach, is another source of sodium bicarbonate; the hypernatremia is accompanied by a profound metabolic alkalosis. In hyperaldosteronism, there is renal retention of sodium and resultant hypertension; hypernatremia may not be present or is usually mild.

Renal Losses

- Osmotic diuretics (mannitol)
- Diabetes mellitus
- Chronic kidney disease (dysplasia and obstructive uropathy)
- Polyuric phase of acute tubular necrosis
- Postobstructive diuresis

The classic causes of hypernatremia from a water deficit are nephrogenic and central diabetes insipidus (see Chapters 548 and 574). Hypernatremia develops in diabetes insipidus only if the patient does not have access to water or cannot drink adequately because of immaturity, neurologic impairment, emesis, or anorexia. Infants are at high risk because of their inability to control their own water intake. Central diabetes insipidus and the genetic forms of nephrogenic diabetes insipidus typically cause massive urinary water losses and very dilute urine. The water losses are less dramatic, and the urine often has the same osmolality as plasma when nephrogenic diabetes insipidus is secondary to intrinsic renal disease (obstructive uropathy, renal dysplasia, sickle cell disease).

The other causes of a water deficit are also secondary to an imbalance between losses and intake. Newborns, especially if premature, have high insensible water losses. Losses are further increased if the infant is placed under a radiant warmer or with the use of phototherapy for hyperbilirubinemia. The renal concentrating mechanisms are not optimal at birth, providing an additional source of water loss. Ineffective breastfeeding, often in a primiparous mother, can cause severe hypernatremic dehydration. Adipsia, the absence of thirst, is usually secondary to damage to the hypothalamus, such as from trauma, tumor, hydrocephalus, or histiocytosis. Primary adipsia is rare.

When hypernatremia occurs in conditions with deficits of sodium and water, the water deficit exceeds the sodium deficit. This occurs only if the patient is unable to ingest adequate water. Diarrhea results in depletion of both Na⁺ and water. Because diarrhea is hypotonic—typical Na⁺ concentration of 35-65 mEq/L—water losses exceed Na⁺ losses, potentially leading to hypernatremia. Most children with gastroenteritis do not have hypernatremia because they drink
enough hypotonic fluid to compensate for stool water losses (see Chapter 366). Fluids such as water, juice, and formula are more hypotonic than the stool losses, allowing correction of the water deficit and potentially even causing hyponatremia. Hypernatremia is most likely to occur in the child with diarrhea who has inadequate intake because of emesis, lack of access to water, or anorexia.

Osmotic agents, including mannitol, and glucose in diabetes mellitus, cause excessive renal losses of water and Na\(^+\). Because the urine is hypotonic (Na\(^+\) concentration of approximately 50 mEq/L) during an osmotic diuresis, water loss exceeds Na\(^+\) loss, and hypernatremia may occur if water intake is inadequate. Certain chronic kidney diseases, such as renal dysplasia and obstructive uropathy, are associated with tubular dysfunction, leading to excessive losses of water and Na\(^+\). Many children with such diseases have disproportionate water loss and are at risk for hypernatremic dehydration, especially if gastroenteritis supervenes. Similar mechanisms occur during the polyuric phase of acute kidney injury and after relief of urinary obstruction (postobstructive diuresis). Patients with either condition may have an osmotic diuresis from urinary losses of urea and an inability to conserve water because of tubular dysfunction.

**Essential hypernatremia** is rare in children and is thought to occur with injury to the hypothalamic-posterior pituitary axis. It is euvoletic, nonhypertensive, and associated with hypodipsia, possibly related to a reset osmol sensor.

### Clinical Manifestations

Most children with hypernatremia are dehydrated and show the typical clinical signs and symptoms (see Chapter 70). Children with hypernatremic dehydration tend to have better preservation of intravascular volume because of the shift of water from the ICS to the ECS. This shift maintains blood pressure and urine output and allows hypernatremic infants to be less symptomatic initially and potentially to become more dehydrated before medical attention is sought. Breastfed infants with hypernatremia are often profoundly dehydrated, with failure to thrive (malnutrition). Probably because of intracellular water loss, the pinched abdominal skin of a dehydrated, hypernatremic infant has a “doughy” feel.

Hypernatremia, even without dehydration, causes central nervous system
(CNS) symptoms that tend to parallel the degree of $Na^+$ elevation and the acuity of the increase. Patients are irritable, restless, weak, and lethargic. Some infants have a high-pitched cry and hyperpnea. Alert patients are very thirsty, even though nausea may be present. Hypernatremia may cause fever, although many patients have an underlying process that contributes to the fever. Hypernatremia is associated with hyperglycemia and mild hypocalcemia; the mechanisms are unknown. Beyond the sequelae of dehydration, there is no clear direct effect of hypernatremia on other organs or tissues, except the brain.

**Brain hemorrhage** is the most devastating consequence of untreated hypernatremia. As the extracellular osmolality increases, water moves out of brain cells, leading to a decrease in brain volume. This decrease can result in tearing of intracerebral veins and bridging blood vessels as the brain moves away from the skull and the meninges. Patients may have subarachnoid, subdural, and parenchymal hemorrhages. Seizures and coma are possible sequelae of the hemorrhage, although seizures are more common during correction of hypernatremia. The cerebrospinal fluid protein is often elevated in infants with significant hypernatremia, probably because of leakage from damaged blood vessels. Neonates, especially if premature, seem especially vulnerable to hypernatremia and excessive sodium intake. There is an association between rapid or hyperosmolar sodium bicarbonate administration and the development of intraventricular hemorrhages in neonates. Even though central pontine myelinolysis is classically associated with overly rapid correction of hyponatremia, both central pontine and extrapontine myelinolysis can occur in children with hypernatremia (see Treatment). Thrombotic complications occur in severe hypernatremic dehydration, including stroke, dural sinus thrombosis, peripheral thrombosis, and renal vein thrombosis. This is secondary to dehydration and possibly hypercoagulability associated with hypernatremia.

**Diagnosis**

The etiology of hypernatremia is usually apparent from the history. Hypernatremia resulting from water loss occurs only if the patient does not have access to water or is unable to drink. In the absence of dehydration, it is important to ask about sodium intake. Children with excess salt intake do not have signs of dehydration, unless another process is present. Severe $Na^+$ intoxication causes signs of volume overload, such as pulmonary edema and weight gain. **Salt poisoning** is associated with an elevated fractional excretion of
Na\(^+\), whereas hypernatremic dehydration causes a low fractional excretion of Na\(^+\). Gastric sodium concentrations are often elevated in salt poisoning. In hyperaldosteronism, hypernatremia is usually mild or absent and is associated with edema, hypertension, hypokalemia, and metabolic alkalosis.

When there is isolated water loss, the signs of volume depletion are usually less severe initially because much of the loss is from the ICS. When pure water loss causes signs of dehydration, the hypernatremia and water deficit are usually severe. In the child with renal water loss, either central or nephrogenic diabetes insipidus, the urine is inappropriately dilute and urine volume is not low. The urine is maximally concentrated and urine volume is low if the losses are extrarenal or caused by inadequate intake. With extrarenal causes of loss of water, the urine osmolality should be >1,000 mOsm/kg. When diabetes insipidus is suspected, the evaluation may include measurement of ADH and a water deprivation test, including a trial of desmopressin acetate (synthetic ADH analog) to differentiate between nephrogenic diabetes insipidus and central diabetes insipidus (see Chapters 548 and 574). A water-deprivation test is unnecessary if the patient has simultaneous documentation of hypernatremia and poorly concentrated urine (osmolality lower than that of plasma). In children with central diabetes insipidus, administration of desmopressin acetate increases the urine osmolality above the plasma osmolality, although maximum osmolality does not occur immediately because of the decreased osmolality of the renal medulla as a result of the chronic lack of ADH. In children with nephrogenic diabetes insipidus, there is no response to desmopressin acetate. Hypercalcemia or hypokalemia may produce a nephrogenic diabetes insipidus–like syndrome.

With combined Na\(^+\) and water deficits, analysis of the urine differentiates between renal and nonrenal etiologies. When the losses are extrarenal, the kidney responds to volume depletion with low urine volume, concentrated urine, and Na\(^+\) retention (urine [Na\(^+\)] <20 mEq/L, fractional excretion of Na\(^+\) <1%). With renal causes, the urine volume is not appropriately low, the urine is not maximally concentrated, and the urine [Na\(^+\)] may be inappropriately elevated.

**Treatment**

As hypernatremia develops, the brain generates **idiogenic osmoles** to increase the intracellular osmolality and prevent the loss of brain water. This mechanism is not instantaneous and is most prominent when hypernatremia has developed gradually. If the serum [Na\(^+\)] is lowered rapidly, there is movement of water
from the serum into the brain cells to equalize the osmolality in the 2 compartments. The resultant brain swelling manifests as seizures or coma.

Because of the associated dangers, chronic hypernatremia should not be corrected rapidly. The goal is to decrease the serum [Na$^+$] by <10 mEq/L every 24 hr. The most important component of correcting moderate or severe hypernatremia is frequent monitoring of the serum [Na$^+$] value so that fluid therapy can be adjusted to provide adequate correction, neither too slow nor too fast. If a child has seizures as a result of brain edema secondary to rapid correction, administration of hypotonic fluid should be stopped. An infusion of 3% saline can acutely increase the serum [Na$^+$], reversing the cerebral edema.

Chapter 70 outlines a detailed approach to the child with hypernatremic dehydration. Acute, severe hypernatremia, usually secondary to sodium administration, can be corrected more rapidly with 5% dextrose in water (D5W) because idiogenic osmoles have not had time to accumulate. This fact balances the high morbidity and mortality rates associated with hypernatremia with the dangers of overly rapid correction. When hypernatremia is severe and is caused by sodium intoxication, it may be impossible to administer enough water to correct the hypernatremia rapidly without worsening the volume overload. In this situation, dialysis allows for removal of the excess Na$^+$, with the precise strategy dependent on the mode of dialysis. In less severe cases, the addition of a loop diuretic increases the removal of excess Na$^+$ and water, decreasing the risk of volume overload. With Na$^+$ overload, hypernatremia is corrected with Na$^+$-free intravenous (IV) fluid (D5W).

Hyperglycemia from hypernatremia is not usually a problem and is not treated with insulin because the acute decrease in glucose may precipitate cerebral edema by lowering plasma osmolality. Rarely, the glucose concentration of IV fluids must be reduced (from 5% to 2.5% dextrose in water). The secondary hypocalcemia is treated as needed.

It is important to address the underlying cause of the hypernatremia, if possible. The child with central diabetes insipidus should receive desmopressin acetate. Because this treatment reduces renal excretion of water, excessive intake of water must be avoided to prevent both overly rapid correction of the hypernatremia and the development of hyponatremia. Over the long term, reduced sodium intake and the use of medications can somewhat ameliorate the water losses in nephrogenic diabetes insipidus (see Chapter 548). The daily water intake of a child receiving tube feeding may need to be increased to compensate for high losses. The patient with significant ongoing losses, such as
through diarrhea, may need supplemental water and electrolytes (see Chapter 69). Sodium intake is reduced if it contributed to the hypernatremia.

**Hyponatremia**

Hyponatremia, a very common electrolyte abnormality in hospitalized patients, is a serum sodium level <135 mEq/L. Both total body sodium and TBW determine the serum sodium concentration. Hyponatremia exists when the ratio of water to Na⁺ is increased. This condition can occur with low, normal, or high levels of body Na⁺. Similarly, body water can be low, normal, or high.

**Etiology and Pathophysiology**

Table 68.2 lists the causes of hyponatremia. **Pseudohyponatremia** is a laboratory artifact present when the plasma contains very high concentrations of protein (multiple myeloma, IVIG infusion) or lipid (hypertriglyceridemia, hypercholesterolemia). It does not occur when a direct ion-selective electrode determines the [Na⁺] in undiluted plasma, a technique that is used by ABG analyzers or POC instruments (see Chapter 68.1). In true hyponatremia, the measured osmolality is low, whereas it is normal in pseudohyponatremia. **Hyperosmolality**, as may occur with hyperglycemia, causes a low [Na⁺] because water moves down its osmotic gradient from the ICS into the ECS, diluting the [Na⁺]. However, because the manifestations of hyponatremia are a result of the low plasma osmolality, patients with hyponatremia resulting from hyperosmolality do not have symptoms of hyponatremia. When the etiology of the hyperosmolality resolves, such as hyperglycemia in diabetes mellitus, water moves back into the cells, and the [Na⁺] rises to its “true” value. Mannitol or sucrose, a component of intravenous immune globulin (IVIG) preparations, may cause hyponatremia because of hyperosmolality.

HYPEROSMOLALITY

Hyperglycemia
Iatrogenic (mannitol, sucrose, glycine)

HYPOVOLEMIC HYponatremia
EXTRARENAL LOSSES

Gastrointestinal (emesis, diarrhea)
Skin (sweating or burns)
Third space losses (bowel obstruction, peritonitis, sepsis)

RENAAL LOSSES

Thiazide or loop diuretics
Osmotic diuresis
Postobstructive diuresis
Polyuric phase of acute tubular necrosis
Juvenile nephronophthisis (OMIM 256100/606966/602088/604387/611498)
Autosomal recessive polycystic kidney disease (OMIM 263200)
Tubulointerstitial nephritis
Obstructive uropathy
Cerebral salt wasting
Proximal (type II) renal tubular acidosis (OMIM 604278)*
Lack of aldosterone effect (high serum potassium):
   Absence of aldosterone (e.g., 21-hydroxylase deficiency [OMIM 201910])
   Pseudohypoaldosteronism type I (OMIM 264350/177735)
   Urinary tract obstruction and/or infection
   Addison disease

EUVOLEMIC HYponatremia

Syndrome of inappropriate antidiuretic hormone secretion
Nephrogenic syndrome of inappropriate antidiuresis (OMIM 304800)
Desmopressin acetate
Glucocorticoid deficiency
Hypothyroidism
Antidepressant medications
Water intoxication
  Iatrogenic (excess hypotonic intravenous fluids)
  Feeding infants excessive water products
  Swimming lessons
  Tap water enema
  Child abuse
  Psychogenic polydipsia
  Diluted formula
  Beer potomania
  Exercise-induced hyponatremia

**HYPERVOLEMIC HYPONATREMIA**

Heart failure
Cirrhosis
Nephrotic syndrome
Acute, chronic kidney injury
Capillary leak caused by sepsis
Hypoalbuminemia caused by gastrointestinal disease (protein-losing enteropathy)

* Most cases of proximal renal tubular acidosis are not caused by this primary genetic disorder. Proximal renal tubular acidosis is usually part of Fanconi syndrome, which has multiple etiologies.

Classification of hyponatremia is based on the patient's volume status. In **hypovolemic hyponatremia** the child has lost Na⁺ from the body. The water balance may be positive or negative, but Na⁺ loss has been higher than water
loss. The pathogenesis of the hyponatremia is usually a combination of Na\(^+\) loss and water retention to compensate for the volume depletion. The patient has a pathologic increase in fluid loss, and this fluid contains Na\(^+\). Most fluid that is lost has a lower [Na\(^+\)] than that of plasma. Viral diarrhea fluid has an average [Na\(^+\)] of 50 mEq/L. Replacing diarrhea fluid, which has [Na\(^+\)] of 50 mEq/L, with formula, which has only approximately 10 mEq/L of Na\(^+\), reduces [Na\(^+\)]. Intravascular volume depletion interferes with renal water excretion, the body's usual mechanism for preventing hyponatremia. The volume depletion stimulates ADH synthesis, resulting in renal water retention. Volume depletion also decreases the GFR and enhances water resorption in the proximal tubule, thereby reducing water delivery to the collecting duct.

Diarrhea as a result of gastroenteritis is the most common cause of hypovolemic hyponatremia in children. Emesis causes hyponatremia if the patient takes in hypotonic fluid, either intravenously or enterally, despite the emesis. Most patients with emesis have either a normal [Na\(^+\)] or hypernatremia. Burns may cause massive losses of isotonic fluid and resultant volume depletion. Hyponatremia develops if the patient receives hypotonic fluid. Losses of sodium from sweat are especially high in children with cystic fibrosis, aldosterone deficiency, or pseudohypoaldosteronism, although high losses can also occur in a hot climate. Third space losses are isotonic and can cause significant volume depletion, leading to ADH production and water retention, which can cause hyponatremia if the patient receives hypotonic fluid. In diseases that cause volume depletion through extrarenal Na\(^+\) loss, the urine Na\(^+\) level should be low (<10 mEq/L) as part of the renal response to maintain the intravascular volume. The only exceptions are diseases that cause both extrarenal and renal Na\(^+\) losses: adrenal insufficiency and pseudohypoaldosteronism.

Renal Na\(^+\) loss may occur in a variety of situations. In some situations the urine [Na\(^+\)] is >140 mEq/L; thus hyponatremia may occur without any fluid intake. In many cases the urine Na\(^+\) level is less than the serum [Na\(^+\)]; thus the intake of hypotonic fluid is necessary for hyponatremia to develop. In diseases associated with urinary Na\(^+\) loss, the urine Na\(^+\) level is >20 mEq/L despite volume depletion. This may not be true if the urinary Na\(^+\) loss is no longer occurring, as is frequently the case if diuretics are discontinued. Because loop diuretics prevent generation of a maximally hypertonic renal medulla, the patient can neither maximally dilute nor concentrate the urine. The inability to maximally retain water provides some protection against severe hyponatremia.
The patient receiving thiazide diuretics can concentrate the urine and is at higher risk for severe hyponatremia. Osmotic agents, such as glucose during diabetic ketoacidosis, cause loss of both water and Na⁺. Urea accumulates during renal failure and then acts as an osmotic diuretic after relief of urinary tract obstruction and during the polyuric phase of acute tubular necrosis. Transient tubular damage in these conditions further impairs Na⁺ conservation. The serum [Na⁺] in these conditions depends on [Na⁺] of the fluid used to replace the losses. Hyponatremia develops when the fluid is hypotonic relative to the urinary losses.

Renal salt wasting occurs in hereditary kidney diseases, such as juvenile nephronophthisis and autosomal recessive polycystic kidney disease. Obstructive uropathy, most often a result of posterior urethral valves, produces salt wasting, but patients with the disease may also have hypernatremia as a result of impaired ability to concentrate urine and high-water loss. Acquired tubulointerstitial nephritis, usually secondary to either medications or infections, may cause salt wasting, along with other evidence of tubular dysfunction. CNS injury may produce cerebral salt wasting, which is theoretically caused by the production of a natriuretic peptide that causes renal salt wasting. In type II renal tubular acidosis (RTA), usually associated with Fanconi syndrome (see Chapter 547.1), there is increased excretion of Na⁺ and bicarbonate in the urine. Patients with Fanconi syndrome also have glycosuria, aminoaciduria, and hypophosphatemia because of renal phosphate wasting.

Aldosterone is necessary for renal Na⁺ retention and for the excretion of K⁺ and acid. In congenital adrenal hyperplasia caused by 21-hydroxylase deficiency, the block of aldosterone production results in hyponatremia, hyperkalemia, and metabolic acidosis. Decreased aldosterone secretion may be seen in Addison disease (adrenal insufficiency). In pseudohypoaldosteronism, aldosterone levels are elevated, but there is no response because of either a defective Na⁺ channel or a deficiency of aldosterone receptors. A lack of tubular response to aldosterone may occur in children with urinary tract obstruction, especially during an acute urinary tract infection.

In hypervolemic hyponatremia there is an excess of TBW and Na⁺, although the increase in water is greater than the increase in Na⁺. In most conditions that cause hypervolemic hyponatremia, there is a decrease in the effective blood volume, resulting from third space fluid loss, vasodilation, or poor cardiac output. The regulatory systems sense a decrease in effective blood
volume and attempt to retain water and \( \text{Na}^+ \) to correct the problem. ADH causes renal water retention, and the kidney, under the influence of aldosterone and other intrarenal mechanisms, retains sodium. The patient's sodium concentration decreases because water intake exceeds sodium intake and ADH prevents the normal loss of excess water.

In these disorders, there is low urine \([\text{Na}^+] < 10 \text{ mEq/L}\) and an excess of both TBW and \( \text{Na}^+ \). The only exception is in patients with renal failure and hyponatremia. These patients have an expanded intravascular volume, and hyponatremia can therefore appropriately suppress ADH production. Water cannot be excreted because very little urine is being made. Serum \( \text{Na}^+ \) is diluted through ingestion of water. Because of renal dysfunction, the urine \([\text{Na}^+] \) may be elevated, but urine volume is so low that urine \( \text{Na}^+ \) excretion has not kept up with \( \text{Na}^+ \) intake, leading to sodium overload. The urine \([\text{Na}^+] \) in renal failure varies. In patients with acute glomerulonephritis, because it does not affect the tubules, the urine \( \text{Na}^+ \) level is usually low, whereas in patients with acute tubular necrosis, it is elevated because of tubular dysfunction.

Patients with hyponatremia and no evidence of volume overload or volume depletion have **euvolemic hyponatremia**. These patients typically have an excess of TBW and a slight decrease in total body \( \text{Na}^+ \). Some of these patients have an increase in weight, implying that they are volume-overloaded. Nevertheless, from a clinical standpoint, they usually appear normal or have subtle signs of fluid overload. In SIADH the secretion of ADH is not inhibited by either low serum osmolality or expanded intravascular volume (see Chapter 575). The result is that the child with SIADH is unable to excrete water. This results in dilution of the serum \( \text{Na}^+ \) and hyponatremia. The expansion of the extracellular volume because of the retained water causes a mild increase in intravascular volume. The kidney increases \( \text{Na}^+ \) excretion to decrease intravascular volume to normal; thus the patient has a mild decrease in body \( \text{Na}^+ \). SIADH typically occurs with disorders of the CNS (infection, hemorrhage, trauma, tumor, thrombosis, Guillain-Barré syndrome), but lung disease (infection, asthma, positive pressure ventilation) and malignant tumors (producing ADH) are other potential causes. A variety of medications may cause SIADH, including recreational use of 3,4-methylenedioxymethylamphetamine (MDMA, or “Ecstasy”), opiates, antiepileptic drugs (carbamazepine, oxcarbazepine, valproate), tricyclic antidepressants, vincristine, cyclophosphamide, and selective serotonin reuptake inhibitors (SSRIs). The
diagnosis of SIADH is one of exclusion, because other causes of hyponatremia must be eliminated (Table 68.3). Because SIADH is a state of intravascular volume expansion, low serum uric acid and BUN levels are supportive of the diagnosis. A rare gain-of-function mutation in the renal ADH receptor causes nephrogenic syndrome of inappropriate antidiuresis. Patients with this X-linked disorder appear to have SIADH but have undetectable levels of ADH.

Table 68.3

Diagnostic Criteria for Syndrome of Inappropriate Antidiuretic Hormone Secretion

- Absence of:
  - Renal, adrenal, or thyroid insufficiency
  - Heart failure, nephrotic syndrome, or cirrhosis
  - Diuretic ingestion
  - Dehydration
- Urine osmolality >100 mOsm/kg (usually > plasma)
- Serum osmolality <280 mOsm/kg and serum sodium <135 mEq/L
- Urine sodium >30 mEq/L
- Reversal of “sodium wasting” and correction of hyponatremia with water restriction

Hyponatremia in hospitalized patients is frequently caused by inappropriate production of ADH and administration of hypotonic IV fluids (see Chapter 69). Causes of inappropriate ADH production include stress, medications such as narcotics or anesthetics, nausea, and respiratory illness. The synthetic analog of ADH, desmopressin acetate, causes water retention and may cause hyponatremia if fluid intake is not appropriately limited. The main uses of desmopressin acetate in children are for the management of central diabetes insipidus and nocturnal enuresis.

Excess water ingestion can produce hyponatremia. In these cases, [Na⁺] decreases as a result of dilution. This decrease suppresses ADH secretion, and there is a marked water diuresis by the kidney. Hyponatremia develops only because the intake of water exceeds the kidney's ability to eliminate water. This
condition is more likely to occur in infants because their lower GFR limits their ability to excrete water.

Hyponatremia may develop in infants <6 mo of age when caregivers offer water to their infant as a supplement, during hot weather, or when they run out of formula. Hyponatremia may result in transient seizures, hypothermia, and poor tone. With cessation of water intake, the hyponatremia rapidly corrects. Infants <6 mo of age should not be given water to drink; infants 6-12 mo of age should not receive >1-2 ounces. If the infant appears thirsty, the parent should offer formula or breastfeed the child.

In some situations the water intoxication causes acute hyponatremia and is caused by a massive acute water load. Causes include infant swimming lessons, inappropriate use of hypotonic IV fluids, water enemas, and forced water intake as a form of child abuse. Chronic hyponatremia occurs in children who receive water but limited sodium and protein. The minimum urine osmolality is approximately 50 mOsm/kg, the kidney can excrete 1 L of water only if there is enough solute ingested to produce 50 mOsm for urinary excretion. Because Na\(^+\) and urea (a breakdown product of protein) are the principal urinary solutes, a lack of intake of Na\(^+\) and protein prevents adequate water excretion. This occurs with the use of diluted formula or other inappropriate diets. Subsistence on beer, a poor source of Na\(^+\) and protein, causes hyponatremia because of the inability to excrete the high water load (“beer potomania”). Exercise-induced hyponatremia, reported frequently during marathons, is caused by excessive water intake, salt losses from sweat, and secretion of ADH.

The pathogenesis of the hyponatremia in glucocorticoid deficiency (adrenal insufficiency) is multifactorial and includes increased ADH secretion. In hypothyroidism there is an inappropriate retention of water by the kidney, but the precise mechanisms are not clearly elucidated.

Cerebral salt wasting, an uncommon disorder in children, may be confused with SIADH and is often associated with CNS injury or lesions. Cerebral salt wasting produces renal salt losses and hypovolemia (orthostatic hypotension and elevated hematocrit, BUN, or creatinine).

**Clinical Manifestations**

Hyponatremia causes a decrease in the osmolality of the ECS. Because the ICS then has a higher osmolality, water moves from the ECS to the ICS to maintain
osmotic equilibrium. The increase in intracellular water causes cells to swell. Although cell swelling is not problematic in most tissues, it is dangerous for the brain, which is confined by the skull. As brain cells swell, there is an increase in intracranial pressure, which impairs cerebral blood flow. Acute, severe hyponatremia can cause brainstem herniation and apnea; respiratory support is often necessary. Brain cell swelling is responsible for most of the symptoms of hyponatremia. Neurologic symptoms of hyponatremia include anorexia, nausea, emesis, malaise, lethargy, confusion, agitation, headache, seizures, coma, and decreased reflexes. Patients may have hypothermia and Cheyne-Stokes respirations. Hyponatremia can cause muscle cramps and weakness; rhabdomyolysis can occur with water intoxication.

The symptoms of hyponatremia are mostly a result of the decrease in extracellular osmolality and the resulting movement of water down its osmotic gradient into the ICS. Brain swelling can be significantly obviated if the hyponatremia develops gradually, because brain cells adapt to the decreased extracellular osmolality by reducing intracellular osmolality. This reduction is achieved by extrusion of the main intracellular ions (K\(^+\), Cl\(^-\)) and a variety of small organic molecules. This process explains why the range of symptoms in hyponatremia is related to both the serum [Na\(^+\)] and its rate of decrease. A patient with chronic hyponatremia may have only subtle neurologic abnormalities with a serum [Na\(^+\)] of 110 mEq/L, but another patient may have seizures because of an acute decline in serum [Na\(^+\)] from 140 to 125 mEq/L.

**Diagnosis**

The history usually points to a likely etiology of the hyponatremia. Most patients with hyponatremia have a history of volume depletion. Diarrhea and diuretic use are common causes of hyponatremia in children. A history of polyuria, perhaps with enuresis, and/or salt craving is present in children with primary kidney diseases or absence of aldosterone effect. Children may have signs or symptoms suggesting a diagnosis of hypothyroidism or adrenal insufficiency (see Chapters 581 and 593). Brain injury raises the possibility of SIADH or cerebral salt wasting, with the caveat that SIADH is much more likely. Liver disease, nephrotic syndrome, renal failure, or congestive heart failure may be acute or chronic. The history should include a review of the patient's intake, both intravenous and enteral, with careful attention to the amounts of water, Na\(^+\), and protein.
The traditional first step in the diagnostic process is determination of the plasma osmolality. This is done because some patients with a low serum $[Na^+]$ do not have low osmolality. The clinical effects of hyponatremia are secondary to the associated low osmolality. Without a low osmolality, there is no movement of water into the intracellular space.

A patient with hyponatremia can have a low, normal, or high osmolality. A normal osmolality in combination with hyponatremia occurs in pseudohyponatremia. Children with elevation of serum glucose concentration or of another effective osmole (mannitol) have a high plasma osmolality and hyponatremia. The presence of a low osmolality indicates “true” hyponatremia. Patients with low osmolality are at risk for neurologic symptoms and require further evaluation to determine the etiology of the hyponatremia.

In some situations, true hyponatremia is present despite a normal or elevated plasma osmolality. The presence of an ineffective osmole, usually urea, increases the plasma osmolality, but because the osmole has the same concentration in the ICS, it does not cause fluid to move into the ECS. There is no dilution of the serum $Na^+$ by water, and the $[Na^+]$ remains unchanged if the ineffective osmole is eliminated. Most importantly, the ineffective osmole does not protect the brain from edema caused by hyponatremia. Therefore, a patient may have symptoms of hyponatremia despite having a normal or increased osmolality because of uremia.

In patients with true hyponatremia, the next step in the diagnostic process is to clinically evaluate the volume status. Patients with hyponatremia can be hypovolemic, hypervolemic, or euvoletic. The diagnosis of volume depletion relies on the usual findings with dehydration (see Chapter 70), although subtle volume depletion may not be clinically apparent. Children with hypervolemia are edematous on physical examination. They may have ascites, pulmonary edema, pleural effusion, or hypertension.

Hypovolemic hyponatremia can have renal or nonrenal causes. The urine $[Na^+]$ is very useful in differentiating between renal and nonrenal causes. When the losses are nonrenal and the kidney is working properly, there is renal retention of $Na^+$, a normal homeostatic response to volume depletion. Thus the urinary $[Na^+]$ is low, typically $<10$ mEq/L, although $Na^+$ conservation in neonates is less avid. When the kidney is the cause of the $Na^+$ loss, the urine $[Na^+]$ is $>20$ mEq/L, reflecting the defect in renal $Na^+$ retention. The interpretation of the urine $Na^+$ level is challenging with diuretic therapy because it is high when
Diuretics are being used but low after the diuretic effect is gone. This becomes an issue only when diuretic use is surreptitious. The urine [Na\(^+\)] is not useful if a metabolic alkalosis is present; the urine [Cl\(^-\)] must be used instead (see Chapter 68.7).

Differentiating among the nonrenal causes of hypovolemic hyponatremia is usually facilitated by the history. Although the renal causes are more challenging to distinguish, a high serum [K\(^+\)] is associated with disorders in which the Na\(^+\) wasting is caused by absence of or ineffectiveness of aldosterone.

In the patient with hypervolemic hyponatremia, the urine [Na\(^+\)] is a helpful parameter. It is usually <10 mEq/L, except in the patient with renal failure.

**Treatment**

The management of hyponatremia is based on the pathophysiology of the specific etiology. The management of all causes requires judicious monitoring and avoidance of an overly quick normalization of the serum [Na\(^+\)]. A patient with severe symptoms (seizures), no matter the etiology, should be given a bolus of hypertonic saline to produce a small, rapid increase in serum sodium. *Hypoxia worsens cerebral edema*, and *hyponatremia may exacerbate hypoxic cell swelling*. Therefore, pulse oximetry should be monitored and hypoxia aggressively corrected.

With all causes of hyponatremia, it is important to avoid overly rapid correction, which may cause **central pontine myelinolysis (CPM)**. This syndrome, which occurs within several days of rapid correction of hyponatremia, produces neurologic symptoms, including confusion, agitation, flaccid or spastic quadripareisis, and death. There are usually characteristic pathologic and radiologic changes in the brain, especially in the pons, but extrapontine lesions are quite common and may cause additional symptoms. Despite severe symptoms, full recovery does occur in some patients.

CPM is more common in patients who are treated for *chronic* hyponatremia than for acute hyponatremia. Presumably, this difference is based on the adaptation of brain cells to the hyponatremia. The reduced intracellular osmolality, an adaptive mechanism for chronic hyponatremia, makes brain cells susceptible to dehydration during rapid correction of the hyponatremia, which may be the mechanism of CPM. Even though CPM is rare in pediatric patients, it is advisable to avoid correcting the serum [Na\(^+\)] by >10 mEq/L/24 hr or >18 mEq/L/48 hr. Desmopressin is a potential option if the serum [Na\(^+\)] is increasing
too rapidly. This guideline does not apply to acute hyponatremia, as may occur with water intoxication, because the hyponatremia is more often symptomatic, and the adaptive decrease in brain osmolality has not had time to occur. The consequences of brain edema in acute hyponatremia exceed the small risk of CPM.

Patients with hyponatremia can have severe neurologic symptoms, such as seizures and coma. The seizures associated with hyponatremia generally are poorly responsive to anticonvulsants. The child with hyponatremia and severe symptoms needs treatment that will quickly reduce cerebral edema. This goal is best accomplished by increasing the extracellular osmolality so that water moves down its osmolar gradient from the ICS to the ECS.

Intravenous hypertonic saline rapidly increases serum [Na$^+$], and the effect on serum osmolality leads to a decrease in brain edema. Each mL/kg of 3% NaCl increases the serum [Na$^+$] by approximately 1 mEq/L. A child with active symptoms often improves after receiving 4-6 mL/kg of 3% NaCl.

The child with hypovolemic hyponatremia has a deficiency in Na$^+$ and may have a deficiency in water. The cornerstone of therapy is to replace the Na$^+$ deficit and any water deficit present. The first step in treating any dehydrated patient is to restore the intravascular volume with isotonic saline. Ultimately, complete restoration of intravascular volume suppresses ADH production, thereby permitting excretion of the excess water. Chapter 70 discusses the management of hyponatremic dehydration.

The management of hypervolemic hyponatremia is difficult; patients have an excess of both water and Na$^+$. Administration of Na$^+$ leads to worsening volume overload and edema. In addition, patients are retaining water and Na$^+$ because of their ineffective intravascular volume or renal insufficiency. The cornerstone of therapy is water and Na$^+$ restriction, because patients have volume overload. Diuretics may help by causing excretion of both Na$^+$ and water. Vasopressin antagonists (vaptans), by blocking the action of ADH and causing a water diuresis, are effective in correcting the hypervolemic hyponatremia caused by heart failure. Vaptans are contraindicated if there are moderate to severe CNS symptoms.

Hyponatremic patients with low albumin from nephrotic syndrome have a better response to diuretics after an infusion of 25% albumin; the [Na$^+$] often normalizes as a result of expansion of the intravascular volume. A child with heart failure may have an increase in renal water and Na$^+$ excretion if there is an
improvement in cardiac output. This improvement will “turn off” the regulatory hormones causing renal water (ADH) and Na\(^+\) (aldosterone) retention. The patient with renal failure cannot respond to any of these therapies except fluid restriction. Insensible fluid losses eventually result in an increase in the [Na\(^+\)] as long as insensible and urinary losses are greater than intake. A more definitive approach in children with renal failure is to perform dialysis, which removes water and Na\(^+\).

In isovolumic hyponatremia there is usually an excess of water and a mild Na\(^+\) deficit. Therapy is directed at eliminating the excess water. The child with acute excessive water intake loses water in the urine because ADH production is turned off as a result of the low plasma osmolality. Children may correct their hyponatremia spontaneously over 3-6 hr. For acute, symptomatic hyponatremia as a result of water intoxication, hypertonic saline may be needed to reverse cerebral edema. For chronic hyponatremia from poor solute intake, the child needs an appropriate formula, and excess water intake should be eliminated.

Children with iatrogenic hyponatremia caused by the administration of hypotonic IV fluids should receive 3% saline if symptomatic. Subsequent management is dictated by the patient's volume status. The hypovolemic child should receive isotonic IV fluids. The child with nonphysiologic stimuli for ADH production should undergo fluid restriction. Prevention of this iatrogenic complication requires judicious use of IV fluids (see Chapter 69).

Specific hormone replacement is the cornerstone of therapy for the hyponatremia of hypothyroidism or cortisol deficiency. Correction of the underlying defect permits appropriate elimination of the excess water.

SIADH is a condition of excess water, with limited ability of the kidney to excrete water. The mainstay of its therapy is fluid restriction with normal sodium intake. Furosemide and NaCl supplementation are effective in the patient with SIADH and severe hyponatremia. Even in a patient with SIADH, furosemide causes an increase in water and Na\(^+\) excretion. The loss of Na\(^+\) is somewhat counterproductive, but this Na\(^+\) can be replaced with hypertonic saline. Because the patient has a net loss of water and the urinary losses of Na\(^+\) have been replaced, there is an increase in the [Na\(^+\)], but no significant increase in blood pressure. Vaptans, which block the action of ADH and cause a water diuresis, are effective at correcting euvolemic hyponatremia, but overly rapid correction is a potential complication. Vaptans are not appropriate for treating symptomatic hyponatremia because it can take a few hours before the water diuresis occurs.
Treatment of chronic SIADH is challenging. Fluid restriction in children is difficult for nutritional and behavioral reasons. Other options are long-term furosemide therapy with Na\(^+\) supplementation, an oral vaptan (tolvaptan), or oral urea.

Potassium Metabolism

Body Content and Physiologic Function

The intracellular \([K^+]\), approximately 150 mEq/L, is much higher than the plasma \([K^+]\) (see Fig. 68.3). The majority of body \(K^+\) is contained in muscle. As muscle mass increases, there is an increase in body \(K^+\). Thus an increase in body \(K^+\) occurs during puberty, and it is more significant in males. The majority of extracellular \(K^+\) is in bone; <1% of total body \(K^+\) is in plasma.

Because most \(K^+\) is intracellular, the plasma concentration does not always reflect the total body \(K^+\) content. A variety of conditions alter the distribution of \(K^+\) between the intracellular and extracellular compartments. \(Na^+ \cdot K^+\)-ATPase maintains the high intracellular \([K^+]\) by pumping \(Na^+\) out of the cell and \(K^+\) into the cell. This activity balances the normal leak of \(K^+\) out of cells via potassium channels that is driven by the favorable chemical gradient. Insulin increases \(K^+\) movement into cells by activating \(Na^+ \cdot K^+\)-ATPase. Hyperkalemia stimulates insulin secretion, which helps mitigate the hyperkalemia. Acid-base status affects \(K^+\) distribution, probably via \(K^+\) channels and the \(Na^+ \cdot K^+\)-ATPase. A decrease in pH drives potassium extracellularly; an increase in pH has the opposite effect. \(\beta\)-Adrenergic agonists stimulate the \(Na^+ \cdot K^+\)-ATPase, increasing cellular uptake of \(K^+\). This increase is protective, in that hyperkalemia stimulates adrenal release of catecholamines. \(\alpha\)-Adrenergic agonists and exercise cause a net movement of \(K^+\) out of the ICS. An increase in plasma osmolality, as with mannitol infusion, leads to water movement out of the cells, and \(K^+\) follows as a result of solvent drag. The serum \([K^+]\) increases by approximately 0.6 mEq/L with each 10 mOsm rise in plasma osmolality.

The high intracellular concentration of \(K^+\), the principal intracellular cation, is maintained through \(Na^+ \cdot K^+\)-ATPase. The resulting chemical gradient is used to produce the resting membrane potential of cells. \(K^+\) is necessary for the
electrical responsiveness of nerve and muscle cells and for the contractility of cardiac, skeletal, and smooth muscle. The changes in membrane polarization that occur during muscle contraction or nerve conduction make these cells susceptible to changes in serum [K\(^+\)]. The ratio of intracellular to extracellular K\(^+\) determines the threshold for a cell to generate an action potential and the rate of cellular repolarization. The intracellular [K\(^+\)] affects cellular enzymes. K\(^+\) is necessary for maintaining cell volume because of its important contribution to intracellular osmolality.

**Potassium Intake**

Potassium is plentiful in food. Dietary consumption varies considerably, even though 1-2 mEq/kg is the recommended intake. The intestines normally absorb approximately 90% of ingested K\(^+\). Most absorption occurs in the small intestine, whereas the colon exchanges body K\(^+\) for luminal Na\(^+\). Regulation of intestinal losses normally has a minimal role in maintaining potassium homeostasis, although renal failure, aldosterone, and glucocorticoids increase colonic secretion of K\(^+\). The increase in intestinal losses in the setting of renal failure and hyperkalemia, which stimulates aldosterone production, is clinically significant, helping to protect against hyperkalemia.

**Potassium Excretion**

Some loss of K\(^+\) occurs in sweat but is normally minimal. The colon has the ability to eliminate some K\(^+\). In addition, after an acute K\(^+\) load, much of the K\(^+\), >40%, moves intracellularly, through the actions of epinephrine and insulin, which are produced in response to hyperkalemia. This process provides transient protection from hyperkalemia, but most ingested K\(^+\) is eventually excreted in the urine. The kidneys principally regulate long-term K\(^+\) balance, and they alter excretion in response to a variety of signals. K\(^+\) is freely filtered at the glomerulus, but 90% is resorbed before reaching the distal tubule and collecting duct, the principal sites of K\(^+\) regulation that have the ability to absorb and secrete K\(^+\). The amount of tubular secretion regulates the amount of K\(^+\) that appears in the urine. The plasma [K\(^+\)] directly influences secretion in the distal nephron. As the [K\(^+\)] increases, secretion increases.

The principal hormone regulating potassium secretion is **aldosterone**, which
is released by the adrenal cortex in response to increased plasma K⁺. Its main site of action is the cortical collecting duct, where aldosterone stimulates Na⁺ movement from the tubule into the cells. This movement creates a negative charge in the tubular lumen, facilitating K⁺ excretion. In addition, the increased intracellular Na⁺ stimulates the basolateral Na⁺,K⁺ -ATPase, causing more K⁺ to move into the cells lining the cortical collecting duct. Glucocorticoids, ADH, a high urinary flow rate, and high Na⁺ delivery to the distal nephron also increase urinary K⁺ excretion. Whereas ADH increases K⁺ secretion, it also causes water resorption, decreasing urinary flow. The net effect is that ADH has little overall impact on K⁺ balance. Alkalosis causes potassium to move into cells, including the cells lining the collecting duct. This movement increases K⁺ secretion, and because acidosis has the opposite effect, it decreases K⁺ secretion.

The kidney can dramatically vary K⁺ excretion in response to changes in intake. Normally, approximately 10–15% of the filtered load is excreted. In an adult, excretion of K⁺ can vary from 5-1,000 mEq/day.

**Hyperkalemia**

Hyperkalemia—because of the potential for lethal arrhythmias—is one of the most alarming electrolyte abnormalities.

**Etiology and Pathophysiology**

Three basic mechanisms cause hyperkalemia (Table 68.4). In the individual patient, the etiology is sometimes multifactorial.

**Table 68.4**

**Causes of Hyperkalemia**

**Spurious Laboratory Value**

- Hemolysis
- Tissue ischemia during blood drawing
- Thrombocytosis
- Leukocytosis
Familial pseudohyperkalemia (OMIM 609153/611184/612126)

**Increased Intake**

- Intravenous or oral
- Blood transfusions

**Transcellular Shifts**

- Acidosis
- Rhabdomyolysis
- Tumor lysis syndrome
- Tissue necrosis
- Hemolysis/hematomas/gastrointestinal bleeding
- Succinylcholine
- Digitalis intoxication
- Fluoride intoxication
- β-Adrenergic blockers
- Exercise
- Hyperosmolality
- Insulin deficiency
- Malignant hyperthermia (OMIM 145600/601887)
- Hyperkalemic periodic paralysis (OMIM 170500)

**Decreased Excretion**

- Renal failure
- Primary adrenal disease
  - Acquired Addison disease
  - 21-Hydroxylase deficiency (OMIM 201910)
  - 3β-Hydroxysteroid dehydrogenase deficiency (OMIM 201810)
  - Lipoid congenital adrenal hyperplasia (OMIM 201710)
  - Adrenal hypoplasia congenita (OMIM 300200)
  - Aldosterone synthase deficiency (OMIM 203400/610600)
  - Adrenoleukodystrophy (OMIM 300100)
- Hyporeninemic hypoaldosteronism
Urinary tract obstruction
Sickle cell disease (OMIM 603903)
Kidney transplant
Lupus nephritis

Renal tubular disease
  Pseudohypoaldosteronism type I (OMIM 264350/177735)
  Pseudohypoaldosteronism type II (OMIM 145260)
  Bartter syndrome, type 2 (OMIM 241200)
  Urinary tract obstruction
  Kidney transplant

Medications
  Renin inhibitors
  Angiotensin-converting enzyme inhibitors
  Angiotensin II blockers
  Potassium-sparing diuretics
  Calcineurin inhibitors
  Nonsteroidal antiinflammatory drugs
  Trimethoprim
  Heparin
  Drospirenone (in some oral contraceptives)

**Spurious hyperkalemia** or **pseudohyperkalemia** is very common in children because of the difficulties in obtaining blood specimens. This laboratory result is usually caused by hemolysis during a heelstick or phlebotomy, but it can be the result of prolonged tourniquet application or fist clenching, either of which causes local potassium release from muscle.

The serum \([K^+]\) is normally 0.4 mEq/L higher than the plasma value, secondary to \(K^+\) release from cells during clot formation. This phenomenon is exaggerated with thrombocytosis because of \(K^+\) release from platelets. For every \(100,000/m^3\) increase in the platelet count, the serum \([K^+]\) rises by approximately 0.15 mEq/L. This phenomenon also occurs with the marked white blood cell (WBC) count elevations sometimes seen with leukemia. Elevated WBC counts, typically \(>200,000/m^3\), can cause a dramatic elevation in the serum \([K^+]\).
Analysis of a plasma sample usually provides an accurate result. It is important to analyze the sample promptly to avoid K\(^+\) release from cells, which occurs if the sample is stored in the cold, or cellular uptake of K\(^+\) and spurious hypokalemia, which occurs with storage at high temperatures. Pneumatic tube transport can cause pseudohyperkalemia if cell membranes are fragile (leukemia). Occasionally, heparin causes lysis of leukemic cells and a false elevation of the plasma sample; a blood gas syringe has less heparin and may provide a more accurate reading than a standard tube. There are rare genetic disorders causing in vitro leakage of K\(^+\) from red blood cells (RBCs) that may causes familial pseudohyperkalemia.

Because of the kidney's ability to excrete K\(^+\), it is unusual for excessive intake, by itself, to cause hyperkalemia. This condition can occur in a patient who is receiving large quantities of IV or oral K\(^+\) for excessive losses that are no longer present. Frequent or rapid blood transfusions can acutely increase the [K\(^+\)] because of the K\(^+\) content of blood, which is variably elevated. Increased intake may precipitate hyperkalemia if there is an underlying defect in K\(^+\) excretion.

The ICS has a very high [K\(^+\)], so a shift of K\(^+\) from the ICS to the ECS can have a significant effect on the plasma [K\(^+\)]. This shift occurs with metabolic acidosis, but the effect is minimal with an organic acid (lactic acidosis, ketoacidosis). A respiratory acidosis has less impact than a metabolic acidosis. Cell destruction, as seen with rhabdomyolysis, tumor lysis syndrome, tissue necrosis, or hemolysis, releases K\(^+\) into the extracellular milieu. The K\(^+\) released from RBCs in internal bleeding, such as hematomas, is resorbed and enters the ECS.

Normal doses of succinylcholine or β-blockers and fluoride or digitalis intoxication all cause a shift of K\(^+\) out of the intracellular compartment. *Succinylcholine should not be used during anesthesia in patients at risk for hyperkalemia.* β-Blockers prevent the normal cellular uptake of K\(^+\) mediated by binding of β-agonists to the β\(_2\) -adrenergic receptors. K\(^+\) release from muscle cells occurs during exercise, and levels can increase by 1-2 mEq/L with high activity. With an increased plasma osmolality, water moves from the ICS, and K\(^+\) follows. This process occurs with hyperglycemia, although in nondiabetic patients the resultant increase in insulin causes K\(^+\) to move intracellularly. In *diabetic ketoacidosis (DKA)*, the absence of insulin causes potassium to leave the ICS, and the problem is compounded by the hyperosmolality. The effect of
hyperosmolality causes a transcellular shift of K\(^+\) into the ECS after mannitol or hypertonic saline infusions. **Malignant hyperthermia**, which is triggered by some inhaled anesthetics, causes muscle release of potassium (see Chapter 629.2). **Hyperkalemic periodic paralysis** is an autosomal dominant disorder caused by a mutated Na\(^+\) channel. It results in episodic cellular release of K\(^+\) and attacks of paralysis (see Chapter 629.1).

The kidneys excrete most of the daily K\(^+\) intake, so a decrease in kidney function can cause hyperkalemia. Newborn infants in general, and especially premature infants, have decreased kidney function at birth and thus are at increased risk for hyperkalemia despite an absence of intrinsic renal disease. Neonates also have decreased expression of K\(^+\) channels, further limiting K\(^+\) excretion.

A wide range of primary **adrenal disorders**, both hereditary and acquired, can cause decreased production of aldosterone, with secondary hyperkalemia (see Chapters 593 and 594). Patients with these disorders typically have metabolic acidosis and salt wasting with hyponatremia. Children with subtle adrenal insufficiency may have electrolyte problems only during acute illnesses. The most common form of **congenital adrenal hyperplasia**, 21-hydroxylase deficiency, typically manifests in male infants as hyperkalemia, metabolic acidosis, hyponatremia, and volume depletion. Females with this disorder usually are diagnosed as newborns because of their ambiguous genitalia; treatment prevents the development of electrolyte problems.

Renin, via angiotensin II, stimulates aldosterone production. A deficiency in renin, a result of kidney damage, can lead to decreased aldosterone production. **Hyporeninemia** occurs in many kidney diseases, with some of the more common pediatric causes listed in Table 68.4. These patients typically have hyperkalemia and a metabolic acidosis, without hyponatremia. Some of these patients have impaired renal function, partially accounting for the hyperkalemia, but the impairment in K\(^+\) excretion is more extreme than expected for the degree of renal insufficiency.

A variety of **renal tubular disorders** impair renal excretion of K\(^+\). Children with **pseudohypoaldosteronism type 1** have hyperkalemia, metabolic acidosis, and salt wasting (kidney, colon, sweat) leading to hyponatremia and volume depletion; aldosterone values are elevated. In the autosomal recessive variant, there is a defect in the renal Na\(^+\) channel that is normally activated by aldosterone. Patients with this variant have severe symptoms (failure to thrive,
diarrhea, recurrent respiratory infections, miliaria-rubra like rash), beginning in infancy. Patients with the autosomal dominant form have a defect in the aldosterone receptor, and the disease is milder, often remitting in adulthood. **Pseudohypoaldosteronism type 2 (familial hyperkalemic hypertension)**, also called **Gordon syndrome**, is an autosomal dominant disorder characterized by hypertension caused by salt retention and impaired excretion of K\(^+\) and acid, leading to hyperkalemia and hyperchloremic metabolic acidosis. Activating mutations in either **WNK1** or **WNK4**, both serine-threonine kinases located in the distal nephron, cause Gordon syndrome. Patients may respond well to thiazide diuretics. In **Bartter syndrome**, caused by mutations in the potassium channel **ROMK** (type 2 Bartter syndrome), there can be transient hyperkalemia in neonates, but hypokalemia subsequently develops (see Chapter 549.1).

Acquired renal tubular dysfunction, with an impaired ability to excrete K\(^+\), occurs in a number of conditions. These disorders, all characterized by **tubulointerstitial disease**, are often associated with impaired acid secretion and a secondary metabolic acidosis. In some affected children, the metabolic acidosis is the dominant feature, although a high K\(^+\) intake may unmask the defect in K\(^+\) handling. The tubular dysfunction can cause renal salt wasting, potentially leading to hyponatremia. Because of the tubulointerstitial damage, these conditions may also cause hyperkalemia as a result of hyporeninemic hypoaldosteronism.

The risk of hyperkalemia resulting from **medications** is greatest in patients with underlying renal insufficiency. The predominant mechanism of medication-induced hyperkalemia is impaired renal excretion, although ACE inhibitors may worsen hyperkalemia in anuric patients, probably by inhibiting GI potassium loss, which is normally upregulated in renal insufficiency. The hyperkalemia caused by trimethoprim generally occurs only at the very high doses used to treat *Pneumocystis jiroveci* pneumonia. Potassium-sparing diuretics may easily cause hyperkalemia, especially because they are often used in patients receiving oral K\(^+\) supplements. Oral contraceptives containing drospirenone, which blocks the action of aldosterone, may cause hyperkalemia and should not be used in patients with decreased renal function.

**Clinical Manifestations**

The most important effects of hyperkalemia result from the role of K\(^+\) in membrane polarization. The cardiac conduction system is usually the dominant
concern. Changes in the electrocardiogram (ECG) begin with peaking of the T waves. This is followed, as K\(^+\) level increases, by ST-segment depression, an increased PR interval, flattening of the P wave, and widening of the QRS complex. However, the correlation between K\(^+\) level and ECG changes is poor. This process can eventually progress to ventricular fibrillation. Asystole may also occur. Some patients have paresthesias, fasciculations, weakness, and even an ascending paralysis, but cardiac toxicity usually precedes these clinical symptoms, emphasizing the danger of assuming that an absence of symptoms implies an absence of danger. Chronic hyperkalemia is generally better tolerated than acute hyperkalemia.

**Diagnosis**

The etiology of hyperkalemia is often readily apparent. Spurious hyperkalemia is very common in children, so obtaining a 2nd potassium measurement is often appropriate. If there is a significant elevation of WBC or platelet count, the 2nd measurement should be performed on a plasma sample that is evaluated promptly. The history should initially focus on potassium intake, risk factors for transcellular shifts of K\(^+\), medications that cause hyperkalemia, and signs of renal insufficiency, such as oliguria and edema. Initial **laboratory evaluation** should include creatinine, BUN, and assessment of the acid-base status. Many etiologies of hyperkalemia cause **metabolic acidosis**, which worsens hyperkalemia through the transcellular shift of K\(^+\) out of cells. Renal insufficiency is a common cause of the combination of metabolic acidosis and hyperkalemia, also seen in diseases associated with aldosterone insufficiency or aldosterone resistance. Children with absent or ineffective aldosterone often have hyponatremia and volume depletion because of salt wasting. Genetic diseases, such as congenital adrenal hyperplasia and pseudohypoaldosteronism, usually manifest in infancy and should be strongly considered in the infant with hyperkalemia and metabolic acidosis, especially if hyponatremia is present.

It is important to consider the various etiologies of a transcellular K\(^+\) shift. In some of these disorders, the K\(^+\) level continues to increase, despite the elimination of all K\(^+\) intake, especially with concurrent renal insufficiency. This increase is potentially seen in tumor lysis syndrome, hemolysis, rhabdomyolysis, and other causes of cell death. All these entities can cause concomitant hyperphosphatemia and hyperuricemia. **Rhabdomyolysis** produces an elevated creatinine phosphokinase (CPK) value and hypocalcemia, whereas children with
hemolysis have hemoglobinuria and a decreasing hematocrit. For the child with diabetes, elevated blood glucose suggests a transcellular shift of $K^+$.

**Treatment**

The plasma $K^+$ level, the ECG, and the risk of the problem worsening determine the aggressiveness of the therapeutic approach. High serum $[K^+]$ and the presence of ECG changes require vigorous treatment. An additional source of concern is the patient in whom plasma $K^+$ levels are rising despite minimal intake. This situation can happen if there is cellular release of $K^+$ (tumor lysis syndrome), especially in the setting of diminished excretion (renal failure).

The first action in a child with a concerning elevation of plasma $[K^+]$ is to stop all sources of additional $K^+$ (oral, intravenous). Washed RBCs can be used for patients who require blood transfusions. If the $[K^+]$ is $>6.5$ mEq/L, an ECG should be obtained to help assess the urgency of the situation. Peak T waves are the first sign of hyperkalemia, followed by a prolonged PR interval, and when most severe, prolonged QRS complex. Life-threatening ventricular arrhythmias may also develop. The treatment of hyperkalemia has 2 basic goals: (1) to stabilize the heart to prevent life-threatening arrhythmias and (2) to remove $K^+$ from the body. The treatments that acutely prevent arrhythmias all have the advantage of working quickly (within minutes) but do not remove $K^+$ from the body. **Calcium** stabilizes the cell membrane of heart cells, preventing arrhythmias; it is given intravenously over a few minutes, and its action is almost immediate. Calcium should be given over 30 min in a patient receiving digitalis; otherwise the calcium may cause arrhythmias. **Bicarbonate** causes potassium to move intracellularly, lowering the plasma $[K^+]$; it is most efficacious in a patient with a metabolic acidosis. **Insulin** causes $K^+$ to move intracellularly but must be given with glucose to avoid hypoglycemia. The combination of insulin and glucose works within 30 min. Nebulized **albuterol**, by stimulation of $\beta_1$-adrenergic receptors, leads to rapid intracellular movement of $K^+$. This has the advantage of not requiring an IV route of administration, allowing it to be given concurrently with the other measures.

It is critical to begin measures that remove $K^+$ from the body. In patients who are not anuric, a **loop diuretic** increases renal excretion of $K^+$. A high dose may be required in a patient with significant renal insufficiency. **Sodium polystyrene sulfonate** (SPS; Kayexalate) is an exchange resin that is given either rectally or
Patiromer is an oral exchange resin for treating hyperkalemia. Some patients require dialysis for acute K\(^+\) removal. Dialysis is often necessary if the patient has either severe renal failure or an especially high rate of endogenous K\(^+\) release, as is sometimes present with tumor lysis syndrome or rhabdomyolysis. Hemodialysis rapidly lowers plasma [K\(^+\)]. Peritoneal dialysis is not nearly as quick or reliable, but it is usually adequate as long as the acute problem can be managed with medications and the endogenous release of K\(^+\) is not high.

Long-term management of hyperkalemia includes reducing intake through dietary changes and eliminating or reducing medications that cause hyperkalemia (see Chapter 550). Some patients require medications to increase potassium excretion, such as SPS, patiromer and loop or thiazide diuretics. Some infants with chronic renal failure may need to start dialysis to allow adequate caloric intake without hyperkalemia. It is unusual for an older child to require dialysis principally to control chronic hyperkalemia. The disorders caused by aldosterone deficiency respond to replacement therapy with fludrocortisone.

### Hypokalemia

Hypokalemia is common in children, with most cases related to gastroenteritis.

### Etiology and Pathophysiology

There are 4 basic mechanisms of hypokalemia (Table 68.5). **Spurious hypokalemia** occurs in patients with leukemia and very elevated WBC counts if plasma for analysis is left at room temperature, permitting the WBCs to take up K\(^+\) from the plasma. With a transcellular shift, there is no change in total body K\(^+\), although there may be concomitant potassium depletion resulting from other factors. Decreased intake, extrarenal losses, and renal losses are all associated with total body K\(^+\) depletion.

Transcellular Shifts

Alkalemia
Insulin
α-Adrenergic agonists
Drugs/toxins (theophylline, barium, toluene, cesium chloride, hydroxychloroquine)
Hypokalemic periodic paralysis (OMIM 170400)
Thyrotoxic periodic paralysis
Refeeding syndrome

Decreased Intake

Anorexia nervosa

Extrarenal Losses

Diarrhea
Laxative abuse
Sweating
Sodium polystyrene sulfonate (Kayexalate) or clay ingestion

Renal Losses

With Metabolic Acidosis

Distal renal tubular acidosis (OMIM 179800/602722/267300)
Proximal renal tubular acidosis (OMIM 604278)*
Ureterosigmoidostomy
Diabetic ketoacidosis

Without Specific Acid–Base Disturbance

Tubular toxins: amphotericin, cisplatin, aminoglycosides
Interstitial nephritis
Diuretic phase of acute tubular necrosis
Postobstructive diuresis
Hypomagnesemia
High urine anions (e.g., penicillin or penicillin derivatives)

**With Metabolic Alkalosis**

Low urine chloride
- Emesis or nasogastric suction
- Chloride-losing diarrhea (OMIM 214700)
- Cystic fibrosis (OMIM 219700)
- Low-chloride formula
- Posthypercapnia
- Previous loop or thiazide diuretic use

High urine chloride and normal blood pressure
- Gitelman syndrome (OMIM 263800)
- Bartter syndrome (OMIM 241200/607364/602522/601678/300971/601198/613090)
- Autosomal dominant hypoparathyroidism (OMIM 146200)
- EAST syndrome (OMIM 612780)
- Loop and thiazide diuretics (current)

High urine chloride and high blood pressure
- Adrenal adenoma or hyperplasia
- Glucocorticoid-remediable aldosteronism (OMIM 103900)
- Renovascular disease
- Renin-secreting tumor
- 17β-Hydroxylase deficiency (OMIM 202110)
- 11β-Hydroxylase deficiency (OMIM 202010)
- Cushing syndrome
- 11β-Hydroxysteroid dehydrogenase deficiency (OMIM 218030)
- Licorice ingestion
- Liddle syndrome (OMIM 177200)

---

* Most cases of proximal renal tubular acidosis are not caused by this primary genetic disorder. Proximal renal tubular acidosis is usually part of Fanconi syndrome, which has multiple etiologies.
Because the intracellular [K⁺] is much higher than the plasma level, a significant amount of K⁺ can move into cells without greatly changing the intracellular [K⁺]. **Alkalemia** is one of the more common causes of a transcellular shift. The effect is much greater with a *metabolic* alkalosis than with a respiratory alkalosis. The impact of exogenous insulin on K⁺ movement into the cells is substantial in patients with DKA. Endogenous insulin may be the cause when a patient is given a bolus of glucose. Both endogenous (epinephrine in stress) and exogenous (albuterol) β-adrenergic agonists stimulate cellular uptake of K⁺. Theophylline overdose, barium intoxication, administration of cesium chloride (a homeopathic cancer remedy), and toluene intoxication from paint or glue sniffing can cause a transcellular shift hypokalemia, often with severe clinical manifestations. Children with **hypokalemic periodic paralysis**, a rare autosomal dominant disorder, have acute cellular uptake of K⁺ (see Chapter 629). **Thyrotoxic periodic paralysis**, which is more common in Asians, is an unusual initial manifestation of hyperthyroidism. Affected patients have dramatic hypokalemia as a result of a transcellular shift of potassium. Hypokalemia can occur during refeeding syndrome (see Chapters 58 and 364.8).

Inadequate K⁺ intake occurs in **anorexia nervosa**; accompanying bulimia and laxative or diuretic abuse exacerbatess the K⁺ deficiency. Sweat losses of K⁺ can be significant during vigorous exercise in a hot climate. Associated volume depletion and hyperaldosteronism increase renal losses of K⁺ (discussed later). Diarrheal fluid has a high concentration of K⁺, and hypokalemia as a result of diarrhea is usually associated with metabolic acidosis resulting from stool losses of bicarbonate. In contrast, normal acid-base balance or mild metabolic alkalosis is seen with laxative abuse. Intake of SPS or ingestion of clay because of pica increases stool losses of potassium.

**Urinary potassium wasting** may be accompanied by a metabolic acidosis (proximal or distal RTA). In DKA, although it is often associated with normal plasma [K⁺] from transcellular shifts, there is significant total body K⁺ depletion from urinary losses because of the osmotic diuresis, and the K⁺ level may decrease dramatically with insulin therapy (see Chapter 607). Both the polyuric
phase of acute tubular necrosis and postobstructive diuresis cause transient, highly variable K⁺ wasting and may be associated with metabolic acidosis. Tubular damage, which occurs either directly from medications or secondary to interstitial nephritis, is often accompanied by other tubular losses, including magnesium, Na⁺, and water. Such tubular damage may cause a secondary RTA with metabolic acidosis. Isolated magnesium deficiency causes renal K⁺ wasting. **Penicillin** is an anion excreted in the urine, resulting in increased K⁺ excretion because the penicillin anion must be accompanied by a cation. Hypokalemia from penicillin therapy occurs only with the sodium salt of penicillin, not with the potassium salt.

Urinary K⁺ wasting is often accompanied by a metabolic alkalosis. This condition is usually associated with increased aldosterone, which increases urinary K⁺ and acid losses, contributing to the hypokalemia and the metabolic alkalosis. Other mechanisms often contribute to both the K⁺ losses and the metabolic alkalosis. With emesis or nasogastric suction, there is gastric loss of K⁺, but this is fairly minimal, given the low K⁺ content of gastric fluid, approximately 10 mEq/L. More important is the gastric loss of hydrochloric acid (HCl), leading to metabolic alkalosis and a state of volume depletion. The kidney compensates for metabolic alkalosis by excreting bicarbonate in the urine, but there is obligate loss of K⁺ and Na⁺ with the bicarbonate. The volume depletion raises aldosterone levels, further increasing urinary K⁺ losses and preventing correction of metabolic alkalosis and hypokalemia until the volume depletion is corrected.

Urinary chloride (Cl⁻) is low as a response to the volume depletion. Because the volume depletion is secondary to Cl⁻ loss, this is a state of Cl⁻ deficiency. There were cases of Cl⁻ deficiency resulting from infant formula deficient in Cl⁻, which caused a metabolic alkalosis with hypokalemia and low urine [Cl⁻]. Current infant formula is not deficient in Cl⁻. A similar mechanism occurs in cystic fibrosis because of Cl⁻ loss in sweat. In congenital chloride-losing diarrhea, an autosomal recessive disorder, there is high stool loss of Cl⁻, leading to metabolic alkalosis, an unusual sequela of diarrhea. Because of stool K⁺ losses, Cl⁻ deficiency, and metabolic alkalosis, patients with this disorder have hypokalemia. During respiratory acidosis, there is renal compensation, with retention of bicarbonate and excretion of Cl⁻. After the respiratory acidosis is corrected, the patients have Cl⁻ deficiency and post–hypercapnic alkalosis with
secondary hypokalemia. Patients with Cl\(^-\) deficiency, metabolic alkalosis, and hypokalemia have a urinary [Cl\(^-\)] of <10 mEq/L. Loop and thiazide diuretics lead to hypokalemia, metabolic alkalosis, and Cl\(^-\) deficiency. During treatment, these patients have high urine chloride levels resulting from the effect of the diuretic. However, after the diuretics are discontinued, there is residual Cl\(^-\) deficiency, the urinary [Cl\(^-\)] is appropriately low, and neither the hypokalemia nor the alkalosis resolves until the Cl\(^-\) deficiency is corrected.

The combination of metabolic alkalosis, hypokalemia, high urine [Cl\(^-\)], and normal blood pressure is characteristic of Bartter syndrome, Gitelman syndrome, and current diuretic use. Patients with any of these conditions have high urinary losses of Cl\(^-\) despite a state of relative volume depletion with secondary hyperaldosteronism (high plasma renin). Bartter and Gitelman syndromes are autosomal recessive disorders caused by defects in tubular transporters (see Chapter 549). **Bartter syndrome** is usually associated with hypercalciuria, and often with nephrocalcinosis, whereas children with **Gitelman syndrome** have low urinary calcium losses but hypomagnesemia because of urinary magnesium losses. Some patients with Bartter syndrome have hypomagnesemia. A transient antenatal form of Bartter syndrome is associated with severe polyhydramnios and mutations in **MAGED2**.

Some patients with hypoparathyroidism and hypocalcemia caused by an activating mutation of the calcium-sensing receptor (**autosomal dominant hypoparathyroidism**) have hypokalemia, hypomagnesemia, and metabolic alkalosis. The reason is that activation of the calcium-sensing receptor in the loop of Henle impairs tubular resorption of sodium and chloride, causing volume depletion and secondary hyperaldosteronism. **EAST syndrome**, an autosomal recessive disorder caused by mutations in the gene for a potassium channel in the kidney, inner ear, and brain, consists of *e*pilepsy, *a*taxia, *s*ensoryneural hearing loss, and *t*ubulopathy (hypokalemia, metabolic alkalosis, hypomagnesemia, and hypocaliuria).

In the presence of high aldosterone levels, there is urinary loss of K\(^+\), hypokalemia, metabolic alkalosis, and elevated urinary [Cl\(^-\)]. Also, renal retention of Na\(^+\) leads to hypertension. Primary hyperaldosteronism caused by adenoma or hyperplasia is much less common in children than in adults (see Chapters 597 and 598). **Glucocorticoid-remediable aldosteronism**, an autosomal dominant disorder that leads to high levels of aldosterone (but low renin levels), is often diagnosed in childhood, although hypokalemia is not
always present.

Increased aldosterone levels may be secondary to increased renin production. Renal artery stenosis leads to hypertension from increased renin and secondary hyperaldosteronism. The increased aldosterone can cause hypokalemia and metabolic alkalosis, although most patients have normal electrolyte levels. Renin-producing tumors, which are extremely rare, can cause hypokalemia.

A variety of disorders cause hypertension and hypokalemia without increased aldosterone levels. Some are a result of increased levels of mineralocorticoids other than aldosterone. Such increases occur in two forms of **congenital adrenal hyperplasia** (see Chapter 594). In **11β-hydroxylase deficiency**, which is associated with virilization, the value of 11-deoxycorticosterone is elevated, causing variable hypertension and hypokalemia. A similar mechanism, increased 11-deoxycorticosterone, occurs in **17α-hydroxylase deficiency**, but patients with this disorder are more uniformly hypertensive and hypokalemic, and they have a defect in sex hormone production. **Cushing syndrome**, frequently associated with hypertension, less frequently causes metabolic alkalosis and hypokalemia, secondary to the mineralocorticoid activity of cortisol. In **11β-hydroxysteroid dehydrogenase deficiency**, an autosomal recessive disorder, the enzymatic defect prevents the conversion of cortisol to cortisone in the kidney. Because cortisol binds to and activates the aldosterone receptor, children with this deficiency have all the features of excessive mineralocorticoids, including hypertension, hypokalemia, and metabolic alkalosis. Patients with this disorder, which is also called **apparent mineralocorticoid excess**, respond to spironolactone therapy, which blocks the mineralocorticoid receptor. An acquired form of 11β-hydroxysteroid dehydrogenase deficiency occurs from the ingestion of substances that inhibit this enzyme. A classic example is glycyrrhizic acid, which is found in natural licorice. **Liddle syndrome** is an autosomal dominant disorder that results from an activating mutation of the distal nephron sodium channel that is normally upregulated by aldosterone. Patients have the characteristics of hyperaldosteronism—hypertension, hypokalemia, and alkalosis—but low serum renin and aldosterone levels. These patients respond to the potassium-sparing diuretics (triamterene and amiloride) that inhibit this sodium channel (see Chapter 549.3). Hypertension exacerbated by pregnancy and syndrome of apparent mineralocortical excess are associated with hypokalemia and low renin levels.
Clinical Manifestations

The heart and skeletal muscle are especially vulnerable to hypokalemia. ECG changes include a flattened T wave, a depressed ST segment, and the appearance of a U wave, which is located between the T wave (if still visible) and the P wave. Ventricular fibrillation and torsades de pointes may occur, although usually only in the context of underlying heart disease. Hypokalemia makes the heart especially susceptible to digitalis-induced arrhythmias, such as supraventricular tachycardia, ventricular tachycardia, and heart block (see Chapter 462).

The clinical consequences of hypokalemia in skeletal muscle include muscle weakness and cramps. Paralysis is a possible complication, generally only at \([K^+] < 2.5 \text{ mEq/L}\). It usually starts in the legs and moves to the arms. Respiratory paralysis may require mechanical ventilation. Some patients have rhabdomyolysis; the risk increases with exercise. Hypokalemia slows GI motility. This effect manifests as constipation; with \(K^+\) levels < 2.5 mEq/L, an ileus may occur. Hypokalemia impairs bladder function, potentially leading to urinary retention.

Hypokalemia causes polyuria and polydipsia by impairing urinary concentrating ability, which produces nephrogenic diabetes insipidus. Hypokalemia stimulates renal ammonia production, an effect that is clinically significant if hepatic failure is present, because the liver cannot metabolize the ammonia. Consequently, hypokalemia may worsen hepatic encephalopathy. Chronic hypokalemia may cause kidney damage, including interstitial nephritis and renal cysts.

Diagnosis

Most causes of hypokalemia are readily apparent from the history. It is important to review the child's diet, GI losses, and medications. Both emesis and diuretic use can be surreptitious. The presence of hypertension suggests excess mineralocorticoid effects or levels. Concomitant electrolyte abnormalities are useful clues. The combination of hypokalemia and metabolic acidosis is characteristic of diarrhea and distal and proximal RTA. A concurrent metabolic alkalosis is characteristic of emesis or nasogastric losses, aldosterone excess, use of diuretics, and Bartter and Gitelman syndromes. Fig. 68.4 shows an approach to persistent hypokalemia.
FIG. 68.4 Diagnostic algorithm to evaluate persistent hypokalemia. *Spurious hypokalemia must be excluded. **Hypokalemia is uncommon in uncomplicated edematous disorders and in conditions associated with excessive glucocorticosteroids. Conditions associated with high circulating levels of glucocorticosteroids often have normal renin activity. 17-OHP, 17-Hydroxyprogesterone; ACTH, adrenocorticotropic hormone; AME, apparent mineralocorticoid excess; BP, blood pressure; Cl−, chloride; DOC, 11-deoxycorticosterone; DR, direct renin assay; GI, gastrointestinal; FH-I, familial hyperaldosteronism type I; FH-II, familial hyperaldosteronism type II; MR, mineralocorticoid receptor; PRA, plasma renin activity; TTKG, transtubular potassium gradient. (From Shoemaker LR, Eaton BV, Buchino JJ: A three-year-old with
If a clear etiology is not apparent, the measurement of urinary K\(^+\) distinguishes between renal and extrarenal losses. The kidneys should conserve K\(^+\) in the presence of extrarenal losses. Urinary K\(^+\) losses can be assessed with a 24 hr urine collection, spot K\(^+\) : creatinine ratio, fractional excretion of K\(^+\), or calculation of the transtubular K\(^+\) gradient (TTKG), which is the most widely used approach in children:

\[
\text{TTKG} = \frac{[K]_{\text{urine}}}{[K]_{\text{plasma}}} \times \left(\frac{\text{plasma osmolality}}{\text{urine osmolality}}\right)
\]

where \([K]_{\text{urine}} = \text{urine potassium concentration}\) and \([K]_{\text{plasma}} = \text{plasma potassium concentration}\).

The urine osmolality must be greater than the serum osmolality for the result of this calculation to be valid. A TTKG >4 in the presence of hypokalemia suggests excessive urinary losses of K\(^+\). The urinary K\(^+\) excretion value can be misleading if the stimulus for renal loss, such as a diuretic, is no longer present.

### Treatment

Factors that influence the treatment of hypokalemia include the K\(^+\) level, clinical symptoms, renal function, the presence of transcellular shifts of K\(^+\), ongoing losses, and the patient’s ability to tolerate oral K\(^+\). Severe, symptomatic hypokalemia requires aggressive treatment. Supplementation is more cautious if renal function is decreased because of the kidney’s limited ability to excrete excessive K\(^+\). The plasma potassium level does not always provide an accurate estimation of the total body K\(^+\) deficit because there may be shifts of K\(^+\) from the ICS to the plasma. Clinically, such shifts occur most often with metabolic acidosis and the insulin deficiency of DKA; the plasma [K\(^+\)] measurement underestimates the degree of total body K\(^+\) depletion. When these problems are corrected, K\(^+\) moves into the ICS, so more K\(^+\) supplementation is required to correct the hypokalemia. Likewise, the presence of a transcellular shift of K\(^+\) into the cells indicates that the total body K\(^+\) depletion is less severe. In an isolated transcellular shift, as in hypokalemic periodic paralysis, K\(^+\) supplementation should be used cautiously, given the risk of hyperkalemia when
the transcellular shift resolves. This caution is especially required in thyrotoxic periodic paralysis, which responds dramatically to propranolol, with correction of weakness and hypokalemia. Patients who have ongoing losses of K+ need correction of the deficit and replacement of the ongoing losses.

Because of the risk of hyperkalemia, intravenous K+ should be used very cautiously. Oral K+ is safer, but not as rapid in urgent situations. Liquid preparations are bitter tasting; microencapsulated or wax matrix formulations are less irritating than tablets to the gastric mucosa. Oral dosing is variable depending on the clinical situation. A typical starting dose is 1-2 mEq/kg/day, with a maximum of 60 mEq/day in divided doses. The dose of IV potassium is 0.5-1.0 mEq/kg, usually given over 1 hr. The adult maximum dose is 40 mEq. Conservative dosing is generally preferred. Potassium chloride is the usual choice for supplementation, although the presence of concurrent electrolyte abnormalities may dictate other options. Patients with acidosis and hypokalemia can receive potassium acetate or potassium citrate. If hypophosphatemia is present, some of the potassium deficit can be replaced with potassium phosphate. It is sometimes possible to decrease ongoing K+ losses. For patients with excessive urinary losses, potassium-sparing diuretics are effective, but they need to be used cautiously in patients with renal insufficiency. If hypokalemia, metabolic alkalosis, and volume depletion are present (with gastric losses), restoration of intravascular volume with adequate NaCl will decrease urinary K+ losses. Correction of concurrent hypomagnesemia is important because it may cause hypokalemia. Disease-specific therapy is effective in many of the genetic tubular disorders.

Magnesium Metabolism

Body Content and Physiologic Function

Magnesium is the 4th most common cation in the body and the 3rd most common intracellular cation (see Fig. 68.3 ). From 50–60% of body magnesium is in bone, where it serves as a reservoir because 30% is exchangeable, allowing movement to the ECS. Most intracellular magnesium is bound to proteins; only approximately 25% is exchangeable. Because cells with higher metabolic rates have higher magnesium concentrations, most intracellular magnesium is present in muscle and liver.

The normal plasma magnesium concentration is 1.5-2.3 mg/dL (1.2-1.9 mEq/L; 0.62-0.94 mmol/L), with some variation among clinical laboratories. Infants have slightly higher plasma magnesium concentrations than older children and adults. Only 1% of body magnesium is extracellular (60% ionized; 15% complexed; 25% protein bound). In the United States, serum magnesium is reported as mg/dL (Table 68.6 ). Values in the left-column unit are converted into the right-column unit by multiplying the conversion factor (e.g., calcium of
10 mg/dL \times 0.25 = 2.5 \text{ mmol/L}. \) Dividing the right-column unit by the conversion factor converts to the units of the left-column unit.

Magnesium is a necessary cofactor for hundreds of enzymes. It is important for membrane stabilization and nerve conduction. Adenosine triphosphate (ATP) and guanosine triphosphate need associated magnesium when they are used by ATPases, cyclases, and kinases.

**Magnesium Intake**

Between 30% and 50% of dietary magnesium is absorbed. Good dietary sources include green vegetables, cereals, nuts, meats, and hard water, although many foods contain magnesium. Human milk contains approximately 35 mg/L of magnesium; formula contains 40-70 mg/L. The small intestine is the major site of magnesium absorption, but the regulation of magnesium absorption is poorly understood. There is passive absorption, which permits high absorption in the presence of excessive intake. It probably occurs by a paracellular mechanism. Absorption is diminished in the presence of substances that complex with magnesium (free fatty acids, fiber, phytate, phosphate, oxalate); increased intestinal motility and calcium also decrease magnesium absorption. Vitamin D and parathyroid hormone (PTH) may enhance absorption, although this effect is limited. Intestinal absorption does increase when intake is decreased, possibly by a saturable, active transport system. If there is no oral intake of magnesium, obligatory secretory losses prevent the complete elimination of intestinal losses.

**Magnesium Excretion**
Renal excretion is the principal regulator of magnesium balance. There is no defined hormonal regulatory system, although PTH may increase tubular resorption. Approximately 15% of resorption occurs in the proximal tubule, and 70% in the thick ascending limb (TAL) of the loop of Henle. Proximal resorption may be higher in neonates. High serum magnesium levels inhibit resorption in the TAL, suggesting that active transport is involved. Approximately 5–10% of filtered magnesium is resorbed in the distal tubule. Hypomagnesemia increases absorption in the TAL and the distal tubule.

**Hypomagnesemia**

Hypomagnesemia is relatively common in hospitalized patients, although most cases are asymptomatic. Detection requires a high index of suspicion because magnesium is not measured in most basic metabolic panels.

**Etiology and Pathophysiology**

Gastrointestinal and renal losses are the major causes of hypomagnesemia (Table 68.7). Diarrheal fluid contains up to 200 mg/L of magnesium; gastric contents have only approximately 15 mg/L, but high losses can cause depletion. Steatorrhea causes magnesium loss as a result of the formation of magnesium-lipid salts; restriction of dietary fat can decrease losses. The potassium-lowering agent patiromer binds magnesium and may cause hypomagnesemia.

- Hungry bone syndrome
- Insulin administration
- Pancreatitis
- Intrauterine growth restriction
- Infants of diabetic mothers
- Exchange transfusion

* This disorder is also associated with renal magnesium wasting.

**Hypomagnesemia with secondary hypocalcemia**, a rare autosomal recessive disorder, is caused by decreased intestinal absorption of magnesium and renal magnesium wasting. Patients with this disorder have mutations in a gene expressed in intestine and kidney; TRPM6 codes for a transient receptor potential cation channel. The patients have seizures, tetany, tremor, or restlessness at 2-8 wk of life as a result of severe hypomagnesemia (0.2-0.8
mg/dL) and secondary hypocalcemia.

Renal losses may occur because of medications that are direct tubular toxins. Amphotericin frequently causes significant magnesium wasting and is typically associated with other tubular defects (especially potassium wasting). Cisplatin produces dramatic renal magnesium losses. Diuretics affect tubular handling of magnesium. Loop diuretics cause a mild increase in magnesium excretion, and thiazide diuretics have even less effect. Chronic use of proton pump inhibitors may cause hypomagnesemia. Potassium-sparing diuretics reduce magnesium losses. Osmotic agents, such as mannitol, glucose in diabetes mellitus, and urea in the recovery phase of acute tubular necrosis, increase urinary magnesium losses. Epidermal growth factor (EGF) receptor inhibitors cause renal magnesium wasting. IV fluid, by expanding the intravascular volume, decreases renal resorption of sodium and water, thereby impairing magnesium resorption. Hypercalcemia inhibits magnesium resorption in the loop of Henle, although this inhibition does not occur in hypercalcemia caused by familial hypercalcemic hypocalciuria or lithium.

A number of rare genetic diseases cause renal magnesium loss. Gitelman and Bartter syndromes, both autosomal recessive disorders, are the most common entities (see Chapter 549). Gitelman syndrome, caused by a defect in the thiazide-sensitive Na\(^+\)-Cl\(^-\) co-transporter in the distal tubule, is usually associated with hypomagnesemia. Hypomagnesemia occurs in a minority of patients with Bartter syndrome, which can be caused by mutations in multiple genes necessary for Na\(^+\) and Cl\(^-\) reabsorption in the loop of Henle. In both disorders there is hypokalemic metabolic alkalosis. Typically, hypomagnesemia is not severe and is asymptomatic, although tetany as a result of hypomagnesemia occasionally occurs.

Familial hypomagnesemia with hypercalciuria and nephrocalcinosis (Michelis-Castrillo syndrome), an autosomal recessive disorder, is caused by mutations in the gene for claudin 16 (paracellin-1), located in the tight junctions of the TAL of the loop of Henle. Patients with the disease have severe renal wasting of magnesium and calcium with secondary hypomagnesemia and nephrocalcinosis; serum calcium levels are normal. Chronic renal failure frequently occurs during childhood. Other features include kidney stones, urinary tract infections, hematuria, increased PTH levels, tetany, seizures, incomplete distal RTA, hyperuricemia, polyuria, and polydipsia. Patients with familial hypomagnesemia with hypercalciuria, nephrocalcinosis, and severe ocular involvement have mutations in the gene for claudin 19.
Autosomal recessive renal magnesium wasting with normocalciuria is caused by mutations in the EGF gene. Clinical manifestations include seizures, mild to moderate psychomotor retardation, and brisk tendon reflexes.

Autosomal dominant renal magnesium wasting is caused by mutations in a number of different genes. A dominant-negative mutation in the gene encoding the Na\(^+\),K\(^+\)-ATPase \(\gamma\) subunit is associated with hypomagnesemia, increased urinary magnesium losses, hypocalciuria, and normocalcemia. Patients may present with seizures; most are asymptomatic, despite serum magnesium levels of 0.8-1.5 mg/dL. Mutations in \(\text{CNNM2}\), which encodes a protein that mediates magnesium-sensitive sodium currents, cause isolated hypomagnesemia. A mutation in \(\text{KCNA1}\), a gene that encodes a K\(^+\) channel, also causes an autosomal dominant form of hypomagnesemia; symptoms may be severe.

Renal cysts and diabetes syndrome, which is caused by mutations in the gene for hepatocyte nuclear factor-1\(\beta\), is associated with hypomagnesemia, despite the frequent presence of renal insufficiency. The hypomagnesemia is usually mild but may cause symptomatic hypocalcemia. EAST syndrome is caused by mutations in a potassium channel, and patients with this autosomal recessive disorder have hypokalemia, metabolic alkalosis, and hypomagnesemia. Autosomal dominant hypoparathyroidism is caused by an activating mutation in the calcium-sensing receptor, which also senses magnesium levels in the kidney (see Chapter 589). The mutated receptor inappropriately perceives that magnesium and calcium levels are elevated, leading to urinary wasting of both cations. Hypomagnesemia, if present, is usually mild. A mutation in a mitochondrially encoded transfer RNA is associated with hypomagnesemia, hypertension, and hypercholesterolemia. Hypomagnesemia is occasionally present in children with other mitochondrial disorders.

Poor intake is an unusual cause of hypomagnesemia, although it can be seen in children who are hospitalized and receive only IV fluids without magnesium. In hungry bone syndrome, which most frequently occurs after parathyroidectomy in patients with hyperparathyroidism, magnesium moves into bone as a result of accelerated bone formation. These patients usually have hypocalcemia and hypophosphatemia through the same mechanism. A similar mechanism can occur during the refeeding phase of protein-calorie malnutrition in children, with high magnesium use during cell growth depleting the patient's limited reserves. Insulin therapy stimulates uptake of magnesium by cells, and in DKA, in which total body magnesium is low because of osmotic losses, hypomagnesemia frequently occurs. In pancreatitis there is
saponification of magnesium and calcium in necrotic fat, causing both hypomagnesemia and hypocalcemia.

**Transient hypomagnesemia in newborns**, which is sometimes idiopathic, is more common in infants of diabetic mothers, presumably as a result of maternal depletion from osmotic losses. Other maternal diseases that cause magnesium losses predispose infants to hypomagnesemia. Hypomagnesemia is more common in infants with intrauterine growth restriction. Hypomagnesemia may develop in newborn infants who require exchange transfusions because of magnesium removal by the citrate in banked blood.

**Clinical Manifestations**

Hypomagnesemia causes secondary hypocalcemia by impairing the release of PTH by the parathyroid gland and through blunting of the tissue response to PTH. Thus, hypomagnesemia is part of the differential diagnosis of hypocalcemia. It usually occurs only at magnesium levels <0.7 mg/dL. The dominant manifestations of hypomagnesemia are caused by hypocalcemia: tetany, presence of Chvostek and Trousseau signs, and seizures. However, with severe hypomagnesemia, these same signs and symptoms may be present despite normocalcemia. Persistent hypocalcemia caused by hypomagnesemia is a rare cause of rickets.

Many causes of hypomagnesemia also result in hypokalemia. Hypomagnesemia may produce renal potassium wasting and hypokalemia that corrects only with magnesium therapy. ECG changes with hypomagnesemia include flattening of the T wave and lengthening of the ST segment. Arrhythmias may occur, almost always in the setting of underlying heart disease.

**Diagnosis**

The etiology of hypomagnesemia is often readily apparent from the clinical situation. The child should be assessed for GI disease, adequate intake, and kidney disease, with close attention paid to medications that may cause renal magnesium wasting. When the diagnosis is uncertain, an evaluation of urinary magnesium losses distinguishes between renal and nonrenal causes. The *fractional excretion of magnesium* \( (\text{FE}_{\text{Mg}}) \) is calculated via the following formula:
\[
\text{FE}_{\text{Mg}} = \frac{U_{\text{Mg}} \times P_{\text{Cr}}}{(0.7 \times P_{\text{Mg}}) \times U_{\text{Cr}}} \times 100
\]

where \( U_{\text{Mg}} \) = urinary magnesium concentration, \( P_{\text{Cr}} \) = plasma creatinine concentration, \( P_{\text{Mg}} \) = plasma magnesium concentration, and \( U_{\text{Cr}} \) = urinary magnesium concentration. The plasma magnesium concentration is multiplied by 0.7 because approximately 30% is bound to albumin and not filtered at the glomerulus.

The FE\textsubscript{Mg} does not vary with age, but it does change according to the serum magnesium concentration. The FE\textsubscript{Mg} ranges from 1–8% in children with normal magnesium levels. In the patient with hypomagnesemia as a result of extrarenal causes, FE\textsubscript{Mg} should be low because of renal conservation, typically <2%. The FE\textsubscript{Mg} is inappropriately elevated in the setting of renal magnesium wasting; values are usually >4% and frequently >10%. The measurement should not be made during a magnesium infusion, because the acute increase in serum magnesium increases urinary magnesium. Other approaches for evaluating urinary magnesium losses include calculation of 24 hr urinary magnesium losses and the urine magnesium/creatinine ratio, both of which vary with age.

The genetic causes of renal magnesium loss are distinguished on the basis of the measurement of other serum and urinary electrolytes. Children with Gitelman or Bartter syndrome have hypokalemia and metabolic alkalosis.

**Treatment**

Severe hypomagnesemia is treated with parenteral magnesium. Magnesium sulfate is given at a dose of 25-50 mg/kg (0.05-0.1 mL/kg of a 50% solution; 2.5-5.0 mg/kg of elemental magnesium). It is administered as a slow IV infusion, although it may be given intramuscularly in neonates. The rate of IV infusion should be slowed if a patient experiences diaphoresis, flushing, or a warm sensation. The dose is often repeated every 6 hr (every 8-12 hr in neonates), for a total of 2-3 doses, before the plasma magnesium concentration is rechecked. Lower doses are used in children with renal insufficiency.

Long-term therapy is usually given orally. Preparations include magnesium gluconate (5.4 mg elemental magnesium/100 mg), magnesium oxide (60 mg elemental magnesium/100 mg), and magnesium sulfate (10 mg elemental magnesium/100 mg). Sustained-release preparations include Slow-Mag (60 mg elemental magnesium/tablet) and Mag-Tab SR (84 mg elemental...
magnesium/tablet). Oral magnesium dosing should be divided to decrease cathartic side effects. Alternatives to oral magnesium are intramuscular injections and nighttime nasogastric infusion, both designed to minimize diarrhea. Magnesium supplementation must be used cautiously in the context of renal insufficiency.

**Hypermagnesemia**

Clinically significant hypermagnesemia is almost always secondary to excessive intake. It is unusual, except in neonates born to mothers who are receiving IV magnesium for preeclampsia or eclampsia (see Chapter 119.5).

**Etiology and Pathophysiology**

There is no feedback mechanism to prevent magnesium absorption from the GI tract. Magnesium is present in high amounts in certain laxatives, enemas, cathartics used to treat drug overdoses, and antacids. It is also usually present in total parenteral nutrition (TPN), and neonates may receive high amounts transplacentally if maternal levels are elevated. Usually the kidneys excrete excessive magnesium, but this ability is diminished in patients with chronic renal failure. In addition, neonates and young infants are vulnerable to excessive magnesium ingestion because of their reduced GFR. Most pediatric cases not related to maternal hypermagnesemia occur in infants as a result of excessive use of antacids or laxatives. Mild hypermagnesemia may occur in chronic renal failure, familial hypocalciuric hypercalcemia, DKA, lithium ingestion, milk-alkali syndrome, and tumor lysis syndrome. The hypermagnesemia in DKA occurs despite significant intracellular magnesium depletion as a result of urinary losses; hypomagnesemia often occurs after insulin treatment.

**Clinical Manifestations**

Symptoms usually do not appear until the plasma magnesium level is >4.5 mg/dL. Hypermagnesemia inhibits acetylcholine release at the neuromuscular junction, producing hypotonia, hyporeflexia, and weakness; paralysis occurs at high concentrations. The neuromuscular effects may be exacerbated by aminoglycoside antibiotics. Direct CNS depression causes lethargy and sleepiness; infants have a poor suck. Elevated magnesium values are associated
with hypotension because of vascular dilation, which also causes flushing. Hypotension can be profound at higher concentrations from a direct effect on cardiac function. ECG changes include prolonged PR interval, QRS complex, and QT interval. Severe hypermagnesemia (>15 mg/dL) causes complete heart block and cardiac arrest. Other manifestations of hypermagnesemia include nausea, vomiting, and hypocalcemia.

**Diagnosis**

Except for the case of the neonate with transplacental exposure, a high index of suspicion and a good history are necessary to make the diagnosis of hypermagnesemia. Prevention is essential; magnesium-containing compounds should be used judiciously in children with renal insufficiency.

**Treatment**

Most patients with normal renal function rapidly clear excess magnesium. Intravenous hydration and loop diuretics can accelerate this process. In severe cases, especially in patients with underlying renal insufficiency, dialysis may be necessary. Hemodialysis works faster than peritoneal dialysis. Exchange transfusion is another option in newborn infants. Supportive care includes monitoring of cardiorespiratory status, provision of fluids, monitoring of electrolyte levels, and the use of pressors for hypotension. In acute emergencies, especially in the context of severe neurologic or cardiac manifestations, 100 mg/kg of IV calcium gluconate is transiently effective.

**Bibliography**

**Magnesium**

Approximately 65% of plasma phosphorus is in phospholipids, but these compounds are insoluble in acid and are not measured by clinical laboratories. It is the phosphorus content of plasma phosphate that is determined. The result is reported as either phosphate or phosphorus, although even when the term phosphate is used, it is actually the phosphorus concentration that is measured
and reported. The result is that the terms phosphate and phosphorus are often used interchangeably. The term *phosphorus* is preferred when referring to the plasma concentration. Conversion from the units used in the United States (mg/dL) to mmol/L is straightforward (see Table 68.6).

**Phosphorus Metabolism**

**Body Content and Physiologic Function**

Most phosphorus is in bone or is intracellular, with <1% in plasma. At a physiologic pH, there are monovalent and divalent forms of phosphate because the $pK_a$ (ionization constant of acid) of these forms is 6.8. Approximately 80% is divalent, and the remainder is monovalent at a pH of 7.4. The remainder can be filtered by the glomerulus, with most existing as free phosphate and a small percentage complexed with calcium, magnesium, or sodium. Phosphate is the most plentiful intracellular anion, although the majority is part of a larger compound (ATP).

More than that of any other electrolyte, the phosphorus concentration varies with age (Table 68.8). The teleologic explanation for the high concentration during childhood is the need for phosphorus to facilitate growth. There is diurnal variation in the plasma phosphorus concentration, with the peak during sleep.

Phosphorus, as a component of adenosine triphosphate (ATP) and other trinucleotides, is critical for cellular energy metabolism. It is necessary for cell signaling and nucleic acid synthesis, and it is a component of cell membranes and other structures. Along with calcium, phosphorus is necessary for skeletal mineralization. A net positive phosphorus balance is required during growth, with the growing skeleton especially vulnerable to deficiency.
Phosphorus Intake

Phosphorus is readily available in food. Milk and milk products are the best sources of phosphorus; high concentrations are present in meat and fish. Vegetables have more phosphorus than fruits and grains. GI absorption of phosphorus is fairly proportional to intake, with approximately 65% of intake being absorbed, including a small amount that is secreted. Absorption, almost exclusively in the small intestine, occurs via a paracellular diffusive process and a vitamin D–regulated transcellular pathway. However, the impact of the change in phosphorus absorption caused by vitamin D is relatively small compared with the effect of variations in phosphorus intake.

Phosphorus Excretion

Despite the wide variation in phosphorus absorption dictated by oral intake, excretion matches intake, except for the needs for growth. The kidney regulates phosphorus balance, which is determined by intrarenal mechanisms and hormonal actions on the nephron.

Approximately 90% of plasma phosphate is filtered at the glomerulus, although there is some variation based on plasma phosphate and calcium concentrations. There is no significant secretion of phosphate along the nephron. Resorption of phosphate occurs mostly in the proximal tubule, although a small amount can be resorbed in the distal tubule. Normally, approximately 85% of the filtered load is resorbed. A sodium-phosphate co-transporter mediates the uptake of phosphate into the cells of the proximal tubule.

The dietary phosphorus determines the amount of phosphate resorbed by the nephron. There are both acute and chronic changes in phosphate resorption that are based on intake. Many of these changes appear to be mediated by intrarenal mechanisms that are independent of regulatory hormones. Fibroblast growth factor-23 (FGF-23) inhibits renal resorption of phosphorus in the proximal tubule, and its level increases in the setting of hyperphosphatemia. FGF-23 also inhibits synthesis of calcitriol in the kidney by decreasing 1α-hydroxylase activity.

Secreted in response to a low plasma calcium level, PTH decreases resorption of phosphate, increasing the urinary phosphate level. This process appears to have a minimal effect during normal physiologic variation in PTH levels. However, it does impact the setting of pathologic changes in PTH synthesis.
Low plasma phosphorus stimulates the 1α-hydroxylase in the kidney that converts 25-hydroxyvitamin D (25-D) to 1,25-dihydroxyvitamin D (1,25-D; calcitriol). Calcitriol increases intestinal absorption of phosphorus and is necessary for maximal renal resorption of phosphate. The effect of a change in calcitriol on urinary phosphate is significant only when the level of calcitriol was initially low, arguing against a role for calcitriol in nonpathologic conditions.

Hypophosphatemia

Because of the wide variation in normal plasma phosphorus levels, the definition of hypophosphatemia is age dependent (see Table 68.8). The normal range reported by a laboratory may be based on adult normal values and therefore may be misleading in children. A serum phosphorus level of 3 mg/dL, a normal value in an adult, indicates clinically significant hypophosphatemia in an infant.

The plasma phosphorus level does not always reflect the total body stores because only 1% of phosphorus is extracellular. Thus, a child may have significant phosphorus deficiency despite a normal plasma phosphorus concentration when there is a shift of phosphorus from the ICS.

Etiology and Pathophysiology

A variety of mechanisms cause hypophosphatemia (Table 68.9). A transcellular shift of phosphorus into cells occurs with processes that stimulate cellular usage of phosphorus (glycolysis). Usually, this shift causes only a minor, transient decrease in plasma phosphorus, but if intracellular phosphorus deficiency is present, the plasma phosphorus level can decrease significantly, producing symptoms of acute hypophosphatemia. Glucose infusion stimulates insulin release, leading to entry of glucose and phosphorus into the cells. Phosphorus is then used during glycolysis and other metabolic processes. A similar phenomenon can occur during the treatment of DKA, and patients with DKA are typically phosphorus depleted because of urinary phosphorus losses.

Volume expansion and intravenous fluids
Metabolic acidosis
Diuretics
Glycosuria
Refeeding of patients with protein-calorie malnutrition causes anabolism, which leads to significant cellular demand for phosphorus. The increased phosphorus uptake for incorporation into newly synthesized compounds containing phosphorus leads to hypophosphatemia, which can be severe and symptomatic. Refeeding hypophosphatemia occurs frequently during treatment of severe anorexia nervosa. It can occur during treatment of children with malnutrition from any cause, such as cystic fibrosis, Crohn disease, burns, neglect, chronic infection, or famine. Hypophosphatemia usually occurs within the 1st 5 days of refeeding and is prevented by a gradual increase in nutrition with appropriate phosphorus supplementation. TPN without adequate phosphorus can cause hypophosphatemia.

Phosphorus moves into the ICS during a respiratory alkalosis and during recovery from a respiratory acidosis. An acute decrease in the carbon dioxide concentration, by raising the intracellular pH, stimulates glycolysis, leading to intracellular use of phosphorus and hypophosphatemia. Because a metabolic alkalosis has less effect on the intracellular pH (CO₂ diffuses across cell membranes much faster than bicarbonate), transcellular phosphorus movement is minimal with a metabolic alkalosis.

Tumors that grow rapidly, such as those associated with leukemia and lymphoma, may use large amounts of phosphorus, leading to hypophosphatemia. A similar phenomenon may occur during the hematopoietic reconstitution that
follows bone marrow transplantation. In **hungry bone syndrome** there is avid bone uptake of phosphorus, along with calcium and magnesium, which can produce plasma deficiency of all 3 ions. Hungry bone syndrome is most common after parathyroidectomy for hyperparathyroidism because the stimulus for bone dissolution is acutely removed, but bone synthesis continues.

Nutritional phosphorus deficiency is unusual because most foods contain phosphorus. However, infants are especially susceptible because of their high demand for phosphorus to support growth, especially of the skeleton. Very-low-birthweight infants have particularly rapid skeletal growth, and phosphorus deficiency and rickets may develop if they are fed human milk, or formula for term infants. There is also a relative deficiency of calcium. The provision of additional calcium and phosphorus, using breast milk fortifier or special premature infant formula, prevents this complication. Phosphorus deficiency, sometimes with concomitant calcium and vitamin D deficiencies, occurs in infants who are not given enough milk or who receive a milk substitute that is nutritionally inadequate.

**Antacids** containing aluminum hydroxide (e.g., Maalox, Mylanta) bind dietary phosphorus and secreted phosphorus, preventing absorption. This process can cause phosphorus deficiency and rickets in growing children. A similar mechanism causes hypophosphatemia in patients who are overtreated for hyperphosphatemia with phosphorus binders. In children with kidney failure, the addition of dialysis to phosphorus binders increases the risk of iatrogenic hypophosphatemia in these normally hyperphosphatemic patients. This complication, which is more common in infants, can worsen renal osteodystrophy.

Excessive renal losses of phosphorus occur in a variety of inherited and acquired disorders. Because PTH inhibits the resorption of phosphorus in the proximal tubule, **hyperparathyroidism** causes hypophosphatemia (see Chapter 591). The dominant clinical manifestation, however, is hypercalcemia, and the hypophosphatemia is usually asymptomatic. The phosphorus level in hyperparathyroidism is not extremely low, and there is no continued loss of phosphorus because a new steady state is achieved at the lower plasma phosphorus level. Renal excretion therefore does not exceed intake over the long term. Occasional malignancies produce PTH-related peptide, which has the same actions as PTH and causes hypophosphatemia and hypercalcemia.

A variety of diseases cause renal phosphate wasting, hypophosphatemia, and rickets resulting from excess FGF-23 (see Chapter 64). These disorders include
X-linked hypophosphatemic rickets, tumor-induced osteomalacia, autosomal dominant hypophosphatemic rickets, and autosomal recessive hypophosphatemic rickets types 1 and 2.

**Fanconi syndrome** is a generalized defect in the proximal tubule leading to urinary wasting of bicarbonate, phosphorus, amino acids, uric acid, and glucose (see Chapter 547.1). The clinical sequelae result from the metabolic acidosis and hypophosphatemia. In children an underlying genetic disease, usually cystinosis, often causes Fanconi syndrome, but it can be secondary to a variety of toxins and acquired diseases. Some patients have incomplete Fanconi syndrome, and phosphorus wasting may be one of the manifestations.

**Dent disease**, an X-linked disorder, can cause renal phosphorus wasting and hypophosphatemia, although the latter is not present in most cases. Other possible manifestations of Dent disease include tubular proteinuria, hypercalcuria, nephrolithiasis, rickets, and decreased kidney function. Dent disease may be secondary to mutations in a gene that encodes a chloride channel or the **OCRL1** gene, which may also cause Lowe syndrome (see Chapter 547.1).

**Hypophosphatemic rickets with hypercalciuria** is a rare autosomal recessive disorder, principally described in kindreds from the Middle East (see Chapter 64). Mutations in a sodium-phosphate co-transporter cause hypophosphatemia in this disorder, and complications may include nephrolithiasis and osteoporosis.

Metabolic acidosis inhibits resorption of phosphorus in the proximal tubule. In addition, metabolic acidosis causes a transcellular shift of phosphorus out of cells because of intracellular catabolism. This released phosphorus is subsequently lost in the urine, leading to significant phosphorus depletion, even though the plasma phosphorus level may be normal. This classically occurs in DKA, in which renal phosphorus loss is further increased by the osmotic diuresis. With correction of the metabolic acidosis and the administration of insulin, both of which cause a transcellular movement of phosphorus into the cells, there is a marked decrease in the plasma phosphorus level.

Volume expansion from any cause, such as hyperaldosteronism or SIADH, inhibits resorption of phosphorus in the proximal tubule. This effect also occurs with high rates of IV fluids. Thiazide and loop diuretics can increase renal phosphorus excretion, but the increase is seldom clinically significant. Glycosuria and glucocorticoids inhibit renal conservation of phosphorus. Hypophosphatemia is common after kidney transplantation as a result of urinary phosphorus losses. Possible explanations include preexisting secondary hyperparathyroidism from chronic renal failure, glucocorticoid therapy, and
upregulation of FGF-23 before transplantation. The hypophosphatemia usually resolves in a few months.

Both acquired and genetic causes of vitamin D deficiency are associated with hypophosphatemia (see Chapter 64). The pathogenesis is multifactorial. By impairing intestinal calcium absorption, vitamin D deficiency causes secondary hyperparathyroidism that leads to increased urinary phosphorus wasting. An absence of vitamin D decreases intestinal absorption of phosphorus and directly decreases renal resorption of phosphorus. The dominant clinical manifestation is rickets, although some patients have muscle weakness that may be related to phosphorus deficiency.

Alcoholism is the most common cause of severe hypophosphatemia in adults. Fortunately, many of the risk factors that predispose alcoholic adults to hypophosphatemia are not usually present in adolescents (malnutrition, antacid abuse, recurrent DKA episodes). Hypophosphatemia often occurs in sepsis, but the mechanism is not clear. Aggressive, protracted hemodialysis, as might be used for the treatment of methanol or ethylene glycol ingestion, can cause hypophosphatemia.

**Clinical Manifestations**

There are acute and chronic manifestations of hypophosphatemia. Rickets occurs in children with long-term phosphorus deficiency. The clinical features of rickets are described in Chapter 64.

Severe hypophosphatemia, typically at levels <1.0-1.5 mg/dL, may affect every organ in the body because phosphorus has a critical role in maintaining adequate cellular energy. Phosphorus is a component of ATP and is necessary for glycolysis. With inadequate phosphorus, 2,3-diphosphoglycerate levels in RBCs decrease, impairing release of oxygen to the tissues. Severe hypophosphatemia can cause hemolysis and dysfunction of WBCs. Chronic hypophosphatemia causes proximal muscle weakness and atrophy. In the intensive care unit, phosphorus deficiency may slow weaning from mechanical ventilation or cause acute respiratory failure. Rhabdomyolysis is the most common complication of acute hypophosphatemia, usually in the setting of an acute transcellular shift of phosphorus into cells in a child with chronic phosphorus depletion (anorexia nervosa). The rhabdomyolysis is actually somewhat protective, in that cellular release of phosphorus occurs. Other manifestations of severe hypophosphatemia include cardiac dysfunction and neurologic symptoms, such as tremor,
paresthesia, ataxia, seizures, delirium, and coma.

**Diagnosis**

The history and basic laboratory evaluation often suggest the etiology of hypophosphatemia. The history should investigate nutrition, medications, and familial disease. Hypophosphatemia and rickets in an otherwise healthy young child suggests a genetic defect in renal phosphorus conservation, Fanconi syndrome, inappropriate use of antacids, poor nutrition, vitamin D deficiency, or a genetic defect in vitamin D metabolism. The patient with Fanconi syndrome usually has metabolic acidosis, glycosuria, aminoaciduria, and a low plasma uric acid level. Measurement of 25-D and 1,25-D, calcium, and PTH differentiates among the various vitamin D deficiency disorders and primary renal phosphate wasting (see Chapter 64). Hyperparathyroidism is easily distinguished by the presence of elevated plasma PTH and calcium values.

**Treatment**

The plasma phosphorus level, the presence of symptoms, the likelihood of chronic depletion, and the presence of ongoing losses dictate the approach to therapy. Mild hypophosphatemia does not require treatment unless the clinical situation suggests that chronic phosphorus depletion is present or that losses are ongoing. Oral phosphorus can cause diarrhea, so the doses should be divided. IV therapy is effective in patients who have severe deficiency or who cannot tolerate oral medications. IV phosphorus is available as either sodium phosphate or potassium phosphate, with the choice usually based on the patient's plasma potassium level. Starting doses are 0.08-0.16 mmol/kg over 6 hr. The oral preparations of phosphorus are available with various ratios of sodium and potassium. This is an important consideration because some patients may not tolerate the potassium load, whereas supplemental potassium may be helpful in some diseases, such as Fanconi syndrome and malnutrition. Oral maintenance dosages are 2-3 mmol/kg/day in divided doses, although the maintenance dose varies considerably between patients.

Increasing dietary phosphorus is the only intervention needed in infants with inadequate intake. Other patients may also benefit from increased dietary phosphorus, usually from dairy products. Phosphorus-binding antacids should be discontinued in patients with hypophosphatemia. Certain diseases require
specific therapy (see Chapter 64).

**Hyperphosphatemia**

**Etiology and Pathophysiology**

*Renal insufficiency* is the most common cause of hyperphosphatemia, with the severity proportional to the degree of kidney impairment (see Chapter 550). This occurs because GI absorption of the large dietary intake of phosphorus is unregulated, and the kidneys normally excrete this phosphorus. As renal function deteriorates, increased excretion of phosphorus is able to compensate. When kidney function is <30% of normal, hyperphosphatemia usually develops, although this varies considerably depending on dietary intake. Many of the other causes of hyperphosphatemia are more likely to develop in the setting of renal insufficiency (Table 68.10).

Hypoparathyroidism or pseudohypoparathyroidism (OMIM 146200/603233/103580/241410/203330)
Acromegaly
Hyperthyroidism
Tumoral calcinosis with hyperphosphatemia (OMIM 211900)

Cellular content of phosphorus is high relative to plasma phosphorus, and cell lysis can release substantial phosphorus. This is the etiology of hyperphosphatemia in tumor lysis syndrome, rhabdomyolysis, and acute hemolysis. These disorders cause concomitant potassium release and the risk of hyperkalemia. Additional features cause tumor lysis and rhabdomyolysis are hyperuricemia and hypocalcemia, whereas indirect hyperbilirubinemia and elevated lactate dehydrogenase (LDH) values are often present with hemolysis. An elevated CPK level is suggestive of rhabdomyolysis. During lactic acidosis or DKA, use of phosphorus by cells decreases, and phosphorus shifts into the ECS. This problem reverses when the underlying problem is corrected, and especially with DKA, patients subsequently become hypophosphatemic as a result of previous renal phosphorus loss.

Excessive intake of phosphorus is especially dangerous in children with renal insufficiency. Neonates are at risk because renal function is normally reduced during the 1st few months of life. In addition, they may erroneously be given doses of phosphorus that are meant for an older child or adult. In infants fed cow's milk, which has higher phosphorus content than breast milk or formula, hyperphosphatemia may develop. Fleet Enema has a high amount of phosphorus that can be absorbed, especially in the patient with an ileus; infants and children with Hirschsprung disease are especially vulnerable. There is often associated hypernatremia from sodium absorption and water loss from diarrhea. Sodium phosphorus laxatives may cause hyperphosphatemia if the dose is excessive or if renal insufficiency is present. Hyperphosphatemia occurs in children who receive overaggressive treatment for hypophosphatemia. Vitamin D intoxication causes excessive GI absorption of both calcium and phosphorus, and the suppression of PTH by hypercalcemia decreases renal phosphorus excretion.

The absence of PTH in hypoparathyroidism or PTH responsiveness in
pseudohypoparathyroidism causes hyperphosphatemia because of increased resorption of phosphorus in the proximal tubule of the kidney (see Chapters 589 and 590). The associated hypocalcemia is responsible for the clinical symptoms. The hyperphosphatemia in hyperthyroidism or acromegaly is usually minor. It is secondary to increased resorption of phosphorus in the proximal tubule from the actions of thyroxine or growth hormone. Excessive thyroxine can also cause bone resorption, which may contribute to the hyperphosphatemia and cause hypercalcemia. Patients with familial tumoral calcinosis, a rare autosomal recessive disorder, have hyperphosphatemia as a result of decreased renal phosphate excretion and heterotopic calcifications. The disease may be secondary to mutations in the genes for a glycosyltransferase, the phosphatonin FGF-23, or the gene for Klotho, which encodes the co-receptor for FGF-23.

Clinical Manifestations

The principal clinical consequences of hyperphosphatemia are hypocalcemia and systemic calcification. The hypocalcemia is probably caused by tissue deposition of calcium-phosphorus salt, inhibition of 1,25-D production, and decreased bone resorption. Symptomatic hypocalcemia is most likely to occur when the phosphorus level increases rapidly or when diseases predisposing to hypocalcemia are present (chronic renal failure, rhabdomyolysis). Systemic calcification occurs because the solubility of phosphorus and calcium in the plasma is exceeded. This is believed to occur when plasma calcium × plasma phosphorus, both measured in mg/dL, is >70. Clinically, this condition is often apparent in the conjunctiva, where it manifests as a foreign body feeling, erythema, and injection. More ominous manifestations are hypoxia from pulmonary calcification and renal failure from nephrocalcinosis.

Diagnosis

Plasma creatinine and BUN levels should be assessed in any patient with hyperphosphatemia. The history should focus on intake of phosphorus and the presence of chronic diseases that may cause hyperphosphatemia. Measurement of $K^+$, uric acid, calcium, LDH, bilirubin, hemoglobin, and CPK may be indicated if rhabdomyolysis, tumor lysis, or hemolysis is suspected. With mild hyperphosphatemia and significant hypocalcemia, measurement of the serum PTH level distinguishes between hypoparathyroidism and
Treatment

The treatment of acute hyperphosphatemia depends on its severity and etiology. Mild hyperphosphatemia in a patient with reasonable renal function spontaneously resolves; the resolution can be accelerated by dietary phosphorus restriction. If kidney function is not impaired, IV fluids can enhance renal phosphorus excretion. For more significant hyperphosphatemia or a situation such as tumor lysis or rhabdomyolysis, in which endogenous phosphorus generation is likely to continue, addition of an oral phosphorus binder prevents absorption of dietary phosphorus and can remove phosphorus from the body by binding what is normally secreted and absorbed by the GI tract. Phosphorus binders are most effective when given with food. Binders containing aluminum hydroxide are especially efficient, but calcium carbonate is an effective alternative and may be preferred if there is a need to treat concomitant hypocalcemia. Preservation of renal function, as with high urine flow in rhabdomyolysis or tumor lysis, is an important adjunct because it will permit continued excretion of phosphorus. If the hyperphosphatemia is not responding to conservative management, especially if renal insufficiency is supervening, dialysis may be necessary to increase phosphorus removal.

Dietary phosphorus restriction is necessary for diseases causing chronic hyperphosphatemia. However, such diets are often difficult to follow, given the abundance of phosphorus in a variety of foods. Dietary restriction is often sufficient in conditions such as hypoparathyroidism and mild renal insufficiency. For more problematic hyperphosphatemia, such as with moderate renal insufficiency and end-stage renal disease, phosphorus binders are usually necessary. They include calcium carbonate, calcium acetate, sevelamer, ferric citrate, sucroferric oxyhydroxide, and lanthanum. Aluminum-containing phosphorus binders are no longer used in patients with chronic kidney disease because of the risk of aluminum toxicity. Dialysis directly removes phosphorus from the blood in patients with end-stage renal disease, but it is only an adjunct to dietary restriction and phosphorus binders; removal by dialysis does not keep up with normal dietary intake.

**Acid-Base Balance**
Acid-Base Physiology

Terminology

Chronic, mild derangements in acid-base status may interfere with normal growth and development, whereas acute, severe changes in pH can be fatal. Control of acid-base balance depends on the kidneys, the lungs, and intracellular and extracellular buffers.

A normal pH is 7.35-7.45. There is an inverse relationship between the pH and the hydrogen ion concentration([H⁺]). At a pH of 7.40, [H⁺] is 40 nmol/L. A normal serum sodium concentration, 140 mEq/L, is 1 million times higher.
Maintaining a normal pH is necessary because hydrogen ions are highly reactive and are especially likely to combine with proteins, altering their function.

An **acid** is a substance that releases ("donates") a hydrogen ion (H\(^+\)). A **base** is a substance that accepts a hydrogen ion. An acid (HA) can dissociate into a hydrogen ion and a conjugate base (A\(^-\)), as follows:

\[
HA \leftrightarrow H^+ + A^-
\]

A strong acid is highly dissociated, so in this reaction, there is little HA. A weak acid is poorly dissociated; not all the hydrogen ions are released from HA. A\(^-\) acts as a base when the reaction moves to the left. These reactions are in equilibrium. When HA is added to the system, there is dissociation of some HA until the concentrations of H\(^+\) and A\(^-\) increase enough that a new equilibrium is reached. Addition of hydrogen ions causes a decrease in A\(^-\) and an increase in HA. Addition of A\(^-\) causes a decrease in hydrogen ions and an increase in HA.

**Buffers** are substances that attenuate the change in pH that occurs when acids or bases are added to the body. Given the extremely low [H\(^+\)] in the body at physiologic pH, without buffers a small amount of hydrogen ions could cause a dramatic decline in the pH. Buffers prevent the decrease in pH by binding the added hydrogen ions, as follows:

\[
A^- + H^+ \rightarrow HA
\]

The increase in [H\(^+\)] drives this reaction to the right. Similarly, when base is added to the body, buffers prevent the pH from increasing by releasing hydrogen ions, as follows:

\[
HA \rightarrow A^- + H^+
\]

The best buffers are weak acids and bases. This is because a buffer works best when it is 50% dissociated (half HA and half A\(^-\)). The pH at which a buffer is 50% dissociated is its pK\(_a\) (ionization constant of acid). The best physiologic buffers have a pK\(_a\) close to 7.40. The concentration of a buffer and its pK\(_a\)
determine the buffer's effectiveness (buffering capacity). When the pH is lower than the pK$_a$ of a buffer, there is more HA than A$^-$ . When the pH is higher than the pK$_a$, there is more A$^-$ than HA.

**Physiologic Buffers**

The bicarbonate and nonbicarbonate buffers protect the body against major changes in pH. The *bicarbonate buffer system* is routinely monitored clinically and is based on the relationship between carbon dioxide (CO$_2$) and bicarbonate (HCO$_3^-$):

\[
\text{CO}_2 + \text{H}_2\text{O} \leftrightarrow \text{H}^+ + \text{HCO}_3^-
\]

CO$_2$ acts as an acid in that, after combining with water, it releases an H$^+$; bicarbonate acts as its conjugate base in that it accepts an H$^+$. The pK$_a$ of this reaction is 6.1. The *Henderson-Hasselbalch equation* expresses the relationship among pH, pK$_a$, and the concentrations of an acid and its conjugate base. This relationship is valid for any buffer. The Henderson-Hasselbalch equation for bicarbonate and CO$_2$ is as follows:

\[
\text{pH} = 6.1 + \log[\text{HCO}_3^-]/[\text{CO}_2]
\]

The *Henderson-Hasselbalch equation* for the bicarbonate buffer system has 3 variables: pH, bicarbonate concentration ([HCO$_3^-$]), and carbon dioxide concentration ([CO$_2$]). Thus, if any 2 of these variables are known, it is possible to calculate the 3rd. When one is using the Henderson-Hasselbalch equation, it is important that CO$_2$ and bicarbonate have the same units. CO$_2$ is reported clinically as mm Hg and must be multiplied by its solubility constant, 0.03 mmol/L/mm Hg, before the equation can be used. Mathematical manipulation of the Henderson-Hasselbalch equation produces the following relationship:
At a normal \([H^+]\) of 40 nmol (pH 7.40), the partial pressure of carbon dioxide (\(PCO_2\)), which is expressed as mm Hg in this equation, is 40 when the \([HCO_3^-]\) is 24 mEq/L. This equation emphasizes that \([H^+]\), and thus pH, can be determined by the ratio of \(PCO_2\) and \([HCO_3^-]\).

The bicarbonate buffer system is very effective because of the high concentration of bicarbonate in the body (24 mEq/L) and because it is an open system. The remaining body buffers are in a closed system. The bicarbonate buffer system is an open system because the lungs increase CO\(_2\) excretion when the blood CO\(_2\) concentration increases. When acid is added to the body, the following reaction occurs:

\[
H^+ + HCO_3^- \rightarrow CO_2 + H_2O
\]

In a closed system, the CO\(_2\) would increase. The higher CO\(_2\) concentration would lead to an increase in the reverse reaction:

\[
CO_2 + H_2O \rightarrow H^+ + HCO_3^- \]

This would increase \([H^+]\), limiting the buffering capacity of bicarbonate. However, because the lungs excrete the excess CO\(_2\), the reverse reaction does not increase; this fact enhances the buffering capacity of bicarbonate. The same principle holds with the addition of base, because the lungs decrease CO\(_2\) excretion and prevent the CO\(_2\) level from falling. The lack of change in \([CO_2]\) dramatically increases the buffering capacity of bicarbonate.

The nonbicarbonate buffers include proteins, phosphate, and bone. Protein buffers consist of extracellular proteins, mostly albumin and intracellular proteins, including hemoglobin. Proteins are effective buffers, largely because of the presence of the amino acid histidine, which has a side chain that can bind or release H\(^+\). The pK\(_a\) of histidine varies slightly, depending on its position in the protein molecule, but its average pK\(_a\) is approximately 6.5. This is close enough
to a normal pH (7.4) to make histidine an effective buffer. Hemoglobin and albumin have 34 and 16 histidine molecules, respectively.

Phosphate can bind up to 3 hydrogen molecules, so it can exist as \( \text{PO}_4^{3-} \), \( \text{HPO}_4^{2-} \), \( \text{H}_2\text{PO}_4^{1-} \), or \( \text{H}_3\text{PO}_4 \). However, at a physiologic pH, most phosphate exists as either \( \text{HPO}_4^{2-} \) or \( \text{H}_2\text{PO}_4^{1-} \). \( \text{H}_2\text{PO}_4^{1-} \) is an acid, and \( \text{HPO}_4^{2-} \) is its conjugate base:

\[
\text{H}_2\text{PO}_4^{1-} \leftrightarrow \text{H}^+ + \text{HPO}_4^{2-}
\]

The pK\textsubscript{a} of this reaction is 6.8, making phosphate an effective buffer. The concentration of phosphate in the ECS is relatively low, limiting the overall buffering capacity of phosphate; it is less important than albumin. However, phosphate is found at a much higher concentration in the urine, where it is an important buffer. In the ICS, most phosphate is covalently bound to organic molecules (ATP), but it still serves as an effective buffer.

Bone is an important buffer. Bone is basic—it is composed of compounds such as sodium bicarbonate and calcium carbonate—and thus dissolution of bone releases base. This release can buffer an acid load, although at the expense of bone density, if it occurs over an extended period. In contrast, bone formation, by consuming base, helps buffer excess base.

Clinically, we measure the extracellular pH, but it is the intracellular pH that affects cell function. Measurement of the intracellular pH is unnecessary because changes in the intracellular pH parallel the changes in the extracellular pH. However, the change in the intracellular pH tends to be less than the change in the extracellular pH because of the greater buffering capacity in the ICS.

**Normal Acid-Base Balance**

The lungs and kidneys maintain a normal acid-base balance. Carbon dioxide generated during normal metabolism is a weak acid. The lungs prevent an increase in the P\textsubscript{CO\_2} in the blood by excreting the CO\textsubscript{2} that the body produces. CO\textsubscript{2} production varies according to the body's metabolic needs, increasing with physical activity. The rapid pulmonary response to changes in the CO\textsubscript{2} concentration occurs via central sensing of the P\textsubscript{CO\_2} and a subsequent increase of
decrease in ventilation to maintain a normal $P_{CO_2}$ (35-45 mm Hg). An increase in ventilation decreases the $P_{CO_2}$, and a decrease in ventilation increases the $P_{CO_2}$.

The kidneys excrete endogenous acid. An adult normally produces approximately 1-2 mEq/kg/24 hr of $H^+$. Children normally produce 2-3 mEq/kg/24 hr of $H^+$. The 3 principal sources of $H^+$ are dietary protein metabolism, incomplete metabolism of carbohydrates and fat, and stool losses of bicarbonate. Because metabolism of protein generates $H^+$, endogenous acid production varies with protein intake. The complete oxidation of carbohydrates or fats to $CO_2$ and water does not generate $H^+$; the lungs remove the $CO_2$. However, incomplete metabolism of carbohydrates or fats produces $H^+$. Incomplete glucose metabolism can produce lactic acid, and incomplete triglyceride metabolism can produce keto acids, such as β-hydroxybutyric acid and acetoacetic acid. There is always some baseline incomplete metabolism that contributes to endogenous acid production. This factor increases in pathologic conditions, such as lactic acidosis and diabetic ketoacidosis (DKA). Stool loss of bicarbonate is the 3rd major source of endogenous acid production. The stomach secretes $H^+$, but most of the remainder of the GI tract secretes bicarbonate, and the net effect is a loss of bicarbonate from the body. To secrete bicarbonate, the cells of the intestine produce hydrogen ions that are released into the bloodstream. For each bicarbonate molecule lost in the stool, the body gains 1 $H^+$. This source of endogenous acid production is normally minimal but may increase dramatically in a patient with diarrhea.

The hydrogen ions formed from endogenous acid production are neutralized by bicarbonate, potentially causing the bicarbonate concentration to decrease. The kidneys regenerate this bicarbonate by secreting $H^+$. The lungs cannot regenerate bicarbonate, even though loss of $CO_2$ lowers the $[H^+]$, as shown in the following reaction:

$$H^+ + HCO_3^- \rightarrow CO_2 + H_2O$$

A decrease in $[CO_2]$ causes the reaction to move to the right, which decreases $[H^+]$, but it also lowers $[HCO_3^-]$. During a metabolic acidosis, hyperventilation can lower $[CO_2]$, decrease $[H^+]$, and thus increase pH. The underlying
metabolic acidosis is still present. Similarly, the kidneys cannot correct an abnormally high \([\text{CO}_2]\), as shown in the following reaction:

\[
H^+ + \text{HCO}_3^- \rightarrow \text{CO}_2 + \text{H}_2\text{O}
\]

An increase in \([\text{HCO}_3^-]\) also causes the reaction to move to the right, which increases \([\text{CO}_2]\) while simultaneously decreasing \([H^+]\). During a respiratory acidosis, increased renal generation of bicarbonate can decrease \([H^+]\) and increase pH, but cannot repair the respiratory acidosis. Both the lungs and the kidneys can affect \([H^+]\) and thus pH. However, only the lungs can regulate \([\text{CO}_2]\), and only the kidneys can regulate \([\text{HCO}_3^-]\).

**Renal Mechanisms**

The kidneys regulate the serum bicarbonate concentration by modifying acid excretion in the urine. This requires a 2-step process. First, the renal tubules resorb the bicarbonate that is filtered at the glomerulus. Second, there is tubular secretion of \(H^+\). The urinary excretion of \(H^+\) generates bicarbonate that neutralizes endogenous acid production. The tubular actions necessary for renal acid excretion occur throughout the nephron (Fig. 68.5).

![Diagram of tubular sites involved in acid-base balance](image_url)

**FIG. 68.5** Tubular sites involved in acid-base balance. The proximal tubule is the site where most filtered bicarbonate is reclaimed, even though other sites along the nephron, especially the thick ascending limb of the loop of Henle, resorb some of the filtered bicarbonate. The collecting duct is the principal location for the hydrogen ion.
secretion that acidifies the urine. The proximal tubule generates the ammonia that serves as a urinary buffer in the collecting duct.

The resorption of filtered bicarbonate is a necessary first step in renal regulation of the acid-base balance. A normal adult has a GFR of approximately 180 L/24 hr. This fluid enters Bowman's space with \([\text{HCO}_3^-]\) that is essentially identical to the plasma concentration, normally 24 mEq/L. Multiplying 180 L by 24 mEq/L indicates that >4,000 mEq of bicarbonate enters Bowman's space each day. This bicarbonate, if not reclaimed along the nephron, would be lost in the urine and would cause a profound metabolic acidosis.

The proximal tubule reclains approximately 85% of the filtered bicarbonate (Fig. 68.6). The final 15% is reclaimed beyond the proximal tubule, mostly in the ascending limb of the loop of Henle. Bicarbonate molecules are not transported from the tubular fluid into the cells of the proximal tubule. Rather, hydrogen ions are secreted into the tubular fluid, leading to conversion of filtered bicarbonate into \(\text{CO}_2\) and water. The secretion of \(\text{H}^+\) by the cells of the proximal tubule is coupled to generation of intracellular bicarbonate, which is transported across the basolateral membrane of the proximal tubule cell and enters the capillaries. The bicarbonate produced in the cell replaces the bicarbonate filtered at the glomerulus.

**FIG. 68.6** Resorption of filtered bicarbonate in the proximal tubule. The \(\text{Na}^+\),\(\text{K}^+\)-ATPase (1) excretes sodium across the basolateral cell membrane, maintaining a low intracellular sodium concentration. The low intracellular sodium concentration provides the energy for the \(\text{Na}^+\),\(\text{H}^+\) antiporter (2), which exchanges sodium from the tubular lumen for intracellular hydrogen ions. The hydrogen ions that are secreted into
Increased bicarbonate resorption by the cells of the proximal tubule—the result of increased H\(^+\) secretion—occurs in a variety of clinical situations. Volume depletion increases bicarbonate resorption. This is partially mediated by activation of the renin-angiotensin system; angiotensin II increases bicarbonate resorption. Increased bicarbonate resorption in the proximal tubule is one of the mechanisms that accounts for the metabolic alkalosis that may occur in some patients with volume depletion. Other stimuli that increase bicarbonate resorption include hypokalemia and an increased P\(\text{CO}_2\). This partially explains the observations that hypokalemia causes a metabolic alkalosis, and that a respiratory acidosis leads to a compensatory increase in serum [HCO\(_3^-\)].

Stimuli that decrease bicarbonate resorption in the proximal tubule may cause a decrease in the serum [HCO\(_3^-\)]. A decrease in the P\(\text{CO}_2\) (respiratory alkalosis) decreases proximal tubule bicarbonate resorption, partially mediating the decrease in serum [HCO\(_3^-\)] that compensates for a respiratory alkalosis. PTH decreases proximal tubule bicarbonate resorption; hyperparathyroidism may cause a mild metabolic acidosis. A variety of medications and diseases cause a metabolic acidosis by impairing bicarbonate resorption in the proximal tubule. Examples are the medication acetazolamide, which directly inhibits carbonic anhydrase, and the many disorders that cause proximal RTA (see Chapter 547.1).

After reclaiming filtered bicarbonate, the kidneys perform the 2nd step in renal acid-base handling, the excretion of the acid created by endogenous acid production. Excretion of acid occurs mostly in the collecting duct, with a small role for the distal tubule.

Along with secretion of H\(^+\) by the tubular cells lining the collecting duct, adequate excretion of endogenous acid requires the presence of urinary buffers. The hydrogen pumps in the collecting duct cannot lower the urine pH below 4.5. The [H\(^+\)] at pH 4.5 is <0.04 mEq/L; it would require >25 L of water with a pH
of 4.5 to excrete 1 mEq H⁺. A 10-kg child, with an endogenous acid production of 20 mEq H⁺ each day, would need to have a daily urinary output of >500 L without the presence of urinary buffers. As in the blood, buffers in the urine attenuate the decrease in pH that occurs with the addition of H⁺. The 2 principal urinary buffers are phosphate and ammonia.

Urinary phosphate is proportional to dietary intake. Whereas most of the phosphate filtered at the glomerulus is resorbed in the proximal tubule, the urinary phosphate concentration is usually much greater than the serum phosphate concentration. This arrangement allows phosphate to serve as an effective buffer through the following reaction:

\[ \text{H}^+ + \text{HPO}_4^{2-} \rightarrow \text{H}_2\text{PO}_4^{1-} \]

The pKₐ of this reaction is 6.8, making phosphate an effective buffer as the urinary pH decreases from 7.0 to 5.0 within the collecting duct. Although phosphate is an effective buffer, its buffering capacity is limited by its concentration; there is no mechanism for increasing urinary phosphate excretion in response to changes in acid-base status.

In contrast, ammonia production can be modified, allowing for regulation of acid excretion. The buffering capacity of ammonia (NH₃) is based on the reaction of ammonia with hydrogen ions to form ammonium:

\[ \text{NH}_3 + \text{H}^+ \rightarrow \text{NH}_4^+ \]

The cells of the proximal tubule are the source of the excreted ammonia, mostly through metabolism of glutamine through the following reactions:

Glutamine → NH₄⁺ + glutamate⁻

\[ \text{Glutamate}^- \rightarrow \text{NH}_4^+ + \alpha\text{-keto glutarate}^{2-} \]

The metabolism of glutamine generates 2 ammonium ions. In addition, the
metabolism of α-ketoglutarate generates 2 bicarbonate molecules. The ammonium ions are secreted into the lumen of the proximal tubule, whereas the bicarbonate molecules exit the proximal tubule cells via the basolateral Na\(^+\),3HCO\(_3\)\(^-\) co-transporter (see Fig. 68.6). This arrangement would seem to accomplish the goal of excreting H\(^+\) (as NH\(_4\)\(^+\)) and regenerating bicarbonate molecules. However, the ammonium ions secreted in the proximal tubule do not remain within the tubular lumen. Cells of the TAL of the loop of Henle resorb the ammonium ions. The result is that there is a high medullary interstitial concentration of ammonia, but the tubular fluid entering the collecting duct does not have significant amounts of ammonium ions. Moreover, the hydrogen ions that were secreted with ammonia, as ammonium ions, in the proximal tubule enter the bloodstream, canceling the effect of the bicarbonate generated in the proximal tubule. The excretion of ammonium ions, and thus of hydrogen ions, depends on the cells of the collecting duct.

The cells of the collecting duct secrete H\(^+\) and regenerate bicarbonate, which is returned to the bloodstream (Fig. 68.7). This bicarbonate neutralizes endogenous acid production. Phosphate and ammonia buffer the H\(^+\) secreted by the collecting duct. Ammonia is an effective buffer because of the high concentrations in the medullary interstitium and because the cells of the collecting duct are permeable to ammonia but not to ammonium. As ammonia diffuses into the lumen of the collecting duct, the low urine pH causes almost all the ammonia to be converted into ammonium. This process maintains a low luminal ammonia concentration. Because the luminal pH is lower than the pH in the medullary interstitium, there is a higher concentration of ammonia within the medullary interstitium than in the tubular lumen, favoring movement of ammonia into the tubular lumen. Even though the concentration of ammonium in the tubular lumen is higher than in the interstitium, the cells of the collecting duct are impermeable to ammonium, preventing back-diffusion of ammonium out of the tubular lumen and permitting ammonia to be an effective buffer.
The kidneys adjust H⁺ excretion according to physiologic needs. There is variation in endogenous acid production, largely a result of diet and pathophysiologic stresses, such as diarrheal losses of bicarbonate, which increase the need for acid excretion. H⁺ excretion is increased by upregulation of H⁺ secretion in the collecting duct, causing the pH of the urine to decrease. This response is fairly prompt, occurring within hours of an acid load, but it is limited by the buffering capacity of the urine; the hydrogen pumps in the collecting duct cannot lower the pH to <4.5. A more significant increase in acid excretion requires upregulation of ammonia production by the proximal tubule so that more ammonia is available to serve as a buffer in the tubular lumen of the collecting duct. This response to a low serum pH reaches its maximum within 5-6 days; ammonia excretion can increase approximately 10-fold over the baseline value.

Acid excretion by the collecting duct increases in a number of different clinical situations. The extracellular pH is the most important regulator of renal acid excretion. A decrease in the extracellular pH from either a respiratory or a metabolic acidosis causes an increase in renal acid excretion. Aldosterone stimulates H⁺ excretion in the collecting duct, causing an increase in the serum
bicarbonate concentration. This explains the metabolic alkalosis that occurs with primary hyperaldosteronism or secondary hyperaldosteronism caused by volume depletion. Hypokalemia increases acid secretion, by both stimulating ammonia production in the proximal tubule and increasing H⁺ secretion in the collecting duct. Hypokalemia therefore tends to produce a metabolic alkalosis. Hyperkalemia has the opposite effects, which may cause a metabolic acidosis.

In patients with an increased pH, the kidney has 2 principal mechanisms for correcting the problem. First, less bicarbonate is resorbed in the proximal tubule, leading to an increase in urinary bicarbonate losses. Second, in a limited number of specialized cells, the process for secretion of H⁺ by the collecting duct can be reversed (Fig. 68.7), leading to secretion of bicarbonate into the tubular lumen and secretion of hydrogen ions into the peritubular fluid, where they enter the bloodstream.

Clinical Assessment of Acid-Base Disorders

The following rearrangement of the Henderson-Hasselbalch equation emphasizes the relationship among $P_{CO_2}$, bicarbonate concentration, and hydrogen ion concentration:

$$[H^+] = 24 \times P_{CO_2}/[HCO_3^-]$$

An increase in the $P_{CO_2}$ or a decrease in $[HCO_3^-]$ increases $[H^+]$; the pH decreases. A decrease in the $P_{CO_2}$ or an increase in $[HCO_3^-]$ decreases $[H^+]$; the pH increases.

Terminology

Acidemia is a pH below normal (<7.35), and alkalemia is a pH above normal (>7.45). An acidosis is a pathologic process that causes an increase in $[H^+]$, and an alkalosis is a pathologic process that causes a decrease in $[H^+]$. Whereas acidemia is always accompanied by an acidosis, a patient can have an acidosis
and a low, normal, or high pH. For example, a patient may have a mild metabolic acidosis but a simultaneous, severe respiratory alkalosis; the net result may be alkalemia. Acidemia and alkalemia indicate the pH abnormality; acidosis and alkalosis indicate the pathologic process that is taking place.

A **simple acid-base disorder** is a single primary disturbance. During a simple metabolic disorder, there is respiratory compensation. With a metabolic acidosis, the decrease in the pH increases the ventilatory drive, causing a decrease in $P_{CO_2}$. The decrease in the carbon dioxide concentration ([CO$_2$]) leads to an increase in the pH. This appropriate respiratory compensation is expected with a primary metabolic acidosis. Despite the decrease in [CO$_2$], appropriate respiratory compensation is not a respiratory alkalosis, even though it is sometimes erroneously called a “compensatory” respiratory alkalosis. A low $P_{CO_2}$ can result either from a primary respiratory alkalosis or from appropriate respiratory compensation for a metabolic acidosis. Appropriate respiratory compensation also occurs with a primary metabolic alkalosis, although in this case [CO$_2$] increases to attenuate the increase in the pH. The respiratory compensation for a metabolic process happens quickly and is complete within 12-24 hr; it cannot overcompensate for or normalize the pH.

During a primary respiratory process, there is metabolic compensation, mediated by the kidneys. The kidneys respond to a respiratory acidosis by increasing H$^+$ excretion, thereby increasing bicarbonate generation and raising the serum [HCO$_3^-$]. The kidneys increase bicarbonate excretion to compensate for a respiratory alkalosis; [HCO$_3^-$] decreases. Unlike respiratory compensation, which occurs rapidly, it takes 3-4 days for the kidneys to complete appropriate metabolic compensation. There is, however, a small and rapid compensatory change in [HCO$_3^-$] during a primary respiratory process. The expected appropriate metabolic compensation for a respiratory disorder depends on whether the process is acute or chronic.

A **mixed acid-base disorder** is present when there is >1 primary acid-base disturbance. An infant with bronchopulmonary dysplasia may have a respiratory acidosis from chronic lung disease and a metabolic alkalosis from the furosemide used to treat the chronic lung disease. More dramatically, a child with pneumonia and sepsis may have severe acidemia as a result of a combined metabolic acidosis caused by lactic acid and respiratory acidosis caused by ventilatory failure.
There are formulas for calculating the appropriate metabolic or respiratory compensation for the 6 primary simple acid-base disorders (Table 68.11). The appropriate compensation is expected in a simple disorder; it is not optional. If a patient does not have the appropriate compensation, a mixed acid-base disorder is present. A patient has a primary metabolic acidosis with a serum $[\text{HCO}_3^-]$ of 10 mEq/L. The expected respiratory compensation is $[\text{CO}_2]$ of 23 mm Hg ± 2 (1.5 × 10 + 8 ± 2 = 23 ± 2; Table 68.11). If the patient's $[\text{CO}_2]$ is >25 mm Hg, a concurrent respiratory acidosis is present; $[\text{CO}_2]$ is higher than expected. A patient may have a respiratory acidosis despite a CO₂ level below the “normal” value of 35-45 mm Hg. In this example, $[\text{CO}_2]$ <21 mm Hg indicates a concurrent respiratory alkalosis; $[\text{CO}_2]$ is lower than expected.

### Diagnosis

A systematic evaluation of an arterial blood gas (ABG) sample, combined with the clinical history, can usually explain the patient's acid-base disturbance. Assessment of an ABG sample requires knowledge of normal values (Table 68.12). In most cases, this is accomplished through a 3-step process (Fig. 68.8):

### Table 68.12

**Normal Values of Arterial Blood Gases**
Most patients with an acid-base disturbance have an abnormal pH, although there are 2 exceptions. One exception is in the patient with a mixed disorder in which the 2 processes have opposite effects on pH (a metabolic acidosis and a respiratory alkalosis) and cause changes in [H$^+$] that are comparable in magnitude, although opposite. The other exception is in the patient with a simple chronic respiratory alkalosis; in some cases the appropriate metabolic compensation is enough to normalize the pH. In both situations the presence of an acid-base disturbance is deduced because of the abnormal CO$_2$ and bicarbonate levels. Determining the acid-base disturbance in these patients
requires proceeding to the 3rd step of the process.

The 2nd step requires inspection of the serum bicarbonate and CO₂ concentrations to determine a cause of the abnormal pH (Fig. 68.8). In most cases, there is only 1 obvious explanation for the abnormal pH. In some mixed disorders, however, there may be 2 possibilities (e.g., a high P\textsubscript{CO₂} and a low [HCO\textsubscript{3}⁻] in a patient with acidemia). In such cases the patient has 2 causes for abnormal pH—a metabolic acidosis and a respiratory acidosis, in this instance—and it is unnecessary to proceed to the 3rd step.

The 3rd step requires determining whether the patient's compensation is appropriate. It is assumed that the primary disorder was diagnosed in the 2nd step, and the expected compensation is calculated (Table 68.11). If the compensation is appropriate, a simple acid-base disorder is present. If the compensation is not appropriate, a mixed disorder is present. The identity of the 2nd disorder is determined by deciding whether the compensation is too little or too much compared with what was expected (see Fig. 68.8).

The history is always useful in evaluating and diagnosing patients with acid-base disturbances. It is especially helpful in a respiratory process. The expected metabolic compensation for a respiratory process changes according to whether the process is acute or chronic, which can be deduced only from the history. The metabolic compensation for an acute respiratory acidosis is less than that for a chronic respiratory acidosis. In a patient with a respiratory acidosis, a small increase in [HCO\textsubscript{3}⁻] would be consistent with a simple acute respiratory acidosis or a mixed disorder (a chronic respiratory acidosis and a metabolic acidosis). Only the history can differentiate among the possibilities. Knowledge of the length of the respiratory process and the presence or absence of a risk factor for a metabolic acidosis (diarrhea) allows the correct conclusion to be reached.

An alternative to the physiologic approach just described (which includes calculation of the anion gap; see later) is the physiochemical approach, often called the Stewart method. Some view this approach as superior to the physiologic approach, but it requires multiple calculations and additional laboratory values and is thus more challenging to use in the clinical setting. The physiochemical approach requires measurement of the blood pH and P\textsubscript{CO₂} and calculation of the apparent strong ion difference (SIDa), the effective strong ion difference (SIDe), the strong ion gap (SIG), and the total concentration of weak acids (A\textsubscript{TOT}).
Metabolic Acidosis

Metabolic acidosis occurs frequently in hospitalized children; diarrhea is the most common etiology. For a patient with an unknown medical problem, the presence of a metabolic acidosis is often helpful diagnostically, because it suggests a relatively narrow differential diagnosis.

Patients with a metabolic acidosis have a low serum $[\text{HCO}_3^-]$, although not every patient with a low serum $[\text{HCO}_3^-]$ has a metabolic acidosis. The exception is the patient with a respiratory alkalosis, which causes a decrease in the serum $[\text{HCO}_3^-]$ as part of appropriate renal compensation. In a patient with an isolated metabolic acidosis, there is a predictable decrease in the blood $[\text{CO}_2^-]$, as follows:

$$\text{Pb} = 1.5 \times [\text{HCO}_3^-] + 8 \pm 2$$

A mixed acid-base disturbance is present if the respiratory compensation is not appropriate. If the $\text{Pb}$ is greater than predicted, the patient has a concurrent respiratory acidosis. A lower $\text{Pb}$ than predicted indicates a concurrent respiratory alkalosis or, less frequently, an isolated respiratory alkalosis. Because the appropriate respiratory compensation for a metabolic acidosis never normalizes the patient's pH, the presence of a normal pH and a low $[\text{HCO}_3^-]$ occurs only if some degree of respiratory alkalosis is present. In this situation, distinguishing an isolated chronic respiratory alkalosis from a mixed metabolic acidosis and acute respiratory alkalosis may be possible only clinically. In contrast, the combination of a low serum pH and a low $[\text{HCO}_3^-]$ occurs only if a metabolic acidosis is present.

Etiology and Pathophysiology

There are many causes of a metabolic acidosis (Table 68.13), resulting from 3 basic mechanisms:

Table 68.13

| Causes of Metabolic Acidosis |
Normal Anion Gap

Diarrhea
Renal tubular acidosis (RTA)
  Distal (type I) RTA (OMIM 179800/602722/267300)*
  Proximal (type II) RTA (OMIM 604278) †
  Mixed (type III) RTA (OMIM 259730)
  Hyperkalemic (type IV) RTA (OMIM 201910/264350/177735/145260) ‡

* Along with these genetic disorders, distal RTA may be secondary to renal disease or medications.

† Most cases of proximal RTA are not caused by this primary genetic disorder. Proximal RTA is usually part of Fanconi syndrome, which has multiple etiologies.

‡ Hyperkalemic RTA can be secondary to a genetic disorder (some of the more common are listed) or other etiologies.

1. Loss of bicarbonate from the body  
2. Impaired ability to excrete acid by the kidney  
3. Addition of acid to the body (exogenous or endogenous)

**Diarrhea**, the most common cause of metabolic acidosis in children, causes a loss of bicarbonate from the body. The amount of bicarbonate lost in the stool depends on the volume of diarrhea and \([HCO_3^-]\) of the stool, which tends to increase with more severe diarrhea. The kidneys attempt to balance the losses by increasing acid secretion, but metabolic acidosis occurs when this compensation is inadequate. Diarrhea often causes volume depletion as a result of losses of sodium and water, potentially exacerbating the acidosis by causing shock and a lactic acidosis. In addition, diarrheal losses of potassium lead to hypokalemia. Moreover, the volume depletion causes increased production of aldosterone. This increase stimulates renal retention of sodium, helping to maintain
intravascular volume, but also leads to increased urinary losses of potassium, exacerbating the hypokalemia.

There are 4 forms of renal tubular acidosis (RTA): distal (type I), proximal (type II), mixed (type III) and hyperkalemic (type IV) (see Chapter 547). In distal RTA, children may have accompanying hypokalemia, hypercalciuria, nephrolithiasis, and nephrocalcinosis. Failure to thrive because of chronic metabolic acidosis is the most common presenting complaint. Patients with distal RTA cannot acidify their urine and thus have a urine pH >5.5 despite a metabolic acidosis.

**Proximal** RTA is rarely present in isolation. In most patients, proximal RTA is part of Fanconi syndrome, a generalized dysfunction of the proximal tubule. The dysfunction leads to glycosuria, aminoaciduria, and excessive urinary losses of phosphate and uric acid. The presence of a low serum uric acid level, glycosuria, and aminoaciduria is helpful diagnostically. Chronic hypophosphatemia leads to rickets in children (see Chapter 64). Rickets and/or failure to thrive may be the presenting complaint. The ability to acidify the urine is intact in proximal RTA; thus untreated patients have a urine pH <5.5. However, bicarbonate therapy increases bicarbonate losses in the urine, and the urine pH increases. A mixed RTA (combined distal and proximal) occurs in patients with autosomal recessive osteopetrosis caused by mutations in the gene for carbonic anhydrase II.

In hyperkalemic RTA, renal excretion of acid and potassium is impaired. Hyperkalemic RTA is the result of hyperkalemia, absence of aldosterone, or inability of the kidney to respond to aldosterone. In severe aldosterone deficiency, as occurs with congenital adrenal hyperplasia because of 21α-hydroxylase deficiency, the hyperkalemia and metabolic acidosis are accompanied by hyponatremia and volume depletion from renal salt wasting. Incomplete aldosterone deficiency causes less severe electrolyte disturbances; children may have isolated hyperkalemic RTA, hyperkalemia without acidosis, or isolated hyponatremia. Patients may have aldosterone deficiency caused by decreased renin production by the kidney; renin normally stimulates aldosterone synthesis. Children with hyporeninemic hypoaldosteronism usually have either isolated hyperkalemia or hyperkalemic RTA. The manifestations of aldosterone resistance depend on the severity of the resistance. In the autosomal recessive form of pseudohypoaldosteronism type I, which is the result of an absence of the sodium channel that normally responds to aldosterone, there is often severe salt wasting and hyponatremia. In contrast, the aldosterone resistance in kidney
transplant recipients usually produces either isolated hyperkalemia or hyperkalemic RTA; hyponatremia is unusual. Similarly, the medications that cause hyperkalemic RTA do not cause hyponatremia. Pseudohypoaldosteronism type II, an autosomal recessive disorder also known as Gordon syndrome, is a unique cause of hyperkalemic RTA because the genetic defect causes volume expansion and hypertension.

Children with abnormal urinary tracts, usually secondary to congenital malformations, may require diversion of urine through intestinal segments. Ureterosigmoidostomy, anastomosis of a ureter to the sigmoid colon, almost always produces a metabolic acidosis and hypokalemia. Consequently, ileal conduits are now the more commonly used procedure, although there is still a risk of a metabolic acidosis.

The appropriate metabolic compensation for a chronic respiratory alkalosis is a decrease in renal acid excretion. The resultant decrease in the serum $[\text{HCO}_3^-]$ lessens the alkalemia caused by the respiratory alkalosis. If the respiratory alkalosis resolves quickly, the patient continues to have a decreased serum $[\text{HCO}_3^-]$, causing acidemia as the result of a metabolic acidosis. This resolves over 1-2 days through increased acid excretion by the kidneys.

**Lactic acidosis** typically occurs when inadequate oxygen delivery to the tissues leads to anaerobic metabolism and excess production of lactic acid. Lactic acidosis may be secondary to shock, severe anemia, or hypoxemia. When the underlying cause of the lactic acidosis is alleviated, the liver is able to metabolize the accumulated lactate into bicarbonate, correcting the metabolic acidosis. There is normally some tissue production of lactate metabolized by the liver. In children with severe liver dysfunction, impairment of lactate metabolism may produce a lactic acidosis. Rarely, a metabolically active malignancy grows so fast that its blood supply becomes inadequate, with resultant anaerobic metabolism and lactic acidosis. Patients who have **short bowel syndrome** resulting from small bowel resection can have bacterial overgrowth. In these patients, excessive intestinal bacterial metabolism of glucose into D-lactic acid can cause a lactic acidosis. Lactic acidosis occurs in a variety of **inborn errors of metabolism**, especially those affecting mitochondrial oxidation (see Chapters 105.4 and 106). **Medications** also can cause lactic acidosis. Nucleoside reverse transcriptase inhibitors that are used to treat HIV infection inhibit mitochondrial replication; lactic acidosis is a rare complication, although elevated serum lactate concentrations without acidosis are quite common. Metformin, used to treat type 2 diabetes mellitus, is most likely to cause a lactic acidosis in patients with renal
insufficiency. High dosages and prolonged use of propofol can cause lactic acidosis. Propylene glycol is a diluent in a variety of oral and IV medications; excessive intake causes a lactic acidosis, principally from accumulation of $D$-lactic acid. Linezolid is another medication that may cause a lactic acidosis.

In **insulin-dependent diabetes mellitus**, inadequate insulin leads to hyperglycemia and DKA (see Chapter 607). Production of acetoacetic acid and $\beta$-hydroxybutyric acid causes the metabolic acidosis. Administration of insulin corrects the underlying metabolic problem and permits conversion of acetoacetate and $\beta$-hydroxybutyrate into bicarbonate, which helps correct the metabolic acidosis. However, in some patients, urinary losses of acetoacetate and $\beta$-hydroxybutyrate may be substantial, preventing rapid regeneration of bicarbonate. In these patients, full correction of the metabolic acidosis requires renal regeneration of bicarbonate, a slower process. The hyperglycemia causes an osmotic diuresis, usually producing volume depletion, along with substantial losses of potassium, sodium, and phosphate.

In **starvation ketoacidosis** the lack of glucose leads to keto acid production, which in turn can produce a metabolic acidosis, although it is usually mild as a result of increased acid secretion by the kidney. In **alcoholic ketoacidosis**, which is much less common in children than in adults, the acidosis usually follows a combination of an alcoholic binge with vomiting and poor intake of food. The acidosis is potentially more severe than with isolated starvation, and the blood glucose level may be low, normal, or high. Hypoglycemia and acidosis also suggest an inborn error of metabolism.

**Renal failure** causes a metabolic acidosis because of the need for the kidneys to excrete the acid produced by normal metabolism. With mild or moderate renal insufficiency, the remaining nephrons are usually able to compensate by increasing acid excretion. When the GFR is $<20–30\%$ of normal, the compensation is inadequate, and a metabolic acidosis develops. In some children, especially those with chronic renal failure because of tubular damage, the acidosis develops at a higher GFR because of a concurrent defect in acid secretion by the distal tubule (distal RTA).

A variety of **toxic ingestions** can cause a metabolic acidosis (see Chapter 77). Salicylate intoxication is now much less common because aspirin is no longer recommended for fever control in children. Acute salicylate intoxication occurs after a large overdose. Chronic salicylate intoxication is possible with gradual buildup of the drug. Especially in adults, respiratory alkalosis may be the dominant acid-base disturbance. In children the metabolic acidosis is usually the
more significant finding. Other symptoms of salicylate intoxication are fever, seizures, lethargy, and coma. Hyperventilation may be particularly marked. Tinnitus, vertigo, and hearing impairment are more likely with chronic salicylate intoxication.

**Ethylene glycol**, a component of antifreeze, is converted in the liver to glyoxylic and oxalic acids, causing a severe metabolic acidosis. Excessive oxalate excretion causes calcium oxalate crystals to appear in the urine, and calcium oxalate precipitation in the kidney tubules can cause renal failure. The toxicity of methanol ingestion also depends on liver metabolism; formic acid is the toxic end product that causes the metabolic acidosis and other sequelae, which include damage to the optic nerve and CNS. Symptoms may include nausea, emesis, visual impairment, and altered mental status. Toluene inhalation and paraldehyde ingestion are other potential causes of a metabolic acidosis.

Many **inborn errors of metabolism** cause a metabolic acidosis (see Chapters 102-105). The metabolic acidosis may be the result of excessive production of keto acids, lactic acid, and other organic anions. Some patients have accompanying hypoglycemia or hyperammonemia. In most patients the acidosis occurs episodically, only during acute decompensations, which may be precipitated by ingestion of specific dietary substrates, the stress of a mild illness, or poor compliance with dietary or medical therapy. In a few inborn errors of metabolism, patients have a chronic metabolic acidosis.

**Clinical Manifestations**

The underlying disorder usually produces most of the signs and symptoms in children with a mild or moderate metabolic acidosis. The clinical manifestations of the acidosis are related to the degree of acidemia; patients with appropriate respiratory compensation and less severe acidemia have fewer manifestations than those with a concomitant respiratory acidosis. At a serum pH <7.2, there may be impaired cardiac contractility and an increased risk of arrhythmias, especially if underlying heart disease or other predisposing electrolyte disorders are present. With acidemia, there may be a decrease in the cardiovascular response to catecholamines, potentially exacerbating hypotension in children with volume depletion or shock. Acidemia causes vasoconstriction of the pulmonary vasculature, which is especially problematic in newborn infants with **persistent pulmonary hypertension** (see Chapter 122.09).

The normal respiratory response to metabolic acidosis—compensatory
hyperventilation—may be subtle with mild metabolic acidosis, but it causes discernible increased respiratory effort with worsening acidemia. The acute metabolic effects of acidemia include insulin resistance, increased protein degradation, and reduced ATP synthesis. Chronic metabolic acidosis causes failure to thrive in children. Acidemia causes potassium to move from the ICS to the ECS, thereby increasing the serum $[K^+]$. Severe acidemia impairs brain metabolism, eventually resulting in lethargy and coma.

**Diagnosis**

The etiology of a metabolic acidosis is often apparent from the history and physical examination. Acutely, diarrhea and shock are common causes of a metabolic acidosis. Shock, which causes a lactic acidosis, is usually apparent on physical examination and can be secondary to dehydration, acute blood loss, sepsis, or heart disease. Failure to thrive suggests a chronic metabolic acidosis, as with renal insufficiency or RTA. New onset of polyuria occurs in children with undiagnosed diabetes mellitus and DKA. Metabolic acidosis with seizures and/or a depressed sensorium, especially in an infant, warrants consideration of an inborn error of metabolism. Meningitis and sepsis with lactic acidosis are more common explanations for metabolic acidosis with neurologic signs and symptoms. Identification of a toxic ingestion (e.g., ethylene glycol, methanol) is especially important because of the potentially excellent response to specific therapy. A variety of medications can cause a metabolic acidosis, whether prescribed or accidentally ingested. Hepatomegaly and metabolic acidosis may occur in children with sepsis, congenital or acquired heart disease, hepatic failure, or inborn errors of metabolism.

Basic laboratory tests in a child with a metabolic acidosis should include measurements of BUN, serum creatinine, serum glucose, urinalysis, and serum electrolytes. Metabolic acidosis, hyperglycemia, glycosuria, and ketonuria support a diagnosis of DKA. Starvation causes ketosis, but the metabolic acidosis, if present, is usually mild ($\text{HCO}_3^- > 18$ mEq/L). Most children with ketosis from poor intake and metabolic acidosis have a concomitant disorder, such as gastroenteritis with diarrhea, that explains the metabolic acidosis. Alternatively, metabolic acidosis with or without ketosis occurs in inborn errors of metabolism; patients with these disorders may have hyperglycemia, normoglycemia, or hypoglycemia. Adrenal insufficiency may cause metabolic acidosis and hypoglycemia. Metabolic acidosis with hypoglycemia also occurs
with liver failure. Metabolic acidosis, normoglycemia, and glycosuria occur in children when type II RTA is part of Fanconi syndrome; the defect in resorption of glucose by the proximal tubule of the kidney causes the glycosuria.

The serum $[K^+]$ is often abnormal in children with a metabolic acidosis. Even though a metabolic acidosis causes potassium to move from the ICS to the ECS, many patients with a metabolic acidosis have a low serum $[K^+]$ because of excessive body losses of $K^+$. With diarrhea, there are high stool losses of $K^+$ and, often, secondary renal losses of $K^+$, whereas in type I or type II RTA, there are increased urinary losses of $K^+$. In DKA, urinary losses of $K^+$ are high, but the shift of $K^+$ out of cells because of a lack of insulin and metabolic acidosis is especially significant. Consequently, the initial serum $[K^+]$ can be low, normal, or high, even though total body $K^+$ is almost always decreased. The serum $[K^+]$ is usually increased in patients with acidosis caused by renal insufficiency; urinary $K^+$ excretion is impaired. The combination of metabolic acidosis, hyperkalemia, and hyponatremia occurs in patients with severe aldosterone deficiency (adrenogenital syndrome) or aldosterone resistance. Patients with less severe, type IV RTA often have only hyperkalemia and metabolic acidosis. Very ill children with metabolic acidosis may have an elevated serum $K^+$ as a result of a combination of renal insufficiency, tissue breakdown, and a shift of $K^+$ from the ICS to the ECS secondary to the metabolic acidosis.

The **plasma anion gap** is useful for evaluating patients with a metabolic acidosis. It divides patients into two diagnostic groups, those with normal anion gap and those with increased anion gap. The following formula determines the anion gap:

$$\text{Anion gap} = [\text{Na}^+] - [\text{Cl}^-] + [\text{HCO}_3^-]$$

A normal anion gap is 4-11, although there is variation among laboratories. Approximately 11 mEq of the anion gap is normally secondary to albumin. A 1 g/dL decrease in the albumin concentration decreases the anion gap by approximately 2.5 mEq/L. Thus, if the albumin is not close to 4 g/dL, the anion gap should be corrected for the albumin concentration:
Anion gap (corrected for albumin)

\[ [\text{Na}^+] - [\text{Cl}^-] - [\text{HCO}_3^-] + 2.5 (4 - \text{albumin}) \]

The number of serum anions must equal the number of serum cations to maintain electrical neutrality (Fig. 68.9). The anion gap is the difference between the measured cation (\( \text{Na}^+ \)) and the measured anions (\( \text{Cl}^- + \text{bicarbonate} \)). The anion gap is also the difference between the unmeasured cations (\( \text{K}^+, \text{magnesium}, \text{calcium} \)) and the unmeasured anions (albumin, phosphate, urate, sulfate). An increased anion gap occurs when there is an increase in unmeasured anions. With a lactic acidosis, there is endogenous production of lactic acid, which is composed of positively charged hydrogen ions and negatively charged lactate anions. The hydrogen ions are largely buffered by serum bicarbonate, resulting in a decrease in \([\text{HCO}_3^-]\). The hydrogen ions that are not buffered by bicarbonate cause the serum pH to decrease. The lactate anions remain, causing the increase in the anion gap.

An increase in unmeasured anions, along with \( \text{H}^+ \) generation, is present in all causes of an increased gap metabolic acidosis (see Table 68.13). In DKA, the keto acids \( \beta \)-hydroxybutyrate and acetoacetate are the unmeasured anions. In
renal failure there is retention of unmeasured anions, including phosphate, urate, and sulfate. The increase in unmeasured anions in renal failure is usually less than the decrease in $[\text{HCO}_3^-]$. Renal failure is thus a mix of an increased-gap and a normal-gap metabolic acidosis. The normal-gap metabolic acidosis is especially prominent in children with renal failure as a result of tubular damage, as occurs with renal dysplasia or obstructive uropathy, because these patients have a concurrent RTA. The unmeasured anions in toxic ingestions vary: formate in methanol intoxication, glycolate in ethylene glycol intoxication, and lactate and keto acids in salicylate intoxication. In inborn errors of metabolism the unmeasured anions depend on the specific etiology and may include keto acids, lactate, and other organic anions. In a few inborn errors of metabolism the acidosis occurs without generation of unmeasured anions; thus the anion gap is normal.

A normal–anion gap metabolic acidosis occurs when there is a decrease in $[\text{HCO}_3^-]$ without an increase in the unmeasured anions. With diarrhea, there is a loss of bicarbonate in the stool, causing a decrease in the serum pH and $[\text{HCO}_3^-]$; the serum $[\text{Cl}^-]$ increases to maintain electrical neutrality (see Fig. 68.9). Hyperchloremic metabolic acidosis is an alternative term for a normal–anion gap metabolic acidosis. Calculation of the anion gap is more precise than using $[\text{Cl}^-]$ to differentiate between a normal-gap and an increased-gap metabolic acidosis, in that the anion gap directly determines the presence of unmeasured anions. Electrical neutrality dictates that the $[\text{Cl}^-]$ increases or decreases according to the serum $[\text{Na}^+]$, making $[\text{Cl}^-]$ a less reliable predictor of unmeasured anions than the more direct measure, calculation of the anion gap.

An increase in unmeasured cations, such as calcium, potassium, and magnesium, decreases the anion gap. Conversely, a decrease in unmeasured cations is a very unusual cause of an increased anion gap. Because of these variables, the broad range of a normal anion gap, and other variables, the presence of a normal or an increased anion gap is not always reliable in differentiating among the causes of a metabolic acidosis, especially when the metabolic acidosis is mild. In some patients there is more than one explanation for the metabolic acidosis, such as the child with diarrhea and lactic acidosis as a result of poor perfusion. The anion gap should not be interpreted in dogmatic isolation; consideration of other laboratory abnormalities and the clinical history improves its diagnostic utility.
**Treatment**

The most effective therapeutic approach for patients with a metabolic acidosis is repair of the underlying disorder, if possible. The administration of insulin in DKA and the restoration of adequate perfusion with IV fluids in lactic acidosis because of hypovolemia or shock eventually result in normalization of the acid-base balance. In other diseases the use of bicarbonate therapy is indicated because the underlying disorder is irreparable. Children with metabolic acidosis caused by RTA or chronic renal failure require long-term base therapy. Patients with acute renal failure and metabolic acidosis need base therapy until their kidneys' ability to excrete hydrogen normalizes. In other disorders the cause of the metabolic acidosis eventually resolves, but base therapy is necessary during the acute illness. In salicylate poisoning, alkali administration increases renal clearance of salicylate and decreases the amount of salicylate in brain cells. Short-term base therapy is often necessary in other poisonings (ethylene glycol, methanol) and inborn errors of metabolism (pyruvate carboxylase deficiency, propionic acidemia). Some inborn errors of metabolism require long-term base therapy.

The use of base therapy in DKA and lactic acidosis is controversial; *there is little evidence that it improves patient outcome, and it has a variety of potential side effects*. The risks of giving sodium bicarbonate include the possibility of causing hypernatremia or volume overload. Furthermore, the patient may have overcorrection of the metabolic acidosis once the underlying disorder resolves, because metabolism of lactate or keto acids generates bicarbonate. The rapid change from acidemia to alkalemia can cause a variety of problems, including hypokalemia and hypophosphatemia. Bicarbonate therapy increases the generation of CO$_2$, which can accumulate in patients with respiratory failure. Because CO$_2$ readily diffuses into cells, the administration of bicarbonate can lower the intracellular pH, potentially worsening cell function. Base therapy is usually reserved for children with severe acute lactic acidosis and severe DKA.

**Oral base therapy** is given to children with chronic metabolic acidosis. Sodium bicarbonate tablets are available for older children. Younger children generally take citrate solutions; the liver generates bicarbonate from citrate. Citrate solutions are available as sodium citrate, potassium citrate, and a 1 : 1 mix of sodium citrate and potassium citrate. The patient's potassium needs dictate the choice. Children with type I or type II RTA may have hypokalemia and benefit from potassium supplements, but most children with chronic renal
failure cannot tolerate additional potassium.

Oral or IV base can be used in acute metabolic acidosis; IV therapy is generally used when a rapid response is necessary. Sodium bicarbonate may be given as a bolus, usually at a dose of 1 mEq/kg, in an emergency situation. Another approach is to add sodium bicarbonate or sodium acetate to the patient's IV fluids, remembering to remove an equal amount of sodium chloride from the solution to avoid giving an excessive sodium load. Careful monitoring is mandatory so that the dose of base can be titrated appropriately.

Tris(hydroxymethyl)aminomethane (tromethamine, THAM) is an option in patients with a metabolic acidosis and a respiratory acidosis, because it neutralizes acids without releasing CO$_2$. THAM also diffuses into cells and therefore provides intracellular buffering.

Hemodialysis is another option for correcting a metabolic acidosis, and it is an appropriate choice in patients with renal insufficiency, especially if significant uremia or hyperkalemia is also present. Hemodialysis is advantageous for correcting the metabolic acidosis caused by methanol or ethylene glycol intoxication, because hemodialysis efficiently removes the offending toxin. In addition, these patients often have a severe metabolic acidosis that does not respond easily to IV bicarbonate therapy. Peritoneal dialysis is another option for correcting the metabolic acidosis due to renal insufficiency.

Many causes of metabolic acidosis require specific therapy. Administration of a glucocorticoid and a mineralocorticoid is necessary in patients with adrenal insufficiency. Patients with DKA require insulin therapy, whereas patients with lactic acidosis respond to measures that alleviate tissue hypoxia. Along with correction of acidosis, patients with methanol or ethylene glycol ingestion should receive an agent that prevents the breakdown of the toxic substance to its toxic metabolites. Fomepizole has supplanted ethanol as the treatment of choice. These agents work by inhibiting alcohol dehydrogenase, the enzyme that performs the first step in the metabolism of ethylene glycol or methanol. There are a variety of disease-specific therapies for patients with a metabolic acidosis resulting from an inborn error of metabolism.

**Metabolic Alkalosis**

Metabolic alkalosis in children is most often secondary to emesis or diuretic use. The serum bicarbonate concentration is increased with a metabolic alkalosis,
although a respiratory acidosis also leads to a compensatory elevation of the serum [HCO$_3^-$]. With a simple metabolic alkalosis, however, the pH is elevated; alkalemia is present. Patients with a respiratory acidosis are acidemic. By decreasing ventilation, a metabolic alkalosis causes appropriate respiratory compensation. P$_{CO_2}$ increases by 7 mm Hg for each 10 mEq/L increase in the serum [HCO$_3^-$]. Appropriate respiratory compensation never exceeds a P$_{CO_2}$ of 55-60 mm Hg. The patient has a concurrent respiratory alkalosis if the P$_{CO_2}$ is lower than the expected compensation. A greater-than-expected P$_{CO_2}$ occurs with a concurrent respiratory acidosis.

**Etiology and Pathophysiology**

The kidneys normally respond promptly to a metabolic alkalosis by increasing base excretion. Two processes are therefore usually present to produce a metabolic alkalosis: (1) the generation of the metabolic alkalosis, which requires the addition of base to the body, and (2) the maintenance of the metabolic alkalosis, which requires impairment in the kidney's ability to excrete base.

The etiologies of a metabolic alkalosis are divided into 2 categories on the basis of urinary chloride level (Table 68.14). The alkalosis in patients with a low urinary [Cl$^-$] is maintained by volume depletion; thus volume repletion is necessary for correction of the alkalosis. The volume depletion in these patients is caused by losses of Na$^+$ and K$^+$, but the loss of Cl$^-$ is usually greater than the losses of Na$^+$ and K$^+$ combined. Because Cl$^-$ losses are the dominant cause of the volume depletion, these patients require Cl$^-$ to correct the volume depletion and metabolic alkalosis; they are said to have Cl$^-$-responsive metabolic alkalosis. In contrast, the alkalosis in a patient with an elevated urinary [Cl$^-$] does not respond to volume repletion and so is termed Cl$^-$-resistant metabolic alkalosis.

- Autosomal dominant hypoparathyroidism (OMIM 146200)
- EAST syndrome (OMIM 612780)
- Base administration

Emesis or nasogastric suction results in loss of gastric fluid, which has a
high content of HCl. Generation of H\(^+\) by the gastric mucosa causes simultaneous release of bicarbonate into the bloodstream. Normally, the hydrogen ions in gastric fluid are reclaimed in the small intestine (by neutralizing secreted bicarbonate). Thus there is no net loss of acid. With loss of gastric fluid, this does not occur, and a metabolic alkalosis develops. This period is the *generation phase* of the metabolic alkalosis.

The *maintenance phase* of the metabolic alkalosis from gastric losses is caused by the volume depletion ("chloride depletion" from gastric loss of HCl). Volume depletion interferes with urinary loss of bicarbonate, the normal renal response to a metabolic alkalosis. During volume depletion, several mechanisms prevent renal bicarbonate loss. First, there is a reduction in the GFR, so less bicarbonate is filtered. Second, volume depletion increases resorption of sodium and bicarbonate in the proximal tubule, limiting the amount of bicarbonate that can be excreted in the urine. This effect is mediated by angiotensin II and adrenergic stimulation of the kidney, both of which are increased in response to volume depletion. Third, the increase in aldosterone during volume depletion increases bicarbonate resorption and H\(^+\) secretion in the collecting duct.

In addition to volume depletion, gastric losses are usually associated with hypokalemia as a result of both gastric loss of K\(^+\) and, most importantly, increased urinary K\(^+\) losses. The increased urinary losses of K\(^+\) are mediated by aldosterone, through volume depletion, and by the increase in intracellular K\(^+\) secondary to the metabolic alkalosis, which causes K\(^+\) to move into the cells of the kidney, causing increased K\(^+\) excretion. Hypokalemia contributes to the maintenance of the metabolic alkalosis by decreasing bicarbonate loss. Hypokalemia increases H\(^+\) secretion in the distal nephron and stimulates ammonia production in the proximal tubule. Ammonia production enhances renal excretion of H\(^+\).

A metabolic alkalosis can develop in patients receiving **loop or thiazide diuretics.** Diuretic use leads to volume depletion, which increases angiotensin II, aldosterone, and adrenergic stimulation of the kidney. Diuretics increase the delivery of sodium to the distal nephron, further enhancing acid excretion. Moreover, these diuretics cause hypokalemia, which increases acid excretion by the kidney. The increase in renal acid excretion generates the metabolic alkalosis, and the decrease in bicarbonate loss maintains it. In addition, patients who are receiving diuretics have a "contraction alkalosis." Diuretic use causes fluid loss without bicarbonate; thus the remaining body bicarbonate is contained.
in a smaller total body fluid compartment. The $[\text{HCO}_3^-]$ increases, helping to generate the metabolic alkalosis.

Diuretics are often used in patients with edema, such as those with nephrotic syndrome, heart failure, or liver failure. In many of these patients, metabolic alkalosis resulting from diuretic use develops despite the continued presence of edema. This is because the effective intravascular volume is low, and it is the effective intravascular volume that stimulates the compensatory mechanisms that cause and maintain a metabolic alkalosis. Many of these patients have a decreased effective intravascular volume before they begin diuretic therapy, increasing the likelihood of diuretic-induced metabolic alkalosis.

Diuretic use increases chloride excretion in the urine. Consequently, while a patient is receiving diuretics, the urine $[\text{Cl}^-]$ is typically high ($>20$ mEq/L). After the diuretic effect has worn off, the urinary $[\text{Cl}^-]$ is low ($<15$ mEq/L) because of appropriate renal $\text{Cl}^-$ retention in response to volume depletion. Thus, categorization of diuretics on the basis of urinary $[\text{Cl}^-]$ depends on the timing of the measurement. However, the metabolic alkalosis from diuretics is clearly $\text{Cl}^-$ responsive; it is corrected after adequate volume repletion. This is the rationale for including this process among the chloride-responsive causes of a metabolic alkalosis.

Most patients with diarrhea have a metabolic acidosis as a result of stool losses of bicarbonate. In chloride-losing diarrhea, an autosomal recessive disorder, there is a defect in the normal intestinal exchange of bicarbonate for chloride, causing excessive stool losses of chloride (see Chapter 364). In addition, stool losses of $\text{H}^+$ and $\text{K}^+$ cause metabolic alkalosis and hypokalemia, both of which are exacerbated by increased renal $\text{H}^+$ and $\text{K}^+$ losses from volume depletion. Treatment is with oral supplements of $\text{K}^+$ and NaCl. Use of a gastric proton pump inhibitor (PPI), by decreasing gastric HCl production, reduces both the volume of diarrhea and the need for electrolyte supplementation.

Formulas with extremely low $\text{Cl}^-$ content have led to $\text{Cl}^-$ deficiency and volume depletion. There is secondary metabolic alkalosis and hypokalemia. Cystic fibrosis can rarely cause metabolic alkalosis, hypokalemia, and hyponatremia because of excessive NaCl losses in sweat (see Chapter 432). The volume depletion causes the metabolic alkalosis and hypokalemia through increased urinary losses, whereas the hyponatremia, a less common finding, is secondary to Na$^+$ loss combined with renal water conservation in an effort to protect the intravascular volume (“appropriate” ADH production).
A **posthypercapnic metabolic alkalosis** occurs after the correction of a chronic respiratory acidosis. This is typically seen in patients with chronic lung disease who are started on mechanical ventilation. During chronic respiratory acidosis, appropriate renal compensation leads to an increase in the serum \([\text{HCO}_3^-]\). Because it is still present after acute correction of the respiratory acidosis, this \([\text{HCO}_3^-]\) causes a metabolic alkalosis. The metabolic alkalosis persists because the patient with a chronic respiratory acidosis is intravascularly depleted because of the \(\text{Cl}^-\) loss that occurred during the initial metabolic compensation for the primary respiratory acidosis. In addition, many children with a chronic respiratory acidosis receive diuretics, which further decrease the intravascular volume. The metabolic alkalosis responds to correction of the intravascular volume deficit.

The **chloride-resistant** causes of metabolic alkalosis can be subdivided according to blood pressure status. Patients with **hypertension** either have increased aldosterone levels or act as if they do. Aldosterone levels are elevated in children with adrenal adenomas or hyperplasia. Aldosterone causes renal retention of sodium, with resultant hypertension. Metabolic alkalosis and hypokalemia result from aldosterone-mediated renal excretion of \(\text{H}^+\) and \(\text{K}^+\). The urinary \(\text{Cl}^-\) level is not low because these patients are volume-overloaded, not volume-depleted. The volume expansion and hypertension allow normal excretion of \(\text{Na}^+\) and \(\text{Cl}^-\) despite the presence of aldosterone. This is known as the **mineralocorticoid escape phenomenon**.

In **glucocorticoid-remediable aldosteronism**, an autosomal dominant disorder, excess production of aldosterone results from the presence of an aldosterone synthase gene regulated by adrenocorticotropic hormone (ACTH) (see **Chapter 594.8**). Glucocorticoids effectively treat this disorder by inhibiting ACTH production by the pituitary, downregulating the inappropriate aldosterone production. Renovascular disease and renin-secreting tumors both cause excessive renin, leading to an increase in aldosterone, although hypokalemia and metabolic alkalosis are less common findings than hypertension. In 2 forms of **congenital adrenal hyperplasia**, 11β-hydroxylase deficiency and 17α-hydroxylase deficiency, there is excessive production of the mineralocorticoid 11-deoxycorticosterone (see **Chapters 594.2** and **594.4**). Hypertension, hypokalemia, and metabolic alkalosis are more likely in 17α-hydroxylase deficiency than in 11β-hydroxylase deficiency. These disorders respond to glucocorticoids because the excess production of 11-deoxycorticosterone is
under the control of ACTH.

**Cushing syndrome** frequently causes hypertension. Cortisol has some mineralocorticoid activity, and high levels can produce hypokalemia and metabolic alkalosis in patients with Cushing syndrome.

Cortisol can bind to the mineralocorticoid receptors in the kidney and function as a mineralocorticoid. This binding normally does not occur because 11β-hydroxysteroid dehydrogenase in the kidney converts cortisol to cortisone, which does not bind to the mineralocorticoid receptor. In 11β-hydroxysteroid dehydrogenase deficiency, also called *apparent mineralocorticoid excess*, cortisol is not converted in the kidney to cortisone. Cortisol is therefore available to bind to the mineralocorticoid receptor in the kidney and act as a mineralocorticoid. Patients with this deficiency, despite low levels of aldosterone, are hypertensive and hypokalemic, and they have a metabolic alkalosis. The same phenomenon can occur with excessive intake of natural licorice, a component of which, glycyrrhizic acid, inhibits 11β-hydroxysteroid dehydrogenase. The autosomal dominant disorder **Liddle syndrome** is secondary to an activating mutation of the sodium channel in the distal nephron (see Chapter 549.3). Upregulation of this sodium channel is one of the principal actions of aldosterone. Because this Na\(^+\) channel is continuously open, children with Liddle syndrome have the features of hyperaldosteronism, including hypertension, hypokalemia, and metabolic alkalosis, but low serum levels of aldosterone.

Bartter and Gitelman syndromes are autosomal recessive disorders associated with **normal blood pressure**, elevated urinary Cl\(^-\), metabolic alkalosis, and hypokalemia (see Chapter 549). In **Bartter syndrome**, patients have a defect in Na\(^+\) and Cl\(^-\) resorption in the loop of Henle. This leads to excessive urinary losses of Na\(^+\) and Cl\(^-\), and as in patients receiving loop diuretics, volume depletion and secondary hyperaldosteronism occur, causing hypokalemia and metabolic alkalosis. **Gitelman syndrome** is usually milder than Bartter syndrome. Patients have renal Na\(^+\) and Cl\(^-\) wasting with volume depletion caused by mutations in the gene encoding the thiazide-sensitive Na\(^+\)-Cl\(^-\) transporter in the distal tubule. As in patients receiving a thiazide diuretic, affected patients have volume depletion and secondary hyperaldosteronism with hypokalemia and metabolic alkalosis. Children with Gitelman syndrome have hypocalciuria and hypomagnesemia. Some patients with autosomal dominant hypoparathyroidism have hypokalemia and metabolic alkalosis from impaired
Na\(^+\) and Cl\(^-\) resorption in the loop of Henle. **EAST syndrome** causes hypokalemia, metabolic alkalosis and hypomagnesemia.

**Excessive base intake** can cause a metabolic alkalosis. Affected patients do not have low urine [Cl\(^-\)], unless there is associated volume depletion. In the absence of volume depletion, excess base is rapidly corrected via renal excretion of bicarbonate. Rarely, massive base intake can cause a metabolic alkalosis by overwhelming the kidney's ability to excrete bicarbonate. This may occur in infants who are given baking soda as a “home remedy” for colic or stomach upset. Each teaspoon of baking soda has 42 mEq of sodium bicarbonate. Infants have increased vulnerability because of a lower GFR, limiting the rate of compensatory renal bicarbonate excretion. A metabolic alkalosis may also occur in patients who receive a large amount of sodium bicarbonate during cardiopulmonary resuscitation. Blood products are anticoagulated with citrate, which is converted into bicarbonate by the liver. Patients who receive large amounts of blood products may have a metabolic alkalosis. Iatrogenic metabolic alkalosis can occur as a result of acetate in TPN. Aggressive use of bicarbonate therapy in a child with a lactic acidosis or DKA may cause a metabolic alkalosis. This event is especially likely in a patient in whom the underlying cause of the lactic acidosis is successfully corrected (restoration of intravascular volume in a patient with severe dehydration). Once the cause of the lactic acidosis resolves, lactate can be converted by the liver into bicarbonate, which when combined with infused bicarbonate can create a metabolic alkalosis. A similar phenomenon can occur in a child with DKA because the administration of insulin allows keto acids to be metabolized, producing bicarbonate. However, this phenomenon rarely occurs because of judicious use of bicarbonate therapy in DKA and because there are usually significant pretreatment losses of keto acids in the urine, preventing massive regeneration of bicarbonate. Base administration is most likely to cause a metabolic alkalosis in patients who have an impaired ability to excrete bicarbonate in the urine. This impairment occurs in patients with concurrent volume depletion or renal insufficiency.

**Clinical Manifestations**

The symptoms in patients with a metabolic alkalosis are often related to the underlying disease and associated electrolyte disturbances. Children with Cl\(^-\) - responsive causes of metabolic alkalosis often have symptoms related to volume depletion, such as thirst and lethargy. In contrast, children with Cl\(^-\) -
unresponsive causes may have symptoms related to hypertension.

Alkalemia causes potassium to shift into the ICS, producing a decrease in the extracellular $[K^+]$. Alkalemia leads to increased urinary losses of $K^+$. Increased $K^+$ losses are present in many of the conditions that cause a metabolic alkalosis. Therefore, most patients with a metabolic alkalosis have hypokalemia, and their symptoms may be related to the hypokalemia (see Chapter 68.4).

The symptoms of a metabolic alkalosis are caused by the associated alkalemia. The magnitude of the alkalemia is related to the severity of the metabolic alkalosis and the presence of concurrent respiratory acid-base disturbances. During alkalemia, the ionized calcium concentration decreases as a result of increased binding of calcium to albumin. The decrease in the ionized calcium concentration may cause symptoms of tetany (carpopedal spasm).

**Arrhythmias** are a potential complication of a metabolic alkalosis, and the risk for arrhythmia increases if there is concomitant hypokalemia. Alkalemia increases the risk of digoxin toxicity, and antiarrhythmic medications are less effective in the presence of alkalemia. In addition, alkalemia may decrease cardiac output. A metabolic alkalosis causes a compensatory increase in the $P_{CO_2}$ by decreasing ventilation. In patients with underlying lung disease, the decrease in ventilatory drive can cause hypoxia. In patients with normal lungs, the hypoventilation seen in severe metabolic alkalosis can cause hypoxia.

## Diagnosis

Measurement of the urine $[Cl^-]$ is the most helpful test in differentiating among the causes of a metabolic alkalosis. The urine $[Cl^-]$ is low in patients with a metabolic alkalosis resulting from volume depletion, unless there is a defect in renal handling of $Cl^-$. The urine $[Cl^-]$ is superior to the urine $[Na^+]$ in assessment of volume status in patients with a metabolic alkalosis, because the normal renal response to a metabolic alkalosis is to excrete bicarbonate. Because bicarbonate is negatively charged, it can be excreted only with a cation, usually $Na^+$ and $K^+$. Therefore, a patient with a metabolic alkalosis may excrete $Na^+$ in the urine despite the presence of volume depletion, which normally causes avid $Na^+$ retention. The urine $[Cl^-]$ is usually a good indicator of volume status, and it differentiates $Cl^-$-resistant and $Cl^-$-responsive causes of a metabolic alkalosis.

Diuretics and gastric losses are the most common causes of metabolic
alkalosis and are usually apparent from the patient history. Occasionally, metabolic alkalosis, usually with hypokalemia, may be a clue to the presence of bulimia or surreptitious diuretic use (see Chapter 41). Patients with bulimia have a low urine Cl\(^{-}\) level, indicating that they have volume depletion as a result of an extrarenal etiology, but there is no alternative explanation for their volume depletion. Surreptitious diuretic use may be diagnosed by obtaining a urine toxicology screen for diuretics. The urine [Cl\(^{-}\)] is increased while a patient is using diuretics but is low when the patient stops taking them. Rarely, children with mild Bartter or Gitelman syndrome are misdiagnosed as having bulimia or abusing diuretics. The urine [Cl\(^{-}\)] is always elevated in Bartter and Gitelman syndromes, and the urine toxicology screen for diuretics has a negative result. Metabolic alkalosis with hypokalemia is occasionally the initial manifestation of cystic fibrosis. An elevated sweat Cl\(^{-}\) finding is diagnostic.

Patients with a metabolic alkalosis and a high urinary [Cl\(^{-}\)] are subdivided according to blood pressure status. Children with normal blood pressure may have Bartter or Gitelman syndrome. Excess base administration is another diagnostic possibility, but it is usually apparent from the history. In patients with sodium bicarbonate ingestion (baking soda), which may be unreported by the parent, the metabolic alkalosis usually occurs with significant hypernatremia. In addition, unless volume depletion is superimposed, the metabolic alkalosis from base ingestion resolves itself once the source of base is eliminated.

Measuring serum concentrations of renin and aldosterone differentiates children with a metabolic alkalosis, a high urinary [Cl\(^{-}\)], and elevated blood pressure. Both renin and aldosterone are elevated in children with either renovascular disease or a renin-secreting tumor. Aldosterone is high and renin is low in patients with adrenal adenomas or hyperplasia and glucocorticoid-remediable aldosteronism. Renin and aldosterone are low in children with Cushing syndrome, Liddle syndrome, licorice ingestion, and 17α-hydroxylase, 11β-hydroxylase, and 11β-hydroxysteroid dehydrogenase deficiencies. An elevated 24 hr urine cortisol value is diagnostic of Cushing syndrome, which is suspected from the presence of the other classic features of this disease (see Chapter 597). Elevations of 11-deoxycorticosterone values are seen in 17α-hydroxylase and 11β-hydroxylase deficiency.

**Treatment**

The approach to treatment of metabolic alkalosis depends on the severity of the
alkalosis and the underlying etiology. In children with a mild metabolic alkalosis ([HCO₃⁻] < 32 mEq/L), intervention is often unnecessary, although this depends on the specific circumstances. In a child with congenital heart disease who is receiving a stable dose of a loop diuretic, a mild alkalosis does not require treatment. In contrast, intervention may be appropriate in a child with a worsening mild metabolic alkalosis because of nasogastric suction. The presence of a concurrent respiratory acid-base disturbance also influences therapeutic decision-making. A patient with a concurrent respiratory acidosis should have some increase in bicarbonate from metabolic compensation; thus the severity of the pH elevation is more important than [HCO₃⁻]. In contrast, a patient with a respiratory alkalosis and a metabolic alkalosis is at risk for severe alkalemia; treatment may be indicated, even if the increase in bicarbonate value is only mild.

Intervention is usually necessary in children with moderate or severe metabolic alkalosis. The most effective approach is to address the underlying etiology. In some children, nasogastric suction may be decreased or discontinued. Alternatively, the addition of a gastric PPI reduces gastric secretion and losses of HCl. Diuretics are an important cause of metabolic alkalosis, and if a change is tolerated, they should be eliminated or the dose reduced. Adequate potassium supplementation or the addition of a potassium-sparing diuretic is also helpful in a child with a metabolic alkalosis from diuretics. Potassium-sparing diuretics not only decrease renal K⁺ losses but, by blocking the action of aldosterone, also decrease H⁺ secretion in the distal nephron, increasing urinary bicarbonate excretion. Many children cannot tolerate discontinuation of diuretic therapy; thus potassium supplementation and potassium-sparing diuretics are the principal therapeutic approach. Arginine HCl may also be used to treat chloride-responsive metabolic acidosis if sodium or potassium salts are not appropriate. Arginine HCl may raise the serum K⁺ levels during administration. Rarely, in cases of severe metabolic alkalosis, acetazolamide is an option. A carbonic anhydrase inhibitor, acetazolamide decreases resorption of bicarbonate in the proximal tubule, causing significant bicarbonate loss in the urine. The patient receiving this drug must be monitored closely, because acetazolamide produces major losses of potassium in the urine and increases fluid losses, potentially necessitating a reduction in dosage of other diuretics.

Most children with a metabolic alkalosis have one of the chloride-responsive
etiolologies. In these situations, administration of sufficient sodium chloride and potassium chloride to correct the volume deficit and the potassium deficit is necessary to correct the metabolic alkalosis. This approach may not be an option in the child who has volume depletion due to diuretics, because volume repletion may be contraindicated. Adequate replacement of gastric losses of sodium and potassium in a child with a nasogastric tube can minimize or prevent the development of the metabolic alkalosis. With adequate intravascular volume and a normal serum [K⁺], the kidney excretes the excess bicarbonate within 2 days.

In children with the chloride-resistant causes of a metabolic alkalosis that are associated with hypertension, volume repletion is contraindicated because it would exacerbate the hypertension and would not repair the metabolic alkalosis. Ideally, treatment focuses on eliminating the excess aldosterone effect. Adrenal adenomas can be resected, licorice intake can be eliminated, and renovascular disease can be repaired. Glucocorticoid-remediable aldosteronism, 17α-hydroxylase deficiency, and 11β-hydroxylase deficiency respond to the administration of glucocorticoids. The mineralocorticoid effect of cortisol in 11β-hydroxysteroid dehydrogenase deficiency can be decreased with the use of spironolactone, which blocks the mineralocorticoid receptor. In contrast, the metabolic alkalosis in children with Liddle syndrome does not respond to spironolactone; however, either triamterene or amiloride is effective therapy because both agents block the sodium channel that is constitutively active in Liddle syndrome.

In children with Bartter or Gitelman syndrome, therapy includes oral potassium and sodium supplementation; potassium-sparing diuretics may be helpful in select cases. Children with Gitelman syndrome often require magnesium supplementation, whereas children with severe Bartter syndrome often benefit from indomethacin.

**Respiratory Acidosis**

A respiratory acidosis is an inappropriate increase in blood carbon dioxide tension (P CO₂). CO₂ is a by-product of metabolism and is removed from the body by the lungs. During a respiratory acidosis, the effectiveness of CO₂ removal by the lungs is decreased. A respiratory acidosis is secondary to either pulmonary disease, such as severe bronchiolitis, or nonpulmonary disease, such as a narcotic overdose. Even though body production of CO₂ can vary, normal
lungs are able to accommodate this variation; excess production of CO₂ is not an isolated cause of a respiratory acidosis. With impairment of alveolar ventilation, the rate of body production of CO₂ may affect the severity of the respiratory acidosis, but this is usually not a significant factor.

A respiratory acidosis causes a decrease in the blood pH, but there is normally a metabolic response that partially compensates, minimizing the severity of the acidemia. The acute metabolic response to a respiratory alkalosis occurs within minutes. The metabolic compensation for an acute respiratory acidosis is secondary to titration of acid by nonbicarbonate buffers. This buffering of H⁺ causes a predictable increase in the serum [HCO₃⁻]: Plasma bicarbonate increases by 1 for each 10 mm Hg increase in the PCO₂ (acute compensation).

With a chronic respiratory acidosis, there is more significant metabolic compensation and thus less severe acidemia than in an acute respiratory acidosis with the same increase in PCO₂. During a chronic respiratory acidosis, the kidneys increase acid excretion. This response occurs over 3-4 days and causes a predictable increase in the serum [HCO₃⁻]: Plasma bicarbonate increases by 3.5 for each 10 mm Hg increase in the PCO₂ (chronic compensation).

The increase of serum [HCO₃⁻] during a chronic respiratory acidosis is associated with a decrease in body chloride. After acute correction of a chronic respiratory acidosis, the plasma bicarbonate continues to be increased, and the patient has a metabolic alkalosis. Because of the Cl⁻ deficit, this is a chloride-responsive metabolic alkalosis; it corrects once the patient's Cl⁻ deficit is replaced.

A mixed disorder is present if the metabolic compensation is inappropriate. A higher-than-expected bicarbonate value occurs in the setting of a concurrent metabolic alkalosis, and a lower-than-expected bicarbonate value occurs in the setting of a concurrent metabolic acidosis. Evaluating whether compensation is appropriate during a respiratory acidosis requires clinical knowledge of the acuity of the process, because the expected compensation is different, depending on whether the process is acute or chronic.

The PCO₂ cannot be interpreted in isolation to determine whether a patient has a respiratory acidosis. A respiratory acidosis is always present if a patient has acidemia and an elevated PCO₂. However, an elevated PCO₂ also occurs as appropriate respiratory compensation for a simple metabolic alkalosis. The patient is alkalemic; this is not a respiratory acidosis. During a mixed
disturbance, a patient can have a respiratory acidosis and a normal or even low PCO$_2$. This condition may occur in a patient with a metabolic acidosis. A respiratory acidosis is present if the patient does not have appropriate respiratory compensation (the PCO$_2$ is higher than expected from the severity of the metabolic acidosis).

**Etiology and Pathophysiology**

The causes of a respiratory acidosis are either pulmonary or nonpulmonary (Table 68.15). CNS disorders can decrease the activity of the central respiratory center, reducing ventilatory drive. A variety of medications and illicit drugs suppress the respiratory center. The signals from the respiratory center need to be transmitted to the respiratory muscles via the nervous system. Respiratory muscle failure can be secondary to disruption of the signal from the CNS in the spinal cord, the phrenic nerve, or the neuromuscular junction. Disorders directly affecting the muscles of respiration can prevent adequate ventilation, causing a respiratory acidosis.

**Table 68.15**

**Causes of Respiratory Acidosis**

**Central Nervous System Depression**

- Encephalitis
- Head trauma
- Brain tumor
- Central sleep apnea
- Primary pulmonary hypoventilation (Ondine curse)
- Stroke
- Hypoxic brain damage
- Obesity-hypoventilation (pickwickian) syndrome
- Increased intracranial pressure
- Medications
  - Narcotics
  - Barbiturates
  - Anesthesia
  - Benzodiazepines
Propofol
Alcohols

**Disorders of Spinal Cord, Peripheral Nerves, or Neuromuscular Junction**

- Diaphragmatic paralysis
- Guillain-Barré syndrome
- Poliomyelitis
- Acute flaccid myelitis
- Spinal muscular atrophies
- Tick paralysis
- Botulism
- Myasthenia
- Multiple sclerosis
- Spinal cord injury

**Medications**

- Vecuronium
- Aminoglycosides
- Organophosphates (pesticides)

**Respiratory Muscle Weakness**

- Muscular dystrophy
- Hypothyroidism
- Malnutrition
- Hypokalemia
- Hypophosphatemia

**Medications**

- Succinylcholine
- Corticosteroids

**Pulmonary Disease**

- Pneumonia
Pneumothorax
Asthma
Bronchiolitis
Pulmonary edema
Pulmonary hemorrhage
Acute respiratory distress syndrome
Neonatal respiratory distress syndrome
Cystic fibrosis
Bronchopulmonary dysplasia
Hypoplastic lungs
Meconium aspiration
Pulmonary thromboembolus
Interstitial fibrosis

**Upper Airway Disease**

Aspiration
Laryngospasm
Angioedema
Obstructive sleep apnea
Tonsillar hypertrophy
Vocal cord paralysis
Extrinsic tumor
Extrinsic or intrinsic hemangioma

**Miscellaneous**

Flail chest
Cardiac arrest
Kyphoscoliosis
Decreased diaphragmatic movement due to ascites or peritoneal dialysis

Mild or moderate lung disease often causes a respiratory alkalosis as a result of hyperventilation secondary to hypoxia or stimulation of lung mechanoreceptors or chemoreceptors. Only more severe lung disease causes a respiratory acidosis. Upper airway diseases, by impairing air entry into the lungs,
may decrease ventilation, producing a respiratory acidosis.

Increased production of CO₂ is never the sole cause of a respiratory acidosis, but it can increase the severity of the disease in a patient with decreased ventilation of CO₂. Increased production of CO₂ occurs in patients with fever, hyperthyroidism, excess caloric intake, and high levels of physical activity. Increased respiratory muscle work also increases CO₂ production.

**Clinical Manifestations**

Patients with a respiratory acidosis are often tachypneic in an effort to correct the inadequate ventilation. Exceptions include patients with a respiratory acidosis resulting from CNS depression and patients who are on the verge of complete respiratory failure secondary to fatigue of the respiratory muscles.

The symptoms of respiratory acidosis are related to the severity of the hypercarbia. Acute respiratory acidosis is usually more symptomatic than chronic respiratory acidosis. Symptoms are also increased by concurrent hypoxia or metabolic acidosis. In a patient breathing room air, hypoxia is always present if a respiratory acidosis is present. The potential CNS manifestations of respiratory acidosis include anxiety, dizziness, headache, confusion, asterixis, myoclonic jerks, hallucinations, psychosis, coma, and seizures.

Acidemia, no matter the etiology, affects the cardiovascular system. An arterial pH <7.2 impairs cardiac contractility and the normal response to catecholamines, in both the heart and the peripheral vasculature. Hypercapnia causes vasodilation, most dramatically in the cerebral vasculature, but hypercapnia produces vasoconstriction of the pulmonary circulation. Respiratory acidosis increases the risk of cardiac arrhythmias, especially in a child with underlying cardiac disease.

**Diagnosis**

The history and physical findings often point to a clear etiology. For the obtunded patient with poor respiratory effort, evaluation of the CNS is often indicated. This may include imaging studies (CT or MRI) and, potentially, a lumbar puncture for cerebrospinal fluid analysis. A toxicology screen for illicit drugs may also be appropriate. A response to naloxone is both diagnostic and therapeutic. In many of the diseases affecting the respiratory muscles, there is evidence of weakness in other muscles. Stridor is a clue that the child may have
upper airway disease. Along with a physical examination, a chest radiograph is often helpful in diagnosing pulmonary disease.

In many patients, respiratory acidosis may be multifactorial. A child with bronchopulmonary dysplasia, an intrinsic lung disease, may worsen because of respiratory muscle dysfunction caused by severe hypokalemia resulting from long-term diuretic therapy. Conversely, a child with muscular dystrophy, a muscle disease, may worsen because of aspiration pneumonia.

For a patient with respiratory acidosis, calculation of the gradient between the alveolar oxygen concentration and the arterial oxygen concentration, the A–A O₂ gradient, is useful for distinguishing between poor respiratory effort and intrinsic lung disease. The A–A O₂ gradient is increased if the hypoxemia is caused by intrinsic lung disease (see Chapter 400).

**Treatment**

Respiratory acidosis is best managed by treatment of the underlying etiology. In some patients the response is very rapid, such as after the administration of naloxone to a patient with a narcotic overdose. In contrast, in the child with pneumonia, a number of days of antibiotic therapy may be required before the respiratory status improves. In many children with a chronic respiratory acidosis, there is no curative therapy, although an acute respiratory illness superimposed on a chronic respiratory condition is usually reversible.

All patients with an acute respiratory acidosis are hypoxic and therefore need to receive supplemental oxygen. Mechanical ventilation is necessary in some children with respiratory acidosis. Children with significant respiratory acidosis caused by CNS disease usually require mechanical ventilation because such a disorder is unlikely to respond quickly to therapy. In addition, hypercarbia causes cerebral vasodilation, and the increase in intracranial pressure can be dangerous in a child with an underlying CNS disease. Readily reversible CNS depression, as from a narcotic overdose, may not require mechanical ventilation. Decisions on mechanical ventilation for other patients depend on a number of factors. Patients with severe hypercarbia—P_co₂ >75 mm Hg—usually require mechanical ventilation (see Chapter 89.1). The threshold for intubation is lower if there is concomitant metabolic acidosis, a slowly responsive underlying disease, or hypoxia that responds poorly to oxygen, or if the patient appears to be tiring and respiratory arrest seems likely.

In patients with a chronic respiratory acidosis the respiratory drive is often
less responsive to hypercarbia and more responsive to hypoxia. Thus, with chronic respiratory acidosis, excessive use of oxygen can blunt the respiratory drive and therefore increase the P_{CO_2}. In these patients, oxygen must be used cautiously.

When possible, it is best to avoid mechanical ventilation in a patient with chronic respiratory acidosis because extubation is often difficult. However, an acute illness may necessitate mechanical ventilation in a child with chronic respiratory acidosis. When intubation is necessary, the P_{CO_2} should be lowered only to the patient's normal baseline, and this should be done gradually. These patients normally have an elevated serum [HCO_3^-] as a result of metabolic compensation for their respiratory acidosis. A rapid lowering of the P_{CO_2} can cause a severe metabolic alkalosis, potentially leading to complications, including cardiac arrhythmias, decreased cardiac output, and decreased cerebral blood flow. In addition, prolonged mechanical ventilation at a normal P_{CO_2} causes the metabolic compensation to resolve. When the patient is subsequently extubated, the patient will no longer benefit from metabolic compensation, causing a more severe acidemia because of the respiratory acidosis.

**Respiratory Alkalosis**

A respiratory alkalosis is an inappropriate reduction in the blood CO_2 concentration. This is usually secondary to hyperventilation, initially causing removal of CO_2 to surpass production. Eventually, a new steady state is achieved, with removal equaling production, although at a lower CO_2 tension (P_{CO_2}). A respiratory alkalosis that is not the result of hyperventilation may occur in children receiving extracorporeal membrane oxygenation or hemodialysis, with CO_2 lost directly from the blood in the extracorporeal circuit.

With a simple respiratory alkalosis, the pH increases but there is a normal metabolic response that attenuates some of the change in the blood pH. A metabolic response to an acute respiratory alkalosis occurs within minutes, mediated by hydrogen ion release from nonbicarbonate buffers. The metabolic response to an acute respiratory alkalosis is predictable: Plasma bicarbonate falls by 2 for each 10 mm Hg decrease in the P_{CO_2} (acute compensation).

A chronic respiratory alkalosis leads to more significant metabolic compensation because of the actions of the kidneys, which decrease acid
secretion, producing a decrease in the serum $[\text{HCO}_3^-]$. Both the proximal and distal tubules decrease acid secretion. Metabolic compensation for a respiratory alkalosis develops gradually and takes 2-3 days to produce the full effect: Plasma bicarbonate falls by 4 for each 10 mm Hg decrease in the PCO$_2$ (chronic compensation).

A chronic respiratory alkalosis is the only acid-base disturbance in which appropriate compensation may normalize the pH, although $>7.4$.

A mixed disorder is present if the metabolic compensation is inappropriate. A higher-than-expected HCO$_3^-$ level occurs in the setting of a concurrent metabolic alkalosis, and a lower-than-expected HCO$_3^-$ level occurs in the setting of a concurrent metabolic acidosis. Evaluating whether compensation is appropriate during a respiratory alkalosis requires clinical knowledge of the acuity of the process, because the expected compensation differs according to whether the process is acute or chronic.

A low PCO$_2$ value does not always indicate a respiratory alkalosis. The PCO$_2$ also decreases as part of the appropriate respiratory compensation for a metabolic acidosis; this is not a respiratory alkalosis. A metabolic acidosis is the dominant acid-base disturbance in a patient with acidemia and a low PCO$_2$, even though there could still be a concurrent respiratory alkalosis. In contrast, a respiratory alkalosis is always present in a patient with alkalemia and a low PCO$_2$. Even a normal PCO$_2$ value may be consistent with a respiratory alkalosis in a patient with a metabolic alkalosis, because an elevated PCO$_2$ is expected as part of appropriate respiratory compensation for the metabolic alkalosis.

**Etiology and Pathophysiology**

A variety of stimuli can increase the ventilatory drive and cause a respiratory alkalosis (Table 68.16). Arterial hypoxemia or tissue hypoxia stimulates peripheral chemoreceptors to signal the central respiratory center in the medulla to increase ventilation. The resultant greater respiratory effort increases the oxygen content of the blood (PO$_2$) but depresses the PCO$_2$. The effect of hypoxemia on ventilation begins when the arterial oxygen saturation (Sao$_2$) decreases to approximately 90% (PO$_2 = 60$ mm Hg), and hyperventilation increases as hypoxemia worsens. Acute hypoxia is a more potent stimulus for hyperventilation than chronic hypoxia; thus chronic hypoxia, as occurs in
cyanotic heart disease, causes a much less severe respiratory alkalosis than an equivalent degree of acute hypoxia. The many causes of hypoxemia or tissue hypoxia include primary lung disease, severe anemia, and carbon monoxide (CO) poisoning.

**Table 68.16**

**Causes of Respiratory Alkalosis**

**Hypoxemia or Tissue Hypoxia**

- Pneumonia
- Pulmonary edema
- Cyanotic heart disease
- Congestive heart failure
- Asthma
- Severe anemia
- High altitude
- Laryngospasm
- Aspiration
- Carbon monoxide poisoning
- Pulmonary embolism
- Interstitial lung disease
- Hypotension

**Lung Receptor Stimulation**

- Pneumonia
- Pulmonary edema
- Asthma
- Pulmonary embolism
- Hemothorax
- Pneumothorax
- Respiratory distress syndrome (adult or infant)

**Central Stimulation**
Central nervous system disease
- Subarachnoid hemorrhage
- Encephalitis or meningitis
- Trauma
- Brain tumor
- Stroke

Fever
Pain
Anxiety (panic attack)
Psychogenic hyperventilation or anxiety
Liver failure
Sepsis
Pregnancy
Mechanical ventilation
Hyperammonemia
Extracorporeal membrane oxygenation or hemodialysis
Medications
- Salicylate intoxication
- Theophylline
- Progesterone
- Exogenous catecholamines
- Caffeine

The lungs contain chemoreceptors and mechanoreceptors that respond to irritants and stretching and send signals to the respiratory center to increase ventilation. Aspiration or pneumonia may stimulate the chemoreceptors, whereas pulmonary edema may stimulate the mechanoreceptors. Most of the diseases that activate these receptors may also cause hypoxemia and can therefore potentially lead to hyperventilation by 2 mechanisms. Patients with primary lung disease may initially have a respiratory alkalosis, but worsening of the disease, combined with respiratory muscle fatigue, often causes respiratory failure and the development of a respiratory acidosis.

**Hyperventilation in the absence of lung disease** occurs with direct stimulation of the central respiratory center. This occurs with CNS diseases such as meningitis, hemorrhage, and trauma. Central hyperventilation caused by lesions, such as infarcts or tumors near the central respiratory center in the midbrain, increases the rate and depth of the respiratory effort. This respiratory
pattern portends a poor prognosis because these midbrain lesions are frequently fatal. Systemic processes may cause centrally mediated hyperventilation. Although the exact mechanisms are not clear, liver disease causes a respiratory alkalosis that is usually proportional to the degree of liver failure. Pregnancy causes a chronic respiratory alkalosis, probably mediated by progesterone acting on the respiratory centers. Salicylates, although often causing a concurrent metabolic acidosis, directly stimulate the respiratory center to produce a respiratory alkalosis. The respiratory alkalosis during sepsis is probably caused by cytokine release.

**Hyperventilation may be secondary to an underlying disease** that causes pain, stress, or anxiety. In psychogenic hyperventilation or in panic attacks, there is no disease process accounting for the hyperventilation. This disorder may occur in a child who has had an emotionally stressful experience. Alternatively, it may be part of a panic disorder, especially if there are repeated episodes of hyperventilation. In such a patient the symptoms of acute alkalemia increase anxiety, potentially perpetuating the hyperventilation.

A respiratory alkalosis is quite common in children receiving mechanical ventilation because the respiratory center is not controlling ventilation. In addition, these children may have a decreased metabolic rate and thus less CO₂ production because of sedation and paralytic medications. Normally, decreased CO₂ production and the resultant hypocapnia decrease ventilation, but this physiologic response cannot occur in a child who cannot reduce ventilatory effort.

**Clinical Manifestations**

The disease process causing the respiratory alkalosis is usually more concerning than the clinical manifestations. Chronic respiratory alkalosis is usually asymptomatic because metabolic compensation decreases the magnitude of the alkalemia.

Acute respiratory alkalosis may cause chest tightness, palpitations, lightheadedness, circumoral numbness, and paresthesias of the extremities. Less common manifestations include tetany, seizures, muscle cramps, and syncope. The lightheadedness and syncope probably result from the reduction in cerebral blood flow caused by hypocapnia. The reduction in cerebral blood flow is the rationale for using hyperventilation to treat children with increased intracranial pressure (ICP). The paresthesias, tetany, and seizures may be partially related to
the reduction in ionized calcium that occurs because alkalemia causes more calcium to bind to albumin. A respiratory alkalosis also causes a mild reduction in the serum potassium level. Patients with psychogenic hyperventilation tend to be most symptomatic as a result of the respiratory alkalosis, and these symptoms, along with a sensation of breathlessness, exacerbate the hyperventilation.

**Diagnosis**

In many patients, hyperventilation producing a respiratory alkalosis is not clinically detectable, even with careful observation of the patient's respiratory effort. Metabolic compensation for a respiratory alkalosis causes a low serum [HCO$_3^-$]. When hyperventilation is not appreciated and only serum electrolytes are evaluated, there is often a presumptive diagnosis of a metabolic acidosis. If a respiratory alkalosis is suspected, only ABG determination can make the diagnosis.

Hyperventilation does not always indicate a primary respiratory disorder. In some patients the hyperventilation is appropriate respiratory compensation for a metabolic acidosis. With a primary metabolic acidosis, acidemia is present, and the serum HCO$_3^-$ level is usually quite low if there is clinically detectable hyperventilation. In contrast, the serum HCO$_3^-$ level never goes below 17 mEq/L as part of the metabolic compensation for acute respiratory alkalosis, and simple acute respiratory alkalosis causes alkalemia.

The etiology of a respiratory alkalosis is often apparent from the physical examination or history, and it may consist of lung disease, neurologic disease, or cyanotic heart disease. **Hypoxemia** is a common cause of hyperventilation, and it is important to diagnose because it suggests a significant underlying disease that requires expeditious treatment. Hypoxemia may be detected on physical examination (cyanosis) or by pulse oximetry. However, normal pulse oximetry values do not eliminate hypoxemia as the etiology of the hyperventilation. There are 2 reasons why pulse oximetry is not adequate for eliminating hypoxemia as a cause of a respiratory alkalosis. First, pulse oximetry is not very sensitive at detecting a mildly low arterial $\text{Pa}_2$ ($\text{Pao}_2$). Second, the hyperventilation during a respiratory alkalosis causes $\text{Pao}_2$ to increase, possibly to a level that is not identified as abnormal by pulse oximetry. Only ABG measurement can eliminate hypoxia as an explanation for a respiratory alkalosis. Along with hypoxemia, it
is important to consider processes that cause tissue hypoxia without necessarily causing hypoxemia. Examples are CO poisoning, severe anemia, and heart failure.

Lung disease without hypoxemia may cause hyperventilation. Although lung disease is often apparent by history or physical examination, a chest radiograph may detect more subtle disease. The patient with a pulmonary embolism may have benign chest radiograph findings, normal PaO₂, and isolated respiratory alkalosis, although hypoxia may eventually occur. Diagnosis of a pulmonary embolism requires a high index of suspicion and should be considered in children without another explanation for respiratory alkalosis, especially if risk factors are present, such as prolonged bed rest and a hypercoagulable state (e.g., nephrotic syndrome, lupus anticoagulant).

**Treatment**

There is seldom a need for specific treatment of respiratory alkalosis. Rather, treatment focuses on the underlying disease. Mechanical ventilator settings are adjusted to correct iatrogenic respiratory alkalosis, unless the hyperventilation has a therapeutic purpose (e.g., treatment of increased ICP).

For the patient with hyperventilation secondary to anxiety, efforts should be undertaken to reassure the child, usually enlisting the parents. Along with reassurance, patients with psychogenic hyperventilation may benefit from benzodiazepines. During an acute episode of psychogenic hyperventilation, rebreathing into a paper bag increases the patient's Pco₂. Using a paper bag instead of a plastic bag allows adequate oxygenation but permits [CO₂] in the bag to increase. The resultant increase in the patient's Pco₂ decreases the symptoms of the respiratory alkalosis that tend to perpetuate the hyperventilation. Rebreathing should be performed only when other causes of hyperventilation have been eliminated; pulse oximetry during the rebreathing is prudent.

**Bibliography**

**Acid-Base Balance**

Adrogue HJ, Madias NE. Assessing acid-base status:
Maintenance intravenous (IV) fluids are used in a child who cannot be fed enterally. Along with maintenance fluids, children may require concurrent replacement fluids if they have continued excessive losses, as may occur with drainage from a nasogastric (NG) tube or with high urine output because of nephrogenic diabetes insipidus. If dehydration is present, the patient also needs to receive deficit replacement (see Chapter 70). A child awaiting surgery may need only maintenance fluids, whereas a child with diarrheal dehydration needs maintenance and deficit therapy and also may require replacement fluids if significant diarrhea continues.

**Maintenance Therapy**

Children normally have large variations in their daily intake of water and electrolytes. The only exceptions are patients who receive fixed dietary regimens orally, via a gastric tube, or as IV total parenteral nutrition (TPN). Healthy children can tolerate significant variations in intake because of the many homeostatic mechanisms that can adjust absorption and excretion of water and electrolytes (see Chapter 68). The calculated water and electrolyte needs that form the basis of maintenance therapy are not absolute requirements. Rather, these calculations provide reasonable guidelines for a starting point to estimate IV therapy. Children do not need to be started on IV fluids simply because their intake is being monitored in a hospital and they are not taking “maintenance fluids” orally, unless there is a pathologic process present that necessitates high fluid intake.
Maintenance fluids are most often necessary in preoperative and postoperative surgical patients; many nonsurgical patients also require maintenance fluids. It is important to recognize when it is necessary to begin maintenance fluids. A normal teenager who is given nothing by mouth (NPO) overnight for a morning procedure does not require maintenance fluids because a healthy adolescent can easily tolerate 12 or 18 hr without oral intake. In contrast, a 6 mo old child waiting for surgery should begin receiving IV fluids within 8 hr of the last feeding. Infants become dehydrated more quickly than older patients. A child with obligatory high urine output from nephrogenic diabetes insipidus should begin receiving IV fluids soon after being classified as NPO.

Maintenance fluids are composed of a solution of water, glucose, sodium (Na\(^+\)), and potassium (K\(^+\)). This solution has the advantages of simplicity, long shelf life, low cost, and compatibility with peripheral IV administration. Such a solution accomplishes the major objectives of maintenance fluids (Table 69.1). Patients lose water, Na\(^+\), and K\(^+\) in their urine and stool; water is also lost from the skin and lungs. Maintenance fluids replace these losses, thereby avoiding the development of dehydration and Na\(^+\) or K\(^+\) deficiency.

Table 69.1

</tr>
</tbody>
</table>

The glucose in maintenance fluids provides approximately 20% of the normal caloric needs of the patient, prevents the development of starvation ketoacidosis, and diminishes the protein degradation that would occur if the patient received no calories. Glucose also provides added osmoles, thus avoiding the administration of hypotonic fluids that may cause hemolysis.

Maintenance fluids do not provide adequate calories, protein, fat, minerals, or vitamins. This fact is typically not problematic for a patient receiving IV fluids for a few days. A patient receiving maintenance IV fluids is receiving inadequate calories and will lose 0.5–1% of weight each day. It is imperative that patients not remain on maintenance therapy indefinitely; TPN should be used for
children who cannot be fed enterally for more than a few days, especially patients with underlying malnutrition.

Prototypical maintenance fluid therapy does not provide electrolytes such as calcium, phosphorus, magnesium, and bicarbonate. For most patients, this lack is not problematic for a few days, although there are patients who will not tolerate this omission, usually because of excessive losses. A child with proximal renal tubular acidosis wastes bicarbonate in urine. Such a patient will rapidly become acidemic unless bicarbonate (or acetate) is added to the maintenance fluids. It is important to remember the limitations of maintenance fluid therapy.

**Maintenance Water**

Water is a crucial component of maintenance fluid therapy because of the obligatory daily water losses. These losses are both measurable (urine, stool) and not measurable (insensible losses from the skin and lungs). Failure to replace these losses leads to a child who is thirsty, uncomfortable, and ultimately dehydrated.

The goal of maintenance water is to provide enough water to replace these losses. Although urinary losses are approximately 60% of the total, the normal kidney can greatly modify water losses, with daily urine volume potentially varying by more than a factor of 20. Maintenance water is designed to provide enough water so that the kidney does not need to significantly dilute or concentrate the urine. It also provides a margin of safety, so that normal homeostatic mechanisms can adjust urinary water losses to prevent overhydration and dehydration. This adaptability obviates the need for absolute precision in determining water requirements. This fact is important, given the absence of absolute accuracy in the formulas for calculation of water needs.

Table 69.2 provides a system for calculating maintenance water on the basis of the patient's weight and emphasizes the high water needs of smaller, less mature patients. This approach is reliable, although calculations based on weight do overestimate the water needs of an overweight child, in whom it is better to base the calculations on the lean body weight, which can be estimated by using the 50th percentile of body weight for the child's height. It is also important to remember that there is an upper limit of 2.4 L/24 hr in adult-sized patients. IV fluids are written as an hourly rate. The formulas in Table 69.3 enable rapid calculation of the rate of maintenance fluids.

- For body weight 10-20 kg: 40 mL/hr + 2 mL/kg/hr × (wt – 10 kg)
- For body weight >20 kg: 60 mL/hr + 1 mL/kg/hr × (wt – 20 kg)*

* The maximum fluid rate is normally 100 mL/hr.

**Intravenous Solutions**

The components of available solutions are shown in Table 69.4. These solutions are available with 5% dextrose (D5), 10% dextrose (D10), or without dextrose. Except for Ringer lactate (lactated Ringer, LR), they are also available with added potassium (10 or 20 mEq/L). A balanced IV fluid contains a base (lactate or acetate), a more physiologic chloride concentration than NS, and additional physiologic concentrations of electrolytes such as potassium, calcium, and magnesium. Examples include LR and PlasmaLyte, and there is evidence suggesting benefit versus NS in certain clinical situations. A hospital pharmacy can also prepare custom-made solutions with different concentrations of sodium or potassium. In addition, other electrolytes, such as calcium, magnesium, phosphate, acetate, and bicarbonate, can be added to IV solutions. Custom-made solutions take time to prepare and are much more expensive than commercial solutions. The use of custom-made solutions is necessary only for patients who have underlying disorders that cause significant electrolyte imbalances. The use of commercial solutions saves time and expense.

* Electrolyte concentrations in mEq/L.

A normal plasma osmolality is 285-295 mOsm/kg. Infusing an IV solution peripherally with a much lower osmolality can cause water to move into red blood cells, leading to hemolysis. Thus, IV fluids are generally designed to have an osmolality that is either close to 285 or greater (fluids with moderately higher osmolality do not cause problems). Thus, 0.2NS (osmolality = 68) should not be administered peripherally, but D5 0.2NS (osmolality = 346) or D5 ½ NS + 20 mEq/L potassium chloride (KCl) with an osmolality of 472 can be administered. Controversy surrounds the appropriate sodium content of maintenance fluids, considering the observation that hypotonic fluids may cause hyponatremia, which may have serious sequelae. Hypotonic fluids seem more physiologic given the low Na⁺ content of breast milk and formula. However, hospitalized children often have impaired water excretion because of volume depletion or nonosmotic stimuli for antidiuretic hormone (ADH) production, such as respiratory disease, central nervous system (CNS) disease, stress, pain, nausea, and medications (e.g., narcotics). Hypotonic fluids increase the risk of hyponatremia; hence, isotonic fluids with 5% dextrose are recommended as standard maintenance fluid except in neonates.

**Glucose**

Maintenance fluids usually contain D5, which provides 17 calories/100 mL and nearly 20% of the daily caloric needs. This level is enough to prevent ketone production and helps minimize protein degradation, but the child will lose weight on this regimen. The weight loss is the principal reason why a patient needs to be started on TPN after a few days of maintenance fluids if enteral feedings are still not possible. Maintenance fluids are also lacking in such crucial nutrients as protein, fat, vitamins, and minerals.
Selection of Maintenance Fluids

An isotonic fluid (NS, LR, PlasmaLyte) with 5% dextrose and KCl (10-20 mEq/L is usually added to NS) is recommended for maintenance IV fluids. Surgical patients typically receive isotonic fluids (NS, LR) during surgery and in the recovery room for 6-8 hr postoperatively; the rate is typically approximately two-thirds the calculated maintenance rate, with dextrose added if clinically indicated. Subsequent maintenance fluids have the addition of 5% dextrose and 10-20 mEq/L KCl based on the serum K\(^+\) and the clinical setting. Electrolytes should be measured at least daily in all children receiving >50% of maintenance fluids intravenously unless the child is receiving prolonged IV fluids (TPN).

These guidelines assume that no disease process is present that would require an adjustment in either the volume or the electrolyte composition of maintenance fluids. Neonates, and especially premature infants, are outside the scope of these guidelines given their unique physiology. Children with renal insufficiency may be hyperkalemic or unable to excrete K\(^+\) and may not tolerate 10 or 20 mEq/L of potassium. Patients with persistent ADH production because of an underlying disease process (syndrome of inappropriate ADH secretion, congestive heart failure, nephrotic syndrome, liver disease) should receive less than maintenance fluids. Children with meningitis are fluid-restricted unless intravascular volume depletion is present (see Chapter 621.1 ). Treatment is individualized, and careful monitoring is critical.

In children with complicated pathophysiologic derangements, it may be necessary to adjust empirically the electrolyte composition and rate of maintenance fluids on the basis of electrolyte measurements and assessment of fluid balance. In all children it is critical to monitor weight, urine output, and electrolytes carefully to identify overhydration or underhydration, hyponatremia, and other electrolyte disturbances, and then adjust the rate or composition of the IV solution accordingly.

Variations in Maintenance Water and Electrolytes

The calculation of maintenance water is based on standard assumptions regarding water losses. In some patients, however, these assumptions are incorrect. To identify such situations, it is helpful to understand the source and
magnitude of normal water losses. Table 69.5 lists the 3 sources of normal water loss.

**Table 69.5**

**Sources of Water Loss**

- Urine: 60%
- Insensible losses: ≈35% (skin and lungs)
- Stool: 5%

Urine is the most important contributor to normal water loss. Insensible losses represent approximately one third of total maintenance water (40% in infants; 25% in adolescents and adults). Insensible losses are composed of evaporative losses from the skin and lungs that cannot be quantitated. The evaporative losses from the skin do not include sweat, which would be considered an additional (sensible) source of water loss. Stool normally represents a minor source of water loss.

Maintenance water and electrolyte needs may be increased or decreased, depending on the clinical situation. This may be obvious, as in the infant with profuse diarrhea, or subtle, as in the patient who has decreased insensible losses while receiving mechanical ventilation. It is helpful to consider the sources of normal water and electrolyte losses and to determine whether any of these sources is being modified in a specific patient. It is then necessary to adjust maintenance water and electrolyte calculations.

Table 69.6 lists a variety of clinical situations that modify normal water and electrolyte losses. The skin can be a source of very significant water loss, particularly in neonates, especially premature infants, who are under radiant warmers or are receiving phototherapy. Very-low-birthweight infants can have insensible losses of 100-200 mL/kg/24 hr. Burns can result in massive losses of water and electrolytes, and there are specific guidelines for fluid management in children with burns (see Chapter 92). Sweat losses of water and electrolytes, especially in a warm climate, can also be significant. Children with cystic fibrosis and some children with pseudohypoaldosteronism have increased sodium losses from the skin.

Fever increases evaporative losses from the skin. These losses are somewhat predictable, leading to a 10–15% increase in maintenance water needs for each 1°C (1.8°F) increase in temperature above 38°C (100.4°F). These guidelines are for a patient with a persistent fever; a 1 hr fever spike does not cause an appreciable increase in water needs.

Tachypnea or a tracheostomy increases evaporative losses from the lungs. A humidified ventilator causes a decrease in insensible losses from the lungs and can even lead to water absorption via the lungs; a ventilated patient has a decrease in maintenance water requirements. It may be difficult to quantify the changes that take place in the individual patient in these situations.

### Replacement Fluids

The gastrointestinal (GI) tract is potentially a source of considerable water loss. GI water losses are accompanied by electrolytes and thus may cause disturbances in intravascular volume and electrolyte concentrations. GI losses are often associated with loss of potassium, leading to hypokalemia. Because of the high bicarbonate concentration in stool, children with diarrhea usually have a metabolic acidosis, which may be accentuated if volume depletion causes hypoperfusion and a concurrent lactic acidosis. Emesis or losses from an NG tube can cause a metabolic alkalosis (see Chapter 68).

In the absence of vomiting, diarrhea, or NG drainage, GI losses of water and electrolytes are usually quite small. All GI losses are considered excessive, and
the increase in the water requirement is equal to the volume of fluid losses. Because GI water and electrolyte losses can be precisely measured, an appropriate replacement solution can be used.

It is impossible to predict the losses for the next 24 hr; it is better to replace excessive GI losses as they occur. The child should receive an appropriate maintenance fluid that does not consider the GI losses. The losses should then be replaced after they occur, with use of a solution with a similar electrolyte concentration as the GI fluid. The losses are usually replaced every 1-6 hr, depending on the rate of loss, with very rapid losses being replaced more frequently.

**Diarrhea** is a common cause of fluid loss in children and can result in dehydration and electrolyte disorders. In the unusual patient with significant diarrhea and a limited ability to take oral fluid, it is important to have a plan for replacing excessive stool losses. The volume of stool should be measured, and an equal volume of replacement solution should be given. Data are available on the average electrolyte composition of diarrhea in children (Table 69.4). With this information an appropriate replacement solution can be designed. The solution shown in Table 69.7 replaces stool losses of Na\(^+\), K\(^+\), Cl\(^-\), and bicarbonate. Each 1 mL of stool should be replaced by 1 mL of this solution. The average electrolyte composition of diarrhea is just an average, and there may be considerable variation. It is therefore advisable to consider measuring the electrolyte composition of a patient's diarrhea if the amount is especially excessive or if the patient's serum electrolyte levels are problematic.

Solution: D5 \( \frac{1}{2} \) NS + 30 mEq/L sodium bicarbonate + 20 mEq/L KCl

Replace stool mL/mL every 1-6 hr
Loss of gastric fluid, through emesis or NG suction, is also likely to cause dehydration, in that most patients with either condition have impaired oral intake of fluids. Electrolyte disturbances, particularly hypokalemia and metabolic alkalosis, are also common. These complications can be avoided by judicious use of a replacement solution. The composition of gastric fluid shown in Table 69.8 is the basis for designing a replacement solution.

**Approach to Replacement of Ongoing Losses**

- Solution: normal saline + 10 mEq/L KCl
- Replace output mL/mL every 1-6 hr

Patients with gastric losses frequently have hypokalemia, although the K⁺ concentration of gastric fluid is relatively low. The associated urinary K⁺ loss is an important cause of hypokalemia in this situation (see Chapter 68). These patients may need additional potassium either in their maintenance fluids or in their replacement fluids to compensate for prior or ongoing urinary losses. Restoration of the patient's intravascular volume, by decreasing aldosterone synthesis, lessens the urinary K⁺ losses.

**Urine output** is normally the largest cause of water loss. Diseases such as renal failure and syndrome of inappropriate ADH secretion can lead to a decrease in urine volume. The patient with oliguria or anuria has a decreased need for water and electrolytes; continuation of maintenance fluids produces fluid overload. In contrast, postobstructive diuresis, the polyuric phase of acute
tubular necrosis, diabetes mellitus, and diabetes insipidus increase urine production. To prevent dehydration, the patient must receive more than standard maintenance fluids when urine output is excessive. The electrolyte losses in patients with polyuria are variable. In diabetes insipidus the urine electrolyte concentration is usually low, whereas children with diseases such as juvenile nephronophthisis and obstructive uropathy usually have increased losses of both water and sodium.

The approach to decreased or increased urine output is similar (Table 69.9). The patient receives fluids at a rate to replace insensible losses. This is accomplished by a rate of fluid administration that is 25–40% of the normal maintenance rate, depending on the patient's age. Replacing insensible losses in the anuric child will theoretically maintain an even fluid balance, with the caveat that 25–40% of the normal maintenance rate is only an estimate of insensible losses. In the individual patient, this rate is adjusted on the basis of monitoring of the patient's weight and volume status. Most children with renal insufficiency receive little or no potassium because the kidney is the principal site of K⁺ excretion.

D5, 5% dextrose; NS, normal saline.

For the oliguric child, it is important to add a urine replacement solution to prevent dehydration. This issue is especially important in the patient with acute renal failure, in whom output may increase, potentially leading to volume depletion and worsening of renal failure if the patient remains on only insensible fluids. A replacement solution of D5 \( \frac{1}{2} \) NS is usually appropriate initially, although its composition may have to be adjusted if urine output increases significantly.

Most children with polyuria (except in diabetes mellitus; see Chapter 607) should be started on replacement of insensible fluid plus urine losses. This approach avoids the need to attempt to calculate the volume of urine output that is “normal” so that the patient can be given replacement fluid for the excess. In these patients, urine output is, by definition, excessive, and it is often helpful to measure Na\(^+\) and K\(^+\) concentrations of the urine to help in formulating the urine replacement solution.

Surgical drains and chest tubes can produce measurable fluid output. These fluid losses should be replaced when they are significant. They can be measured and replaced with an appropriate solution. Third space losses, which manifest as edema and ascites, are caused by a shift of fluid from the intravascular space into the interstitial space. Although these losses cannot be quantitated easily, third space losses can be large and may lead to intravascular volume depletion, despite the patient's weight gain. Replacement of third space fluid is empirical but should be anticipated in patients who are at risk, such as children who have burns or abdominal surgery. Third space losses and chest tube output are isotonic, so they usually require replacement with an isotonic fluid, such as NS or LR. Adjustments in the amount of replacement fluid for third space losses are based on continuing assessment of the patient's intravascular volume status. Protein losses from chest tube drainage can be significant, occasionally necessitating that 5% albumin be used as a replacement solution.

**Bibliography**

Dehydration, most often caused by gastroenteritis, is a common problem in children. Most cases can be managed with oral rehydration (see Chapter 366).

Even children with mild to moderate hyponatremic or hypernatremic dehydration can be managed with oral rehydration.

Clinical Manifestations

The 1st step in caring for the child with dehydration is to assess the degree of dehydration (Table 70.1), which dictates both the urgency of the situation and the volume of fluid needed for rehydration. The infant with mild dehydration (3–5% of body weight dehydrated) has few clinical signs or symptoms. The infant may be thirsty; the alert parent may notice a decline in urine output. The history is most helpful. The infant with moderate dehydration has clear physical signs and symptoms. Intravascular space depletion is evident from an increased heart rate and reduced urine output. This patient needs fairly prompt intervention. The infant with severe dehydration is gravely ill. The decrease in blood pressure indicates that vital organs may be receiving inadequate perfusion. Immediate and aggressive intervention is necessary. If possible, the child with severe dehydration should initially receive intravenous (IV) therapy. For older children and adults, mild, moderate, or severe dehydration represents a lower percentage of body weight lost. This difference occurs because water accounts for a higher percentage of body weight in infants (see Chapter 68).

Table 70.1

Clinical Evaluation of Dehydration
**Mild dehydration (<5% in an infant; <3% in an older child or adult):**
Normal or increased pulse; decreased urine output; thirsty; normal physical findings

**Moderate dehydration (5–10% in an infant; 3–6% in an older child or adult):** Tachycardia; little or no urine output; irritable/lethargic; sunken eyes and fontanel; decreased tears; dry mucous membranes; mild delay in elasticity (skin turgor); delayed capillary refill (>1.5 sec); cool and pale

**Severe dehydration (>10% in an infant; >6% in an older child or adult):** Peripheral pulses either rapid and weak or absent; decreased blood pressure; no urine output; very sunken eyes and fontanel; no tears; parched mucous membranes; delayed elasticity (poor skin turgor); very delayed capillary refill (>3 sec); cold and mottled; limp, depressed consciousness

Clinical assessment of dehydration is only an estimate; thus the patient must be continually reevaluated during therapy. The degree of dehydration is underestimated in hypernatremic dehydration because the movement of water from the intracellular space (ICS) to the extracellular space (ECS) helps preserve the intravascular volume.

The history usually suggests the etiology of the dehydration and may predict whether the patient will have a normal sodium concentration (isotonic dehydration), hyponatremic dehydration, or hypernatremic dehydration. The neonate with dehydration caused by poor intake of breast milk often has hypernatremic dehydration. **Hypernatremic dehydration** is likely in any child with losses of hypotonic fluid and poor water intake, as may occur with diarrhea, and poor oral intake because of anorexia or emesis. **Hyponatremic dehydration** occurs in the child with diarrhea who is taking in large quantities of low-salt fluid, such as water or formula.

Some children with dehydration are appropriately thirsty, but in others the lack of intake is part of the pathophysiology of the dehydration. Even though decreased urine output is present in most children with dehydration, good urine output may be deceptively present if a child has an underlying renal defect, such as diabetes insipidus or a salt-wasting nephropathy, or in infants with hypernatremic dehydration.

**Physical examination** findings are usually proportional to the degree of dehydration. Parents may be helpful in assessment of the child for the presence of sunken eyes, because this finding may be subtle. Pinching and gently twisting
the skin of the abdominal or thoracic wall detects tenting of the skin (turgor, elasticity). Tented skin remains in a pinched position rather than springing quickly back to normal. It is difficult to properly assess tenting of the skin in premature infants or severely malnourished children. Activation of the sympathetic nervous system causes **tachycardia** in children with intravascular volume depletion; diaphoresis may also be present. Postural changes in blood pressure are often helpful for evaluating and assessing the response to therapy in children with dehydration. **Tachypnea** in children with dehydration may be present secondary to a metabolic acidosis from stool losses of bicarbonate or lactic acidosis from shock (see Chapter 88).

**Laboratory Findings**

Several laboratory findings are useful for evaluating the child with dehydration. The serum sodium concentration determines the type of dehydration. **Metabolic acidosis** may be a result of stool bicarbonate losses in children with diarrhea, secondary renal insufficiency, or lactic acidosis from shock. The anion gap is useful for differentiating among the various causes of a metabolic acidosis (see Chapter 68). Emesis or nasogastric losses usually cause a **metabolic alkalosis**. The serum potassium ($K^+$) concentration may be low as a result of diarrheal losses. In children with dehydration as a result of emesis, gastric $K^+$ losses, metabolic alkalosis, and urinary $K^+$ losses all contribute to hypokalemia. Metabolic acidosis, which causes a shift of $K^+$ out of cells, and renal insufficiency may lead to hyperkalemia. A combination of mechanisms may be present; thus, it may be difficult to predict the child's acid-base status or serum $K^+$ level from the history alone.

The blood urea nitrogen (BUN) value and serum creatinine concentration are useful in assessing the child with dehydration. Volume depletion without parenchymal renal injury may cause a disproportionate increase in the BUN with little or no change in the creatinine concentration. This condition is secondary to increased passive resorption of urea in the proximal tubule as a result of appropriate renal conservation of sodium and water. The increase in the BUN with moderate or severe dehydration may be absent or blunted in the child with poor protein intake, because urea production depends on protein degradation. The BUN may be disproportionately increased in the child with increased urea production, as occurs with a gastrointestinal bleed or with the use of
glucocorticoids, which increase catabolism. A significant elevation of the creatinine concentration suggests renal insufficiency, although a small, transient increase can occur with dehydration. **Acute kidney injury** (see Chapter 550.1) because of volume depletion is the most common etiology of renal insufficiency in a child with volume depletion, but occasionally the child may have previously undetected chronic renal insufficiency or an alternative explanation for the acute renal failure. **Renal vein thrombosis** is a well-described sequela of severe dehydration in infants; findings may include thrombocytopenia and hematuria (see Chapter 540.2).

Hemoconcentration from dehydration causes increases in hematocrit, hemoglobin, and serum proteins. These values normalize with rehydration. A normal hemoglobin concentration during acute dehydration may mask an underlying anemia. A decreased albumin level in a dehydrated patient suggests a chronic disease, such as malnutrition, nephrotic syndrome, or liver disease, or an acute process, such as capillary leak. An acute or chronic protein-losing enteropathy may also cause a low serum albumin concentration.

**Calculation of the Fluid Deficit**

Determining the fluid deficit necessitates clinical determination of the percentage of dehydration and multiplication of this percentage by the patient's weight; a child who weighs 10 kg and is 10% dehydrated has a fluid deficit of 1 L.

**Approach to Severe Dehydration**

The child with dehydration needs acute intervention to ensure that there is adequate tissue perfusion. This resuscitation phase requires rapid restoration of the circulating intravascular volume and treatment of **shock** with an isotonic solution, such as normal saline (NS), Ringer lactate (lactated Ringer solution, LR), or PlasmaLyte (see Chapter 88). The child is given a fluid bolus, usually 20 mL/kg of the isotonic fluid, over approximately 20 min. The child with severe dehydration may require multiple fluid boluses and may need to receive the boluses as fast as possible. In a child with a known or probable metabolic alkalosis (e.g., child with isolated vomiting), LR or PlasmaLyte should not be used because the lactate or acetate would worsen the alkalosis. However, LR or
PlasmaLyte may be preferable to NS in shock since it is a balanced solution (see Chapter 69); NS may cause a hyperchloremic metabolic acidosis.

Colloids, such as blood, 5% albumin, and plasma, are rarely needed for fluid boluses. A crystalloid solution (NS or LR) is satisfactory, with both lower risk of infection and lower cost. Blood is obviously indicated in the child with significant anemia or acute blood loss. Plasma is useful for children with a coagulopathy. The child with hypoalbuminemia may benefit from 5% albumin, although there is evidence that albumin infusions increase mortality in adults. The volume and the infusion rate for colloids are generally modified compared with crystalloids (see Chapter 500).

The initial resuscitation and rehydration phase is complete when the child has an adequate intravascular volume. Typically, the child shows clinical improvement, including a lower heart rate, normalization of blood pressure, improved perfusion, better urine output, and a more alert affect.

With adequate intravascular volume, it is appropriate to plan the fluid therapy for the next 24 hr. A general approach is outlined in Table 70.2, with the caveat that there are many different approaches to correcting dehydration. A balanced solution can be substituted for NS. In isonatremic or hyponatremic dehydration, the entire fluid deficit is corrected over 24 hr; a slower approach is used for hypernatremic dehydration (discussed later). The volume of isotonic fluids that the patient has received is subtracted from this total. The remaining fluid volume is then administered over 24 hr. The potassium concentration may need to be decreased or, less frequently, increased, depending on the clinical situation. Potassium is not usually included in the IV fluids until the patient voids and normal renal function is documented by measurement of BUN and creatinine. Children with significant ongoing losses need to receive an appropriate replacement solution (see Chapter 69).

**Monitoring and Adjusting Therapy**

The formulation of a plan for correcting a child's dehydration is only the beginning of management. *All calculations in fluid therapy are only approximations.* This statement is especially true for the assessment of percentage dehydration. It is equally important to monitor the patient during treatment and to modify therapy on the basis of the clinical situation. Table 70.3 lists the cornerstones of patient monitoring. The patient's vital signs are useful indicators of intravascular volume status. The child with decreased blood pressure and an increased heart rate will probably benefit from a fluid bolus.

Electrolytes

The patient's intake and output are critically important in the dehydrated child. The child who, after 8 hr of therapy, has more output than input because of continuing diarrhea needs to be started on a replacement solution. See the guidelines in Chapter 69 for selecting an appropriate replacement solution. Urine output is useful for evaluating the success of therapy. Good urine output indicates that rehydration has been successful.
Signs of dehydration on physical examination suggest the need for continued rehydration. Signs of fluid overload, such as edema and pulmonary congestion, are present in the child who is overhydrated. An accurate daily weight measurement is critical for the management of the dehydrated child. There should be a gain in weight during successful therapy.

Measurement of serum electrolyte levels at least daily is appropriate for any child who is receiving IV rehydration. Such a child is at risk for sodium, potassium, and acid-base disorders. It is always important to look at trends. For example, a sodium concentration ([Na\(^+\)]\(\text{mEq/L}\)) of 144 mEq/L is normal; but if the [Na\(^+\)] was 136 mEq/L 12 hr earlier, there is a distinct risk that the child will be hypernatremic in 12 or 24 hr. It is advisable to be proactive in adjusting fluid therapy.

Both hypokalemia and hyperkalemia are potentially serious (see Chapter 68). Because dehydration can be associated with acute renal failure and hyperkalemia, potassium is withheld from IV fluids until the patient has voided. The potassium concentration in the patient's IV fluids is not rigidly prescribed. Rather, the patient's serum K\(^+\) level and underlying renal function are used to modify potassium delivery. The patient with an elevated creatinine value and K\(^+\) level of 5 mEq/L does not receive any potassium until the serum K\(^+\) level decreases. Conversely, the patient with a K\(^+\) level of 2.5 mEq/L may require additional potassium.

Metabolic acidosis can be quite severe in dehydrated children. Although normal kidneys eventually correct this problem, a child with renal dysfunction may be unable to correct a metabolic acidosis, and a portion of the patient's IV sodium chloride may have to be replaced with sodium bicarbonate or sodium acetate.

The serum K\(^+\) level is modified by the patient's acid-base status. Acidosis increases serum K\(^+\) by causing intracellular K\(^+\) to move into the ECS. Thus, as acidosis is corrected, the serum potassium concentration ([K\(^+\)]) decreases. Again, it is best to anticipate this problem and to monitor the serum [K\(^+\)] and adjust potassium administration appropriately.

**Hyponatremic Dehydration**

The pathogenesis of hyponatremic dehydration usually involves a combination of sodium and water loss and water retention to compensate for the volume
depletion. The patient has a pathologic increase in fluid loss, and the lost fluid contains sodium. Most fluid that is lost has a lower sodium concentration, so patients with only fluid loss would have hypernatremia. Diarrhea has, on average, a sodium concentration of 50 mEq/L. Replacing diarrheal fluid with water, which has almost no sodium, causes a reduction in the serum \([\text{Na}^+]\). The volume depletion stimulates synthesis of antidiuretic hormone (ADH), resulting in reduced renal water excretion. Therefore, the body's usual mechanism for preventing hyponatremia, renal water excretion, is blocked. The risk of hyponatremia is further increased if the volume depletion is a result of loss of fluid with a higher sodium concentration, as may occur with renal salt wasting, third space losses, or diarrhea with high sodium content (cholera).

The initial goal in treating hyponatremia is correction of intravascular volume depletion with isotonic fluid. An overly rapid (>12 mEq/L over 1st 24 hr) or overcorrection in the serum \([\text{Na}^+]\) (>135 mEq/L) is associated with an increased risk of central pontine myelinolysis (see Chapter 68). Most patients with hyponatremic dehydration do well with the same basic strategy outlined in Table 70.2. Again, \(K^+\) delivery is adjusted according to the initial serum \(K^+\) level and the patient's renal function. Potassium is not given until the patient voids.

The patient's \([\text{Na}^+]\) is monitored closely to ensure appropriate correction, and the sodium concentration of the fluid is adjusted accordingly. Patients with ongoing losses require an appropriate replacement solution (see Chapter 69). Patients with neurologic symptoms (seizures) as a result of hyponatremia need to receive an acute infusion of hypertonic (3%) saline to increase the serum \([\text{Na}^+]\) rapidly (see Chapter 68).

**Hypernatremic Dehydration**

Hypernatremic dehydration is the most dangerous form of dehydration because of complications of hypernatremia itself and of its therapy. Hypernatremia can cause serious neurologic damage, including central nervous system hemorrhages and thrombosis. This damage appears to be secondary to the movement of water from the brain cells into the hypertonic extracellular fluid (ECF), causing brain cell shrinkage and tearing blood vessels within the brain (see Chapter 68).

The movement of water from the ICS to the ECS during hypernatremic dehydration partially protects the intravascular volume. Unfortunately, because the initial manifestations are milder, children with hypernatremic dehydration are
often brought for medical attention with more profound dehydration. Children with hypernatremic dehydration are often lethargic, and they may be irritable when touched. Hyponatremia may cause fever, hypertonicity, and hyperreflexia. More severe neurologic symptoms may develop if cerebral bleeding or thrombosis occurs.

Overly rapid treatment of hypernatremic dehydration may cause significant morbidity and mortality. Idiogenic osmoles are generated within the brain during the development of hypohydremia; they increase the osmolality within the cells of the brain, providing protection against brain cell shrinkage caused by movement of water out of the cells and into the hypertonic ECF. Idiogenic osmoles dissipate slowly during the correction of hypohydremia. With overly rapid lowering of the extracellular osmolality during the correction of hypohydremia, an osmotic gradient may be created that causes water movement from the ECS into the cells of the brain, producing cerebral edema. Symptoms of the resultant cerebral edema can range from seizures to brain herniation and death.

To minimize the risk of cerebral edema during the correction of hypohydremic dehydration, the serum sodium concentration should not decrease by >10 mEq/L every 24 hr. The deficits in severe hypohydremic dehydration may need to be corrected over 2-4 days (Table 70.4).

| Determine time for correction on basis of initial sodium concentration: | • [Na] 145-157 mEq/L: 24 hr  
• [Na] 158-170 mEq/L: 48 hr  
• [Na] 171-183 mEq/L: 72 hr  
• [Na] 184-196 mEq/L: 84 hr |
| Administer fluid at constant rate over time for correction: | Typical fluid: 5% dextrose + half-normal saline (with 20 mEq/L KCl unless contraindicated)  
Typical rate: 1.25-1.5 times maintenance |
Follow serum sodium concentration
Adjust fluid on basis of clinical status and serum sodium concentration:
   Signs of volume depletion: administer normal saline (20 mL/kg)
   Sodium decreases too rapidly; either:
   • Increase sodium concentration of IV fluid
   • Decrease rate of IV fluid
   Sodium decreases too slowly; either:
   • Decrease sodium concentration of IV fluid
   • Increase rate of IV fluid
Replace ongoing losses as they occur

The initial resuscitation of hypernatremic dehydration requires restoration of
the intravascular volume with NS. LR should not be used because it is more
hypotonic than NS and may cause too rapid a decrease in the serum [Na⁺],
especially if multiple fluid boluses are necessary.

To avoid cerebral edema during correction of hypernatremic dehydration, the
fluid deficit is corrected slowly. The rate of correction depends on the initial
sodium concentration (Table 70.4). There is no general agreement on the choice
or the rate of fluid administration for correcting hypernatremic dehydration;
these factors are not nearly as important as vigilant monitoring of the serum [Na⁺]
and adjustment of the therapy according to the result. The rate of decrease of
the serum [Na⁺] is roughly related to the “free water” delivery, although there is
considerable variation between patients. Free water is water without sodium. NS
contains no free water, half-normal saline (½ NS) is 50% free water, and water
is 100% free water. Smaller patients, to achieve the same decrease in the sodium
concentration, tend to need higher amounts of free water delivery per kilogram
because of higher insensible fluid losses. Five percent dextrose (D5) with ½
NS is usually an appropriate starting solution for correction of a patient with
hypernatremic dehydration. Some patients, especially infants with ongoing high
insensible water losses, may rarely need to receive D5 0.2NS, which should be
used with great caution and constant monitoring. Others require D5 NS. A child
with dehydration as a result of pure free water loss, as usually occurs with
diabetes insipidus, usually needs a more hypotonic fluid than a child with
depletion of both sodium and water from diarrhea.

Adjustment in the sodium concentration of the IV fluid is the most common
approach to modify the rate of decrease in the serum concentration (see Table
For difficult-to-manage patients with severe hypernatremia, having two IV solutions (e.g., D5 ½ NS and D5 NS, both with the same concentration of potassium) at the bedside can facilitate this approach by allowing for rapid adjustments of the rates of the 2 fluids. If the serum [Na⁺] decreases too rapidly, the rate of D5 NS can be increased and the rate of D5 ½ NS can be decreased by the same amount. Adjustment in the total rate of fluid delivery is another approach to modifying free water delivery. For example, if the serum [Na⁺] is decreasing too slowly, the rate of the IV fluid can be increased, thereby increasing the delivery of free water. There is limited flexibility in modifying the rate of the IV fluid because patients generally should receive 1.25-1.5 times the normal maintenance fluid rate. Nevertheless, in some situations, it can be a helpful adjustment.

Because increasing the rate of the IV fluid increases the rate of decline of the sodium concentration, signs of volume depletion are treated with additional isotonic fluid boluses. The serum [K⁺] and the level of renal function dictate the potassium concentration of the IV fluid; potassium is withheld until the patient voids. Patients with hypernatremic dehydration need an appropriate replacement solution if they have ongoing, excessive losses (see Chapter 69).

Seizures and a depressed level of consciousness are the most common manifestations of cerebral edema from an overly rapid decrease of the serum [Na⁺] during correction of hypernatremic dehydration. Signs of increased intracranial pressure or impending herniation may develop quite rapidly (see Chapter 85). Acutely, increasing the serum [Na⁺] through an infusion of 3% sodium chloride can reverse the cerebral edema. Each 1 mL/kg of 3% NaCl increases the serum [Na⁺] by approximately 1 mEq/L. An infusion of 4 mL/kg often results in resolution of the symptoms. This strategy is similar to that used for treating symptomatic hyponatremia (see Chapter 68).

Many patients with mild to moderate hypernatremic dehydration as a result of gastroenteritis can be managed with oral rehydration (see Chapter 366). In patients with severe hypernatremia, oral fluids must be used cautiously. Infant formula, because of its low sodium concentration, has a high free water content, and especially if added to IV therapy, it may contribute to a rapid decrease in the serum [Na⁺]. Less hypotonic fluid, such as an oral rehydration solution, may be more appropriate initially. If oral intake is allowed, its contribution to free water delivery must be taken into account, and adjustment in the IV fluid is usually appropriate. Judicious monitoring of the serum [Na⁺] is critical.

Interindividual variability in the response to similar doses of a given medication is an inherent characteristic of both adult and pediatric populations. **Pharmacogenetics**, the role of genetic factors in drug disposition and response, has resulted in many examples of how variations in human genes can lead to interindividual differences in pharmacokinetics and drug response at the level of individual patients. Pharmacogenetic variability contributes to the broad range of drug responses observed in children at any given age or developmental stage. Therefore, it is expected that children will benefit from the promise of **personalized medicine**—identifying the right drug for the right patient at the right time (Fig. 72.1). However, pediatricians are keenly aware that children are not merely small adults. Numerous maturational processes occur from birth through adolescence such that utilization of information resulting from the Human Genome Project and related initiatives must take into account the changing patterns of gene expression that occur over development to improve pharmacotherapeutics in children.
Definition of Terms

The terms pharmacogenomics and pharmacogenetics tend to be used interchangeably, and precise, consensus definitions are often difficult to determine. Pharmacogenetics classically is defined as the study or clinical
testing of genetic variations that give rise to interindividual response to drugs. Examples of pharmacogenetic traits include specific adverse drug reactions, such as unusually prolonged respiratory muscle paralysis due to succinylcholine, hemolysis associated with antimalarial therapy, and isoniazid-induced neurotoxicity, all of which were found to be a consequence of inherited variations in enzyme activity. The importance of pharmacogenetic differences has become better understood and is exemplified by the half-life of several drugs being more similar in monozygotic twins than in dizygotic twins. However, it is important to note that in addition to pharmacogenetic differences, environmental factors (diet, smoking status, concomitant drug or toxicant exposure), physiologic variables (age, sex, disease, pregnancy), and patient adherence all contribute to variations in drug metabolism and response. Likewise, ethnicity is another potential genetic determinant of drug variability. Chinese patients who are HLA-B*1502 positive have an increased risk of carbamazepine-induced Stevens-Johnson syndrome; white patients who are HLA-B*5701 positive have an increased risk of hypersensitivity to abacavir (Table 72.1).

| **TPMT** | Thiopurine S-methyltransferase | Azathioprine 6-Mercaptopurine | Individuals homozygous for an inactivating mutation have severe toxicity if treated with standard doses of azathioprine or 6-mercaptopurine; rapid metabolism causes undertreatment. |
| **UGT1A1** | Uridine diphospho-glucuronosyltransferase 1A1 | Irinotecan | UGT1A1*28 allele is associated with decreased glucuronidation of SN-38, the active metabolite of irinotecan, and increased risk of neutropenia. |
| **VKORC1** | Vitamin K oxidoreductase complex 1 | Warfarin | Individuals with a haplotype associated with reduced expression of VKORC1 protein (therapeutic target of warfarin) require lower doses of the drug for stable anticoagulation. |

SJS, Stevens-Johnson syndrome; TEN, toxic epidermal necrolysis.

**Pharmacogenomics** represents the marriage of pharmacology and genomics and can be defined as the broader application of genome-wide technologies and strategies to identify both disease processes that represent new targets for drug development and factors predictive of efficacy and risk of adverse drug reactions.

**Pharmacokinetics** describes what the body does to a drug. It is often studied in conjunction with **pharmacodynamics**, which explores what a drug does to the body. The **pharmacokinetic properties** of a drug are determined by the genes that control the drug’s disposition in the body (absorption, distribution, metabolism, excretion). Drug-metabolizing enzymes and drug transporters play a particularly important role in this process (Table 72.2), and the functional consequences of genetic variations in many drug-metabolizing enzymes have been described between individuals of both similar and different ethnic groups. The most common clinical manifestation of pharmacogenetic variability in drug biotransformation is an increased risk of concentration-dependent toxicity caused by reduced clearance and consequent drug accumulation. However, an equally important manifestation of this variability is lack of efficacy caused by variations in metabolism of prodrugs that require biotransformation to be converted into a pharmacologically active form of a medication. The pharmacogenetics of drug receptors and other target proteins involved in signal transduction or disease pathogenesis can also be expected to contribute
significantly to interindividual variability in drug disposition and response.

**Therapeutic drug monitoring (TDM)** programs recognize that all patients are unique and that the serum concentration-time data for an individual patient theoretically can be used to optimize pharmacotherapy. TDM programs have been the earliest application of personalized pharmacotherapy; however, routine TDM does not necessarily translate to improved patient outcome in all situations.
The concept of **personalized medicine** is based on the premise that the information explosion accompanying the application of genomic technologies to patient-related problems will allow (1) stratification of patient populations according to their response to a particular medication (e.g., lack of drug efficacy or excessive toxicity) and (2) stratification of diseases into specific subtypes that are categorized according to genomic criteria and by response to particular treatments. Personalized medicine has become supplanted by **individualized medicine**, which takes into consideration the vast amount of information that can be collected from an individual patient and applied to inform decisions for that patient. **Precision medicine** is an emerging approach for disease treatment and prevention that considers individual variability in genes, environment, and lifestyle for each person; it reflects the progression in delivery of care for more accurately diagnosing or treating a patient at an individual level. As the amount of data specific to an individual patient increases (e.g., genomic data, electronic health records), precision medicine can be further divided into **precision diagnosis** and **precision therapeutics**; pharmacokinetics, pharmacodynamics, and pharmacogenomics all represent tools that can be applied to implement precision therapeutics for children.

**Genetic polymorphisms** (variations) result when copies of a specific gene present within a population do not have identical nucleotide sequences. The term **allele** refers to one of a series of alternative DNA sequences for a particular gene. In humans, there are 2 copies of every gene. An individual's genotype for a given gene is determined by the set of alleles that the individual possesses. The most common form of genetic variation involves a single base change at a given location, referred to as a **single nucleotide polymorphism (SNP)** (see Chapter 95). At the other end of the spectrum are **copy number variations (CNVs)**, which refer to the deletion or duplication of identical or near-identical DNA sequences that may be thousands to millions of bases in size. CNVs occur less frequently than SNPs, but may constitute 0.5–1% of an individual's genome and thereby contribute significantly to phenotypic variation. **Haplotypes** are collections of SNPs and other allelic variations that are located close to each other; when inherited together, these create a catalog of haplotypes, or **HapMap**. When the alleles at a particular gene locus on both chromosomes are identical, a **homozygous** state exists, whereas the term **heterozygous** refers to the situation in which different alleles are present at the same gene locus. The term **genotype** refers to an individual's genetic constitution, whereas the observable characteristics or physical manifestations constitute the **phenotype**, which is the
net consequence of genetic and environmental effects (see Chapters 94–101). Pharmacogenetics focuses on the phenotypical consequences of allelic variation in single genes. Pharmacogenetic polymorphisms are monogenic traits that are functionally relevant to drug disposition and action and are caused by the presence (within one population) of >1 allele (at the same gene locus) and >1 phenotype with regard to drug interaction with the organism. The key elements of pharmacogenetic polymorphisms are heritability, the involvement of a single gene locus, functional relevance, and the fact that distinct phenotypes are observed within the population only after drug challenge.

**Developmental or Pediatric Pharmacogenetics and Pharmacogenomics**

Our current understanding of pharmacogenetic principles involves enzymes responsible for drug biotransformation. Individuals are classified as being “fast,” “rapid,” or “extensive” metabolizers at one end and “slow” or “poor” metabolizers at the other end of the continuum. This may or may not also include an “intermediate” metabolizer group, depending on the particular enzyme. With regard to biotransformation, children are more complex than adults; fetuses and newborns may be phenotypically “slow” or “poor” metabolizers for certain drug-metabolizing pathways because of their stage of development and may acquire a phenotype consistent with their genotype at some point later in the developmental process as they mature. Examples of drug-metabolizing pathways that are significantly affected by ontogeny include glucuronidation and some of the cytochrome P450 (CYP) activities. It is also apparent that not all infants acquire drug metabolism activity at the same rate, a result of interactions between genetics and environmental factors. Interindividual variability in the trajectory (i.e., rate and extent) of acquired drug biotransformation capacity may be considered a developmental phenotype (Fig. 72.2). This helps to explain the considerable variability in some CYP activities observed immediately after birth.
FIG. 72.2 “Developmental” phenotypes. Variability in developmental changes in gene expression and functional enzyme activity are superimposed on pharmacogenetic determinants. Top, Developmental profile of a theoretical drug-metabolizing enzyme over a 25 yr span in 20 individuals. Bottom, At maturity (adults), allelic variation within the coding region of the gene gives rise to 2 distinct phenotypes: high activity in 92% of the population (“extensive metabolizers”; red circles) and low activity in 8% of the population (“poor metabolizers”; yellow circles). However, there is also interindividual variability in the rate at which functional activity is acquired after birth. For example, the 2 phenotypes may not be readily distinguishable in newborn infants immediately after birth. Furthermore, there may be discrete periods during childhood in which the genotype-phenotype relationship may differ from that observed in adults (e.g., developmental stages at which enzyme activity appears to be greater in children than in adults). (Adapted from Leeder JS: Translating pharmacogenetics and pharmacogenomics into drug development for clinical pediatric and beyond, Drug Discov Today 9:567–573, 2004.)

In contrast to pharmacogenetic studies that typically target single genes, pharmacogenomic analyses are considerably broader in scope and focus on complex and highly variable drug-related phenotypes with targeting of many genes. Genome-wide genotyping technologies and massively parallel “next-generation” sequencing platforms for genomic analyses continue to evolve and allow evaluation of genetic variation at more than 1 million sites throughout an
individual genome for SNP and CNV analyses. Genome-wide association studies (GWAS) have been conducted in several pediatric settings, in part to identify novel genes involved in disease pathogenesis that can lead to new therapeutic targets. GWAS are also being applied to identify genetic associations with response to drugs, such as warfarin and clopidogrel, and risk for drug-induced toxicity, including statin-induced myopathy and flucloxacillin hepatotoxicity. The “Manhattan plot,” a form of data presentation for GWAS, is becoming more common in many medical journals (Fig. 72.3A). Whole genome and exome sequencing have been applied in a diagnostic setting to identify disease-causing genetic variation, usually in the context of rare, undiagnosed diseases that would otherwise require a “diagnostic odyssey” lasting several years before a definitive diagnosis is made (and thereby delaying therapeutic intervention). Contained within this genome sequence is the pharmacogenome, and an area of intense interest is the development of bioinformatics tools to determine a patient’s drug metabolism and response genotype from whole genome sequence data.

FIG. 72.3 Presentations of pharmacogenomic data. A, Manhattan plot from a genome-wide association study (GWAS). Derived from its similarity to the Manhattan skyline, the Manhattan plot presents the genome-wide significance of several hundred thousand single nucleotide polymorphisms (SNPs) distributed throughout the genome with the trait or phenotype of interest. In this example, each SNP included on the “chip”
is plotted along the x axis according to its chromosomal coordinate, with each color representing an individual chromosome from chromosome 1 to the X chromosome. The y axis represents the inverse log_{10} of the p value for the association: the higher the value on the y-axis, the smaller the p value. A value of “15” corresponds to a p value of $10^{-15}$. SNPs exceeding a particular threshold are subject to further verification and validation. B, “Heat map” constructed from gene expression data. In a heat map the level of expression of many genes, as obtained from microarray analysis, is presented as a 2-dimensional matrix of values. Each column represents an individual patient, and each row is an individual RNA transcript designated by the gene name. The level of gene expression is indicated by the color of each rectangle on a continuum from high expression (red) to low expression (green). In this example, acute lymphoblastic leukemia (ALL) patients are clustered by their response to methotrexate (MTX); patients responding to MTX have markedly different patterns of gene expression compared to nonresponders. One of the goals of personalized medicine is to use genomic information (e.g., microarray data) to identify signatures of drug response (or risk of drug toxicity), to select the most appropriate drug among available options for each patient. (A, Reprinted with permission from Search Collaborative Group. SLCO1B1 variants and statin-induced myopathy: a genome-wide study, N Engl J Med 359:789–799, 2008; B, from Sorich MJ et al. In vivo response to methotrexate forecasts outcome of acute lymphoblastic leukemia and has a distinct gene expression profile, PLoS Med 5(4):e83, 2008.)

Investigating differential gene expression before and after drug exposure has the potential to correlate gene expression with variable drug responses and uncover the mechanisms of tissue-specific drug toxicities. These types of studies use **microarray technology** to monitor global changes in expression of thousands of genes (the **transcriptome** ) simultaneously. Genomic sequencing technologies can also be applied to RNA (RNA-Seq) and result in a more complete and quantitative assessment of the transcriptome. Gene expression profiling data from microarrays or RNA-Seq analyses are used to improve disease classification and risk stratification and are common in oncology. This approach has been widely used to address treatment resistance in acute lymphoblastic leukemia and has provided clinically relevant insights into the mechanistic basis of drug resistance and the genomic basis of interindividual variability in drug response. Subsets of transcripts, or gene expression “signatures,” are being investigated as potential prognostic indicators for identifying patients at risk for treatment failure (Fig. 72.3B ).

**Pharmacoproteomic and Metabolomic Tools**

**Proteomic studies** use many different techniques to detect, quantify, and identify proteins in a sample (**expression proteomics**) and to characterize protein function in terms of activity and protein-protein or protein–nucleic acid interactions (**functional proteomics**). Mass spectrometry–based analyses are able to provide quantitative data regarding protein abundance, and several studies have been applied to pediatric liver samples, for example, to generate
more accurate developmental trajectories for several drug-metabolizing enzymes and transporters.

Metabolomics and metabonomics utilize sophisticated analytical platforms, such as nuclear magnetic resonance (NMR) spectroscopy and liquid or gas chromatography coupled with mass spectral detection, to measure the concentrations of all small molecules present in a sample. Metabolomics refers to the complete set of low-molecular-weight molecules (metabolites) present in a living system (cell, tissue, organ or organism) at a particular developmental or pathologic state. Metabonomics is defined as the study of how the metabolic profile of biologic systems change in response to alterations caused by pathophysiologic stimuli, toxic exposures, or dietary changes. Pharmacometabonomics involves prediction of the outcome, efficacy, or toxicity of a drug or xenobiotic intervention in an individual patient based on a mathematical model of preintervention metabolite signatures.

**Drug Biotransformation: Applications to Pediatric Therapy**

The major consequence of pharmacogenetic polymorphisms in drug-metabolizing enzymes is concentration-dependent toxicity caused by impaired drug clearance. In certain cases, reduced conversion of prodrug to therapeutically active compounds is also of clinical importance (see Table 72.2). Chemical modification of drugs by biotransformation reactions generally results in termination of biologic activity through decreased affinity for receptors or other cellular targets as well as more rapid elimination from the body. The process of drug biotransformation can be very complex but is characterized by 3 important features: (1) the concept of broad substrate specificity, in which a single isozyme may metabolize a large variety of chemically diverse compounds; (2) many different enzymes may be involved in the biotransformation of a single drug (enzyme multiplicity); and (3) a given drug may undergo several different types of reactions. One example of this product multiplicity occurs with racemic warfarin, in which at least 7 different hydroxylated metabolites are produced by different CYP isoforms.

Drug biotransformation reactions are conveniently classified into 2 main types, which occur sequentially and serve to terminate biologic activity and enhance elimination (see Chapter 73). Phase I reactions introduce or reveal
(through oxidation, reduction, or hydrolysis) a functional group within the substrate drug molecule that serves as a site for a phase II conjugation reaction. **Phase II** reactions involve conjugation with endogenous substrates, such as acetate, glucuronic acid, glutathione, glycine, and sulfate. These reactions further increase the polarity of an intermediate metabolite, make the compound more water soluble, and thereby enhance its renal excretion. Interindividual variability in drug biotransformation activity (for both phase I and phase II reactions) is a consequence of the complex interplay among genetic (genotype, sex, race or ethnic background) and environmental (diet, disease, concurrent medication, other xenobiotic exposure) factors. The pathway and rate of a given compound's biotransformation are a function of each individual's unique phenotype with respect to the forms and amounts of drug-metabolizing enzymes expressed.

The CYP enzymes (CYPs) are quantitatively the most important of the **phase I enzymes**. These heme-containing proteins catalyze the metabolism of many lipophilic endogenous substances (steroids, fatty acids, fat-soluble vitamins, prostaglandins, leukotrienes, thromboxanes) as well as exogenous compounds, including a multitude of drugs and environment toxins. CYP nomenclature is based on evolutionary considerations and uses the root symbol CYP for *cytochrome P450*. CYPs that share at least 40% homology are grouped into families denoted by an Arabic number after the CYP root. Subfamilies, designated by a letter, appear to represent clusters of highly related genes. Members of the human CYP2 family, for example, have >67% amino acid sequence homology. Individual P450s in a subfamily are numbered sequentially (e.g., CYP3A4, CYP3A5). CYPs that have been identified as being important in human drug metabolism are predominantly found in the CYP1, CYP2, and CYP3 gene families. Importantly, enzyme activity may be induced or inhibited by various agents (see Table 72.2).

**Phase II enzymes** include arylamine N -acyetyltransferases (NAT1, NAT2), uridine diphospho-glucuronosyltransferases (UGTs), epoxide hydrolase, glutathione S -transferases (GSTs), sulfotransferases (SULTs), and methyltransferases (catechol O -methyltransferase, thiopurine S -methyltransferase, several N -methyltransferases). As with the CYPs, UGTs, SULTs, and GSTs are gene families with multiple individual isoforms, each having its own preferred substrates, mode of regulation, and tissue-specific pattern of expression.

For most CYPs, genotype-phenotype relationships are influenced by development in that fetal expression is limited (with the exception of CYP3A7).
and functional activity is acquired postnatally in isoform-specific patterns. Clearance of some compounds appears to be greater in children relative to adults, and the correlation between genotype and phenotype in neonatal life through adolescence may be obscured.

**CYP2D6**

The *CYP2D6* gene locus is highly polymorphic, with >110 allelic variants identified to date ([http://www.imm.ki.se/CYPalleles/cyp2d6.htm](http://www.imm.ki.se/CYPalleles/cyp2d6.htm); see Table 72.2). Individual alleles are designated by the gene name (*CYP2D6*) followed by an asterisk, and an Arabic number. By convention, *CYP2D6*/*1* designates the fully functional wild-type allele. Allelic variants are the consequence of point mutations, single–base pair deletions or additions, gene rearrangements, or deletion of the entire gene, resulting in a reduction or complete loss of activity. Inheritance of 2 recessive, nonfunctional or “null' alleles results in the **poor-metabolizer (PM) phenotype**, which is found in approximately 5–10% of whites and approximately 1–2% of Asians. In whites the *3, *4, *5, and *6 alleles are the most common loss-of-function alleles and account for approximately 98% of PM phenotypes. In contrast, CYP2D6 activity on a population basis tends to be lower in Asian and African American populations because of a lower frequency of nonfunctional alleles (*3, *4, *5, and *6) and a relatively high frequency of population-selective alleles associated with decreased activity (“reduced function” alleles) relative to the wild-type *CYP2D6*/*1* allele. The *CYP2D6*/*10* allele occurs at a frequency of approximately 50% in Asians, whereas *CYP2D6*/*17* and *CYP2D6*/*29* occur at relatively high frequencies in persons of black African origin.

In addition to nonfunctional and partial-function alleles, the presence of gene duplication and multiplication events (≥3 copies of *CYP2D6* gene in tandem on a single chromosome) further complicates the prediction of phenotype from genotype information. The concept of “activity score” has been developed to simplify translation of *CYP2D6* genotype information into a predicted phenotype of CYP2D6 activity for a particular patient. Fully functional alleles (*1, *2, *35, etc.) are assigned a value of “1”, reduced-function alleles (*9, *10, *17, *29) are assigned a value of “0.5”, and nonfunctional alleles (*3–*6, etc.) are assigned a value of “0”; for duplications/multiplication events, the allele score is multiplied by the number of copies detected (*10 × 2 = 0.5 × 2 = “1”). The activity score for an individual is the sum of the scores for each chromosome,
with poor metabolizers (PMs) defined by a score of “0”, whereas a score of “0.5” indicates an intermediate-metabolizer (IM) phenotype, and a score >2 indicating an ultrarapid-metabolizer (UM) phenotype; scores of 1 to 2 are referred to as extensive metabolizers (EMs). The activity score classification system has been adopted by the Clinical Pharmacogenetics Implementation Consortium (CPIC; see below). In the past, individuals with an activity score of “1” have been referred to as “IMs,” and any reference to IM status in literature before 2012 likely refers to a genotype with the equivalent of 1 functional allele, in contrast to the current definition (0.5).

CYP2D6 is involved in the biotransformation of >40 therapeutic entities, including several β-receptor antagonists, antiarrhythmics, antidepressants, antipsychotics, and morphine derivatives† (see Table 72.2). CYP2D6 substrates commonly encountered in pediatrics include selective serotonin reuptake inhibitors (SSRIs; fluoxetine, paroxetine), risperidone, atomoxetine, promethazine, tramadol, and codeine. Furthermore, over-the-counter cold remedies (e.g., dextromethorphan, diphenhydramine, chlorpheniramine) are also CYP2D6 substrates. An analysis of CYP2D6 ontogeny in vitro that utilized a relatively large number of samples revealed that CYP2D6 protein and activity remain relatively constant after 1 wk of age up to 18 yr. Similarly, results from an in vivo longitudinal phenotyping study involving >100 infants over the 1st year of life demonstrated considerable interindividual variability in CYP2D6 activity, but no relationship between CYP2D6 activity and postnatal age between 2 wk and 12 mo. Furthermore, a cross-sectional study involving 586 children reported that the distribution of CYP2D6 phenotypes in children was comparable to that observed in adults by at least 10 yr of age. Thus, both available in vitro and in vivo data, although based on phenotype data rather than information on drug clearance from pharmacokinetic studies, imply that genetic variation is more important than developmental factors as a determinant of CYP2D6 variability in children.

One consequence of CYP2D6 developmental pharmacogenetics may be the syndrome of irritability, tachypnea, tremors, jitteriness, increased muscle tone, and temperature instability in neonates born to mothers receiving SSRIs during pregnancy. Controversy exists as to whether these symptoms reflect a neonatal withdrawal (hyposerotonergic) state or represent manifestations of serotonin toxicity analogous to the hyperserotonergic state associated with the SSRI-induced serotonin syndrome in adults. Delayed expression of CYP2D6 (and CYP3A4) in the 1st few weeks of life is consistent with a hyperserotonergic state
caused by delayed clearance of paroxetine and fluoxetine (CYP2D6) or sertraline (CYP3A4) in neonates exposed to these compounds during pregnancy. Furthermore, decreases in plasma SSRI concentrations and resolution of symptoms would be expected with increasing postnatal age and maturation of these pathways. Given that treatment of a “withdrawal” reaction may include administration of an SSRI, there is considerable potential for increased toxicity in affected neonates. Resolution of the question whether symptoms are caused by withdrawal vs a hyperserotonergic state is essential for appropriate management of SSRI-induced neonatal adaptation syndromes. Until further data are available, it would be prudent to consider newborns and infants <28 days of age as CYP2D6 PMs.

In older children, drug accumulation and resultant concentration-dependent toxicities in CYP2D6 genotypic poor metabolizers should be anticipated in the same way that they are in adults due to the risk of significant morbidity and mortality. Although a fluoxetine-related death has been reported in a 9 yr old child with a CYP2D6 PM genotype, experience with paroxetine indicates that the risk of drug accumulation may also occur, under certain conditions, in individuals at the opposite end of the activity spectrum. For example, chronic dosing of paroxetine may lead to greater-than-anticipated drug accumulation in children classified as CYP2D6 EMs. In fact, the largest decreases in paroxetine clearance observed with ascending doses are seen in patients who have the greatest clearance at the initial dose level (10 mg/day) and are predicted to have the greatest CYP2D6 activity based on CYP2D6 genotype. This seemingly paradoxical effect appears to involve oxidation of paroxetine within the CYP2D6 active site to form a reactive intermediate that is associated with irreversible modification of the CYP2D6 protein in or near the active site and loss of enzyme activity. As a consequence, CYP2D6 activity progressively declines such that drug accumulation may occur over time, placing CYP2D6 EM patients also at increased risk of concentration-dependent toxicity.

Theoretically, younger children may experience decreased efficacy or therapeutic failure with drugs such as codeine and tramadol that are dependent on functional CYP2D6 activity for conversion to the pharmacologically active species. CYP2D6 catalyzes the O-demethylation of codeine to morphine. Infants and children appear capable of converting codeine to morphine and achieving morphine:codeine ratios comparable to those of adults. However, in one study, morphine and its metabolites were not detected in 36% of children receiving codeine making the level of analgesia from codeine unreliable in the
studied pediatric population. Interestingly, levels of morphine and its metabolites were not related to CYP2D6 phenotype. Finally, ultrarapid CYP2D6 metabolism of codeine may result in opiate intoxication, including maternal ultrarapid metabolism of codeine, which can result in high serum and breast milk concentrations of morphine and may have adverse effects in the breastfed neonate.

Rapid metabolism and clearance of CYP2D6 substrates may also contribute to poor therapeutic response because of an inability to achieve adequate plasma concentrations, even when medications are dosed at the maximum approved dose level. The product label for atomoxetine (Strattera) indicates that CYP2D6 PMs have a systemic exposure to the drug (e.g., amount of drug in body over time as determined by area under plasma concentration-time curve) that is 10 times greater than in typical individuals (EMs), and yet the same starting dose of 0.5 mg/kg is recommended for all patients. A genotype-stratified pharmacokinetic study of atomoxetine in children and adolescents with attention-deficit/hyperactivity disorder (ADHD) confirmed an 11-14-fold difference in average systemic exposure between PM and EM groups. However, the most informative finding was the 50-fold range in exposure (30-fold, if exposure corrected for actual mg dose administered) between the PM participant with the highest exposure and the UM participant (3 functional alleles) with the lowest exposure. Using the results of this single-dose study to simulate atomoxetine exposure at steady state for each study participant revealed that even at the maximum recommended dose of atomoxetine, exposure was likely to be subtherapeutic for the majority of patients with ≥1 functional CYP2D6 alleles.

Avoiding ineffective treatment at one end of the spectrum and excessive toxicity at the other are potential benefits of individualizing doses based on genomic information for medications dependent on a polymorphic clearance pathway, such as CYP2D6. The CPIC has published several guidelines that include CYP2D6 substrates, such as the CPIC guideline for codeine,* SSRIs, † and tricyclic antidepressants.‡ Although pediatric data are sparse, these links serve as valuable sources of information regarding the effect of genotype on the dose-exposure relationship for several CYP2D6 substrates.

**CYP2C9**

Although several clinically useful compounds are substrates for CYP2C9 § (see Table 72.2 ), the effects of allelic variation are most profound for drugs with a
narrow therapeutic index, such as phenytoin, warfarin, and tolbutamide. In vitro studies show a progressive increase in CYP2C9 expression from 1–2% of mature levels in the 1st trimester to approximately 30% at term. Considerable variability (approximately 35-fold) in expression is apparent over the 1st 5 mo of life, with about half the samples studied exhibiting values equivalent to those observed in adults. One interpretation of these data is that broad interindividual variability exists in the rate at which CYP2C9 expression is acquired after birth, and in general, the ontogeny of CYP2C9 activity in vivo, as inferred from pharmacokinetic studies of phenytoin in newborns, is consistent with the in vitro results. The apparent half-life of phenytoin is prolonged (approximately 75 hours) in preterm infants, but decreases to approximately 20 hr in term newborns. By 2 wk of age, the half-life has further declined to 8 hr. The appearance of concentration-dependent (saturable) metabolism of phenytoin, reflecting the functional acquisition of CYP2C9 activity, does not appear until approximately 10 days of age. The maximal velocity of phenytoin metabolism has been reported to decrease from an average of 14 mg/kg/day in infants to 8 mg/kg/day in adolescents, which may reflect changes in the ratio of liver mass to total body mass observed over this period of development, as has been observed for warfarin.

Several allelic variants of CYP2C9 have been reported, but not all have been evaluated for their functional consequences. The CYP2C9*2 allele is associated with approximately 5.5-fold decreased intrinsic clearance for S-warfarin relative to the wild-type enzyme. Allelic variations resulting in amino acid changes within the enzyme active site, such as the CYP2C9*3, CYP2C9*4, and CYP2C9*5 alleles, are associated with activities that are approximately 5% of the wild-type protein. Approximately one third of the white population carries a variant CYP2C9 allele (typically *2 and *3 alleles), whereas the *2 and *3 alleles are virtually nonexistent in African American, Chinese, Japanese, or Korean populations. In contrast, the *5 allele has been detected in blacks but not in whites. The risk of bleeding complications in patients treated with warfarin and with concentration-dependent toxicity in patients treated with phenytoin is most pronounced for individuals with a CYP2C9*3/*3 genotype. Although the relationship between the CYP2C9 genotype and warfarin dosing and pharmacokinetics has not been as extensively studied in children, consequences of allelic variation can be expected to be similar to those observed in adults. In adults, CYP2C9 and VKORC1 genotype and patient age, sex, and weight can account for 50–60% of the variation in warfarin dose requirements. A large part
of the variation is still unknown, but may be at least partially attributed to interactions with other drugs and foods.

**CYP2C19**

In vitro, CYP2C19 protein and catalytic activity can be detected at levels representing 12–15% of mature values by 8 wk of gestation and remain essentially unchanged throughout gestation and at birth. Over the 1st 5 mo of postnatal age, CYP2C19 activity increases linearly. Adult levels are achieved by 10 yr of age, although variability in expression is estimated to be approximately 21-fold between 5 mo and 10 yr of age. The major source of this variability is likely pharmacogenetic in nature. The CYP2C19 PM phenotype (also known as *mephenytoin hydroxylase deficiency*) is present in 3–5% of the white population and 20–25% of Asians. Although 25 variant alleles have been reported to date, the 2 most common variant alleles, CYP2C19*2 and CYP2C19*3, result from single-base substitutions that introduce premature stop codons and, consequently, truncated polypeptide chains that possess no functional activity. Despite consistent increases in CYP2C19 activity observed in vitro over the 1st 5 months of life, the results of an in vivo phenotyping study with omeprazole in Mexican children revealed a broad range of activity and implied that 17% of infants <4 mo of age could be classified as PMs (no PMs were detected beyond that point). In contrast, 20% of children 3–9 mo old were classified as ultrarapid metabolizers (UMs) compared with 6% of infants 1-3 mo of age. For omeprazole, pharmacokinetic parameters comparable to those observed in adults are achieved by age 2 yr.

CYP2C19 also plays an important role in the metabolism of lansoprazole. In Japanese adults treated with lansoprazole, amoxicillin, and clarithromycin for *Helicobacter pylori* infection, the eradication rate for CYP2C19 PMs (97.8%) and heterozygous EMs (1 functional CYP2C19 allele; 92.1%) was significantly greater than that observed in homozygous EMs (72.7%). Initial treatment did not eradicate *H. pylori* in 35 patients, 34 of whom had at least 1 functional CYP2C19 allele, and eradication could be achieved with higher lansoprazole doses in almost all cases. Given that the frequency of the functional CYP2C19*1 allele is considerably greater in whites (0.84 [84%]) than Japanese (0.55 [55%]), eradication failure can be expected to occur more frequently in whites. Because proton pump inhibitors are widely used in children, pharmacogenetic as well as developmental considerations should guide pediatric dosing strategies.
CYP3A4, CYP3A5, and CYP3A7

The CYP3A subfamily consists of four members in humans (CYPs 3A4, 3A5, 3A7, and 3A43) and is quantitatively the most important group of CYPs in terms of human hepatic drug biotransformation. These isoforms catalyze the oxidation of many different therapeutic entities, several of which are of potential importance to pediatric practice (see Table 72.2). CYP3A7 is the predominant CYP isoform in fetal liver and can be detected in embryonic liver as early as 50–60 days' gestation. CYP3A4, the major CYP3A isoform in adults, is essentially absent in fetal liver, but increases gradually throughout childhood. Over the 1st 6 mo of life, CYP3A7 expression exceeds that of CYP3A4, although its catalytic activity toward most CYP3A substrates is rather limited compared with CYP3A4. CYP3A4 is also abundantly expressed in intestine, where it contributes significantly to the first-pass metabolism of oral drugs, which are substrates (e.g., midazolam). CYP3A5 is polymorphically expressed and is present in approximately 25% of adult liver samples studied in vitro.

Several methods have been proposed to measure CYP3A activity. Using these various phenotyping probes, CYP3A4 activity has been reported to vary widely (up to 50-fold) among individuals, but the population distributions of activity are essentially unimodal and evidence for polymorphic activity has been elusive. Although 20 allelic variants have been identified (http://www.imm.ki.se/CYPalleles/cyp3a4.htm), most occur relatively infrequently and do not appear to be of clinical importance. Of interest to pediatrics is the CYP3A4*1B allele present in the CYP3A4 promoter region. The clinical significance of this allelic variant appears limited with respect to drug biotransformation activity, despite in vitro assays showing 2-fold increased activity over the wild-type CYP3A4*1 allele. Although no association appears to exist between the CYP3A4*1B allele and age of menarche, a significant relationship does exist between the number of CYP3A4*1B alleles and the age at onset of puberty, as defined by Tanner breast score. In one study, 90% of 9 yr old girls with a CYP3A4*1B/*1B genotype had a Tanner breast score of ≥2 vs 56% of CYP3A4*1A/*1B heterozygotes and 40% of girls homozygous for the CYP3A4*1A allele. Because CYP3A4 plays an important role in testosterone catabolism, it was proposed that the estradiol:testosterone ratio may be shifted toward higher values in the presence of the CYP3A4*1B allele and might trigger the hormonal cascade that accompanies puberty. Intestinal CYP3A4 activity is inhibited by grapefruit juice and may result in higher levels of the many drugs...
metabolized by this enzyme; very large quantities of grapefruit juice may also inhibit the hepatic CYP3A4.

Polymorphic CYP3A5 expression is largely caused by an SNP in intron 3 that creates a cryptic splice site and gives rise to messenger RNA splice variants that retain part of intron 3 with a premature stop codon. The truncated mRNA transcripts associated with this allele, CYP3A5*3, cannot be translated into a functional protein. Individuals with at least one wild-type CYP3A5*1 allele express functional CYP3A5 protein, whereas those homozygous for CYP3A5*3 (CYP3A5*3/*3) do not express appreciable amounts of functional protein. Approximately 60% of African Americans show functional hepatic CYP3A5 activity, compared with only 33% of European Americans.

Clinically important consequences of CYP3A5 allelic variation have been reported in children. In pediatric heart transplant patients with a CYP3A5*1/*3 genotype, tacrolimus concentrations were approximately 25% of those observed in patients with CYP3A5*3/*3 genotypes, when corrected for dose, in the highly vulnerable period immediately after transplant (≤2 wk), and 50% less at 3, 6, and 12 mo after transplant. Thus, larger doses of tacrolimus are required in patients with functional CYP3A5 protein to achieve comparable blood levels and to minimize the risk of rejection. Of concern, <15% of tacrolimus concentrations in the immediate posttransplant period were within the therapeutic target range, highlighting the need for prospective, precision-guided tacrolimus trials in the pediatric population. In addition to CYP3A5 expressor genotype, younger age was associated with lower tacrolimus concentrations. The same age and genotype relationship is observed for renal transplantation. Conversely, the same age- and genotype-tailored treatment is more challenging in liver transplantation unless the donor CYP3A5 is known. In pediatric liver transplant recipients, CYP3A5 expressor genotype was not associated with tacrolimus concentrations and dosing. This implies that hepatic metabolism, from the donor liver and genotype status, plays a larger role in tacrolimus concentrations than intestinal metabolism or the recipient's CYP3A5 genotype status. Collectively, these pediatric tacrolimus datasets have informed the CPIC to recommend a 1.5-2-fold increase in tacrolimus dosing, followed by close plasma drug monitoring, in children and adolescents with at least one CYP3A5*1 allele (https://cpicpgx.org/guidelines/guideline-for-tacrolimus-and-cyp3a5/).

Glucuronosyl Transferases (UGTs)
The UGT gene superfamily catalyzes the conjugation (with glucuronic acid) of several drugs used clinically in pediatrics, including morphine, acetaminophen, nonsteroidal antiinflammatory drugs, and benzodiazepines. The effect of development on glucuronidation capacity has been well described and is illustrated by hyperbilirubinemia, gray baby syndrome (cardiovascular collapse associated with high doses of chloramphenicol in newborns), and the 3.5-fold increase in morphine clearance observed in premature neonates at 24-39 wk postconception age. As with the CYPs, there are multiple UGT isoforms, and the acquisition of functional UGT activity appears to be isoform and substrate specific.

UGT1A1 is the major UGT gene product responsible for bilirubin glucuronidation, and >100 genetic alterations have been reported (Table 72.3), most of which are rare and are more properly considered mutations rather than gene polymorphisms. Inheritance of 2 defective alleles is associated with reduced bilirubin-conjugating activity and gives rise to clinical conditions such as Crigler-Najjar and Gilbert syndromes. More frequently occurring polymorphisms involve a dinucleotide (TA) repeat in the atypical TATA box of the UGT1A1 promoter. The wild-type UGT1A1*1 allele has 6 repeats (TA₆), and the TA₅ (UGT1A1*33), TA₇ (UGT1A1*28), and TA₈ (UGT1A1*34) variants are all associated with reduced activity. UGT1A1*28, the most frequent variant, is a contributory factor to prolonged neonatal jaundice. This variant is also associated with impaired glucuronidation and thus toxicity of the active metabolite SN-38 of the chemotherapeutic agent irinotecan. Allelic variations in UGT1A7 and UGT1A9 have also been associated with irinotecan toxicity in adults with colorectal cancer.

The consequences of allelic variation in the UGT2B family are less certain. The predominant routes of morphine elimination include biotransformation to the pharmacologically active 6-glucuronide (M6G) and the inactive 3-glucuronide (M3G). M6G formation is almost exclusively catalyzed by UGT2B7, whereas several UGTs in the UGT1A subfamily and UGT2B7, both contribute to M3G formation. Increased M6G:morphine ratios have been reported in individuals homozygous for the SNPs constituting the *UGT2B7*2 allele. Although individuals genotyped as *UGT2B7*2/*2 may produce higher-than-anticipated concentrations of pharmacologically active morphine and its metabolites, prospective studies addressing phenotype-genotype correlations and the consequences of morphine analgesia have had conflicting results.

**Thiopurine S-Methyltransferase**

Thiopurine S-methyltransferase (TPMT) is a cytosolic enzyme that catalyses the S-methylation of aromatic and heterocyclic sulfur-containing compounds,
such as 6-mercaptopurine (6MP), azathioprine, and 6-thioguanine, used in the treatment of acute lymphoblastic leukemia (ALL), inflammatory bowel disease (IBD), and juvenile idiopathic arthritis and the prevention of renal allograft rejection. To exert its cytotoxic effects, 6MP requires metabolism to thioguanine nucleotides by a multistep process initiated by hypoxanthine guanine phosphoribosyltransferase. TPMT prevents thioguanine nucleotide production by methylating 6MP (Fig. 72.4A). TPMT activity is usually measured in erythrocytes, with erythrocyte activity reflecting what is found in other tissues, including liver and leukemic blasts. Although approximately 89% of whites and blacks have high TPMT activity and 11% have intermediate activity, 1 in 300 individuals inherits TPMT deficiency as an autosomal recessive trait (Fig. 72.4B). In newborn infants, peripheral blood TPMT activity is 50% greater than in race-matched adults and shows a distribution of activity consistent with the polymorphism characterized in adults. No data currently indicate how long this higher activity is maintained, although TPMT activities were comparable to previously reported adult values in a population of Korean schoolchildren age 7–9 yr. In patients with intermediate or low activity, more drug is shunted toward production of cytotoxic thioguanine nucleotides. TPMT can also methylate 6-thiopurine 5'-monophosphate to generate a methylated metabolite capable of inhibiting de novo purine synthesis (Fig. 72.4C).
FIG. 72.4  Thiopurine S-methyltransferase (TPMT) polymorphism. A, 6-Mercaptopurine (6MP) undergoes metabolism to thioguanine nucleotides (TGNs) to exert its cytotoxic effects. TPMT and xanthine oxidase reduce the amount of 6MP available for the bioactivation pathway to TGNs. TPMT can also methylate 6-thioinosine 5'-monophosphate (TIMP) to generate a methylated compound capable of inhibiting de novo purine synthesis. B, Distribution of TPMT activity in humans. Of the population, 89% has high activity, whereas 11% has intermediate activity. Approximately 1 in 300...
Multiple SNP variants have been identified in the TPMT gene, and a GWAS from 2 independent pediatric ALL cohorts confirmed that TPMT activity is a monogenic pharmacogenetics trait; 3 variants (TPMT*2, *3A, *3C) account for 98% of whites with low activity and have high predictive capacity for TPMT phenotype. TPMT*3A is the most common and is characterized by 2 nucleotide transition mutations, G460A and A719G, that lead to 2 amino acid substitutions, Ala154Thr and Tyr240Cys (Fig. 72.4D). The TPMT*3A allele occurs more frequently in white (9.5%) and Hispanic (7.0%) patients and is absent in black patients. In contrast, TPMT*3C is reported to be the predominant variant allele in black patients (12.2%), and only rarely observed in white or Hispanic patients; overall, black patients have lower TPMT activities than nonblack patients. The *3A and *3C variants each result in loss of functional activity through the production of unstable proteins that are subject to accelerated proteolytic degradation.

The relatively few patients with low to absent TPMT activity (0.3%) are at increased risk for severe myelosuppression if treated with routine doses of thiopurines; thus they require a 10-15-fold reduction in dose to minimize this risk. Furthermore, if not dosed properly, patients may be at increased risk for relapse as a result of inadequate or a lack of treatment with thiopurines. Given the expanding use of 6MP and azathioprine in pediatrics to treat IBD and juvenile arthritis and to prevent renal allograft rejection, TPMT pharmacogenetics is not trivial, and a CPIC guideline assists with genotype-guided dosing. However, TPMT genotype is not the only determinant of intolerance to thiopurines. Multiple studies have also implicated genetic variation in NUDT15, a nucleotide diphosphatase that converts thioguanine triphosphate to thioguanine monophosphate, thereby reducing incorporation of thioguanine into DNA; reduction or loss of this activity results in greater-than-expected thioguanine incorporation into DNA and thus increased cytotoxicity. Reduced-function NUDT15 alleles are more common in Hispanic patients and those with Asian ancestry, and patients who have inherited 2 reduced-function
alleles tolerate thiopurine doses that are much lower (10%) than normal. Thus it is reasonable to expect that both TPMT and NUDT15 genotype will need to be considered for individualized thiopurine treatment.

**Pharmacogenetics of Drug Transporters**

There are several major types of membrane transporters, including organic anion transporters (OATs), organic anion–transporting polypeptides (OATPs), organic cation transporters (OCTs), and the adenosine triphosphate–binding cassette (ABC) transporters, such as P-glycoprotein and the multidrug-resistant proteins. Membrane transporters are heavily involved in drug disposition and actively transport substrate drugs between organs and tissues. Drug transporters are expressed at numerous epithelial barriers, such as intestinal epithelial cells, hepatocytes, renal tubular cells, and the blood-brain barrier (BBB) (Fig. 72.5). Transporters often are also determinants of drug resistance, and many drugs work by affecting the function of transporters. As such, polymorphisms in the genes encoding these proteins may have a significant effect on the absorption, distribution, metabolism, and excretion as well as the pharmacodynamic effect of a wide variety of compounds.
Adenosine Triphosphate–Binding Cassette Superfamily

The ATP-binding cassette (ABC) transporters belong to the largest known transporter gene family and translocate a variety of substrates, including chemotherapy agents. ABC multidrug transporter expression has been implicated in tumor cell resistance to anticancer therapy, altered disposition of chemotherapy drugs, and toxic side effects associated with chemotherapy. More recently, the genetic heterogeneity of several ABC transporter genes has been described. Apart from having at least one ATP-binding domain, these transporters are characterized by a signature sequence of amino acid residues within the domain. In humans the ABC transporters function as efflux pumps, which together with detoxification enzymes, constitute a complex, integrated, “chemoimmunologic defense” system against drugs and other foreign chemicals. A variety of epithelial barriers, including the kidney, liver, and BBB have abundant expression of ABC transporters, such as P-glycoprotein (P-gp; also known as MDR1), and multidrug-resistant proteins (MRPs) 1, 2, and 3. Powered by ATP, these transporters actively extrude substrates from the respective cell and organ.

Considerable genetic variation has been reported in the superfamily of ABC transporter genes. Many studies have investigated the relationship between ABCB1 genotype or haplotype and P-gp expression, activity, or drug response, yielding inconsistent results, largely due to methodological limitations. No association between genotype and drug disposition or response would be expected if the drug of interest were not substrate for P-gp. However, even when drugs are tested for transport by P-gp using in vitro systems, the results are not necessarily conclusive, as is the case for carbamazepine. On the other hand, an association between ABCB1 genotype and drug response was observed in patients receiving antidepressants that were ABC substrates (e.g., citalopram, paroxetine, amitriptyline, venlafaxine), but not in drugs that were not substrates (e.g., mirtazapine).
Studies conducted in children need to also consider the ontogeny of P-gp expression. Based on studies using human lymphocytes, it appears that P-gp activity is high at birth, decreases between 0 and 6 mo, and stabilizes between 6 mo and 2 yr of age. In contrast, P-gp can be detected in human neural stem/progenitor cells and decreases with differentiation. Furthermore, P-gp has been proposed as an endothelial marker for development of the BBB, and expression increases with postnatal age as the BBB matures. Proteomic analysis of the ontogeny of hepatic P-gp has demonstrated that P-gp expression increases through infancy, achieving 50% of adult expression at approximately 3 yr and reaching a plateau during adolescence. Thus the developmental patterns of P-gp expression likely are tissue specific, but data still are sparse in this regard. Nevertheless, expression of P-gp at a young age in gut and liver likely represents a protective mechanism in which both endogenous and exogenous toxins are efficiently excreted from the body. However, developmental patterns of expression in tissues of drug response, such as lymphocytes and tumors, may also affect the efficacy of intracellular drugs. For example, polymorphisms in the gene have been shown to be predictive of the ability to wean corticosteroids after heart transplantation, as well as the susceptibility to and clinical outcome of treatment for pediatric ALL. On the other hand, immaturity of P-gp expression in the developing BBB may contribute to discrete periods of increased susceptibility to drug toxicity in the central nervous system. However, for most other drugs, including immunosuppressants and protease inhibitors, studies investigating the effect of ABCB1 polymorphisms in drug disposition and response have yielded conflicting results. In one study investigating the relationship between ABCB1 genotype and cyclosporin pharmacokinetics, an effect of genotype on oral availability was only apparent in children >8 yr of age. Although these results require further replication, the implication is that a better understanding of transporter ontogeny is required to properly design and interpret pharmacogenetic studies of ABCB1 in pediatric populations.

Organic Anion–Transporting Polypeptides

Organic anion–transporting polypeptides (OATPs) in the solute carrier organic anion transporter (SLCO) are a family of glycoprotein transporters with 12 transmembrane-spanning domains expressed in various epithelial cells. There are 11 OATPs in humans, some of which are ubiquitously expressed and others whose expression is restricted to specific tissues. Typical substrates include bile
salts, hormones and their conjugates, toxins, and various drugs. The solute carrier, human OATP 1A2 (OATP1A2, OATP-A, OATP1, and OATP) is highly expressed in the intestine, kidney, cholangiocytes, and BBB and may be important in the absorption, distribution, and excretion of a broad array of clinically important drugs. Several nonsynonymous polymorphisms have been identified in the gene encoding OATP1A2, SLCO1A2 (SLC21A3), with some of these variants demonstrating functional changes in the transport of OATP1A2 substrates.

OATP1B1 (SLCO1B1) and OATP1B3 (SLCO1B3) are liver-specific transporters and promote the cellular uptake of endogenous substrates, such as bilirubin, bile acids, DHEA-sulfate, and leukotriene C4, as well as various drugs, including several statins, methotrexate, and enalapril. Allelic variation in OATP1B1 (specifically the SLCO1B1*5 allele) results in reduced clearance and increased systemic exposure of several statin drugs (atorvastatin, pravastatin, simvastatin) and has been associated with an increased risk of musculoskeletal side effects from simvastatin. The expression of OATP1B1 in human pediatric liver tissue was independent of age in all samples, but age dependency was demonstrated in samples homozygous for the SLCO1B1 reference sequence (i.e., SLCO1B1*1A/*1A genotype). Therefore, not only genotype, but also growth and development, may influence OATP1B1 protein expression in the developing child. To date, only one study has investigated the effect of SLCO1B1 genotype on statin disposition in children, reporting a genotype-phenotype relationship for pravastatin that was discordant with the relationship observed in adults. However, data with simvastatin in dyslipidemic children and adolescents (LDL >130 mg/dL) suggest that the genotype-phenotype relationships observed in adults are also present in this population, but the magnitude of the genetic effect may be greater in pediatric patients.

Several studies have confirmed that the 2 SNPs determining the most common SLCO1B1 haplotypes (*1a, *1b, *5, and *15), rs4149056 and rs2306283, are associated with decreased clearance of high-dose methotrexate in children with ALL. Genotyping for SLCO1B1 may be helpful in identifying patients at increased risk of toxicity from reduced clearance or increased accumulation of methotrexate. In the pediatric liver proteomic analysis, OATP1B3 expression was age dependent, with a 3-fold difference observed between neonates and adults. Similar to P-gp, expression steadily increased during childhood; however, 50% of adult level expression was much earlier (6 mo) compared with P-gp.
Organic Cation Transporters

Organic cation transporters (OCTs) in the SCL22A subfamily are primarily expressed on the basolateral membrane of polarized epithelia and mediate the renal secretion of small organic cations. Originally, OCT1 (also known as SLC22A1) was thought to be primarily expressed in liver, but recent studies have also localized its expression to the apical side of proximal and distal renal tubules. Hepatic OCT1 expression was found to be age dependent with almost a 5-fold difference between neonates and adults. OCT2 (SLC22A2) is predominantly expressed on the basolateral surface of proximal renal tubules. In adults, allelic variation in OCT1 and OCT2 is associated with increased renal clearance of metformin. The role of genetic variation of OCT1 and OCT2 has not been studied in children, but developmental factors appear to be operative. Neonates possess very limited ability to eliminate organic cations, but this function increases rapidly during the 1st few months of life, and when standardized for body weight or surface area, it tends to exceed adult levels during the toddler stage.

Polymorphisms in Drug Receptors

Receptors are the targets for drugs and endogenous transmitters because of their inherent molecular recognition sites. Drugs and transmitters bind to the receptor to produce a pharmacologic effect. Variability in the receptor protein or the ion channel may determine the magnitude of the pharmacologic response. Polymorphisms of the $\beta_2$-adrenergic receptor gene ($ADRB2$) are associated with variable responses to bronchodilator drugs.

Drug responses are seldom monogenic events because multiple genes are involved in both drug binding to the pharmacologic target and the subsequent downstream signal transduction events that ultimately manifest collectively as a therapeutic effect. Although genotypes at a particular locus may show a statistically significant effect on the outcome of interest, they may account for only a relatively small amount of the overall population variability for that outcome. A particular group of SNPs in the corticotropin-releasing hormone receptor 1 gene ($CRHR1$) is associated with a statistically significant improvement in forced expiratory volume in 1 second ($FEV_1$), but accounts for only 6% of the overall variability in response to inhaled corticosteroids. A series of subsequent studies has determined that allelic variation in several genes in the
steroid pathway contributes to overall response to this form of therapy.

The listing and classification of receptors is a major initiative of the International Union of Pharmacology (IUPHAR). The list of receptors and voltage-gated ion channels is available on the IUPHAR website (http://www.iuphar-db.org). The effect of growth and development on the activities and binding affinities of these receptors, effectors, and ion channels has been studied in animals to some extent but remains to be elucidated in humans.

**Current and Future Applications in Pediatrics**

Progress in the treatment of acute lymphoblastic leukemia shows how the application of pharmacogenomic principles can improve pediatric drug therapy (see Chapter 522.1). Despite improved understanding of the genetic determinants of drug response, however, many complexities remain to be resolved. Patients with ALL who have 1 wild-type allele and intermediate TPMT activity tend to have a better response to 6MP therapy than patients with 2 wild-type alleles and full activity. Reduced TPMT activity also places patients at risk for irradiation-induced secondary brain tumors and etoposide-induced acute myeloid leukemia. Pharmacogenetic polymorphisms of several additional genes, such as *NUDT15*, also have the potential to influence successful treatment of ALL. Multiple genetic and treatment-related factors interact to create patient subgroups with varying degrees of risk. These represent an opportunity for pharmacogenomic approaches to identify subgroups of patients who will benefit from specific treatment regimens and those who will be at risk for short-term and long-term toxicities (Fig. 72.6).
FIG. 72.6 Polygenic determinants of drug response. The potential effects of 2 genetic polymorphisms are illustrated. In each panel, there is a profile for individuals who have 2 wild-type alleles (WT/WT), those who are heterozygous for 1 wild-type and 1 variant (V) allele (WT/V), and those who have 2 variant alleles (V/V) for the depicted gene. The top panels illustrate a potential polymorphism involving a drug-metabolizing enzyme where variant alleles result in decreased drug metabolism and greater exposure (as shown by the increasing area under the concentration-time curve [AUC]). The middle panels illustrate a potential polymorphism involving a drug receptor and depicts variant alleles which result in decreased receptor sensitivity. Note that for each receptor type, there are 3 possibilities for drug exposure. The bottom table shows the 9 resulting combinations of drug-metabolism and drug-receptor genotypes and the...
corresponding drug-response phenotypes calculated from data shown in the middle panels. These phenotypes allow for calculation of a therapeutic index (i.e., efficacy:toxicity; here this ranges from 13 [65%:5%] to 0.1 [10%:80%]), which results in the ability to perform an individualized risk/benefit assessment. (Adapted from Evans WE, McLeod HL: Pharmacogenomics—drug disposition, drug targets, and side effects, *N Engl J Med* 348:538–549, 2003.)

The clinical pharmacology of a given drug reflects a multifaceted set of properties that pertain to not only the disposition and action of drugs, but also the response (e.g., adverse effects, therapeutic effects, therapeutic outcomes) to their administration or use. The 3 most important facets of clinical pharmacology are pharmacokinetics, pharmacodynamics, and pharmacogenomics.

**Pharmacokinetics** describes the movement of a drug throughout the body and the concentrations (or amounts) of a drug that reach a given body space or tissue and its residence time there. Pharmacokinetics of a drug are conceptualized by considering the characteristics that collectively are the determinants of the dose-concentration-effect relationship: absorption, distribution, metabolism, and excretion. **Pharmacodynamics** describes the relationship between drug dose or drug concentration and response. The response may be desirable (*effectiveness*) or untoward (*toxicity*). Although in clinical practice the response to drugs in different patient populations is often described by a standard dosing or concentration range, response is best conceptualized along a continuum where the relationship between dose and response(s) is not linear. **Pharmacogenomics** is the study of how variant forms of human genes contribute to interindividual variability in drug response. The finding that drug responses can be influenced by the patient’s genetic profile has offered great hope for realizing individualized pharmacotherapy, in which the relationship between genotype and phenotype (either disease and/or drug response) is predictive of drug response (see Chapter 72). In the developing child, ontogeny has the potential to modulate drug response through altering both pharmacokinetics and pharmacodynamics.
Pharmacodynamic Principles

A drug effect is produced only when an exposure (both amount and duration) occurs that is sufficient to produce a drug-receptor interaction capable of modulating the cellular milieu and inducing a physiologic response. Thus, exposure-response relationships for a given drug represent an interface between pharmacokinetics and pharmacodynamics, which can be simply conceptualized by consideration of 2 profiles: plasma concentration vs effect (Fig. 73.1) and plasma concentration vs time (Fig. 73.2).

**FIG. 73.1** Plasma concentration vs effect curve. The percent effect is measured as a function of increasing drug concentration in the plasma. E₀, Dose at which no effect is seen in the population; EC₅₀, dose of a drug required to produce a specified effect in 50% of the population; Eₘₐₓ, concentration associated with the maximal effect that can be produced by a drug. (From Abdel-Rahman SM, Kearns GL: The pharmacokinetic-pharmacodynamic interface: determinants of anti-infective drug action and efficacy in pediatrics. In Feigin RD, Cherry JD, Demmler-Harrison GJ, Kaplan SL, editors: Textbook of pediatric infectious disease, ed 6, Philadelphia, 2009, Saunders-Elsevier, pp 3156–3178; reproduced with permission.)
FIG. 73.2  Semilogarithmic plot of the plasma concentration vs time curve for a hypothetical drug following extravascular administration. The area under the plasma level-time curve (AUC) is a concentration- and time-dependent measure of systemic drug exposure. After administration, the drug is absorbed and reaches the maximal concentration \( C_{\text{max}} \) at its peak time \( T_{\text{max}} \). Following completion of drug absorption and distribution, plasma drug concentrations decline in an apparent monoexponential manner in which the slope of the apparent elimination phase represents the apparent elimination rate constant \( k_e \). (From Abdel-Rahman SM, Kearns GL: The pharmacokinetic-pharmacodynamic interface: determinants of anti-infective drug action and efficacy in pediatrics. In Feigin RD, Cherry JD, Demmler-Harrison GJ, Kaplan SL, editors: Textbook of pediatric infectious disease, ed 6, Philadelphia, 2009, Saunders-Elsevier, pp 3156–3178; reproduced with permission.)

The relationship between drug concentration and effect for most drugs is not linear (Fig. 73.1). At a drug concentration of zero, the effect from the drug is generally zero or not perceptible \( (E_0) \). After drug administration and with dose escalation, the concentration increases, as does the effect, first in an apparent linear fashion (at low drug concentrations), followed by a nonlinear increase in effect to an asymptotic point in the relationship where a maximal effect \( (E_{\text{max}}) \) is attained that does not perceptibly change with further increases in drug concentration. The point in the concentration-effect relationship where the observed effect represents 50% of the \( E_{\text{max}} \) is defined as \( \text{EC}_{50} \), a common pharmacodynamic term used to compare concentration-effect relationships between patients (or research participants) and between drugs that may be in a given drug class.

Because it is rarely possible to measure drug concentrations at or near the receptor, it is necessary to utilize a surrogate measurement to assess exposure-response relationships. In most cases this surrogate is represented by the plasma drug concentration vs time curve. For drugs whose pharmacokinetic properties are best described by first-order (vs zero- or mixed-order) processes, a semilogarithmic plot of plasma drug concentration vs time data for an agent
given by an extravascular route of administration (e.g., intramuscular, subcutaneous, intracisternal, peroral, transmucosal, transdermal, rectal) produces a pattern depicted by Fig. 73.2. The ascending portion of this curve represents a time during which the liberation of a drug from its formulation, dissolution of the drug in a biologic fluid (e.g., gastric or intestinal fluid, interstitial fluid; a prerequisite for absorption), and absorption of the drug are rate limiting relative to its elimination. After the time \( T_{\text{max}} \) where maximal plasma concentrations \( C_{\text{max}} \) are observed, the plasma concentration decreases as metabolism and elimination become rate limiting; the terminal portion of this segment of the plasma concentration vs time curve is representative of drug elimination from the body. Finally, the area under the plasma concentration vs time curve (AUC), a concentration- and time dependent parameter reflective of the degree of systemic exposure from a given drug dose, can be determined by integrating the plasma concentration data over time.

Being able to characterize the pharmacokinetics of a specific drug allows the clinician to use the data to adjust “normal” dosing regimens and individualize them to produce the degree of systemic exposure associated with desired pharmacologic effects. For drugs where a therapeutic plasma concentration range or “target” systemic exposure (i.e., AUC) is known, a priori knowledge of pharmacokinetic parameters for a given population or patient within a population can facilitate the selection of a drug dosing regimen. Along with information on the pharmacodynamic behavior of a drug and the status of the patient (e.g., age, organ function, disease state, concomitant medications), the application of pharmacokinetics allows the practitioner to exercise a real degree of adaptive control over therapeutic decision-making through the selection of a drug and dosing regimen with the greatest likelihood of producing both efficacy and safety.

**Impact of Ontogeny on Drug Disposition**

**Development** represents a continuum of biologic events that enable adaptation, somatic growth, neurobehavioral maturation, and eventually reproduction. The impact of development on the pharmacokinetics of a given drug is determined to a great degree by age-related changes in body composition and the acquisition of function in organs and organ systems important in determining drug metabolism and excretion. Although it is often convenient to classify pediatric patients on
the basis of postnatal age in providing drug therapy, with neonates ≤1 mo of age, infants 1-24 mo, children 2-12 yr, and adolescents 12-18 yr, it is important to recognize that the changes in physiology are not linearly related to age and may not correspond to these age-defined breakpoints. In fact, the most dramatic changes in drug disposition occur during the 1st 18 mo of life, when the acquisition of organ function is most dynamic. It is important to note that the pharmacokinetics of a given drug may be altered in pediatric patients because of intrinsic (e.g., gender, genotype, ethnicity, inherited diseases) or extrinsic (e.g., acquired diseases, xenobiotic exposure, diet) factors that may occur during the 1st 2 decades of life.

Selection of an appropriate drug dose for a neonate, infant, child, or adolescent requires an understanding of the basic pharmacokinetic properties of a given compound and how the process of development impacts each facet of drug disposition. Accordingly, it is most useful to conceptualize pediatric pharmacokinetics by examining the impact of development on the physiologic variables that govern drug absorption, distribution, metabolism, and elimination (ADME).

Pediatrics encompasses a broad range of ages at which certain stages of life profoundly influence drug response and disposition. Dramatic pharmacokinetic, pharmacodynamic, and psychosocial changes occur as preterm infants mature toward term, as infants mature through the 1st few years of life, and as children reach puberty and adolescence (Fig. 73.3). To meet the needs of these different pediatric groups, different formulations are needed for drug delivery that can influence drug absorption and disposition, and different psychosocial issues influence compliance, timing of drug administration, and reactions to drug use. These additional factors must be considered in conjunction with known pharmacokinetic and pharmacodynamic influences of age when developing an optimal, patient-specific drug therapy strategy.
FIG. 73.3 Developmental changes in physiologic factors that influence drug disposition in infants, children, and adolescents. Physiologic changes in multiple organ systems during development are responsible for age-related differences in drug disposition. As reflected by panel A, the activity of many cytochrome P450 (CYP) isoforms and a single glucuronosyltransferase (UGT) isoform is markedly diminished during the 1st 2 mo of life. In addition, the acquisition of adult activity over time is enzyme and isoform specific. Panel B shows age-dependent changes in body composition, which influence the apparent volume of distribution of drugs. Infants in the 1st 6 mo of life have markedly expanded total-body water and extracellular water, expressed as a percentage of total body weight, compared with older infants and adults. Panel C summarizes the age-dependent changes in both structure and function of the gastrointestinal tract. As with hepatic drug-metabolizing enzymes (A), the activity of CYP1A1 in the intestine is low during early life. Panel D shows the effect of postnatal development on the processes of active tubular secretion, represented by the clearance of paraaminohippuric acid and the glomerular filtration rate, both of which approximate adult activity by 6-12 mo of age. Panel E shows age dependence in the thickness, extent of perfusion, and extent of hydration of the skin and the relative size of the skin-surface area (reflected by the ratio of body surface area to body weight). Although skin thickness is similar in infants and adults, the extent of perfusion and hydration diminishes from infancy to adulthood. (From Kearns GL et al: Developmental pharmacology—drug disposition, action, therapy in infants and children, N Engl J Med 349:1160–1167, 2003. Copyright © 2003, reproduced with permission.)
Drug Absorption

Drug absorption mainly occurs through passive diffusion, but active transport or facilitated diffusion may also be necessary for drug entry into cells. Several physiologic factors affect this process, one or more of which may be altered in certain disease states (e.g., inflammatory bowel disease, diarrhea), and thus produce changes in drug bioavailability. The rate and extent of absorption can be significantly affected by a child's normal growth and development.

Peroral Absorption

The most important factors that influence drug absorption from the gastrointestinal (GI) tract are related to the physiology of the stomach, intestine, and biliary tract (Fig. 73.3C and Table 73.1). The rate and extent of peroral absorption of drugs depend primarily on the pH-dependent passive diffusion and motility of the stomach and intestinal tract, because both these factors will influence transit time of the drug. Gastric pH changes significantly throughout development, with the highest (alkaline) values occurring during the neonatal period. In the fully mature neonate the gastric pH ranges from 6-8 at birth and drops to 2-3 within a few hours of birth. However, after the 1st 24 hr of life, the gastric pH increases because of the immaturity of the parietal cells. As the parietal cells mature, the gastric acid secretory capacity increases (pH decreases) over the 1st few months of life, reaching adult levels by age 3-7 yr. As a result, the peroral bioavailability of acid-labile drugs (e.g., penicillin, ampicillin) is increased. In contrast, the absorption of weak organic acids (e.g., phenobarbital, phenytoin) is relatively decreased, a condition that may necessitate administration of larger doses in very young patients to achieve therapeutic plasma levels.

Direction of alteration given relative to expected normal adult pattern.

_Gastric emptying_ time is prolonged throughout infancy and childhood as a result of reduced motility, which may impair drug passage into the intestine, where most absorption takes place. Gastric emptying rates reach or exceed adult values by 6-8 mo of life. As such, intestinal motility is important for the rate of drug absorption and, as with other factors, is dependent on the age of the child. Consequently, the rate of absorption of drugs with limited water solubility (e.g., phenytoin, carbamazepine) can be dramatically altered consequent to changes in GI motility. In older infants and young children, more rapid rates of intestinal drug transit can reduce the bioavailability for some drugs (e.g., phenytoin) and drug formulations (e.g., sustained-release) by reducing their residency time at the absorption surfaces in the small intestine.

Neonates, particularly premature neonates, have a reduced bile acid pool and biliary function, resulting in a decreased ability to solubilize and absorb lipophilic drugs. Biliary function develops in the 1st few months of life, but it may be difficult for the neonate and young infant to absorb fat-soluble vitamins because low concentrations of bile acids are necessary for their absorption.

**Extravascular Drug Absorption**

Intravenous (IV) drug administration is assumed to be the most dependable and accurate route for drug delivery, with a bioavailability of 100%. Absorption of drugs from tissues and organs (e.g., intramuscular, transdermal, rectal) can also be affected by development (Table 73.2). Intramuscular (IM) blood flow changes with age, which can result in variable and unpredictable absorption. Reduced muscular blood flow in the 1st few days of life, the relative inefficiency of muscular contractions (useful in dispersing an IM drug dose), and an increased percentage of water per unit of muscle mass may delay the rate and extent of drugs given intramuscularly to the neonate. Muscular blood flow increases into infancy, and thus the bioavailability of drugs given by the IM route is comparable to that seen in children and adolescents.

---

**Table 73.2**

_Influence of Ontogeny on Drug Absorption_
Directions of alteration given relative to expected normal adult pattern.

In contrast, mucosal permeability (rectal and buccal) in the neonate is increased and thus may result in enhanced absorption by this route. Transdermal drug absorption in the neonate and very young infant is increased because of the thinner and more hydrated stratum corneum (Fig. 73.3E). In addition, the ratio of body surface area to body weight is greater in infants and children than in adults. Collectively, these developmental differences may predispose the child to increased exposure and risk for toxicity for drugs or chemicals placed on the skin (e.g., silver sulfadiazine, topical corticosteroids, benzocaine, diphenhydramine), with higher likelihood of occurrence during the 1st 8-12 mo of life.

Normal developmental differences in drug absorption from most all extravascular routes of administration can influence the dose–plasma concentration relationship in a manner sufficient to alter pharmacodynamics. The presence of disease states that influence a physiologic barrier for drug absorption or the time that a drug spends at a given site of absorption can further influence drug bioavailability and effect.

### Drug Distribution

Drug distribution is influenced by a variety of drug-specific physiochemical factors, including the role of drug transporters, blood-tissue protein binding, blood-tissue pH, and perfusion. However, age-related changes in drug distribution are primarily related to developmental changes in body composition and the quantity of plasma proteins capable of drug binding. Age-dependent changes in the relative sizes of body water — total body water (TBW) and extracellular water (ECW)—and fat compartments may alter the apparent volume of distribution (VD) for a given drug. The absolute amounts and distribution of body water and fat depend on a child's age and nutritional status. Also, certain disease states (e.g., ascites, dehydration, burn injuries, skin
disruption involving large surface area) can influence body water compartment sizes and thereby, further impact the VD for certain drugs.

Newborns have a much higher proportion of body mass in the form of water (approximately 75% TBW) than older infants and children (Fig. 73.3B). In addition, the percentage of ECW changes (decreases) from the newborn stage (approximately 45%) into adulthood (20–30%). In fact, the increase of TBW in the neonate is attributable to ECW. The reduction in TBW is rapid in the 1st year of life, with adult values (approximately 55%) achieved by approximately 12 yr of age. In contrast, the percentage of intracellular water (ICW) as a function of body mass remains stable from the 1st months of life through adulthood. The impact of developmental changes in body water spaces are exemplified by drugs such as the aminoglycoside antibiotics; compounds that distribute predominantly throughout the extracellular fluid space and have a higher VD (0.4-0.7 L/kg) in neonates and infants than in adults (0.2-0.3 L/kg).

Body fat percentage and composition increase during normal development. The body fat percentage in a neonate is approximately 16% (60% water and 35% lipid). Despite the relatively low body fat content in the neonate, it is important to note that the lipid content in the developing central nervous system (CNS) is high, which has implications for the distribution of lipophilic drugs (e.g., propranolol) and their CNS effects during this period. The body fat percentage tends to increase up to about age 10 yr, then changes composition with respect to puberty and sex to approach adult body fat composition (26% water and 71% lipid). In addition, a sex difference exists as the child transitions into adolescence. Whereas the total body fat in males is reduced to 50% between 10 and 20 yr of life, the reduction in females is not as dramatic and decreases 28–25% during this same developmental stage.

Albumin, total proteins, and total globulins (e.g., α₁-acid glycoprotein) are the most important circulating proteins responsible for drug binding in plasma. The absolute concentration of these proteins is influenced by age, nutrition, and disease (Table 73.3). The concentrations of almost all circulating plasma proteins are reduced in the neonate and young infant (approximately 80% of adult) and reach adult values by 1 yr of age. A similar pattern of maturation is observed with α₁-acid glycoprotein (an acute-phase reactant capable of binding basic drugs), for which neonatal plasma concentrations are approximately 3 times lower than in maternal plasma and attain adult values by approximately 1 yr of age.
The extent of drug binding to proteins in the plasma may influence distribution characteristics. Only free, unbound drug can be distributed from the vascular space into other body fluids and, ultimately, to tissues where drug-receptor interaction occurs. Drug protein binding depends on a number of age-related variables, including the absolute amount of proteins and their available binding sites, the conformational structure of the binding protein (e.g., reduced binding of acidic drugs to glycated albumin in patients with poorly controlled diabetes mellitus), the affinity constant of the drug for the protein, the influence of pathophysiologic conditions that either reduce circulating protein concentrations (e.g., ascites, major burn injury, chronic malnutrition, hepatic failure) or alter their structure (e.g., diabetes, uremia), and the presence of endogenous or exogenous substances that may compete for protein binding (i.e., protein displacement interactions).

Developmentally associated changes in drug binding can occur because of altered protein concentrations and binding affinity. Circulating fetal albumin in the neonate has significantly reduced binding affinity for acid drugs such as phenytoin, which is extensively (94–98%) bound to albumin in adults, compared to 80–85% in the neonate. The resultant 6-8-fold difference in the free fraction can result in CNS adverse effects in the neonate when total plasma phenytoin concentrations are within the generally accepted “therapeutic range” (10-20 mg/L). The importance of reduced drug-binding capacity of albumin in the neonate is exemplified by interactions between endogenous ligands (e.g., bilirubin, free fatty acids) and drugs with greater binding affinity (e.g., ability of sulfonamides to produce kernicterus).
**Drug transporters** such as P-glycoprotein and multidrug-resistant proteins 1 and 2 can influence drug distribution. These drug transporters can greatly influence the extent that drugs cross membranes in the body and whether drugs can penetrate or are secreted from the target sites (inside cancer cells or microorganisms or crossing the blood-brain barrier). Thus, drug resistance to cancer chemotherapy, antibiotics, or epilepsy may be conferred by these drug transport proteins and their effect on drug distribution. Growing evidence on the ontogeny of drug transport proteins demonstrates their presence as early as 12 wk gestation and low levels in the neonatal period, which rapidly increase to adult values by 1 to 2 yr of age, depending on the transporter. In addition, genetic variation can affect drug transporter expression and function but may not be readily apparent until adult levels are obtained (see Chapter 72).

**Drug Metabolism**

Metabolism reflects the biotransformation of an endogenous or exogenous molecule by one or more enzymes to moieties that are more hydrophilic and thus can be more easily eliminated by excretion, secretion, or exhalation. Although metabolism of a drug generally reduces its ability to produce a pharmacologic action, metabolism also can result in metabolites that have significant potency and thereby contribute to the drug's overall pharmacodynamic profile (e.g., biotransformation of the tricyclic antidepressant amitriptyline to nortriptyline; codeine to morphine; cefotaxime to desacetyl cefotaxime; theophylline to caffeine). In the case of prodrugs (e.g., zidovudine, enalapril, fosphenytoin) or some drug salts or esters (e.g., cefuroxime axetil, clindamycin phosphate), biotransformation is required to produce a pharmacologically active moiety. Finally, for some drugs, cellular injury and associated adverse reactions are the result of drug metabolism (e.g., acetaminophen hepatotoxicity, Stevens-Johnson syndrome associated with sulfamethoxazole).

The primary organ responsible for drug metabolism is the liver, although the kidney, intestine, lung, adrenals, blood (phosphatases, esterases), and skin can also biotransform certain compounds. Drug metabolism occurs primarily in the endoplasmic reticula of cells through 2 general classes of enzymatic processes: phase I (nonsynthetic) and phase II (synthetic) reactions. **Phase I** reactions include oxidation, reduction, hydrolysis, and hydroxylation reactions. **Phase II** reactions primarily involve conjugation with an endogenous ligand (e.g., glycine, glucuronide, glutathione or sulfate). Many drug-metabolizing enzymes
demonstrate an ontogenetic profile with generally low activity at birth and maturation over months to years (Table 73.4 and Fig. 73.3A).

Direction of alteration given relative to expected normal adult pattern.

Many enzymes are capable of catalyzing the biotransformation of drugs and xenobiotics, but quantitatively the most important are represented by cytochrome P450 (CYP), a supergene family with at least 16 primary enzymes. The specific CYP isoforms responsible for the majority of human drug metabolism are represented by CYP1A2, CYP2C9, CYP2C19, CYP2D6, CYP2E1, and CYP3A4. These enzymes represent the products of genes that in some cases are polymorphically expressed, with allelic variants producing enzymes generally resulting in either no or reduced catalytic activity (a notable exception being the *17 allele of CYP2C19, which may have increased activity) (see Chapter 72).

At birth the concentration of drug-oxidizing enzymes in fetal liver (corrected for liver weight) appears similar to that in adult liver. However, the activity of these oxidizing enzyme systems is reduced, which results in slow clearance (and prolonged elimination) of many drugs that are substrates for them (e.g., phenytoin, caffeine, diazepam). Postnatally, the hepatic CYPs appear to mature at different rates. Within hours after birth, CYP2E1 activity increases rapidly, with CYP2D6 being detectable soon thereafter. CYP2C (CYP2C9 and CYP2C19) and CYP3A4 are present within the 1st mo of life, a few months before CYP1A2. CYP3A4 activity in young infants may exceed that observed in adults, as reflected by the clearance of drugs that are substrates for this enzyme (e.g., cyclosporine, tacrolimus).

Compared to phase I drug-metabolizing enzymes, the impact of development on the activity of phase II enzymes (acetylation, glucuronidation, sulfation) is not characterized as well. Phase II enzyme activity is decreased in the newborn
and increases into childhood. Conjugation of compounds metabolized by isoforms of glucuronosyltransferase (UGT) (e.g., morphine, bilirubin, chloramphenicol) is reduced at birth but can exceed adult values by 3-4 yr of age. Also, the ontogeny of UGT expression is isoform specific. Newborns and infants primarily metabolize the common analgesic acetaminophen by sulfate conjugation, since the UGT isoforms responsible for its glucuronidation (UGT1A1 and UGT1A9) have greatly reduced activity. As children age, the glucuronide conjugate becomes predominant in the metabolism of therapeutic doses of acetaminophen. In contrast, the glucuronidation of morphine (a UGT2B7 substrate) can be detected as early as 24 wk gestation.

The activity of certain hydrolytic enzymes, including blood esterases, is also reduced during the neonatal period. Blood esterases are important for the metabolic clearance of cocaine, and the reduced activity of these plasma esterases in the newborn may account for the delayed metabolism (prolonged effect) of local anesthetics in the neonate. In addition, this may account for the prolonged effect that cocaine has on the fetus with prenatal exposures. Adult esterase activity is achieved by 10-12 mo of age.

The development of presystemic clearance or “first-pass” metabolism is unclear given the involvement of multiple enzymes and transporters in the small intestine, many of which have patterns of developmental expression that may be more or less concordant. However, given that the activity of almost all drug-metabolizing enzymes is markedly reduced in the neonate, the extent of bioavailability of drugs given by the peroral route that may be subjected to significant presystemic clearance in older children and adults would appear to be greatly increased during the 1st days to weeks of life. It is important for the clinician to recognize that estimates of bioavailability for a host of drugs available in reference texts and therapeutic compendia are most often derived from studies conducted in young adults. Thus, estimates of the rate and extent of absorption (including a propensity to be affected by presystemic clearance) from adults cannot be accurately used to extrapolate how a peroral drug dose may need to be age-adjusted for a neonate or infant.

With regard to the impact of development on drug metabolism, it must be recognized that most therapeutic drugs are polyfunctional substrates for a host of enzymes and transporters. It is the isoform-specific ontogenic profile (Fig. 73.3) that must be considered in the context of deducing how development can affect the metabolic portion of drug clearance. True developmental dependence of drug clearance must also consider the role of pharmacogenetic constitution on the
activity of enzymes and transporters (see Chapter 72) and the impact of ontogeny on the nonmetabolic routes (e.g., renal drug excretion, salivary/biliary drug excretion, pulmonary drug excretion), which contribute to the overall drug clearance (Total CL = CL$_{hepatic}$ + CL$_{renal}$ + CL$_{nonrenal}$).

**Renal Drug Elimination**

The kidney is the primary organ responsible for the elimination of drugs and their metabolites. The development of renal function begins during early fetal development and is complete by early childhood (Fig. 73.3D and Table 73.5). Total renal drug clearance (CL$_{renal}$) can be conceptualized by considering the following equation:

**Table 73.5**

Direction of alteration given relative to expected normal adult pattern.

\[
\text{CL}_{\text{renal}} = (\text{GFR} + \text{ATS}) - \text{ATR}
\]

where glomerular filtration rate (GFR), active tubular secretion (ATS), and active tubular reabsorption (ATR) of drugs can contribute to overall clearance. As for hepatic drug metabolism, only free (unbound) drug and metabolite can be filtered by a normal glomerulus and secreted or reabsorbed by a renal tubular transport protein.

Renal clearance is limited in the newborn because of anatomic and functional immaturity of the nephron unit. In both the term and the preterm neonate, GFR
 averages 2-4 mL/min/1.73 m² at birth. During the 1st few days of life, a decrease in renal vascular resistance results in a net increase in renal blood flow and a redistribution of intrarenal blood flow from a predominantly medullary to a cortical distribution. All these changes are associated with a commensurate increase in GFR. In term neonates, GFR increases rapidly over the 1st few months of life and approaches adult values by 10-12 mo (Fig. 73.3D ). The rate of GFR acquisition is blunted in preterm neonates because of continued nephrogenesis in the early postnatal period. In young children 2-5 yr of age, GFR may exceed adult values, especially during periods of increased metabolic demand (e.g., fever).

In addition, a relative glomerular/tubular imbalance results from a more advanced maturation of glomerular function. Such an imbalance may persist up to 6 mo of age and may account for the observed decrease in the ATS of drugs commonly used in neonates and young infants (e.g., β-lactam antibiotics). Finally, some evidence suggests that ATR is reduced in neonates and that it appears to mature at a slower rate than the GFR.

Altered renal drug clearance in the newborn and infants result in the different dosing recommendations seen in pediatrics. The aminoglycoside antibiotic gentamicin provides an illustrative example. In adolescents and young adults with normal values for GFR (85-130 mL/min/1.73 m²), the recommended dosing interval for gentamicin is 8 hours. In young children who may have a GFR >130 mL/min/1.73 m², a gentamicin dosing interval of every 6 hr may be necessary in selected patients who have serious infections that require maintaining steady-state peak and trough plasma concentrations near the upper boundary of the recommended therapeutic range. In contrast, to maintain “therapeutic” gentamicin plasma concentrations in neonates during the 1st few weeks of life, a dosing interval of 18-24 hr is required.

The impact of developmental differences in GFR on the elimination characteristics of a given drug can be assessed by estimating the apparent elimination rate constant (Kel) for a drug by using the following equation:

\[
Kel \text{ (in reduced renal function)} = Kel_{\text{normal}} \cdot \left\{ [(GFR_{\text{observed}}/GFR_{\text{normal}}) - 1] \cdot Fel \right\} + 1
\]

where the Fel represents the fraction of the drug excreted unchanged in an
adult with normal renal function; $GFR_{\text{observed}}$ is the value calculated (from creatinine clearance or age-appropriate estimation equation) for the patient (in mL/min/1.73 m$^2$); and $GFR_{\text{normal}}$ is the average value considered for a healthy adult (120 mL/min/1.73 m$^2$). $Kel_{\text{normal}}$ is estimated from the average elimination $T_{1/2}$ for a drug taken from the medical literature using the following equation:

$$
Kel_{\text{normal}} \text{[hr}^{-1}] = 0.693/T_{1/2_{\text{normal}}} \text{[hr]}
$$

Likewise, the elimination half-life ($T_{1/2}$) for a drug in patients with reduced renal function can be estimated as follows:

$$
T_{1/2} \text{ (in reduced renal function)} = 0.693/Kel \text{ (in reduced function)}
$$

An estimate of the drug elimination $T_{1/2}$ in patients with reduced renal function with knowledge of the desired interdose excursion in steady-state plasma concentrations can allow determination of the desired drug dosing interval.

**Impact of Ontogeny on Pharmacodynamics**

Although it is generally accepted that developmental differences exist in drug action, there is little evidence of true age related pharmacodynamic variation among children of differing age-groups and adults. **Drug action** is typically mediated by interaction of a small molecule with 1 or more receptors that may be located either on or in a cell. **Drug effect** is mediated at the receptor by 4 main biochemical mechanisms involved in cell signaling. **Binding** of the receptors on the cell surface or within the cell activates downstream pathways that mediate a specific cellular action. Some receptors act as enzymes, whereby on ligand binding the enzyme phosphorylates downstream effector proteins, thereby activating or inhibiting a cellular signal (e.g., guanosine triphosphate–binding regulatory protein, also known as G-protein–coupled receptors). Other receptors mediate their actions through **ion channels**, whereby on ligand binding
the cell's membrane potential or ionic composition is altered, allowing cellular activation or inhibition. Lastly, some receptors act as transcription factors, which when bound by a ligand activate transcription of specific genes within the cell.

Drug action is concentration dependent, with onset and offset generally associated with appearance and disappearance, respectively, of the drug at the receptor(s) in an amount that is sufficient to initiate the cascade of biologic effects that terminate in drug action (see Fig. 73.1). The minimum effective concentration of a drug is that observed with the immediate onset of effect, whereas the duration of action is predicated on the maintenance of drug concentrations at the receptor within a range associated with the desirable pharmacologic action(s). Receptor binding by a drug may have varying consequences. Drugs that are agonists bind to and activate the receptor, directly or indirectly achieving the desired effect. An agonist binding to a receptor results in the same biologic effect as binding of the endogenous ligand. Partial agonist binding results in activation of the receptor, but maximal effect is not achieved, even in the presence of receptor saturation. Antagonists bind to a receptor, preventing binding of other molecules, thereby preventing activation of the receptor.

Evidence supports developmental differences in receptor number, density, distribution, function, and ligand affinity for some drugs. Human data are limited, so much of what is known has been derived from animal studies. In the CNS, unique developmental aspects of drug-receptor interaction affect therapeutic efficacy of both analgesics and sedatives in neonates. The number of γ-aminobutyric acid (GABA) receptors, which mediate inhibitory signal transduction in the CNS, is reduced in newborns compared to adults. Functional differences have also been observed between neonatal and adult brain on GABA receptor activation. These changes may explain observed differences in dosing of drugs such as midazolam in infants and in part may explain seizures experienced by infants on benzodiazepine exposure. Another CNS example is the µ-opioid receptor, whereby receptor number is reduced in newborns and receptor distribution also differs between newborns and adults.

For the clinician, consideration of age-dependent differences in pharmacodynamics is particularly relevant when associated with adverse drug reactions (e.g., higher incidence of valproic acid-associated hepatotoxicity in young infants; greater frequency of paradoxical CNS reactions to diphenhydramine in infants; weight gain associated with atypical antipsychotic
drugs in adolescents) or when drugs have a narrow therapeutic index (Fig. 73.4). The age-associated pharmacodynamics of warfarin observed in children with congenital heart disease is related to developmental differences in serum concentrations of vitamin K–dependent coagulation factors (II, VII, IX, X) between children and adults. Developmental differences in drug action have been observed between prepubertal children and adults in regard to warfarin action. Prepubertal children exhibit a more profound response, demonstrated by lower protein C concentration, prothrombin fragments 1 and 2, and greater rise in INR, to comparable doses of warfarin. Thus, when age-dependent pharmacodynamics of a given drug is evident, the use of simple allometric approaches for “scaling” the pediatric dose from the usual adult dose may not produce the desired pharmacologic effects. Pharmacokinetic and pharmacodynamic (PK/PD) modeling techniques that use known developmental changes in body composition, enzyme function, renal function, effector proteins, and receptors are being used to predict optimal dosing in children. However, data regarding differences in pharmacodynamic response across the age continuum remain lacking and limit the application of these techniques to accurately predict dose-response relationships in the pediatric population.

![Quantal dose–effect curve.](image)

**FIG. 73.4** Quantal dose–effect curve. Age-related pharmacokinetic variation may result in alterations in drug concentration at the receptor resulting in ineffective, therapeutic or toxic results. LD50, Dose at which 50% of the population is lethal. The ratio of the LD50 to the ED50 is an indication of the therapeutic index, which is a reflection of drug potency relative to its concentration.

**Surrogate Endpoints**
Biomarkers and surrogate endpoints (markers) are ideally simple, reliable, inexpensive, and easily obtainable measures of a biologic response or disease phenotype that can be used to facilitate either clinical research or patient care. Biomarkers have been defined by the U.S. National Institutes of Health as “a characteristic that is objectively measured and evaluated as an indicator of normal biological processes, pathogenic processes, or pharmacologic responses to a therapeutic intervention.” A surrogate endpoint is defined “as a biomarker that is intended to substitute for a specific clinical endpoint. A surrogate endpoint is expected to predict clinical benefit (or harm or lack of benefit or harm) based on epidemiologic, therapeutic, pathophysiologic, or other scientific evidence.” Reliable surrogate endpoints predict a specific physiologic event (e.g., intraesophageal pH to assess gastroesophageal reflux) that may be used diagnostically, prognostically, or in predicting a specific drug response (therapeutic, subtherapeutic, or adverse) or potentially the impact of ontogeny on pharmacodynamics. Specific examples of surrogate endpoints used in pediatric pharmacology include measurement of esophageal pH to assess the action of prokinetic or acid-modifying drugs and pulmonary function tests (e.g., FEV\textsubscript{1}) to evaluate the effect of drugs on pulmonary function in patients with conditions such as asthma and cystic fibrosis. Biomarkers used in pediatric studies to assess drug disposition or effect include hemoglobin A\textsubscript{1c} plasma concentration (to assess efficacy of peroral hypoglycemic agents), urinary leukotriene concentrations (to assess effects of nonsteroidal antiinflammatory drugs), and minimal inhibitory concentration (MIC) and minimal bacteriocidal concentration (MBC) of drugs to select antiinfective agents.

**Additional Considerations in Pediatric Therapeutics**

**Pediatric Dose and Regimen Selection**

Incomplete developmental profiles for hepatic and extrahepatic drug-metabolizing enzymes and drug transporters that may influence drug clearance and bioavailability prevent the use of simple formulas or allometric scaling for effective pediatric dose prediction. Although these approaches may have some clinical utility in older children (>8 yr) and adolescents whose organ function and body composition approximate that of young adults, their utility is severely
limited in neonates, infants, and young children, in whom ontogeny produces dramatic differences in drug disposition. This is especially problematic for therapeutic drugs whose doses cannot be easily individualized using patient-specific pharmacokinetic data obtained from therapeutic drug monitoring. In the absence of such pharmacokinetic data or established pediatric dosing guidelines, alternate methods must often be employed.

To date, >20 different approaches for initial selection of a drug dose for pediatric patients have been described. The majority use either total body weight (BW) or body surface area (BSA) as surrogates that reflect the developmental changes of body composition or organ function, which collectively are the major determinants of drug disposition. Selection based on BW or BSA will generally produce similar relationships between drug dose and resultant plasma concentration, except for those drugs whose apparent volume of distribution (VD) corresponds to the extracellular fluid pool (i.e., VD <0.3 L/kg), in which a BSA-based approach is preferable. In contrast, for drugs whose apparent VD exceeds the extracellular fluid space (i.e., VD >0.3 L/kg), a BW-based approach for dose selection is preferable, which is the most frequently used method in pediatrics. When the pediatric dose for a given drug is not known, these principles can be used to best approximate a proper dose for the initiation of treatment, as illustrated by the following equations:

\[
\text{Child dose (if VD < 0.3 L/kg)} = (\text{Child BSA in m}^2/1.73 \text{ m}^2) \times \text{Adult dose}
\]

\[
\text{Infant dose (if VD ≥ 0.3 L/kg)} = (\text{Infant BW in kg/70 kg}) \times \text{Adult dose}
\]

It should be noted that this approach assumes that the child's weight, height, and body composition are age appropriate and normal, and that the "reference" normal adult has a BW and BSA of 70 kg and 1.73 m², respectively. It is useful only for selection of dose size and does not offer information regarding dosing interval, because the equations contain no specific variable that describes potential age-associated differences in drug clearance.

Similar to obese adults, obesity in children would be expected to result in to alterations in drug pharmacokinetics. Unfortunately, few data exist on drug
dosing in obese pediatric patients. Alterations in VD, which is important for loading-dose calculations, is related to the lipophilicity or water solubility of the medication to be administered. Some limited data are available on the impact of obesity on VD in children with the antibiotics cefazolin and tobramycin. The impact of obesity in pediatric patients on absorption and drug metabolism (phase I and II pathways) is not known. No validated estimate of GFR in obese children exists, but current information suggests that serum creatinine concentration may be higher or no different in obese children than in those of normal weight. Drug dosing in normal-weight children typically uses age-based dosing, allometric scaling, BSA, or BW. These same estimates can be used in obese children, although use of an adjusted BW should be considered. Variations on weight used in adults include ideal body weight (IBW), lean body weight, adjusted body weight, and total body weight. However, in children, standards for calculating adjusted weights may not be standardized (e.g., IBW). When dosing medications in obese children, it is important to consider information regarding drug dosing in obese adults, recommended adult maximum doses, and the physiochemical properties of the drug to be given.

In neonates and young infants with developmental immaturity in GFR or ATS, it is often necessary to adjust the “normal” dosing interval (i.e., that used for older infants and children who have attained developmental competence of renal function) for drugs with significant (>50%) renal elimination, to prevent excessive drug accumulation (and possible associated toxicity) with administration of multiple doses. To accomplish this therapeutic goal, it is necessary to estimate the apparent elimination half-life ($T_{1/2}$) of the drug (see equations earlier).

**Therapeutic Drug Monitoring**

Clinically, systemic drug exposure is usually evaluated through assessing the plasma drug concentration, a surrogate measurement for a drug reaching its pharmacologic receptor(s). In the patient, drug level monitoring can be used to facilitate 2 approaches for evaluating the dose-concentration-effect relationship: single-concentration (e.g., trough or random level) therapeutic drug monitoring (TDM) and multilevel pharmacokinetic-based TDM. Both lead to dose individualization for a given patient.

Drug-level monitoring largely entails measurement of drug concentrations in plasma (primarily) or other biologic fluids at some point during a drug's dosing
interval. These levels are then compared with those that are “desired” for a given drug based on published information and used to adjust the dose/dosing regimen. For single trough-level measurement (at the end of a dosing interval) or random-level measurement (nonspecific time point during a dosing interval), adjustment of the medications dose is done empirically without pharmacokinetic parameters. In using a TDM approach, it should be recognized that for many drugs which are therapeutically monitored in the clinical setting (e.g., aminoglycoside antibiotics, vancomycin, phenytoin, phenobarbital, cyclosporine, tacrolimus, mycophenolate mofetil, selected antiretroviral drugs, acyclovir), “desired” plasma concentrations are generally determined from studies in adult patients where drug disposition and disease states may be quite different from those in infants and children.

Clinical pharmacokinetics represents a proactive approach where multiple plasma drug concentrations are used to estimate pharmacokinetic parameters for a specific patient to a specific drug at that point in time (e.g., apparent elimination rate constant, elimination $T_{1/2}$, apparent VD, total plasma clearance, AUC), which are then used to calculate a dosing regimen required to attain a desired level of systemic exposure (e.g., AUC, steady-state peak/trough plasma drug concentrations) that would portend a desired pharmacologic response. Of these 2 approaches, the use of drug-level data for performing clinical pharmacokinetics provides the better approach for individualizing dose/dosing regimen and maintaining some adaptive control over the dose-concentration-effect relationship. This approach is particularly useful for patients who may have “abnormal” pharmacokinetics because of their age and/or disease states. Approaches used to enable the performance of clinical pharmacokinetics include the manual use of established formulas for calculating pharmacokinetic parameters (generally using a simple 1-compartment open model consequent to the few plasma drug-level observations obtained in clinical patient care) or computer-based algorithms (e.g., bayesian estimation, population-based pharmacokinetic approaches).

Common to both of the aforementioned approaches is the need to accurately assess plasma drug concentrations in a given patient. Fig. 73.5 represents a hypothetical general steady-state plasma concentration vs time profile for a drug given by an extravascular route, illustrating the following general principles to recognize and follow when plasma drug-level monitoring is used in patients as a “tool” to individualize drug treatment:
◆ When a drug reaches a pharmacokinetic steady state (a period corresponding to 5 times the apparent elimination $T_{1/2}$ for a given drug), both the excursion between the peak ($C_{\text{max}}$) and trough ($C_{\text{min}}$) plasma concentration and the AUC are identical between dose intervals provided that (1) the dose is not changed; (2) an exact dose-to-dose interval is maintained for drug administration; and (3) the route or rate of drug administration between dosing intervals has not changed.

◆ Steady-state plasma drug concentrations provide the best surrogate for assessing exposure-response relationships for a given drug. These drug concentrations provide the most accurate estimation
of patient-specific pharmacokinetic parameters. Plasma concentrations assessed before the attainment of steady state can be useful for evaluating exaggerated drug response or predicting eventual steady-state drug levels and exposure.

◆ To reliably interpret any drug plasma concentration, it is imperative that the clinician know and consider the following:

1. The expected pharmacokinetic profile for a given drug (e.g., time after dosing required for completion of drug absorption [for extravascularly administered drugs] and distribution)
2. The exact time that the drug was administered
3. For drugs given by IV infusion, the total duration of infusion (including time required to flush the dose from the IV tubing)
4. Pertinent limitations of the analytic method used to measure the plasma drug level (e.g., range of linearity, potential for analytic interference from concomitant drugs)
5. The method used to obtain the blood specimen(s) used for plasma level determination (e.g., venous puncture vs cutaneous puncture; use of vascular
catheter different from one used for drug administration)

6. Whether the blood specimen was adequate for accurate drug-level measurement (e.g., sufficient volume, presence or absence of hemolysis or lipemia)

7. The *exact* time that the blood specimens were obtained in relationship to the time of drug administration and the drug dosing interval

This last point is illustrated by Fig. 73.5, which denotes the “true” peak ($C_{max}$) and trough ($C_{min}$) plasma concentrations in relationship to apparent values. This situation frequently occurs when “peak” and “trough” blood levels are ordered, and nursing/phlebotomy procedures allow some period of leeway as to when they can be obtained. When such a discrepancy is realized, and the exact timing of the samples relative to dose administration is known, corrections can be made to insure pharmacokinetic parameters estimated from the data are accurate. If such a discrepancy is not realized, errant parameter estimation and dose regimen calculation/determination may result, thereby compromising safety or efficacy of drug treatment.

**Drug Formulation and Administration**

One of the more unique challenges in pediatric therapeutics is the drug formulation itself. Despite the increasing sensitivity for the need to study pediatric drugs before their use in children and to have available “pediatric-friendly” formulations, many drug products formulated only for adult use are routinely given to pediatric patients. Their use can result in inaccurate dosing (e.g., administration of a fixed dose to children with widely varying body weights), loss of desired performance characteristics of the formulation (e.g., crushing sustained-release tablet, cutting transdermal patch), and exposure of
infants and children to excipients (e.g., binding agents, preservatives) in amounts capable of producing adverse effects.

**Peroral Drug Administration**

One of the principal determinants of peroral drug administration in children is the ability to get the drug into the body. Peroral formulations are often expelled by children because of poor taste and texture. This is a significant issue, especially when considering that taste sensation differs because of development and on an interindividual basis. Solid peroral formulations such as tablets and capsules are not easily administered to the majority of infants and children because of their inability to swallow them easily and safely. Incomplete development of swallowing coordination may result in choking or aspiration when solid peroral formulations are given to infants and small children. Further, solid peroral formulations limit the ability for dose titration and dosing flexibility. Drug developers are working to address this limitation with new techniques suitable for both oral and peroral drug administration that encompass both products (e.g., dispersible peroral tablets, oral films, titratable granules, oral melts) and drug administration devices (e.g., dosing straws, graduated cylinders for peroral granules).

With regard to dosing accuracy with peroral formulations, **liquids** (e.g., drops, solutions, syrups, suspensions, elixirs) are preferred for infants and young children. The utility of these formulations is often limited by palatability when taste-masking of the active ingredient(s) cannot be effectively achieved. In the case of suspension formulations, improper reconstitution and/or resuspension before dose administration can introduce problems related to accuracy of dosing. Other potential limitations of peroral liquid formulations (e.g., those that may be extemporaneously compounded by the pharmacist from drug powder or from solid peroral dosage forms of a given drug) include potential problems related to drug stability, contamination (chemical or bacterial), portability, and for some products the need for refrigeration.

Administration of liquid medications can be associated with risk if the device for administering the medication is not appropriate (e.g., use of a kitchen teaspoon vs 5.0 mL dosing spoon) or is used improperly to insure the drug dose is measured appropriately for the patient's age or weight. The low cost and convenience of hypodermic syringes has prompted many physicians and pharmacists to dispense them with liquid medications in order to improve
accuracy. While this approach would seemingly be associated with greater accuracy in dosing, parents/caregivers can have difficulty in reading the graduations on a syringe, and the plastic caps on the plungers of syringes can produce a choking hazard for infants and young children. These problems can be obviated by education of parents/caregivers on how to reliably use peroral dosing syringes, which pharmacists should dispense with every liquid drug formulation.

**Parenteral Drug Administration**

In contrast to adults, in whom vascular access is relatively easy to obtain, difficulties are often present in the infant and young child, resulting from the smaller diameter of peripheral vessels (relative to size of IV cannula), developmentally associated differences in body composition (e.g., body fat distribution), and use of topical anesthetic agents, which can produce venous constriction. The small peripheral blood vessels in infants and young children can also limit the volume and rate of parenteral drug administration due to issues of capacity and with drugs capable of producing venous irritation, which induces infusion-related pain.

An underappreciated complicating issue for parenteral drug administration to infants is the relative lack of formulations in concentrations suitable for IV administration. Errors consequent to improper dilution of adult formulations necessary to ensure appropriate osmolarity and volume for IV administration (the most common resulting in a 10-fold overdose) are not uncommon. Morphine, a drug commonly used in neonates, infants, and children, is commonly available in an 8 mg/mL concentration. A usual 0.1 mg/kg morphine dose for a 1 kg infant using this formulation would require a nurse or pharmacist to accurately withdraw 0.013 mL and administer it into a length of IV tubing with a dead space volume that may exceed that of the dose by 100-fold. In this situation, accuracy of dose and infusion time can be significantly compromised. Although underdosing is often a serious problem when attempting to administer very small volumes, overdoses also occur from inaccurate extemporaneous dilutions. Moreover, attempts to compensate for the volumes present within the IV tubing further predispose the patient to receive an incorrect, possibly unsafe, dose. Whenever such concentrated drug formulations are the only source for use, appropriate alteration of the stock parenteral solution should be performed and manufactured by the pharmacy department. Also, many errors can be avoided by
the use of standard dilutions that all practitioners are aware of and using standardized approaches for IV drug administration that minimize complications associated with unrealized drug dilution and errant infusion times (e.g., pediatric syringe pumps attached to low-volume tubing).

Although used rather infrequently, intramuscular (IM) drug administration offers a route of administration for many drugs when venous access is not immediately available or when a therapeutic drug regimen involves use of a single or limited number of doses. While appealing with respect to immediacy, this route of administration can be associated with problems (e.g., muscle/nerve damage, sterile abscess formation, variable rate of drug absorption because of developmental differences in vascular perfusion of muscle beds), especially in the neonate and small infant. Lastly, the decision to use the IM route must take into consideration the physicochemical properties (e.g., pH, osmolarity, solubility) of the drug formulation and any diluent used to prepare it.

Other Routes for Drug Administration

Neonates, infants, children, and adolescents with certain pulmonary conditions (e.g., reactive airway disease, viral-induced bronchiolitis, asthma, cystic fibrosis) frequently receive drugs (e.g., corticosteroids, β-adrenergic agonists, antimicrobial agents, mucolytic drugs) by inhalation. The pulmonary surface area in pediatric patients of all ages is a very effective, easily traversable barrier for drug absorption. Rate-limiting factors for pulmonary drug absorption include physicochemical factors associated with the drug and delivery system (e.g., particle size, diffusion coefficient, chemical stability of drug molecule in the lung) and physical factors that influence intrapulmonary drug disposition (e.g., active vs passive drug delivery to tracheobronchial tree, respiratory minute volume, internal airway diameter), many of which are developmentally determined. For drugs formulated for delivery using a metered-dose inhaler (either drug powder or suspended particles using a carrier gas), developmental factors (e.g., incoordination of device actuation with inhalation, inability to follow instructions for clearing of airway, passive inhalation with actuation of delivery device) either prevent their use (as in infants and small children) or limit the bioavailability of the drug to be administered. In these instances, specific devices (e.g., masks, spacer chambers) and methods of delivery (e.g., continuous aerosolization by mask) can be used to improve the efficiency of drug delivery and thus drug efficacy.
In pediatric patients, **percutaneous** drug administration is generally reserved for agents intended to produce a local effect within the dermis. Development has an impact on the barrier of the skin that, if not recognized and controlled for with proper drug administration techniques, can produce situations in which systemic toxicity can result. Similar therapeutic challenges occur when **transmucosal** routes (e.g., buccal, sublingual, rectal) are used for drug administration. Specifically, unpredictable systemic bioavailability may complicate treatment consequent to variability in the rate and/or extent of drug absorption. As a consequence, transmucosal drug administration to pediatric patients is no longer widely used as a matter of convenience but, rather, when the condition of the patient does not enable drug administration by the peroral or the parenteral routes. Direct **intraosseous** drug administration through puncture of the tibia is occasionally used in infants and small children for administration of drugs and crystalloid fluids given acutely during resuscitation efforts. It is particularly useful when vascular access sufficient for drug administration cannot be immediately accomplished, since the onset of action by the intraosseous route is comparable to that after IV administration.

**Adherence and Compliance**

The success of drug treatment in a pediatric patient depends on the successful administration of the drug. Physical and cognitive immaturity makes the infant and the child a dependent creature in almost all respects, including those related to therapeutic drug administration. Until a child reaches an age at which the child can physically self-administer a drug in an accurate, proficient manner and can mentally assume this responsibility (generally 7-14 yr of age, depending on the individual child), **compliance** with a drug regimen becomes the responsibility of an adult. In a hospital environment, compliance is ensured through the actions of physicians, nurses, and pharmacists who, collectively through an integrated system of medical care, assume this responsibility. On discharge, the responsibility is transferred to parents/guardians or other adult caregivers in an environment that is generally nonmedical. At this juncture, therapeutic compliance morphs into **adherence**, as defined by the potential for conflicting demands, such as multiple adult caregivers, different external environments (e.g., home, daycare, school), and parents tending to the needs of multiple children, to introduce variability (anticipated and unpredictable) in drug administration. Whether treatment is for a self-limiting (e.g., antibiotic
administration) or chronic (e.g., asthma, diabetes) condition, challenges to therapeutic adherence can serve as rate-limiting events in the determination of drug safety and efficacy in infants and young children.

In contrast to the period encompassing infancy and childhood, adolescence poses its own unique challenges to therapeutic adherence. During this period, psychosocial maturation almost always lags behind physical maturation. Development of cognitive and physical skills in most adolescents enables them to self-administer a prescribed medication in a proper manner with little to no supervision. However, psychodynamic issues experienced by a substantial number of adolescents (e.g., complete understanding of the ramifications of undertreatment, disease progression, and roles of disease prevention and health maintenance; perceptions of immortality and associated lack of need for treatment; disorganized patterns of thinking capable of confounding treatment schedules; defiant/oppositional behavior toward authority figures) can often precipitate therapeutic failure, through either undertreatment or overtreatment, the latter occasionally leading to drug toxicity.

Unfortunately, the only approach that can be used to facilitate therapeutic compliance and adherence in the pediatric patient is the combination of vigilance (on behalf of all caregivers) and repetitive education coupled with positive reinforcement. When children reach the age of assent (generally by 7 yr in children who have normal neurobehavioral development), they have the beginning level of cognitive ability sufficient to engender understanding about their medical condition(s) and how effective treatment can be used to improve their life. Through diligent patient education and reeducation, older children and adolescents can assume a level of responsibility for active partnership in their overall medical management, one that will mature as educational efforts, driven by a shared desire for an optimal outcome, are regularly made.

Drug-Drug Interactions

Pharmacokinetic and pharmacodynamic properties of drugs may be altered when ≥2 drugs are administered to a patient (Table 73.6). Interactions largely occur at the level of drug metabolism but may occur at the level of drug absorption (e.g., inhibition of intestinal CYP3A4 activity by grapefruit juice or St. John's wort and consequent reduction in presystemic clearance of CYP3A4 substrates), distribution (e.g., displacement of warfarin plasma protein binding by ibuprofen with consequent increased hemorrhagic risk), or elimination (e.g., inhibition of
ATS of β-lactam antibiotics by probenecid). Also, drug-drug interactions may occur at the level of the receptor (through competitive antagonism); many of which are intentional and produce therapeutic benefit in pediatric patients (e.g., antihistamine reversal of histamine effects, naloxone reversal of opiate adverse effects).

5 Inhibitors and inducers of CYP enzymes and P-glycoprotein. Med Lett Drugs Ther 2017; September 18 (epub). Available at: www.medicalletter.org/downloads/CYP_PGP_Tables.pdf
6 Cytochrome P450 (CYP) isozymes that can affect drug metabolism include CYP1A2, 2C8, 2C9, 2C19, 2D6, and 3A4.
7 Some protease inhibitors metabolized by CYP3A4 include atazanavir, darunavir, fosamprenavir, indinavir, lopinavir/ritonavir, nelfinavir, and saquinavir.
8 Itraconazole, ketoconazole, posaconazole, and voriconazole are strong inhibitors of CYP3A4. Fluconazole is a moderate CYP3A4 inhibitor.

This table is not an all-inclusive list of drug interactions. The prescriber is encouraged to assess the possibility of drug interactions when prescribing medications. This table does not address the chemical compatibility of drugs (eg, IV-line compatibility).

CYP = cytochrome P-450; P-gp = P-glycoprotein.

Drug interactions may also occur at a pharmaceutical level as a result of a physicochemical incompatibility of 2 medications when combined. Such interactions generally alter the chemical structure of one or both constituents and thereby renders them inactive and potentially dangerous (e.g., IV infusion of crystalline precipitate or unstable suspension). Ceftriaxone should be avoided in infants <28 days of age if they are receiving or expected to receive IV calcium-containing products, due to reports of neonatal deaths resulting from crystalline deposits in the lungs and kidneys. Alternatively, 2 drugs simultaneously administered perorally may form a complex that can inhibit drug absorption (eg., co-administration of doxycycline with a food or drug containing divalent cations).

Drug-drug interactions at the level of drug metabolism can be somewhat
predictable based on a priori knowledge of a given drug's biotransformation profile. Although such information can be derived from the primary literature, it may not be immediately translated into a useful clinical context because of limitations associated with in vitro to in vivo extrapolation, including (1) use of animal models for characterizing metabolism; (2) extrapolating enzyme kinetics derived from pooled human liver microsomes or recombinant human drug-metabolizing enzymes to estimates of in vivo drug clearance; (3) extrapolating in vitro data obtained from fully competent (i.e., adult activity) hepatic microsomes to estimates of clearance in patients who may have developmental or disease-associated compromise in enzyme activity; (4) inaccurate accounting for pharmacogenetic variation in drug-metabolizing activity (i.e., constitutive activity) and the contribution of multiple different drug-metabolizing enzymes in overall drug biotransformation; and (5) the potential role of enzyme induction or inhibition in vivo that is not reflected by conditions used for in vitro metabolism studies.

Despite these limitations, information pertaining to a drug's impact on drug-metabolizing enzymes (e.g., substrate, inducer, inhibitor) can be useful in understanding if the drug has the potential to compete for, induce, or inhibit the metabolism of another drug (e.g., enzyme inhibition enhanced effect vs enzyme induction → diminished effect) of a drug-drug interaction. While multiple sources for this information exist (e.g., primary and secondary literature, drug product labeling), it may not be complete or updated. In examining multiple information sources pertaining to this topic, the authors have found the website https://www.pharmgkb.org/ (accessed 21 February 2017) to be the most complete and useful for understanding drug metabolism pathways.

Extensive databases of reported and/or potential (e.g., theoretical mechanism-or metabolism-based) drug interactions exist and are widely available via the internet,* some of which provide some assessment as to their potential significance. Also, many computer-based information systems used by hospital and community pharmacies will routinely screen a patient's medication profile (generally restricted to prescription drugs) against new prescriptions to evaluate the potential for drug-drug interactions. When using drug-drug interaction databases or online resources, it is advisable to use multiple sources to check for complete information because information regarding interactions is evolving, and all databases may not be fully complete or may provide different information. The clinician is subsequently challenged with determining whether drug-drug or drug-food interactions found by searching these databases is of
sufficient magnitude as to be clinically significant. Utilizing primary literature should be assessed when information is not available in online sources.

Over-the-counter (OTC) preparations, herbal supplements, and certain foods also have the potential to produce interactions with drugs. These are often quite challenging for the clinician, especially for alternative therapies, in that their composition (or potency) may not be completely discernible from the product labels, and the disposition of many natural products has not been studied in either children or adults. Further, many patients and their parents do not consider alternative therapies (including nutriceuticals) to be “medicines” (and consequently will not disclose their use during a routine medication history) but rather safe “nutritional supplements” despite absent regulation for their testing. An assessment should therefore begin with a thorough medication history that includes discussions of which OTC medications and herbal products are used as well as the regularity of their use. This will allow the clinician to identify the primary ingredients contained in these products and query their potential for producing clinically significant drug-drug interactions.

The provision of individualized, optimal drug therapy requires that the clinician make an assessment of potential drug-drug interactions and their significance. This requires knowledge of the interaction, the patient's condition, concomitant treatments (prescriptions, OTC drugs, alternative medicines), the impact of development on the dose-concentration-response relationship and a consideration of the risk vs benefit profile of the drug being prescribed. The clinician must be cognizant that if he or she treats a potential drug-drug interaction as a contraindication to drug use, it is possible that an alternative drug choice could produce a treatment associated with either less benefit or greater risk. Although many drugs have the potential to cause drug interactions, not all cases are deemed clinically relevant. For patients with complex histories requiring multiple medications, consultation with a clinical pharmacologist or pharmacist can help provide guidance on drug-drug interactions and their potential to impact therapy.

**Adverse Drug Reactions**

The World Health Organization has defined adverse drug reactions (ADRs) as “a response to a drug that is noxious and unintended and occurs at doses normally used in man for the prophylaxis, diagnosis or therapy of disease or for the modification of physiological function.” There are 2 traditional pharmacologic
classifications. **Type A**, generally referred to as “side effects,” are dose-dependent and predictable reactions that account for 85–90% of all ADRs. **Type B** reactions, generally referred to as “idiosyncratic” or “allergies,” are not dose dependent and are unpredictable and account for approximately 10–15% of all ADRs. Patients sometimes misinterpret some side effects as allergies (e.g., diarrhea with amoxicillin/clavulanate), which may be perpetuated through the patient's medical record.

In the pediatric population, ADRs are common occurrences that produce a major burden to patients and the healthcare system. While ADRs have not been as thoroughly studied in children as in adults, their significance has been widely recognized in pediatrics for >25 yr. Studies concerning ADRs in pediatric patients suggest the following:

1. Approximately 9% of all pediatric patients admitted to the hospital experience an ADR during their treatment.
2. The apparent incidence of ADRs in children in outpatient clinics is approximately 1.5%.
3. ADRs have been reported as being responsible for up to 10% of pediatric admissions to children's hospitals, with a pooled estimate data of about 3%.
4. Approximately 40% of ADRs occurring in hospitalized children are potentially life threatening.

In considering these “statistics,” it should be recognized that the true incidence of ADRs in children is not known because of generalized underreporting by healthcare providers (physicians > nurses > pharmacists), parents/caregivers, and patients (who may not recognize signs/symptoms and/or may be unable to report them) and in many countries (including the United States) the lack of a standardized surveillance and real-time reporting system.

Despite the limitations associated with determining the incidence of ADRs in children, it is estimated that their occurrence in patients 0-4 yr of age (3.8%) is more than double that seen at any other time during childhood or adolescence. In the outpatient setting, children age 0-4 yr accounted for 43% of clinic and emergency department visits for ADRs. One study reported that 60% of the ADRs occurred in those <1 yr. The reasons for this are not currently known but may involve developmental differences in pharmacokinetics and pharmacodynamics (i.e., altered dose-concentration-effect relationship), age-
associated differences in physiologic “systems” that modulate drug- and metabolite-mediated cellular injury (e.g., immune system), and therapeutic use of drugs known to have a relatively high incidence of producing ADRs (e.g., delayed hypersensitivity reactions associated with β-lactam antibiotics). Also, it is important to recognize that infants can experience ADRs from drugs that are not directly administered to them therapeutically, but rather from maternal drug exposure (transplacental, breastfeeding). Examples include neonatal abstinence syndrome associated with maternal opiate use, production of a hyperserotonergic state in neonates born to mothers who received selective serotonin reuptake inhibitors during pregnancy, and opiate toxicity in breastfed infants whose mothers were taking codeine for pain management. In these cases, drug accumulation caused by reduced activity of drug-metabolizing enzymes associated with development and, potentially, pharmacogenetically determined phenotypical changes, which in concert can produce a level of systemic drug exposure capable of producing an exaggerated response or frank toxicity.

Specific ADRs occur at a much greater frequency in infants and children than in adults. Examples include aspirin-associated Reye syndrome, cefaclor-associated serum sickness–like reactions, lamotrigine-induced cutaneous toxicity, and valproic acid (VPA)–induced hepatotoxicity in infants <2 yr of age. It is not clear whether the age predilection for these specific ADRs is associated with developmental differences in drug biotransformation, related to both metabolite formation and detoxification, or alternatively, has a pharmacogenetic basis. Also, children experience hypersensitivity reactions to drugs such as anticonvulsants (e.g., phenytoin, carbamazepine, phenobarbital), sulfonamides (e.g., sulfamethoxazole, sulfasalazine), minocycline, cefaclor, and abacavir. These specific ADRs are not characteristic of type I (i.e., immediate) hypersensitivity reactions (e.g., true penicillin allergy) or anaphylactoid reactions, but rather have been previously classified as idiosyncratic with respect to their origin. A relatively common constellation of symptoms (fever, rash, and lymphadenopathy) suggests that abnormal activation/regulation of the immune system is a predominant component of the pathogenesis. Data from in vitro studies of sulfamethoxazole hypersensitivity also support this assertion. In addition, a requisite role for metabolic bioactivation (for anticonvulsants, sulfamethoxazole, and cefaclor) and possibly genetic factors such as allelic variants in HLA-B (e.g., HLA-B*6001 and HLA-B*1502 associated with hypersensitivity reactions to abacavir and carbamazepine) appears also to be involved in their etiology.
Personalized Medicine

The general concept of personalized medicine involves the application of genomic information to predicting a disease, disease severity, and therapeutic response (see Chapter 72). This “new vision of medicine” has been described as the “3 Ps”: predictive, personalized, and preventive. In children, however, ontogeny should also be considered when discussing personalizing therapy. Thus the aim of pediatric personalized medicine is uniquely to combine genetic variation with developmental stage to provide a tailored preventive, diagnostic, and therapeutic regimen.

Bibliography

The continuum of anesthesia includes varying degrees of sedation (i.e., mild, moderate, or deep) and general anesthesia. All forms of sedation are characterized by some preservation of purposeful movement (see Chapter 75), whereas general anesthesia is defined by the complete loss of consciousness. Potent pharmacologic agents are required to suppress the perception and physiologic response to noxious stimuli. Perioperatively, the anesthesiologist is responsible for providing analgesia while preserving physiologic and metabolic stability (Table 74.1). This responsibility begins with the performance of a comprehensive preanesthesia history (Table 74.2). Although anesthetic risk has greatly decreased with advancements in pharmacology and monitoring technology, the persistent risk of perioperative morbidity and mortality demands vigilance. The risk is elevated in certain disease states (Table 74.3).

The Preanesthetic History
Child's previous anesthetic and surgical procedures:
  • Review previous anesthetic records:
    Ease of mask ventilation
    Grade of laryngoscopy; type and size of laryngoscope; endotracheal tube size
    Issues during emergence (awakening) from anesthesia (postoperative vomiting, emergence delirium)
    History of hyperthermia or acidosis in the child or family members.
Perinatal problems (especially for infants):
  • Prematurity
  • Need for supplemental oxygen or intubation and ventilation
  • History of apnea and bradycardia
  • History of cardiovascular compromise
Other major illnesses and hospitalizations
Family history of anesthetic complications, malignant hyperthermia, or pseudocholinesterase deficiency
Respiratory problems:
  • Long-term exposure to environmental tobacco smoke
  • Obstructive breathing score
  • STBUR (snoring, trouble breathing, un-refreshed)
  • Cyanosis (especially in infants <6 mo of age)
  • Recurrent respiratory infections
  • Recent lower respiratory tract infection
  • Previous laryngotracheitis (croup) or laryngomalacia
  • Reactive airway disease
  • Airway abnormalities, facial anomalies, mucopolysaccharidosis
Cardiac problems:
  • Murmur or history of congenital heart disease
  • Dysrhythmia
  • Exercise intolerance
  • Syncope
  • Cyanosis
Gastrointestinal problems:
  • Reflux and vomiting
  • Feeding difficulties
  • Failure to thrive
• Liver disease
Exposure to infectious pathogens
Neuromuscular problems:
  • Neuromuscular diseases
  • Developmental delay
  • Myopathy
  • Seizure disorder
Hematologic problems:
  • Anemia
  • Bleeding diathesis
  • Tumor
  • Immunocompromise
  • Prior blood transfusions and reactions
Renal problems:
  • Renal insufficiency, oliguria, anuria
  • Fluid and electrolyte abnormalities
Psychosocial considerations:
  • Drug abuse, use of cigarettes or alcohol
  • Physical or sexual abuse
  • Family dysfunction
  • Previous traumatic medical or surgical experience
  • Psychosis, anxiety, depression
Gynecologic considerations:
  • Sexual history (sexually transmitted infections)
  • Possibility of pregnancy
Current medications:
  • Prior administration of corticosteroids
Allergies:
  • Drugs
  • Iodine
  • Latex products
  • Surgical tape
  • Food (especially soya and egg albumin)
Dental condition (loose or cracked teeth)
When and what the child last ate (especially in emergency procedures)
Specific Pediatric Diseases and Their Anesthetic Implications

Preanesthetic Evaluation

All children presenting for surgery should undergo a preanesthetic history and multiorgan system assessment with assignment of American Society of Anesthesiologists Physical Status (ASA-PS) (Table 74.4). Children of ASA-PS I-II generally require a brief history, notation of medical allergies, and physical examination focusing on the neurologic and cardiorespiratory systems, with no additional testing. Patients with complex medical history of ASA-PS ≥III require a more comprehensive preanesthetic assessment often with ancillary preoperative testing. Children should be screened for anesthetic risks, including drug allergies, previous reactions to anesthetics, and family history of problems with anesthesia (e.g., sudden perioperative death, hyperthermia after surgery),
which may indicate risk of malignant hyperthermia.

Additional classification: “E”—emergency surgery

Respiratory System

Recent respiratory tract infections should be noted. *Clear rhinorrhea without fever is not associated with increased anesthetic risk.* Respiratory illnesses associated with fever, mucopurulent nasal discharge, productive cough, or lower respiratory symptoms (wheezing, rales) are associated with increased airway reactivity and anesthetic complications for up to 6 wk thereafter. There may also be increased risk of perioperative laryngospasm and bronchospasm, reduced mucociliary clearance, atelectasis, and hypoxemia. It is recommended that elective procedures requiring general anesthesia be postponed 4-6 wk in this setting.

Children with reactive airway disease require a thorough preanesthetic assessment. Acute, potentially fatal bronchospasm can occur during induction of anesthesia and endotracheal intubation for routine, minor surgery in children with asthma. Children at increased risk for anesthetic complications have
experienced asthma exacerbations requiring (1) hospital admission within the previous year; (2) emergency department (ED) care within the last 6 mo; (3) previous intensive care unit (ICU) admission; or (4) previous parenteral systemic corticosteroids. Ideally, children should be free of wheezing for at least several days before surgery, even if this necessitates increased controller medication administration (β-adrenergic agonist and corticosteroids). Active wheezing is an indication for delaying elective surgery. Chronic respiratory conditions such as bronchopulmonary dysplasia and cystic fibrosis are also associated with significant intraoperative risks. Every effort should be made to ensure that children with such disorders achieve optimal respiratory status before surgery.

**Airway Evaluation**

Induction of general anesthesia is associated with reduced spontaneous ventilation and airway reflexes. Prediction of difficult bag-mask ventilation and/or intubation before anesthesia is critical. Congenital anomalies associated with airway compromise include micrognathia, macroglossia, and thoracic anomalies (Table 74.5). Conditions that impair mouth opening (e.g., temporomandibular joint disease) should also be noted. A history of wheezing or stridor may indicate postoperative airway complications and difficult intraoperative airway management. It is also essential to ask about a history of sleep-disordered breathing using the STBUR (snoring, trouble breathing, un-refreshed) index, which may be predictive of perioperative respiratory complications.

Cardiovascular System
Most anesthetic agents possess myocardial depressant properties. All patients should be screened for the presence of heart disease. Important cardiovascular considerations include history of congenital heart disease (CHD), cyanosis, arrhythmias, or cardiomyopathy. Room-air pulse oximetry should be performed as part of the preanesthetic evaluation. Accurate diagnosis of cardiac murmurs in neonates is essential. A history of cardiac dysrhythmias should be investigated because inhalational anesthetics may be arrhythmogenic. A pediatric cardiologist should evaluate children with known CHD undergoing surgery. Preoperative ancillary studies may include electrocardiogram (ECG), echocardiogram, or cardiac catheterization. Lesions associated with increased anesthetic risk include single-ventricle heart disease, fixed obstructive outflow tract lesions (aortic valve and pulmonary valve stenosis), and cardiomyopathy. Children with these conditions should be cared for by a cardiac anesthesia service. Antibiotic prophylaxis for the prevention of bacterial endocarditis may also be indicated, and the American Heart Association (AHA) guidelines should be followed.

Hematologic System
Evidence of coagulopathy should be sought. Easy bruising, familial bleeding disorders, and anticoagulant (e.g., aspirin, heparin, warfarin) use should be discussed. Preoperative adequacy of hemostatic function (e.g., platelet count, fibrinogen, prothrombin time, partial thromboplastin time) and correction of coagulopathic disorders may be indicated for complex procedures associated with significant risk of perioperative hemorrhage. In neonates, assurance of vitamin K prophylaxis and adequate coagulation status is critical before any major surgery. Although anemia may be well tolerated in healthy children,
anesthesia and surgery increase oxygen consumption. Preoperative anemia should be corrected in the setting of reduced oxygen delivery or expected blood loss. In the patient with life threatening hemorrhage (trauma), massive transfusion protocols of 1 : 1:1 replacement of packed red blood cells:fresh-frozen plasma:platelets should be used.

**Neurologic System**

A history of neurologic and neuromuscular disorders should be sought. Preoperative developmental assessments may be helpful in interpreting age-dependent variation in the response to pain. Maintenance of appropriate perioperative anticonvulsant therapy is essential in children with seizure disorders because the seizure threshold may be lowered perioperatively. Children with obstructive hydrocephalus typically require ventriculoperitoneal (VP) shunt insertion to divert cerebrospinal fluid (CSF) and to prevent intracranial hypertension (ICH). Repeated shunt malfunction is common, and these children may present for shunt revision with signs of ICH (vomiting, altered mentation, sundowning). Similarly, shunt patency and function should be ensured preoperatively in children with VP shunts presenting for nonneurosurgical procedures.

**Psychological Assessment**

Surgery and painful medical procedures are psychologically traumatic events for children and families. Children who require anesthesia may experience fear and anxiety. They may also sense stressful signals from parents and caregivers. Many children undergoing surgery have new-onset negative behavioral changes postoperatively. These maladaptive behavioral responses may include enuresis, separation anxiety, temper tantrums, and nighttime crying, as well as fear of strangers, doctors, and hospitals. Sleep quality may be altered postoperatively, resulting in further behavioral compromise. Risk factors for postoperative behavioral changes include preoperative anxiety and emergence excitation. Need for recurrent procedures is another risk factor. Preoperative psychological preparation programs decrease the incidence of postoperative behavioral changes. **Parental presence during induction (PPI)** has not been shown to improve postoperative behavior (see later). Oral midazolam (0.5 mg/kg) may decrease negative behavioral changes after surgery. Midazolam has the benefit of
providing rapid-onset anxiolysis and amnesia.

Genetic Evaluation

Children with genetic conditions may have syndrome-specific anesthetic considerations. For example, children with trisomy 21 may have cardiac anomalies, macroglossia, upper airway obstruction, and hypothyroidism (see Chapter 98.2). Atlantoaxial instability, common in trisomy 21, has been linked to cervical dislocation and spinal cord trauma with neck extension during intubation. Some anesthesiologists recommend extension and flexion lateral neck films to detect instability before surgery. For children with other known genetic disorders it is essential to review specific anesthetic considerations.

Preoperative Preparation

Preoperative Fasting

Preoperative fasting guidelines have been developed to reduce the incidence of aspiration of gastric contents during anesthesia. Aspiration may lead to laryngospasm, bronchospasm, and postoperative pneumonitis. Aspiration of gastric contents may be a potentially lethal complication in children with chronic lung disease or critical illness. Table 74.6 lists preoperative fasting guidelines (e.g., nothing by mouth, or nil per os [NPO] status). Clear, sweet liquids (e.g., Pedialyte, 5% dextrose in water [D5W]) facilitate gastric emptying, prevent hypoglycemia, and may be given up to 2 hr before anesthesia. Breast milk may be given to infants up to 4 hr before surgery. Solids should be avoided for 6-8 hr before surgery. Many conditions delay gastric emptying and may require prolonged periods of fasting.

* These are general guidelines and may differ among hospitals.
The Full Stomach

Gastric emptying may be delayed for up to 96 hr after an acute episode of trauma or surgical illness. Because of the serious complications of aspiration of gastric contents, it is desirable to secure the airway as rapidly as possible during induction of anesthesia in patients at risk for having a full stomach. Under these circumstances, rapid sequence induction of anesthesia is indicated (rapid sequence induction; see Chapter 89).

Parental Presence During Induction of Anesthesia

Parents may expect to be with their child during the induction of anesthesia. Removing a fearful child from the comforting arms of a parent is stressful for the child, parents, and caregivers. When parental separation cannot be achieved comfortably with premedication and behavioral modification (patient education and desensitization to the operative environment), there may be a need to defer parent–child separation until general anesthesia is induced. Premedication with the oral benzodiazepine midazolam more frequently provides calm, smooth induction conditions than PPI without pharmacologic preparation. Although PPI in the hands of a confident, competent anesthesia practitioner may replace the need for preoperative medication, it does not reliably predict smooth induction. PPI has not been shown to decrease emergence delirium or postoperative behavioral changes, and it does not appear to be superior to premedication with oral midazolam.

General Anesthesia Analgesia

Pediatric anesthesiologists are responsible for providing analgesia to children for procedures within operating room (OR) and non-OR settings (Table 74.7). Multimodal techniques exist to provide pain relief during operative procedures for children of all ages, including critically ill infants. Effective analgesia is essential to blunt physiologic responses to painful stimuli (surgery) and modulate the deleterious physiologic and metabolic consequences. The response to painful and stressful stimuli may provoke systemic inflammatory response.
syndrome \textit{(SIRS)}, which has been linked to increased catabolism, physiologic instability, and mortality (see Chapter 88).

Table 74.7

\textbf{Definitions of Anesthesia Care}

\textbf{Monitored Anesthesia Care}

A designated anesthesia service in which an anesthesiologist has been requested to participate in the care of a patient undergoing a diagnostic or therapeutic procedure.

Monitored anesthesia care includes all aspects of anesthesia care: a preprocedure assessment, intraprocedure care, and postprocedure anesthesia management.

During monitored anesthesia care, the anesthesiologist or a member of the anesthesia care team provides a number of specific services, which may include but are not limited to the following:

- Discussing anesthesia care with the family and child, obtaining consent for anesthesia, allaying anxiety and answering questions—family-centered anesthesia care.
- Monitoring of vital signs, maintenance of the patient's airway, and continual evaluation of vital functions.
- Diagnosing and treating clinical problems that occur during the procedure.
- Administering sedatives, analgesics, hypnotics, anesthetic agents, or other medications as necessary to ensure patient safety and comfort.
- Providing other medical services as needed to accomplish the safe completion of the procedure.

Anesthesia care often includes the administration of medications for which the loss of normal protective reflexes or loss of consciousness is likely. \textit{Monitored anesthesia care} refers to those clinical situations in which the patient remains able to protect the airway for the majority of the procedure.

If the patient is rendered unconscious and/or loses normal protective reflexes for an extended period, this is considered a general anesthetic.
Light Sedation

Administration of anxiolysis or analgesia that obtunds consciousness but does not obtund normal protective reflexes (cough, gag, swallow, hemodynamic), or spontaneous ventilation.

Deep Sedation

Sedation that obtunds consciousness and normal protective reflexes or possesses a significant risk of blunting normal protective reflexes (cough, gag, swallow, hemodynamic), hemodynamic and respiratory insufficiency may occur.

General Anesthesia

Administration of hypnosis, sedation, and analgesia that results in the loss of normal protective reflexes.

Regional Anesthesia

Induction of neural blockade (either central, neuraxial, epidural, or spinal; or peripheral nerve block, e.g., digital nerve block, brachial plexus block), which provides analgesia and is associated with regional motor blockade.

Consciousness is not obtunded.

Special expertise is required.

Frequently, in children, anxiolysis and sedation are also necessary for this technique to be successful.

Regional anesthesia (e.g., caudal epidural blockade) is used to supplement general anesthesia and provide postoperative analgesia.

Local Anesthesia

Provision of analgesia by local infiltration of an appropriate anesthetic agent.
Does not require the presence or involvement of an anesthesiologist, although an anesthesiologist may provide local anesthesia services.

No Anesthesiologist

An anesthesiologist will not be involved in the care of the child.

Hypnosis and Amnesia

The attenuation of both consciousness (**hypnosis**) and conscious recall (**amnesia**) is critical during pediatric anesthesia care. Awareness during procedures may be as physically and psychologically deleterious as the experience of pain. A primary goal of anesthetic management is to minimize fear and anxiety during both painful and nonpainful procedures. Many drugs provide anxiolysis and amnesia for such events (Table 74.8). However, it is important to remember that sedative-hypnotic agents may alter consciousness without producing analgesia; **analgesia** and **hypnosis** are not synonymous. It is also possible to provide analgesia (local, spinal, or epidural) without altering consciousness.

</table>

**Etomidate**
- Cardiovascular stability on induction
- Inhibits corticosteroid synthesis
- Increases ICU mortality after use
- Associated with myoclonus and pain on injection

**Ketamine**
- Hypnotic analgesic
- Causes sialorrhea and should be co-administered with an antisialogue, such as atropine or glycopyrrolate
- Induces endogenous catecholamine release and tachycardia
- Bronchodilator
- Increases intracranial and intraocular pressures
- Decreases the seizure threshold

**SEDATIVE-ANXIOLYTICS**

**Benzodiazepines**
- Produce sedation, anxiolysis, amnesia, and hypnosis
- All agents raise the seizure threshold, are metabolized by the liver, and depress respiration, especially when administered with opioids.
- Effective as premedication
- Diazepam may be painful on injection and has active metabolites.
- Midazolam can be administered by various routes.
- Lorazepam has no active metabolites.
- Reversed with flumazenil

**Dexmedetomidine**
- Produces anxiolysis, sedation, sympatholysis, by α<sub>2</sub>-receptor stimulation centrally; has mild analgesic properties
- Side effects include hypertension, hypotension, and bradycardia.
- Commonly used for procedural and ICU sedation
- Continuous infusion for ICU sedation

**ANALGESIC-SEDATIVES**

**Opioids**
- Gold standard for providing analgesia
- All cause respiratory depression.
- Morphine and, to a lesser extent, hydromorphone may cause histamine release.
- The synthetic opioids fentanyl, sufentanil, and short-acting alfentanil may have a greater propensity to cause chest wall rigidity when administered rapidly or in high doses and are also associated with the rapid development of tolerance. These drugs have particular utility in cardiac surgery because of the hemodynamic stability associated with their use.
- Remifentanil is an ultrashort-acting synthetic opioid that is metabolized by plasma cholinesterase; it may have particular utility when deep sedation and analgesia are required along with the ability to assess neurologic status intermittently.

**INHALATIONAL AGENTS**

**Nitrous oxide**
- Produces amnesia and analgesia at low concentrations
- Danger of hypoxic gas mixture if the oxygen concentration is not monitored and preventive safety mechanisms are not in place

**Potent vapors, sevoflurane, desflurane, isoflurane**
- "Complete anesthetics"—induce hypnosis, analgesia, and amnesia
- All are myocardial depressants, and some are vasodilators.
- May trigger malignant hyperthermia in susceptible individuals
- Sevoflurane is used for induction of anesthesia in children.
- All bronchodilate at equipotent concentrations.
- Isoflurane and desflurane are associated with laryngospasm and should not be used for anesthesia induction.
Sedation describes a medically induced state in the continuum between wakefulness and general anesthesia (see Table 74.7). General anesthesia is characterized by unconsciousness, amnesia, and reduced physiologic reflexes. Cardiorespiratory reflexes (airway-protective and vasomotor reflexes) are reduced with general anesthesia. Light (minimal) sedation is anxiolysis with minimally reduced reflexes or airway patency. Deep sedation occurs when cardiorespiratory reflexes are obtunded or lost. Respiratory depression and hemodynamic compromise may be profound. As sedation deepens toward general anesthesia, loss of airway patency, loss of airway-protective reflexes, and loss of cardiovascular stability occur. Individuals providing sedation and anesthesia for children must be able to detect and support cardiorespiratory insufficiency.

Akinesia (Immobility or Muscular Relaxation)

Akinesia, the absence of movement, is commonly indicated to ensure safe and adequate operative conditions. Neuromuscular blocking agents (NMBAs) may be used to produce akinesia (see Table 74.8). However, the absence of movement is not indicative of hypnosis, amnesia, or analgesia. Whenever NMBAs are used, analgesia and sedation must be provided.

Monitoring

Administration of anesthesia increases the need to monitor and support physiologic integrity and homeostasis due to potentially life-threatening physiologic consequences (see Tables 74.7 and 74.8). Consequently, ASA mandates routine monitoring of oxygenation, ventilation, and circulation during the provision of anesthesia. This includes assessment of continuous pulse oximetry, capnography, electrocardiography, intermittent blood pressure measurements (every 5 min), and temperature when temperature instability is anticipated. The use of advanced invasive or noninvasive monitors varies based on procedural complexity and ASA-PS.

Specific Medications

Inhalational Anesthetics

Inhalational anesthetics are frequently used for the induction and maintenance of
general anesthesia in children. Pediatric inhalational anesthetics include sevoflurane, isoflurane, and desflurane. Although halothane is the prototypical pediatric inhalational anesthetic, it has been replaced by sevoflurane and is no longer used in the United States.

The **minimum alveolar concentration (MAC)** of an inhalational anesthetic is the alveolar concentration (expressed as percent at 1 atmosphere) that provides sufficient depth of anesthesia for surgery in 50% of patients. For potent inhalational agents, the alveolar concentration of an anesthetic reflects the arterial concentration of anesthetic in the blood perfusing the brain. Thus the MAC is an indication of anesthetic potency and is analogous to the \( \text{ED}_{50} \) (effective dose in 50% of recipients) of a drug. MAC is age dependent. MAC is lower in premature than in full-term infants and decreases from term through infancy to preadolescence. In adolescence, MAC again increases, falling thereafter.

**Respiratory Effects.**

The advantages of inhalational anesthesia are rapid onset and offset with the convenient route of delivery and respiratory excretion. These agents provide profound analgesia and amnesia. Inhalational anesthetic agents are poorly soluble in blood but rapidly equilibrate between alveolar gas and blood. They are airway irritants that may provoke laryngospasm. All inhalational anesthetics depress ventilation in a dose-dependent manner. Thus, expired carbon dioxide (CO\(_2\)) and Paco\(_2\) (arterial partial pressure of CO\(_2\)) will increase in spontaneously breathing children. Inhalational anesthetics also shift the CO\(_2\) response curve to the right, thus decreasing the normal increase in minute ventilation with increasing Paco\(_2\). Inhalational anesthesia decreases end-expiratory lung volume (functional residual capacity). Small lung volumes are associated with reduced lung compliance, increased pulmonary vascular resistance, and restrictive lung defects. Volatile agents depress normal hypoxic pulmonary vasoconstriction, increasing intrapulmonary arteriovenous shunting and hypoxemia.

**Cardiovascular Effects.**

All volatile anesthetic agents reduce cardiac output and peripheral vascular resistance; hypotension is common. This is accentuated in hypovolemic patients and more pronounced in neonates. Inhalational anesthetics also depress
baroreceptor and heart rate responses. The administration of inhalational anesthesia may result in decreased tissue oxygen delivery. Perioperatively, cellular metabolism increases, creating a potential imbalance between oxygen demand and oxygen delivery. Development of intraoperative dysoxia is a sign of this imbalance. All volatile inhalational anesthetic agents cause **cerebrovasodilation** and uncouple cerebral blood flow with cerebral metabolic rate. Although inhalational anesthetics decrease cerebral oxygen consumption, they may also disproportionately increase cerebral oxygen blood flow. Thus, inhalational anesthetics should be used with caution in children who have elevated intracranial pressure (ICP) or impaired cerebral perfusion (i.e., traumatic brain injury).

**Sevoflurane**
Sevoflurane is the most commonly used inhalational agent for induction and maintenance of general anesthesia in children. Sevoflurane is not a significant airway irritant and is a useful induction agent when co-administered with nitrous oxide. Emergence from sevoflurane anesthesia is rapid; however, there is a significant incidence of **emergence delirium**, especially with inadequate pain control. This effect may be attenuated with adequate analgesia and supplemental hypnotic agents (e.g., midazolam, dexmedetomidine, propofol), although hypnotics may delay recovery from anesthesia. Metabolism of sevoflurane by cytochrome P450 (CYP) yields free fluoride, which may be potentially nephrotoxic. Sevoflurane degradation by desiccated CO₂ absorbents at low fresh gas flows (<2 L/min) may produce the nephrotoxin Compound A. Large-scale studies of sevoflurane-associated renal injury in humans are lacking. However, the U.S. Food and Drug Administration (FDA) has recommended maintenance of fresh gas flow rates >2 L/min for surgical cases lasting >2 MAC hr.

**Isoflurane**
Isoflurane is a pungent volatile anesthetic and airway irritant, not suitable for induction because of the high incidence of complications, such as laryngospasm. However, maintenance of anesthesia with isoflurane is common after induction with sevoflurane or an intravenous (IV) hypnotic. Emergence from anesthesia with isoflurane is slower than for sevoflurane. Isoflurane administration in the setting of desiccated CO₂ absorbents may yield the production of carbon monoxide.
Desflurane
Desflurane is a potent airway irritant associated with coughing, breath holding, and laryngospasm and is not useful for induction. Desflurane has the lowest solubility and potency of all commonly used volatile agents. It is frequently administered for maintenance of anesthesia. Emergence from desflurane anesthesia is rapid due to its low tissue solubility.

Nitrous Oxide
Nitrous oxide (N\textsubscript{2}O) is a tasteless, colorless, odorless gas with potent analgesic properties. It produces a state of euphoria (thus its nickname, “laughing gas”). The MAC of N\textsubscript{2}O is >100; consequently, it may not be used as a sole agent to maintain anesthesia. N\textsubscript{2}O produces little hemodynamic or respiratory depression. N\textsubscript{2}O is typically used in combination with volatile and IV anesthetic agents during maintenance of general anesthesia. The deleterious effects of N\textsubscript{2}O include postoperative nausea and vomiting and, with long-term use (i.e., days), bone marrow suppression. N\textsubscript{2}O diffuses out of blood rapidly and is contraindicated in patients with closed gas-filled body cavities (pneumothorax, lung cysts, bowel injury).

Intravenous Anesthetic Agents
Intravenous anesthetics may be administered for induction and maintenance of anesthesia in bolus form or as continuous infusions. Common IV agents include propofol, opioids, benzodiazepines, ketamine, dexmedetomidine, and barbiturates. For children with vascular access, IV induction should be routine. All IV agents affect cardiorespiratory function.

Propofol
Propofol is the most commonly administered IV induction agent. Administered in doses of 2-5 mg/kg, propofol rapidly produces unconsciousness. Propofol may burn and itch on injection. After induction of anesthesia, propofol is a useful agent for maintaining hypnosis and amnesia and may be used as a sole anesthetic agent for nonpainful procedures (e.g., radiation therapy) and imaging studies. When combined with opioids, propofol provides excellent anesthesia for brief painful procedures, such as lumbar puncture and bone marrow aspiration.
Although hemodynamic stability, and even spontaneous respirations, may be maintained during propofol administration, it remains a potent anesthetic that obtunds airway reflexes, respiration, and hemodynamic function, and should not be considered a “sedation agent.” Propofol frequently induces both respiratory depression and hypotension. Extrapyramidal symptoms are a rarer complication. Prolonged use may cause hemodynamic collapse, bradycardia, metabolic acidosis, cardiac failure, rhabdomyolysis, hyperlipidemia, profound shock, and death (propofol infusion syndrome). Prolonged propofol administration (>24-48 hr) in the ICU in children is not recommended. Propofol is formulated in 10% soy emulsion with egg emulsifiers and was once thought to be contraindicated in patients with soy or egg allergy. According to the American Academy of Allergy, Asthma, and Immunology, however, patients with soy and egg allergies may safely receive propofol for anesthesia.

**Etomidate**

Etomidate is an imidazole derivative used for the induction of anesthesia, frequently in emergent situations. Its onset of action is slower than propofol. Etomidate lacks significant cardiovascular depressant effects, making it a popular induction agent in patients with hemodynamic compromise, cardiac disease, and septic shock. However, etomidate inhibits 11β-hydroxylase, thereby suppressing mineralocorticoid and glucocorticoid synthesis for up to 72 hr after a single induction dose. Etomidate is associated with increased mortality when used as a sedative in the ICU (for which it is now contraindicated), even with a single induction dose. Any decision to use etomidate must weigh the short-term benefits of hemodynamic stability with the serious risks of adrenal suppression.

**Ketamine**

Ketamine (1-3 mg/kg IV) produces rapid induction of general anesthesia that lasts for 15-30 min. Ketamine is effective when given intramuscularly, subcutaneously, nasally, or orally. However, the dose must be increased for alternative routes. Ketamine dissociates connections between the cerebral cortex and limbic system (dissociative anesthesia) through inhibition of N -methyl-D - aspartate receptors. Ketamine is also an analgesic and may be used as a sole IV agent to provide general anesthesia. It has few side effects and generally preserves blood pressure and cardiac output. However, ketamine increases myocardial oxygen demand and should be used cautiously in patients with
impaired myocardial oxygen delivery or ventricular outflow tract obstruction. With low-dose (1-2 mg/kg) ketamine, airway reflexes and spontaneous ventilation may be maintained; at higher doses (3-5 mg/kg), loss of airway reflexes, apnea, and respiratory depression occur. Aspiration of gastric contents remains a risk during deep sedation with ketamine. IV ketamine is a useful general anesthetic agent for short procedures.

Ketamine has been linked to disturbing postanesthetic dreams and hallucinations following emergence from anesthesia. In adults the incidence of this effect is 30–50%; in prepubertal children it may be 5–10%. Benzodiazepines (e.g., midazolam) reduce these sequelae and should be routinely given to children receiving ketamine. Ketamine is also a potent secretagogue, enhancing oral and bronchial secretions. An antispasmodic, such as atropine or glycopyrrolate, should also be considered before the administration of ketamine. Ketamine is a bronchodilator and is a useful agent for sedating asthmatic patients in the ICU. Ketamine has been reported to increase ICP and therefore is contraindicated in patients with elevated ICP.

**Opioids**

Opioids are superb analgesics for painful procedures and postprocedural pain (see Chapter 75). Opioids are respiratory depressants that suppress CO₂ responsiveness and can produce apnea. Importantly, in equianalgesic doses, all opioids are equally potent respiratory depressants. Other inhalational or IV anesthetics generally potentiate opioid-induced respiratory depression.

**Morphine** is a long-acting opioid analgesic with important age-dependent pharmacokinetics. Large doses of morphine (0.5-2 mg/kg), combined with N₂O provide adequate analgesia for painful procedures. Equivalent doses of morphine per kilogram are associated with higher blood levels in neonates than in older children, with plasma concentrations approximating 3 times those of adults. Morphine exhibits a longer elimination half-life (14 hr) in young children than in adults (2 hr). The immature blood-brain barrier of neonates is more permeable to morphine. Morphine is often associated with hypotension and bronchospasm from histamine release and should be used with caution in children with asthma. Morphine has renally excreted active metabolites and is relatively contraindicated in renal failure. Because of morphine's prolonged duration of action and cardiorespiratory side effects, the fentanyl class of synthetic opioids has increased in popularity for perioperative analgesia.
**Fentanyl** is a potent synthetic opioid with a shorter duration of action and a more stable hemodynamic profile than morphine. Fentanyl attenuates the hemodynamic response to surgery and provides stable operating conditions. Effective analgesia and anesthesia may be provided with IV fentanyl administered as a 2-3 µg/kg bolus followed by a 1-3 µg/kg/hr continuous infusion. Nitrous-narcotic anesthetic techniques that incorporate fentanyl are effective for maintenance of stable hemodynamics while still providing adequate hypnosis and analgesia. Fentanyl is the most commonly used *synthetic* opioid, but other formulations of varying potency are available (alfentanil < fentanyl < sufentanil). **Sufentanil** is 10 times more potent than fentanyl and is frequently used during pediatric cardiac anesthesia. **Alfentanil** is approximately ⅓ as potent as fentanyl. **Remifentanil** has very rapid onset and offset of action. In doses of 0.25 µg/kg/min, surgical anesthesia can be maintained with this agent. Remifentanil is metabolized through nonspecific ester hydrolysis and has a short elimination half-life (<10 min) advantageous for rapid emergence from anesthesia. Unfortunately, this short duration of action has been linked to inadequate postprocedural analgesia and increased need for postprocedural opioid analgesic supplementation, limiting remifentanil's use.

**Benzodiazepines**

Benzodiazepines induce hypnosis, anxiolysis, sedation, and amnesia and have anticonvulsant properties. In high doses, benzodiazepines cause respiratory depression and are synergistic with opioids and barbiturates in their respiratory depressant effects. Benzodiazepines are γ-aminobutyric acid (GABA) agonists. **Midazolam** is the most commonly used benzodiazepine in pediatric anesthesia. Short acting and water soluble, it can be injected without pain. It is a potent hypnotic-anxiolytic-anticonvulsant and is approximately 4 times more potent than diazepam. Midazolam may be administered orally, nasally, rectally, intravenously, or intramuscularly. Midazolam (0.10-0.15 mg/kg IV) has minimal effect on respiratory rate, heart rate, or blood pressure and provides excellent preoperative anxiolysis and amnesia. Premedication with oral midazolam (0.5-1.0 mg/kg) mixed in sweet-flavored syrup induces anxiolysis in approximately 90% of children without hemodynamic or respiratory depressant effects. However, children may experience loss of coordination (head control), blurred vision, and rarely dysphoria. A child sedated with midazolam should not be left unattended. Most children rapidly accept an inhalational anesthetic by face mask after oral midazolam premedication. The widespread use of preoperative oral
midazolam has decreased the practice of PPI.

**Dexmedetomidine**

Dexmedetomidine is a central $\alpha_2$ adrenergic receptor agonist similar to clonidine. Dexmedetomidine lacks respiratory depressant effects and produces anxiolysis, sedation, mild analgesia, and sympatholysis. Interestingly, rapid bolus administration may produce hypertension and bradycardia, whereas continuous infusions may produce hypotension and bradycardia. Dexmedetomidine is frequently used for sedation in ICU patients as well as for procedures. Dexmedetomidine has become a popular adjuvant for general anesthesia during pediatric cardiac surgery.

**Barbiturates**

*Sodium thiopental* is the classic barbiturate IV induction agent, although it is now rarely used. Side effects of thiopental include respiratory depression, apnea, and hypotension. Induction with 3-5 mg/kg of thiopental produces unconsciousness within seconds, lasting 5-10 min. Thiopental is not useful for maintenance of anesthesia, which requires other IV or inhalational anesthetics. Pentobarbital is a barbiturate frequently administered IV for sedation in children during imaging procedures of intermediate duration (e.g., imaging studies) that require akinesia. **Pentobarbital** is a potent respiratory depressant, particularly when combined with opioids and benzodiazepines. Pentobarbital has a prolonged duration of action. Pentobarbital sedation for nonpainful procedures generally results in delayed emergence. *Sodium methohexitol* (Brevital) is another IV induction agent, similar to sodium thiopental in respiratory depressant effects. Barbiturates lack analgesic properties, and painful procedures require supplemental analgesia.

**Neuromuscular Blocking Agents**

Neuromuscular blockade is performed to facilitate endotracheal intubation and akinesia during surgery. NMBAs may be *depolarizing* (e.g., succinylcholine) or *nondepolarizing* (e.g., vecuronium, rocuronium, cisatracurium). **Succinylcholine** has a high-risk profile in children. Its use is associated with postoperative pain from muscle spasms; hyperkalemia; elevated intracranial, intraocular, and intragastric pressures; malignant hyperthermia; myoglobinuria; and renal damage. Consequently, succinylcholine is now rarely used, except to provide
rapid relief of laryngospasm. Endotracheal intubation is most often facilitated with nondepolarizing NMBAs. **Rocuronium** is most commonly used for intubation because of its rapid onset of action. For procedures that last >40 min, **vecuronium** and **cisatracurium** are also suitable to induce muscle relaxation for intubation. After intubation, repeat administration of NMBAs may be indicated to maintain muscle relaxation to facilitate surgery. Prolonged use of nondepolarizing NMBAs in critical illness may contribute to myopathy, especially when combined with high-dose corticosteroids.

### Induction of General Anesthesia

The primary goal of induction of general anesthesia is the rapid and safe transition to a state of unconsciousness. Induction in children is usually achieved by inhalational anesthetics, although IV agents are indicated when patients have IV access. Many children will not tolerate the establishment of vascular access before induction of anesthesia, and it is routine to induce anesthesia by face mask with inhaled anesthetics. Before the induction of anesthesia, monitors applied may include pulse oximetry, ECG, and noninvasive blood pressure cuff. The child is then cautiously introduced to the face mask, which contains a high gas flow (5-7 L/min $O_2$), frequently mixed with $N_2$O. Inhalation of $N_2$O and $O_2$ for 60-90 sec induces a state of euphoria. Nitrous oxide blunts the airway responses to potent volatile inhalational agents, and sevoflurane may then be safely introduced into the inhaled gas mixture. This leads to unconsciousness within 30-60 sec while the child continues to breathe spontaneously.

Following induction, IV access is obtained, and comprehensive intraoperative monitoring initiated. Thereafter, definitive airway management is performed. Airway management for short procedures (i.e., myringotomy tubes) frequently includes a mask airway and spontaneous ventilation; this is safe when the airway is secure, and patent and aspiration risk is low. Longer procedures (>30-60 min) are not usually performed with mask airways. Definitive artificial airways include laryngeal mask airways and endotracheal tubes. The **laryngeal mask** is a supraglottic airway generally reserved for procedures in spontaneously ventilating patients and does not effectively prevent the aspiration of gastric contents.

For complex surgical procedures, **endotracheal intubation** in required (e.g., intraabdominal, intrathoracic, airway). Although endotracheal intubation may be
performed under deep inhalational anesthesia, the depth of anesthesia required to attenuate airway reflexes may produce hemodynamic instability. Therefore, NMBAs are frequently administered to facilitate intubation. The depolarizing NMBA succinylcholine is rarely used, and nondepolarizing NMBAs such as rocuronium and vecuronium are most frequently used (see earlier). After muscle relaxation, direct laryngoscopy and endotracheal intubation can be performed. Correct endotracheal tube (ETT) placement is confirmed by direct laryngoscopy, end-tidal CO\textsubscript{2} measurement, and bilaterally equal breath sounds. Additional confirmatory tests include chest radiograph and fiberoptic bronchoscopy. After endotracheal intubation, controlled mechanical ventilation is required in the setting of neuromuscular blockade (see Chapter 89).

Children with full stomach precautions may require rapid sequence induction. Before performing a rapid sequence induction, preoxygenation with 100% oxygen for 2-5 min increases alveolar oxygen content and provides an extra margin of safety if intubation is difficult. Rapid sequence induction involves concurrent administration of hypnotic and NMBAs. Assisted ventilation before or after drug administration is avoided due to the risk of gastric distention, regurgitation, and aspiration. After administering a sedative and NMBA, the Sellick maneuver (cricoid pressure) is performed by applying firm pressure in a posterior direction, against the cricoid cartilage. This displaces the cricoid cartilage into the esophagus, forming an artificial sphincter to prevent reflux of the gastroesophageal contents. Cricoid pressure should be maintained until correct ETT placement is verified by positive end-tidal CO\textsubscript{2} and bilateral breath sounds.

The major risk of rapid sequence induction is intubation failure. In this situation the child is paralyzed without a protected airway, and ventilation may be hazardous or impossible. Only experienced airway specialists should undertake rapid sequence induction. It should be avoided in patients with a history of failed endotracheal intubation or features (micrognathia) associated with difficult intubation. Under these circumstances, bronchoscopic awake intubation may be indicated.

**Complications During Induction**

During induction of anesthesia the transition between full wakefulness to unconsciousness is fraught with potential complications, including laryngospasm, bronchospasm, vomiting, and aspiration. Concerns for vomiting
and aspiration dictate adherence to preanesthetic fasting guidelines and may be an indication for rapid sequence anesthetic induction.

During induction of anesthesia, especially with inhalational anesthetics, a period of excitement may occur. This period is associated with heightened airway reflexes, which can lead to coughing, gagging, laryngospasm, and bronchospasm. **Laryngospasm** is the reflex closure of the larynx, which prevents spontaneous or assisted ventilation. The child may make violent inspiratory efforts against a closed glottis, generating significantly negative intrathoracic pressure. This may affect cardiovascular function and cause postobstructive pulmonary edema. Laryngospasm can be prolonged, and hypoxia may ensue. Laryngospasm occurs in up to 2% of all anesthetic inductions in children <9 yr old and is much less common in older patients. Laryngospasm occurs twice as frequently in children with active or recent upper respiratory tract infection. A history of tobacco exposure increases the likelihood of laryngospasm significantly.

Laryngospasm can be relieved by increasing the depth of anesthesia, either intravenously or through inhalation (although with the glottis closed, further administration of inhalational anesthesia is not possible). Neuromuscular blockade relieves laryngospasm, and an acute situation may be an indication for succinylcholine administration. Continuous positive airway pressure administration may be beneficial in alleviating laryngospasm. Laryngospasm may also occur during emergence from anesthesia because airway tone is increased during the transition to wakefulness.

**Bronchospasm** may result from increased airway reactivity during the hyperexcitable stage of induction, or secondary to histamine release induced by anesthetic agents. Endotracheal intubation may provoke bronchospasm, especially in asthmatic patients, which may be associated with life-threatening hypoxemia and inability to ventilate. Alternative airway management strategies such as laryngeal mask should be considered when appropriate in children with severe reactive airway disease. The use of histamine-releasing anesthetic agents has been associated with severe bronchospasm, and in rare instances cardiorespiratory failure. Environmental tobacco smoke is another risk factor.

Hypoxemia during induction may be secondary to reduced functional residual capacity, atelectasis, and ventilation-perfusion (V/Q) mismatch. Volatile anesthetics blunt hypoxic pulmonary vasoconstriction further contributing to V/Q abnormalities. **Hypersecretion** may result in airway obstruction and should managed with antisialogues, such as glycopyrrolate and atropine. The newer
inhalation agents are less potent secretagogues, and the routine use of atropine premedication is much less common, but often indicated when ketamine is used. Hemodynamic complications may also develop during induction of anesthesia. **Hypotension** is common and may be exaggerated patients with hypervolemia, decreased myocardial function, or CHD. Inhalational anesthetics sensitize the myocardium to circulating catecholamines, and induction and excitement are associated with a hypercatecholaminergic state.

**Maintenance of Anesthesia**

Maintenance of anesthesia is the period between induction and emergence. The child should be unaware of pain, unresponsive to painful stimuli, and physiologically supported. Anesthesia is typically maintained with a volatile anesthetic (e.g., isoflurane, sevoflurane) supplemented with opioid-based analgesia. IV hypnotic agents (e.g., dexmedetomidine, benzodiazepines) may be administered to augment hypnosis and amnesia. Choice of ventilatory strategy (spontaneous, assisted, or controlled) varies according to procedure type and patient condition (see Chapter 89). Surgical trauma may result in hypothermia and hypovolemia due to blood loss and significant fluid shifts (third spacing). Management of these physiologic disturbances is the responsibility of the anesthesiologist during maintenance.

**Temperature Management**

**Thermoregulation** is critical during anesthesia. The absence of movement and inhibition of shivering reduce thermogenesis. Mechanisms of heat loss during anesthesia include convection, radiation, evaporation, and conduction. Although temperature sensing may remain normal, the autonomic response to hypothermia is reduced. Anesthetic agents cause vasoparesis, which further impairs thermoregulation and increases heat loss. In newborns, inhalational anesthetics inhibit nonshivering thermogenesis from brown fat, increasing the risk for hypothermia. Humidification and warming of inspired gases is required. Additional warming devices, such as forced-air warming blankets and radiant warmers, should also be used.

**Fluid Management**
Most anesthetics produce vasodilation and increase venous capacitance, effectively reducing myocardial preload. Surgical bleeding and insensible/third space fluid losses further contribute to intravascular volume depletion. Volume expansion with isotonic salt-containing solutions (normal saline, lactated Ringer, Plasmalyte) may be required to maintain cardiac output and organ perfusion. Increased renin-angiotensin-aldosterone axis activation and antidiuretic hormone (ADH) secretion further complicate fluid regulation.

Intraoperative fluid management must account for (1) deficits acquired during preoperative fasting, (2) maintenance fluid requirements, (3) surgical blood loss, and (4) insensible fluid loss. Infants should receive glucose-containing isotonic fluid to prevent perioperative hypoglycemia. Table 74.9 is a guideline for determining fluid deficits and maintenance requirements in the OR. For longer procedures, fluid deficits should be replaced with isotonic fluid over the 1st 3 hr of intraoperative management. Deficits are generally calculated as the number of hours of fasting status multiplied by the hourly maintenance rate for the child. Half the deficit is replaced during the 1st hr and half during the subsequent 2 hr. If hypotension or tachycardia persists in the early stages of anesthesia, more rapid replacement of the fluid deficit may be indicated.

</tbody>
</table>

*Example:* 22 kg child requires $(4 \times 10) + (2 \times 10) + (1 \times 2) = 62$ mL/hr

Third space interstitial fluid losses should be replaced with isotonic salt solutions. For smaller operations, such as herniorrhaphy, pyloromyotomy, and minor procedures, fluid replacement at 3-5 mL/kg/hr is indicated for insensible losses. Complex abdominal or thoracic procedures with large insensible losses may require an additional 8-10 mL/kg/hr of IV fluid replacement. Crystalloid solution is indicated for blood loss as a 3 : 1 ratio. Allogenic blood products should be replaced as a 1 : 1 ratio. Colloid (albumin) administration also decreases the amount of crystalloid replacement needed for blood loss. During large-volume transfusions, active fluid warming should be performed to prevent hypothermia. With major surgery and resultant SIRS, capillary integrity is lost.
and third space losses are common. Failure to replace fluid loss and restore intravascular volume may lead to shock.

Perioperative hypoglycemia may result from preoperative fasting, most often in neonates or in children with metabolic disorders. In neonates, perioperative glucose monitoring is indicated and glucose replacement is frequently required. In older children with normal nutritional status, isotonic salt solutions without glucose are adequate. In patients receiving total parenteral alimentation containing high glucose concentrations (>10%), continuous glucose administration should be ensured to avoid rebound hypoglycemia.

Postprocedural care includes supervision of emergence and recovery from anesthesia and surgery. Emergence describes the transition period between the anesthetized state and consciousness. During emergence, patients experience decreased anesthetic effect and increased physiologic and psychological responses to painful stimuli (e.g., reactive autonomic tone, excitement, anxiety). Inhalational anesthetic agents are rapidly excreted during ventilation, and muscle relaxants can be reversed; however, the effects of opioids, benzodiazepines, and IV hypnotics may be prolonged. Normal physiologic functions such as spontaneous ventilation resume, and hemodynamic function improves. Before leaving the OR after routine elective procedures, the child should be conscious with intact airway reflexes and a patent airway. The effects of muscle relaxants should be reversed. Ideally, emergence should be as brief as possible, with maintenance of analgesia and anxiolysis and restoration of cardiorespiratory function. However, critically ill patients scheduled for ICU admission may require postoperative endotracheal intubation and mechanical ventilation. In these patients, deeper levels of sedation and analgesia should be maintained after the procedure.

During emergence, it is essential to assess whether residual neuromuscular blockade (NMB) exists. If weakness or respiratory depression is observed in the postoperative phase, prolonged NMB should be considered. Reversal of residual NMB is standard anesthetic practice. With the virtual abandonment of succinylcholine, only nondepolarizing NMBAs are routinely used for intubation. The termination of NMB depends on metabolism and elution away from the neuromuscular junction. Classically, nondepolarizing muscle relaxants are reversed by increasing the acetylcholine concentration at the neuromuscular junction with acetylcholine esterase inhibitors (neostigmine, edrophonium), which work through competitive antagonism. Vagolytic agents (e.g., atropine, glycopyrrolate) must be co-administered to prevent bradycardia. This process,
even for the shortest-acting muscle relaxant, rocuronium, can take several minutes. An intubating dose of rocuronium to rapidly induce paralysis in emergency situations may not spontaneously reverse for 20 min or longer (compared with about 3 min for succinylcholine). The effects of long-acting, nondepolarizing NMBAs (vecuronium, pancuronium) are invariably reversed. Residual NMB is common despite reversal with these agents. Sugammadex is an alternative reversal agent that has a very low rate of residual NMB. Its mechanism of action involves noncompetitive antagonism through encapsulation of neuromuscular agents.

**Postanesthesia Care Unit**

In the postanesthesia care unit (PACU), the child is observed until there is adequate recovery from anesthesia and sedation. Achievement of spontaneous breathing, adequate pulse oximetry saturation (> 95%), and hemodynamic stability are key recovery end-points. The child should be arousable, responsive, and oriented before discharge from the PACU. The amount of time spent in the PACU varies based on disposition (transfer to acute care or ICU, transfer to day surgery postrecovery unit, or discharge to home). Parents should be permitted to comfort their children in the PACU. Discharge from the PACU depends on the child's overall functional status—not merely the physiologic end-points, but also the adequate provision of analgesia and control of postoperative nausea and vomiting. Various scoring systems have been used for determining readiness for discharge from the PACU (Table 74.10).

**Postanesthetic Complications**

**Respiratory insufficiency** following general anesthesia is common. Prolonged emergence from anesthesia and respiratory depression may be caused by the residual effects of opioids, hypnotic agents, or NMBAs. Pain may also cause significant hypoventilation, especially after thoracic or abdominal surgery. Delayed emergence from anesthesia may result from retention of inhaled anesthetics worsened by hypoventilation. Hypothermia, especially in neonates, delays metabolism and excretion of anesthetics and prolongs NMB. Hypoventilation after surgery is associated with the development of atractasis. Microatelectasis may lead to postoperative infections. When airway obstruction is present, maintenance of airway patency may necessitate oropharyngeal or nasopharyngeal airway placement. In the setting of profound respiratory depression, endotracheal intubation and mechanical ventilation may be indicated.

Opioid reversal with naloxone may be indicated in rare instances when excessive opioid effect is suspected. However, naloxone reverses both the respiratory depressant and the analgesic effects of opioids. Following naloxone reversal, a somnolent child with respiratory depression may experience increased pain. Opioid reversal requires bedside attention by the physician to monitor the
child's behavioral, hemodynamic, and respiratory status. Importantly, naloxone is shorter-acting than most opioid analgesics, which may result in re-narcotization.

**Postoperative stridor** occurs in up to 2% of all pediatric patients. The use of appropriately sized ETTs and assurance of an air leak <30 cm H₂O pressure decreases the risk of airway trauma or edema. A history of stridor increases the likelihood of postoperative complications. Stridor may be severe enough after extubation to require reintubation. Racemic epinephrine aerosols and dexamethasone are effective therapies; their use requires prolonged observation because of the potential for rebound stridor. Stridor in infants suggests the need for overnight observation.

**Cardiovascular complications** are less frequently encountered in the PACU. Volume expansion may be required to maintain adequate cardiac output, peripheral perfusion, and urine output. Large-volume fluid resuscitation (>30 mL/kg) in the postoperative period may be an indication of evolving shock physiology, and sources of hypovolemia (e.g., occult bleeding) or myocardial dysfunction (e.g., tamponade, pneumothorax) should be considered.

**Emergence delirium** immediately after anesthesia is noted in 5–10% of children and is more common in those 3-9 yr old. Manifestations include restlessness, combativeness, disorientation, and inconsolability. Almost all anesthetic agents have been linked to the development of delirium, especially newer volatile anesthetic agents (e.g., sevoflurane, desflurane). Potential postoperative complications, such as hypoglycemia and hypoxemia, should also be ruled out. Occasionally, it is necessary to provide additional sedation (e.g., propofol, dexmedetomidine, benzodiazepines) although these agents prolong postanesthesia recovery time and may not effectively reduce delirium.

**Awareness During Anesthesia**

A fundamental aim of anesthesia is to prevent recall by inducing hypnosis and amnesia. In adults, certain anesthetic techniques and surgical procedures have been associated with recall during anesthesia. The long-term sequelae of recall in children are unknown. Continuous cerebral bispectral index (BIS) electroencephalographic monitoring has been used to assess intraoperative awareness. Unfortunately, pediatric studies have not confirmed the usefulness of BIS monitoring as a means of determining anesthetic depth. Existing data do not support the routine use of BIS monitoring during pediatric anesthesia. Volatile anesthetic agents reliably produce dose-dependent hypnotic and amnestic effects and remain a mainstay of general anesthesia.
Postoperative Nausea and Vomiting

Following general anesthesia, 40–50% of children may experience postoperative nausea and vomiting (PONV) that generally lasts for several hours. This complication prolongs recovery room times and requires significant nursing attention. The etiology is not completely understood but is likely multifactorial related to the emetic effects of anesthetics, pain, and surgical stress. Opioid analgesics may provoke nausea and vomiting. Importantly, preoperative fasting does not decrease the incidence of PONV. Indeed, hydration and glucose supplementation appear to be important factors in decreasing PONV. Multimodal analgesia with nonopioid agents (e.g., acetaminophen, ibuprofen, ketorolac) and regional or local anesthesia may decrease PONV. The serotonin antagonist ondansetron is an effective treatment of PONV. Ondansetron prophylaxis is also recommended for patients at increased risk of PONV, such as after eye and otolaryngology surgery. Serotonin antagonists are contraindicated in children taking serotonin reuptake inhibitors for migraine headaches. Dexamethasone may also be used for the treatment of PONV.

Thermoregulation and Malignant Hyperthermia

Following anesthesia, thermoregulation remains abnormal for several hours. Hypothermia, especially in neonates, may lead to cardiorespiratory depression and prolongation of the effect of opioids and NMBAs. Although hypothermia has deleterious effects, active rewarming should be performed cautiously to avoid hyperthermia and cutaneous burns. Postoperative shivering is common and may occur in the absence of hypothermia. Hyperthermia, with temperatures in excess of 39°C (102.2°F), is of concern in the postoperative period. When high fevers occur within hours of the use of an inhalational anesthetic, especially if succinylcholine was used, malignant hyperthermia must be ruled out.

Malignant hyperthermia (MH) is a hypermetabolic syndrome triggered by volatile anesthetic agents and succinylcholine. The onset of MH may be acute, fulminant, and lethal without appropriate interventions. The disease is genetically heterogeneous, with >10 genes contributing to susceptibility, but typically displays an autosomal dominant inheritance pattern. A family history of death or febrile reactions during anesthesia should alert the anesthesiologist to its potential. Mutations within the gene encoding for the ryanodine receptor (the calcium channel of the sarcoplasmic reticulum) predispose to MH susceptibility and have been identified in 20–40% of humans with MH. Certain myopathies.
are associated with the risk of MH, including Duchenne muscular dystrophy, central core disease, and King Denborough syndrome.

The pathophysiology of MH involves uncontrolled intracellular calcium release from skeletal muscle sarcolemma, resulting in prolonged muscle contraction, adenosine triphosphate (ATP) depletion, and muscle cell death. Myolysis results in the release of myoglobin, creatine phosphokinase (CPK), and potassium into the blood. The clinical course of MH is characterized by rapid onset of high fever (>38.5°C), muscle rigidity, acidosis (metabolic and respiratory), high end-tidal CO₂, and multiorgan dysfunction. Death may ensue secondary to hemodynamic collapse from shock and cardiac dysrhythmias. Signs of MH generally occur within the 1st 2 hr of anesthesia, but (rarely) can occur up to 24 hr later.

Aggressive therapy involves discontinuation of all inhalational anesthetics, correction of the metabolic acidosis, and treatment with the muscle relaxant dantrolene. IV dantrolene (2.5 mg/kg as initial dose) should be initiated when MH is suspected. The need for repeat doses, up to a maximum of 10 mg/kg, is indicated for persistent fever, muscle rigidity, acidosis, and tachycardia. Once symptoms are controlled, the patient should be observed for at least 24 hr, because recrudescence may occur. The MH mortality rate was once >70% and is now <5% with standardized treatment algorithms. A MH cart with sufficient supplies of dantrolene should be present at every site where pediatric anesthesia is provided.

Certain phenomena suggest an increased risk of MH. Masseter spasm during induction, with rigid clenching of the masseter muscles and an inability to open the mouth, may signal MH susceptibility. Acute myoglobinuria associated with an MH-triggering agent is another clue. The child may not be hypermetabolic or febrile, but may have dark urine, high CPK levels, and risk of myoglobin-induced renal tubular damage. The finding of dark urine after administration of an anesthetic requires further investigation, including measurement electrolytes on CPK. Prevention of MH in susceptible patients requires the avoidance of triggering agents, which include inhalational anesthetics and succinylcholine. IV anesthesia and nitrous-opioid techniques are safe. MH-safe anesthesia machines devoid of trace concentrations of volatile anesthetic vapors should be used. Dantrolene prophylaxis is not recommended because MH is rapidly treatable and the drug causes respiratory depression and muscle weakness. For a child in whom MH is suspected, the MH hotline, 1-800-MHHYPER (1-800-644-9737), should be used to notify the Malignant Hyperthermia Association of the United
States (MHAUS). MHAUS registers susceptible patients and provides diagnostic and therapeutic information. Preanesthesia susceptibility testing includes genetic analysis of the ryanodine receptor gene, muscle biopsies, in vitro contraction studies, and possibly measurement of muscle CO\textsubscript{2} production in response to intramuscular caffeine.

**Mediastinal Masses**

Children with anterior mediastinal masses such as lymphomas, teratomas, and other primary mediastinal tumors are at serious risk for cardiorespiratory failure during anesthesia. Even mild sedation may result in airway compromise, inability to ventilate, cardiac tamponade, vascular obstruction, and circulatory collapse. These patients generally require surgical tissue diagnosis before treatment is initiated. Significant compression of vital structures can occur with seemingly mild symptoms. Tachypnea, orthopnea, wheezing, and avoidance of prone or supine positions are significant indications of serious risk. Echocardiographic or CT evidence of pericardial tamponade, right ventricular compression, or compression of the pulmonary artery suggests severe risk. Biopsy with light sedation under local anesthesia may be indicated. When anesthesia is required, preservation of spontaneous ventilation is critical during induction of anesthesia. Rigid bronchoscopy may be used to assist with ventilation in the setting of external airway compression. Provisions to provide mechanical circulatory support (cardiopulmonary bypass) should also be available. In high-risk children, consideration should be given to initiating treatment with corticosteroids, radiation therapy, and chemotherapy before obtaining a tissue diagnosis.

**Postoperative Apnea**

Neonates and infants are at increased risk for the development of postoperative apnea after exposure to potent hypnotic and analgesic medications. Both central and obstructive apnea may occur. Postanesthetic apnea is most common within the 1st 12 hr, although apnea has been reported in premature infants up to 48 hr later. The risk of apnea is inversely proportional to postconceptual age at surgery and is highest in premature neonates <44 wk postconceptual age. This risk is minimal by the time premature infants have reached 60 wk postconceptual age. Theophyllines do not reliably decrease the incidence of postoperative apnea and are not routinely used. When surgery is required within the 1st mo of life,
overnight observation and monitoring are indicated. In term infants >44 wk postconceptual age, management should include observation and monitoring for 6 hr with at least 1 sleep-wake-feed cycle without hypoxia, bradycardia, or supplemental oxygen. Premature infants <56 wk postconceptual age require observation for 12 hr after anesthesia.

**Postoperative Pain Management**

Postprocedural pain management should ensure adequate analgesia and anxiolysis (see Chapter 76). Preoperative education focusing on pain management through development of skills designed to decrease anticipatory anxiety and participation in treatment planning can be helpful for children and families. Pediatric pain management relies on multimodal therapy, including opioid and nonopioid analgesics. Nonsteroidal antiinflammatory drugs, cyclooxygenase-2 inhibitors, IV acetaminophen, opioids, and regional analgesia all have roles in postoperative pain management. Repeated evaluation is critical to effective pain management. Adjunctive therapy, such as pet therapy, may also decrease the need for potent analgesics postoperatively.

**Patient-controlled analgesia (PCA) and parent/nurse-controlled analgesia (PNCA)** are widely accepted postoperative pain regimens. PCA/PNCA provide a low-dose continuous (basal) infusion of opioid with intermittent (bolus) supplements as needed. The practitioner must determine the basal rate, bolus dose, lockout interval, and acceptable number of bolus doses per hour. PCA/PNCA safety requires appropriate medication dosing and assumes that patients are unlikely to overdose because somnolence will limit repeated self-administration. In young children, use of the *pain button* (for pain relief) may be more difficult to ensure, although children as young as 5 yr have been able to use PNCA successfully. In older children and adolescents, PCA is a standard modality of postoperative pain management.

**Regional Anesthesia**

Regional anesthesia is the use of anesthetics to block the conduction of afferent neural impulses to the central nervous system. Forms of regional anesthesia include local anesthesia, peripheral nerve blocks, nerve plexus blocks, and neuraxial (epidural and subarachnoid/spinal) blocks. Anesthetics may be administered as a single injection or as a continuous infusion. Regional
anesthesia may be used for both intraoperative and postoperative analgesia. It has been linked to shortened recovery times and hospital stays in children. A major benefit of regional anesthesia is lesser central cardiorespiratory depressant effects. Injection of local anesthetics (e.g., lidocaine, bupivacaine) into the affected area may provide procedural analgesia lasting for hours to days. Wound infiltration with local anesthetics at the conclusion of surgery may also decrease early postoperative pain.

**Neuraxial (epidural, spinal) analgesia** is common in pediatric practice. The epidural space lies between the dura and the pia and arachnoid membranes, an area through which all nerve roots pass. Caudal epidural analgesia is placed through the sacral hiatus, inferior to the distal end of the spinal cord. This site is often used for pelvic and lower-limb anesthesia during urologic and orthopedic surgery in infants and toddlers. A single dose of caudal epidural anesthesia may provide hours of pain relief, and a continuous infusion may provide effective pain relief for hours to days. The epidural injection of opioids can provide analgesia for 12-24 hr and is a potential supplement to postoperative analgesia. Longer-acting local anesthetics (e.g., bupivacaine, ropivacaine) combined with an opioid (e.g., fentanyl, preservative-free morphine) are typically used in single-injection and continuous epidural therapy. It is also possible to provide epidural PCA with a continuous infusion pump and the patient's ability to self-administer analgesia as needed. Epidural analgesia can also provide pain relief in patients with chronic pain or pain caused by advanced malignant conditions.

Complications of neuraxial anesthesia include cephalad spread of blockade with respiratory depression, paralysis of respiratory muscles, and brainstem depression. Common complications of neuraxial analgesia are paresthesias and, if opioids are used, pruritus, nausea, and vomiting. Neuraxial opioid use necessitates antipruritic and antiemetic therapy. Infection and epidural hematoma are extremely rare. Neuraxial opioids, especially when administered intrathecally, may cause respiratory depression and require postoperative monitoring.

### 74.1

**Anesthetic Neurotoxicity**
Keywords

general anesthesia
neurodevelopment
neurotoxicity
apoptosis

Laboratory animal studies have suggested a link between anesthetic exposure at an early age and neurotoxicity in developing brains. Existing nonclinical data implicate N-methyl-D-aspartate and γ-aminobutyric acid (GABA) pathways in apoptosis and neuronal cell death. Both histopathologic changes and adverse neurodevelopmental outcomes have been associated with exposure to both inhalational and IV anesthetics, including isoflurane, sevoflurane, ketamine, benzodiazepines, and propofol. Animal studies were initially performed in nonprimates (rodents), and controversy remains concerning experimental design (dose, duration of treatment, species differences). However, work in nonhuman primates has also shown an increased incidence of adverse neurodevelopmental outcomes after prolonged and/or multiple exposures to volatile anesthetics.

Human studies of anesthesia-induced neurotoxicity have yielded conflicting results. Further complicating the situation are other potential triggers for adverse neurodevelopmental outcomes, including comorbidities, surgical trauma, and perioperative cardiorespiratory status. Multiple population-based epidemiologic studies have suggested a potential association between anesthetic exposure and adverse neurodevelopmental outcomes following multiple or prolonged anesthetic exposures. Large-scale European and Canadian cohort studies utilizing national registries have revealed subtle differences in standardized psychometric testing of early school-aged children after exposure to general anesthesia. Interestingly, other studies in children have failed to yield similar results. The Pediatric Anesthesia and Neurodevelopmental Assessment (PANDA), a multicenter matched-sibling control study, revealed no association between brief anesthetic exposure for inguinal hernia repair and aptitude on psychometric testing. Similarly, the General Anaesthesia and Awake-Regional Anaesthesia in Infancy (GAS) study, a prospective multicenter randomized
controlled trial comparing general and neuraxial spinal anesthesia in infants for hernia repair, did not demonstrate any significant differences in neurodevelopment at 2 yr of age between groups. The primary outcome of the GAS study is neurodevelopment at 5 yr of age, and these results have not yet been made available. Importantly, studies have not shown an association between adverse neurodevelopmental outcomes and anesthetic exposure <3 hr.

Alternatives to general anesthesia for many procedures in young children do not exist. Regional anesthetic techniques and narcotic-based anesthetics may gain popularity. Dexmedetomidine may also have some neuroprotective properties. Currently, there is insufficient data to make conclusions regarding the safety of one anesthetic approach over another. Ultimately, the potential for neurotoxicity must be balanced against the necessity of providing adequate anesthesia for children presenting for surgery.

CHAPTER 75

Procedural Sedation

John P. Scott

See also Chapters 74 and 76.

Sedation describes the continuum between wakefulness and general anesthesia (see Table 74.7). Many of the same drugs used to induce general anesthesia may be used to provide sedation (see Table 74.8). Analogous to the provision of anesthesia, performance of procedural sedation requires a comprehensive presedation evaluation, intraprocedural monitoring, and postsedation recovery care. The term conscious sedation refers to a condition in which a patient is sleepy, comfortable, and cooperative but maintains airway-protective and ventilatory reflexes. Depending on the choice of pharmacotherapy, sedation may not provide analgesia. Sedation that is sufficient to obtund painful responses describes deep sedation. Deep sedation is a state of unarousability to voice and is accompanied by suppression of reflex responses.

Pediatric procedural sedation requires vigilance and knowledge to ensure safety and is governed by the same guidelines as anesthesia care (Table 75.1). Adherence to guidelines for appropriate monitoring and management of sedation in children is imperative. Sedative doses that cause minimal sedation in one patient may produce complete unconsciousness and apnea in another. Anxiolysis or light sedation with chloral hydrate, benzodiazepines, and dexmedetomidine is often sufficient for nonpainful procedures. The use of dexmedetomidine for procedural sedation is safe; recovery time can be prolonged and success variable. For painful procedures (e.g., bone marrow aspiration), the combination of hypnosis and analgesia is required. The addition of opioids to sedation regimens increases the risk of respiratory insufficiency. Short-acting anesthetics (e.g., propofol, methohexital, remifentanil) provide effective procedural sedation, but their use carries a higher likelihood of inadvertent induction of general anesthesia. Use of these medications requires the presence of an anesthesiologist.
and/or specially trained, experienced, credentialed, and qualified physicians.

Table 75.1

Systematic Approach to Sedation in Children

| Comprehensive medical history and organ system assessment, anticipating underlying medical problems that predispose the patient to anesthetic complications |
| Careful physical examination focused on the cardiorespiratory system and airway |
| Appropriate fasting |
| Informed consent |
| Pediatric drug dosing (mg/kg) |
| Appropriately sized equipment |
| Documentation of vital signs and condition on a time-based record |
| Rapid response (“code”) team to respond to emergencies with “crash cart” |
| Fully equipped and staffed recovery area |
| Discharge criteria documenting recovery from sedation |

Many pediatric subspecialists provide sedation and anesthesia care for children. The use of anesthetic agents is not limited to anesthesiologists, but anesthesiology departments are obligated to help develop, manage, and oversee sedation services. Together, hospitals and providers, including anesthesiologists, share responsibility for the oversight and credentialing of individuals administering sedation and anesthesia.

The elements of a safe pediatric procedural sedation system include the following:

◆ Clearly defined knowledge and skill sets
◆ Adequate prerequisite training
◆ Credentialing of providers
◆ Maintenance of certification
◆ Ensuring that sedation sites meet recognized standards
Continuous quality improvement

Table 75.2 provides an approach to proper language to help the child cope with procedural pain.

Doctor K, Roback MG, Teach SJ. An update on pediatric

Pain is both a sensory and an emotional experience. When unrecognized and undertreated, pain extracts a significant physiologic, biochemical, and psychological toll on both the child and the family. Many disease processes and most interventional diagnostic or treatment procedures in pediatrics are associated with pain. Similarly, traumatic, developmental, cognitive, psychological, and social experiences can also trigger and maintain chronic pain.

**Definition and Categories of Pain**

The International Association for the Study of Pain (IASP) defines pain as “an unpleasant sensory and emotional experience associated with actual or potential tissue damage or described in terms of such damage.” The important elements to emphasize in this definition are (1) pain encompasses both peripheral physiologic and central neural components and (2) pain may or may not be associated with ongoing tissue damage. The experience of pain lies primarily in the strength and patterning of central neural connectivity (Fig. 76.1). While immediate upstream neural activation can originate from inflammatory, structural, or biochemical events, processes not only in the periphery of the body but also in the spinal cord and the brain influence the intensity and duration of pain. Similarly, central neural processes in the brain are associated with the location, intensity, and distress associated with pain. Chronic pain can develop when the upstream neural signaling continues to activate central neural circuits, such as with continued peripheral inflammatory or structural pain-associated processes.
Often, however, pediatricians face the most difficult problems when either acute pain becomes chronic or chronic pain develops and is maintained without a definable infectious, inflammatory, metabolic, or structural cause. When no “cause” can be found, patients are often referred to mental health specialists, or the cause for the pain is labeled as “stress.” Children read this message as, “The
doctor thinks I am faking pain or am crazy.” Parents see their child suffering and often seek care elsewhere, with the child undergoing numerous tests, procedures, medication trials, and visits and many physicians looking for the cause of the pain so it can be “fixed.” Meanwhile, the child may be missing school, social, and physical activities and developing poor sleep habits with increasing fatigue.

It is recognized that chronic pain, in the absence of a specific identified structural, biochemical, or inflammatory cause, develops through the initiation, maintenance, and strength of central neural connectivity patterns, the *connectome* of the child's brain (see Chapter 147). That is, what is now called “centrally mediated pain” derives from neural connectivity patterns in the brain that include centers involved in autonomic nervous system control, memory, and other cognitive centers, as well as emotional centers of the brain. In pediatrics, birth history and child development overlay these central patterns that contribute to the development of chronic pain. A child with high-functioning autism spectrum disorder (ASD) may perseverate on a pain symptom (e.g., headache) in the same way the child might perseverate on an idea or point of view (e.g., the parents may never “win” an argument with their child). Parents may understand the concept of a “sticky nervous system” as the perpetuator of the continued pain in such a child. This model of brain connectivity patterns or “top-down” mediators of chronic pain is important, since it explains how psychological and other nonpharmacologic interventions work to reduce pain and suffering. Science has come a long way since the model of pain as “psychological” or “physical.” The current model of pain also includes the impact of the gut microbiome in altering central neural processes in relation to the development and maintenance of pain.

Table 76.1 specifies important pain categories typically treated (somatic, visceral, and neuropathic) and defines the elements and characteristics of nociception, the peripheral physiologic aspect of pain perception. Nociception refers to how specialized fibers (largely but not exclusively the small, unmyelinated A-delta and C fibers) in the peripheral nervous system transmit nerve impulses (usually transmitting signals originating from peripheral mechano- and chemoreceptors) through synapses in the spinal cord's dorsal horn through (but not exclusively through) the spinothalamic tracts to the brain's higher centers, where the development of neural connectivity patterns creates the experience of pain.

## Assessment and Measurement of Pain in Children

Assessing pain entails much more than merely quantifying it. Whenever feasible, the physician should ask the patient about the character, location, quality,
duration, frequency, and intensity of the pain. Some children may not report pain because of fears (often well founded) of talking to strangers, disappointing or bothering others, receiving an injection if they report pain, returning to the hospital if they admit to pain, and other negative reactions. For infants and nonverbal children, their parents, pediatricians, nurses, and other caregivers are constantly challenged to interpret whether the child's distressed behaviors represent pain, fear, hunger, or a range of other perceptions or emotions. Similarly, lack of normal interest in play without behavioral distress signals can be manifestations of pain. Therapeutic trials of comfort measures (cuddling, feeding) and analgesic medication may be helpful in clarifying the triggers of the behaviors.

Behavior and physiologic signs are useful but can be misleading. A toddler may scream and grimace during an ear examination because of fear rather than pain. Conversely, children with inadequately relieved persistent pain from cancer, sickle cell disease, trauma, or surgery may withdraw from their surroundings and appear very quiet, leading observers to conclude falsely that these children are comfortable or sedated or, for adolescent patients, are “drug seeking.” In these situations, increased dosing of analgesics may make the child become more, not less, interactive and alert. Similarly, neonates and young infants may close their eyes, furrow their brows, and clench their fists in response to pain. Adequate analgesia is often associated with eye opening and increased involvement in surroundings. A child who is experiencing significant chronic pain may play normally as a way to distract attention away from pain. This coping behavior is sometimes misinterpreted as evidence of the child's “faking” or exaggerating pain at other times.

**Age-Specific and Developmentally Specific Measures**

Because infants, young children, and nonverbal children cannot express the quantity of pain they experience, several pain scales have been devised in an attempt to quantify pain in these populations ([Fig. 76.2](#) and [Table 76.2](#)).
Behavioral Indicators

Facial grimacing: The Neonatal Facial Coding System uses several facial actions that may be indicators of pain. Pain is characterized by a bulging brow with tight creases in between; tightly closed eyelids; a deeply furrowed nasolabial groove; a horizontal, wide opened mouth; and a taut tongue that may be quivering along with the chin.

Crying:May be an indicator of pain.

Activity: Withdrawal or immobilization of a limb may be an indicator of pain.

Response to comfort measures: Feeding, swaddling, holding, and ensuring that the infant is neither wet nor cold may help to discriminate between pain and other conditions.

Physiologic indicators: Alterations in heart rate, blood pressure, SpO₂, respiratory rate, or alterations in pattern of respiration may be nonspecific indicators of pain.

Self-Report of Pain

Categorical description: Toddlers or young children are asked to say if they are having "a little bit," a "middle amount," or "a lot" of pain.

Faces Scale: Children who do not have an appreciation of ordinal numbering are asked to rate their pain based upon cartoons depicting facial indicators of distress.

NRS: Older children and teenagers are asked to rate their pain on a scale of "0" (no pain) to "10" (worst pain).

VAS: Children or teenagers are asked to move an indicator along a mechanical slide to depict the level of pain; the clinician reads a number along a 10-cm indicator on the back to determine the numeric score.

Multidimensional Instrument

FLACC: Scoring System: May be used in preverbal, mechanically ventilated, or cognitively impaired patients; it is an acronym that includes five indicators, each scored as a 0, 1, or 2 that forms a ten-point composite scale with a range from "0" (no pain) to "10" (worst pain).

### The Newborn and Infant

There are several behavioral distress scales for the infant and young child, mostly emphasizing the patient's facial expressions, crying, and body movement. Facial expression measures appear most useful and specific in neonates. Autonomic and vital signs can indicate pain, but because they are nonspecific, they may reflect other processes, including fever, hypoxemia, and cardiac or renal dysfunction (Table 76.3).
### Table 76.3

**Signs and Symptoms of Pain in Infants and Young Children**

**Physiologic Changes**

- Increase in heart rate, respiratory rate, blood pressure, muscle tone
- Oxygen desaturation
- Sweating
- Flushing
- Pallor

**Behavioral Changes**

- Change in facial expression (grimacing, furrowing of the brow, nasal flaring, deep nasolabial groove, curving of the tongue, quivering of the chin)
- Finger clenching
- Thrashing of limbs
- Writhing
- Back arching
- Head banging
- Poor feeding
- Sleep disturbance
- Pseudoparalysis

**The Older Child**

Children age 3-7 yr become increasingly articulate in describing the intensity, location, and quality of pain. Pain is occasionally referred to adjacent areas;
referral of hip pain to the thigh or area above the knee is common in this age range. Self-report measures for children this age include using drawings, pictures of faces, or graded color intensities. Children ≥8 yr can usually use verbal numerical rating scales or visual analog pain scales (VAS) accurately (Fig. 76.2). Verbal numerical ratings are preferred and considered the gold standard; valid and reliable ratings can be obtained from children ≥8 yr. The numerical rating scale (NRS) consists of numbers from 0-10, in which 0 represents no pain and 10 represents very severe pain. There is debate about the label for the highest pain rating, but the current agreement is not to use the phrase “worst pain possible,” because children can always imagine a greater pain. In the United States, regularly documented pain assessments are required for hospitalized children and children attending outpatient hospital clinics and emergency departments (EDs). Pain scores do not always correlate with changes in heart rate or blood pressure.

The Cognitively Impaired Child

Measuring pain in cognitively impaired children remains a challenge. Understanding pain expression and experience in this population is important, because behaviors may be misinterpreted as indicating that cognitively impaired children are more insensitive to pain than cognitively competent children. Children with trisomy 21 may express pain less precisely and more slowly than the general population. Pain in children with ASD may be difficult to assess because these children may be both hyposensitive and hypersensitive to many different types of sensory stimuli, and they may have limited communication abilities. Although self-reports of pain can be elicited from some children who are cognitively impaired, observational measures have better validation among these children. The Noncommunicating Child's Pain Checklist—Postoperative Version is recommended for children up to 18 yr. Maladaptive behaviors and reduction in function may also indicate pain. Children with severe cognitive impairments experience pain frequently, mostly not because of accidental injury. Children with the fewest abilities experience the most pain.

Conceptual Framework for Treatment of Pediatric Pain

A number of models have been developed to understand the various factors that
influence children's pain. Many of these theories focus on factors that explain the interindividual variability in pain perception and the chronicity and impairment experienced with pain. Central to these models are interrelationships among biologic, cognitive, affective, and social factors that influence children's pain and disability, commonly referred to as “biopsychosocial models” of pain. **Biologic** factors include the child's physical health, central nervous system (CNS) factors (pain processing), sex, pubertal status, and genetic factors. Individual child **cognitive and affective** factors related to perception of pain are anxiety, fear, negative affect, pain behaviors, and functional disability, whereas **social** factors include such areas as culture, socioeconomic status, school environment, social and peer interactions, and parental and family factors. For children, **developmental** factors need to be considered, such as cognitive and motor development, birth history, and epigenetic factors (the interaction in development between genetic and environmental factors).

A framework that considers the interplay of biologic, psychological, and social factors is useful for understanding pediatric pain and to guide pain assessment and the delivery of pain prevention and management. Many simple interventions designed to promote relaxation and patient control can work either alone or synergistically with pain medications for relief of pain and related distress. Moreover, psychological interventions are often coupled with physical therapy interventions to assist in the management of disabling chronic pain.

**Pharmacologic Treatment of Pain**

The pharmacokinetics and pharmacodynamics of analgesics vary with age; drug responses in infants and young children differ from those in older children and adults. The elimination half-life of most analgesics is prolonged in neonates and young infants because of their immature hepatic enzyme systems and glomerular filtration. Clearance of analgesics may also be variable in young infants and children. Renal blood flow, glomerular filtration, and tubular secretion increase dramatically in the 1st few weeks, approaching adult values by 3-5 mo of age. Renal clearance of analgesics is often greater in toddlers and preschool-aged children than in adults, whereas in premature infants, clearance is reduced. Age-related differences in body composition and protein binding also exist. Total body water as a fraction of body weight is greater in neonates than in children or adults. Tissues with high perfusion, such as the brain and heart, account for a larger proportion of body mass in neonates than do other tissues, such as muscle.
and fat. Because of decreased serum concentrations of albumin and α₁-acid glycoprotein, neonates have reduced protein binding of some drugs, resulting in higher amounts of free, unbound, pharmacologically active drug.

**Acetaminophen, Aspirin, Nonsteroidal Antiinflammatory, and Coxib Drugs**

Acetaminophen and nonsteroidal antiinflammatory drugs (NSAIDs) have replaced aspirin as the most commonly used antipyretics and oral, nonopioid analgesics (Table 76.4).

FDA, U.S. Food and Drug Administration; IV, intravenously; NSAIDs, nonsteroidal antinflammatory drugs; PDD, pervasive developmental disorder; PDR, Physicians’ Desk Reference ; PO, orally; PR, rectally; QTc, corrected QT interval on an electrocardiogram; SSRI, selective serotonin reuptake inhibitor.

**Acetaminophen**, a generally safe, nonopioid analgesic and antipyretic, has the advantage of intravenous (IV), rectal, and oral routes of administration.
Acetaminophen is not associated with the gastrointestinal (GI) or antiplatelet effects of aspirin and NSAIDs, making it a particularly useful drug in patients with cancer. Unlike aspirin and NSAIDs, acetaminophen has only mild antiinflammatory action.

Acetaminophen toxicity can result from a large single dose or cumulative excessive dosing over days or weeks (see Chapter 77). A single massive overdose overwhelms the normal glucuronidation and sulfation metabolic pathways in the liver, whereas long-term overdosing exhausts supplies of the sulfhydryl donor glutathione, leading to alternative cytochrome P-450 (CYP)–catalyzed oxidative metabolism and the production of the hepatotoxic metabolite \( N - \text{acetyl}-p -\text{benzoquinone imine} \) (NAPQI). Toxicity manifests as fulminant hepatic necrosis and failure in infants, children, and adults. Drug biotransformation processes are immature in neonates, very active in young children, and somewhat less active in adults. Young children are more resistant to acetaminophen-induced hepatotoxicity than are adults as a result of metabolic differences; sulfation predominates over glucuronidation in young children, leading to a reduction in NAPQI production.

**Aspirin** is indicated for certain rheumatologic conditions and for inhibition of platelet adhesiveness, as in the treatment of Kawasaki disease. Concerns about Reye syndrome have resulted in a substantial decline in pediatric aspirin use.

The **NSAIDs** are used widely to treat pain and fever in children. NSAIDs are nonspecific cyclooxygenase (COX) inhibitors, that is, drugs that nonspecifically block the activity of both COX-1 (found in gastric mucosa and platelets) and COX-2 (active in inflammatory pathways and cortical renal blood flow regulation) enzymes that synthesize prostaglandins. In children with juvenile idiopathic arthritis, ibuprofen and aspirin are equally effective, but ibuprofen is associated with fewer side effects and better drug adherence. NSAIDs and coxibs used adjunctively in surgical patients reduce opioid requirements (and therefore opioid side effects) by as much as 35–40%. Although NSAIDs can be useful postoperatively, they should be used as an adjunct to, not as a substitute for, opioids in patients with acute, moderate to severe pain.

Ketorolac, an IV NSAID, is useful in treating moderate to severe acute pain in patients who are unable or unwilling to swallow oral NSAIDs. U.S. Food and Drug Administration (FDA) recommendations limit ketorolac to 5 consecutive days of administration. IV ibuprofen (Caldolor) is FDA approved for the management of pain and fever in infants and children >6 mo of age. Adverse effects of NSAIDs are uncommon but may be serious when they occur,
including inhibition of bone growth and healing; gastritis with pain and bleeding; decreased renal blood flow that may reduce glomerular filtration and enhance sodium reabsorption, in some cases leading to tubular necrosis; hepatic dysfunction and liver failure; inhibition of platelet function; and an increased incidence of cardiovascular events in patients predisposed to stroke and myocardial infarction. Although the overall incidence of bleeding is very low, gastric bleeding is the most common cause of mortality related to this class of analgesics. NSAIDs should not be used in the child with a bleeding diathesis or at risk for bleeding or when surgical hemostasis is a concern, such as after tonsillectomy. The drug class is usually not used in the setting of bone healing, except perhaps in the 1st few days after surgery. Renal injury from short-term use of ibuprofen in euvolemic children is quite rare; the risk is increased by hypovolemia or cardiac dysfunction. The safety of both ibuprofen and acetaminophen for short-term use is well established (see Table 76.4).

**Coxib** drugs available in the United States are limited to oral celecoxib, whereas in Europe and elsewhere parenteral parecoxib and oral rofecoxib are available. Parecoxib was not FDA approved, whereas rofecoxib was approved and withdrawn from marketing due to concern of enhanced risk of heart attack and stroke in high-risk adults, which has subsequently been found to be associated with all the coxibs and all the NSAID drugs as well. The coxib drugs are selective COX-2 enzyme inhibitors; therefore they are effective antiinflammatory and analgesic molecules that generally do not result in platelet inhibition or bleeding, or in gastric inflammation or ulceration, findings that may be seen with the nonselective COX inhibitors in the NSAID class. However, coxib drugs do inhibit regulation of cortical renal blood flow, and therefore carry the same risk of renal toxicity and acute tubular necrosis, particularly in the setting of low cardiac output states or dehydration. Celecoxib is therefore an appropriate primary or adjunctive analgesic to use in children after surgery, children with gastric mucosal pathology, or oncology patients in whom concern for hemostasis contraindicates conventional NSAIDs.

**Opioids**

Opioids are analgesic substances either derived from the opium poppy (opiates) or synthesized to have a similar chemical structure and mechanism of action (opioids). The older, pejorative term “narcotics” (narcotic analgesics) should not be used for these agents because it connotes criminality and lacks pharmacologic descriptive specificity. Opioids are administered for moderate
and severe pain, such as acute postoperative pain, sickle cell crisis pain, and cancer pain. Opioids can be administered by the oral, rectal, oral transmucosal, transdermal, intranasal, IV, epidural, intrathecal, subcutaneous (SC), or intramuscular (IM) route. Regardless of route of administration, the site of action is at mu (µ) opioid receptors in the peripheral nervous system, spinal cord, brainstem, and higher CNS centers. Historically, infants and young children have been underdosed with opioids because of concern about significant respiratory side effects. Once thought to represent infants' particular sensitivity, the opioids' respiratory depressant effects are now known to result from infants' lower metabolic clearance of opioids and higher blood levels with frequent dosing. With proper understanding of the pharmacokinetic and pharmacodynamics of opioids, children can receive effective relief of pain and suffering with a good margin of safety, regardless of pharmacokinetic maturity, age, or size (Tables 76.5 to 76.8).

Table 76.5

**Practical Aspects of Prescribing Opioids**

- Morphine, hydromorphone, or fentanyl is regarded as 1st choice for severe pain.
- Dosing should be titrated and individualized. There is no “right” dose for everyone.
- The right dose is the dose that relieves pain with a good margin of safety.
- Dosing should be more cautious in infants, in patients with coexisting diseases that increase risk or impair drug clearance, and with concomitant administration of sedatives.
- Hydromorphone is metabolized by CYP2D6 and fentanyl by CYP3A4, and to some extent 2D6; drugs that compete for 2D6 enzyme will raise blood levels and increase risk of respiratory depression.
- Morphine is metabolized by glucuronidation to an active metabolite, morphine-6-glucuronide, which accumulates and causes CNS toxicity in renal impairment.
- Anticipate and treat peripheral side effects, including constipation, nausea, and itching.
- Give doses at sufficient frequency to prevent the return of severe pain before the next dose.
Use a drug delivery method, such as patient-controlled anesthesia or continuous infusions, that avoids the need for “prn” decision-making.

With opioid dosing for >1 wk, taper gradually to avoid abstinence syndrome.

When converting between parenteral and oral opioid doses, use appropriate potency ratios (see Table 76.6).

_Tolerance_ refers to decreasing drug effect with continued administration of a drug. Over time a patient will need higher dosing to achieve the same clinical effect; however, tolerance to sedation and respiratory depression develop more rapidly than tolerance to analgesia. Thus, with higher doses, patients do not experience oversedation or respiratory depression.

_Dependence_ refers to the need for continued drug dosing to prevent abstinence syndrome when a drug is abruptly discontinued, or its dose reduced. Abstinence syndrome is characterized by irritability, agitation, autonomic arousal, nasal congestion, piloerection, diarrhea, jitteriness, and yawning; it is produced by administration of potent opioids for >5-7 days.

_Addiction_, a psychiatric pathology, refers to psychological craving, compulsive drug-seeking behavior, and drug use despite medical harm. Addiction has strong genetic and environmental determinants. Opioid therapy will not lead to addiction in nonsusceptible individuals, and opioid underdosing does not prevent addiction; it may in fact increase drug-seeking behavior for relief of pain (e.g., watching the clock), referred to as “pseudoaddiction.”

Table 76.7
Management of Opioid-Induced Adverse Effects

| Respiratory | Naloxone: 0.01-0.02 mg/kg up to a full reversal dose of 0.1 mg/kg. May be given IV, IM, |
**Depression**

SC, or via ET.

The full reversal dose should initially be used for apnea in opioid-naive patients. In opioid-tolerant patients, a reduced dose should be given and titrated up slowly to treat symptoms but prevent acute withdrawal.

Ventilation may need to be supported during this process.

Dose may be repeated every 2 min to a total of 10 mg.

Adult maximum dose is 2 mg/dose. Give with caution to patients who are receiving long-term opioid therapy, as it may precipitate acute withdrawal.

Duration of effect is 1-4 hr; therefore close observation for re-narcotization is essential to prevent re-narcotization.

<table>
<thead>
<tr>
<th>Excessive sedation without evidence of respiratory depression</th>
<th>Methylphenidate *: 0.3 mg/kg per dose PO (typically 10-20 mg/dose to a teenager) before breakfast and lunch. Do not administer to patients receiving clonidine, because dysrhythmias may develop. Dextroamphetamine: 2.5-10 mg on awakening and at noon. Not for use in young children or in patients with cardiovascular disease or hypertension. Modafinil: Pediatric dose not established. May be useful in selected patients. Typical adult dose: 50-200 mg/day.</th>
</tr>

* Rapidly hydrolyzed to morphine.

† Only part of its analgesic action results from action on μ-opioid receptors.

NOTES:

- Published reports vary in the suggested doses considered to be equianalgesic to morphine. Therefore, titration to clinical response in each patient is necessary.
- Suggested doses are the results of single-dose studies.
only. Therefore, use of the data to calculate total daily dose requirements and repeated or continuous doses may not be appropriate.

• There may be incomplete cross-tolerance between these drugs. In patients who have been receiving one opioid for a prolonged period, it is usually necessary to use a dose lower than the expected equianalgesic dose when changing to another opioid, and to titrate to effect.

Opioids act by mimicking the actions of endogenous opioid peptides, binding to receptors in the brain, brainstem, spinal cord, and to a lesser extent in the peripheral nervous system, and thus leading to inhibition of nociception. Opioids also bind to µ receptors in the pleasure centers of the midbrain, particularly in genetically susceptible individuals, a factor responsible for the euphoric effect in some individuals as well as the predilection to psychological dependence and addictive behavior. Opioids also have dose-dependent respiratory depressant effects when interacting with the µ-opioid receptors in the respiratory centers of the brainstem, depressing ventilator drive and blunting ventilatory responses to both hypoxia and hypercarbia. These respiratory depressant effects are increased with co-administration of other sedating drugs, particularly benzodiazepines or barbiturates.

Optimal use of opioids requires proactive and anticipatory management of side effects (see Table 76.7). Common side effects include sedation, constipation, nausea, vomiting, urinary retention, and pruritus. Tolerance usually develops to the side effect of nausea, which typically subsides with long-term dosing, but nausea may require treatment with antiemetics, such as a phenothiazine, butyrophenones, antihistamines, or a serotonin receptor antagonist such as ondansetron or granisetron. Pruritus and other complications during patient-controlled analgesia with opioids may be effectively managed by low-dose IV naloxone.

The most common, troubling, but treatable side effect is constipation. Patients who take opioids for chronic pain for long periods predictably develop tolerance to the sedative and analgesic effects of opioids over time, but tolerance
to constipation does not occur, and constipation remains a troublesome and distressing problem in almost all patients with long-term opioid administration. Stool softeners and stimulant laxatives should be administered to most patients receiving opioids for more than a few days. Osmotic and bulk laxatives are less effective, usually producing more distention and discomfort. A peripherally acting opiate µ-receptor antagonist, methylnaltrexone, promptly and effectively reverses opioid-induced constipation in patients with chronic pain who are receiving opioids daily. Methylnaltrexone is approved for use as either an injectable or oral formulation, but only the SC injection is commercially available, which most children will object to receiving. Naldemedine and naloxegol are other agents with actions similar to methylnaltrexone. A novel laxative, lubiprostone, is a colonic chloride channel inhibitor that impairs water reabsorption in the colon and is very effective for opioid-induced constipation.

Media and government attention the “opioid epidemic” has reasonably led to scrutiny of the prescription of opioids to children, and recent FDA approval of opioid formulations for children has raised alarm and criticism by some vocal critics of the use of opioids for medical purposes. Thus, one of the potent barriers to effective management of pain with opioids is the fear of addiction held by many prescribing pediatricians and parents alike. Pediatricians should understand the phenomena of tolerance, dependence, withdrawal, and addiction (see Table 76.5). Opioid addiction is the result of the complex interplay of genetic predisposition, psychiatric pathology, and social forces, including poverty, joblessness, hopelessness, and despair. The dramatic increase in the amount of opioid abuse and overdoses and opioid-related deaths since 2001 has been largely restricted to the adult white population age 30-55 yr, not in children or adolescents. A longitudinal study of children and adolescents treated for medical reasons with opioids found that there was no increased risk of the development of substance abuse, at least until their mid-20s. Other epidemiologic studies have shown a negligible increase in opioid overdoses and deaths in the black and Latino populations, but rather a relationship to the unemployment rate. Thus the rational short- or even long-term use of opioids in children does not lead to a predilection for or risk of addiction in a child not otherwise at risk because of genetic background, race, or social milieu.

It is equally important for pediatricians to realize that even patients with recognized substance abuse diagnoses are entitled to effective analgesic management, which often includes the use of opioids. If legitimate concerns exist about addiction in a patient, safe effective opioid pain management is often
best managed by specialists in pain management and addiction medicine. Table 76.9 outlines the U.S. Centers for Disease Control and Prevention (CDC) opioid recommendations for chronic pain (primarily in adults).

Table 76.9

<table>
<thead>
<tr>
<th>CDC Recommendations for Prescribing Opioids for Chronic Pain Outside of Active Cancer, Palliative, and End-of-Life Care</th>
</tr>
</thead>
</table>

**Determining When to Initiate or Continue Opioids for Chronic Pain**

1. Nonpharmacologic therapy and nonopioid pharmacologic therapy are preferred for chronic pain. Clinicians should consider opioid therapy only if expected benefits for both pain and function are anticipated to outweigh risks to the patient. If opioids are used, they should be combined with nonpharmacologic therapy and nonopioid pharmacologic therapy, as appropriate.

2. Before starting opioid therapy for chronic pain, clinicians should establish treatment goals with all patients, including realistic goals for pain and function, and should consider how therapy will be discontinued if benefits do not outweigh risks. Clinicians should continue opioid therapy only if there is clinically meaningful improvement in pain and function that outweighs risks to patient safety.

3. Before starting and periodically during opioid therapy, clinicians should discuss with patients known risks and realistic benefits of opioid therapy and patient and clinician responsibilities for managing therapy.

**Opioid Selection, Dosage, Duration, Follow-Up, and Discontinuation**

4. When starting opioid therapy for chronic pain, clinicians should prescribe immediate-release opioids instead of extended-release/long-acting (ER/LA) opioids.

5. When opioids are started, clinicians should prescribe the lowest effective dosage. Clinicians should use caution when prescribing opioids at any dosage, should carefully reassess evidence of individual benefits and risks when increasing dosage to ≥50 morphine milligram equivalents (MME)/day, and should avoid increasing dosage to ≥90 MME/day or
carefully justify a decision to titrate dosage to ≥90 MME/day.

6. Long-term opioid use often begins with treatment of acute pain. When opioids are used for acute pain, clinicians should prescribe the lowest effective dose of immediate-release opioids and should prescribe no greater quantity than needed for the expected duration of pain severe enough to require opioids. Three days or less will often be sufficient; more than seven days will rarely be needed.

7. Clinicians should evaluate benefits and harms with patients within 1 to 4 weeks of starting opioid therapy for chronic pain or of dose escalation. Clinicians should evaluate benefits and harms of continued therapy with patients every 3 months or more frequently. If benefits do not outweigh harms of continued opioid therapy, clinicians should optimize other therapies and work with patients to taper opioids to lower dosages or to taper and discontinue opioids.

Assessing Risk and Addressing Harms of Opioid Use

8. Before starting and periodically during continuation of opioid therapy, clinicians should evaluate risk factors for opioid-related harms. Clinicians should incorporate into the management plan strategies to mitigate risk, including considering offering naloxone when factors that increase risk for opioid overdose, such as history of overdose, history of substance use disorder, higher opioid dosages (≥50 MME/day), or concurrent benzodiazepine use, are present.

9. Clinicians should review the patient's history of controlled substance prescriptions using state prescription drug monitoring program (PDMP) data to determine whether the patient is receiving opioid dosages or dangerous combinations that put him or her at high risk for overdose. Clinicians should review PDMP data when starting opioid therapy for chronic pain and periodically during opioid therapy for chronic pain, ranging from every prescription to every 3 months.

10. When prescribing opioids for chronic pain, clinicians should use urine drug testing before starting opioid therapy and consider urine drug testing at least annually to assess for prescribed medications as well as other controlled prescription drugs and illicit drugs.

11. Clinicians should avoid prescribing opioid pain medication and benzodiazepines concurrently whenever possible.
Clinicians should offer or arrange evidence-based treatment (usually medication-assisted treatment with buprenorphine or methadone in combination with behavioral therapies) for patients with opioid use disorder.

All recommendations are category A (apply to all patients outside of active cancer treatment, palliative care, and end-of-life care) except recommendation 10 (designated category B, with individual decision making required); see full guideline for evidence ratings.

There is no longer a reason to administer opioids by IM injection. Continuous IV infusion of opioids is an effective option that permits more constant plasma concentrations and clinical effects than intermittent IV bolus dosing, without the pain associated with IM injection. The most common approach in pediatric centers is to administer a low-dose basal opioid infusion, while permitting patients to use a patient-controlled analgesia (PCA) device to titrate the dosage above the infusion (Fig. 76.3) (see Chapter 74). Compared with children given intermittent IM morphine, children using PCA reported better pain scores. PCA has several other advantages: (1) dosing can be adjusted to account for individual pharmacokinetic and pharmacodynamic variation and for changing pain intensity during the day; (2) psychologically the patient is more in control, actively coping with the pain; (3) overall opioid consumption tends to be lower; (4) therefore fewer side effects occur; and (5) patient satisfaction is generally much higher. Children as young as 5-6 yr can effectively use PCA. The device can also be activated by parents or nurses, known as PCA-by-proxy (PCA-P), which produces analgesia in a safe, effective manner for children who cannot activate the PCA demand button themselves because they are too young or intellectually or physically impaired. PCA overdoses have occurred when well-meaning, inadequately instructed parents pushed the PCA button in medically complicated situations, with or without the use of PCA-P, highlighting the need for patient and family education, use of protocols, and adequate nursing supervision.
Patient-controlled analgesia is more likely to keep blood concentrations of opioid within the “analgesic corridor” and allows rapid titration if there is an increase in pain stimulus requiring higher blood levels of opioid to maintain the analgesia. (From Burg FD, Ingelfinger JR, Polin RA, et al, editors: Current pediatric therapy, ed 18. Philadelphia, 2006, Saunders/Elsevier, p 16.)

Because of the high risk of adverse side effects (respiratory depression), the FDA has issued contraindications for the pediatric use of codeine and tramadol (Table 76.10).

**Summary of FDA Recommendations**

- Use of codeine to treat pain or cough in children <12 yr old is contraindicated.
- Use of tramadol to treat pain in children <12 yr old is contraindicated.
- Use of tramadol for treatment of pain after tonsillectomy or adenoidectomy in patients <18 yr old is contraindicated. (Codeine was already contraindicated in such patients).
- Use of codeine or tramadol in children 12-18 yr old who are obese or who have an increased risk of serious breathing problems, such as those with obstructive sleep apnea or severe lung disease, is not recommended.
- Use of codeine or tramadol in breastfeeding women should be avoided.

Local Anesthetics

Local anesthetics are widely used in children for topical application, cutaneous infiltration, peripheral nerve block, neuraxial blocks (intrathecal or epidural infusions), and IV infusions (Table 76.11) (see Chapter 74). Local anesthetics can be used with excellent safety and effectiveness. Local anesthetics interfere with neural transmission by blocking neuronal sodium channels. Excessive systemic dosing can cause seizures, CNS depression, and (by cardiac and arteriolar sodium channel blockade) hypotension, arrhythmias, cardiac depression, and cardiovascular collapse. Local anesthetics therefore require a strict maximum dosing schedule. Pediatricians should be aware of the need to calculate these doses and adhere to guidelines.

* Also referred to as ALA on the basis of alternative names for the constituents: adrenaline, lignocaine, amethocaine. These mixtures are locally made by hospital formularies, with a common formula being lidocaine 4% plus epinephrine 0·1% plus tetracaine 0·5%. The cocaine-based formulation was historically avoided on wounds of digits, ears, penis, nose, mucous membranes, close to the eye, or deep wounds involving bone, cartilage, tendon, or vessels. The lidocaine-based formulation can be used in such settings.

Adapted from Krauss BS, Calligaris L, Green SM, Barbi E: Current concepts in management of

Topical local anesthetic preparations do not generally result in measurable systemic blood levels and can reduce pain in diverse circumstances: suturing of lacerations, placement of peripheral IV catheters, lumbar punctures, and accessing indwelling central venous ports. The application of tetracaine, epinephrine, and cocaine results in good anesthesia for suturing wounds but should not be used on mucous membranes. Combinations of tetracaine with phenylephrine and lidocaine-epinephrine-tetracaine are equally as effective, eliminating the need to use a controlled substance (cocaine). EMLA, a topical eutectic mixture of lidocaine and prilocaine used to anesthetize intact skin, is frequently applied for venipuncture, lumbar puncture, and other needle procedures. A 5% lidocaine cream (Elemax) is also effective as a topical anesthetic.

**Lidocaine** is the most commonly used local anesthetic for cutaneous infiltration. Maximum safe doses of lidocaine are 5 mg/kg without epinephrine and 7 mg/kg with epinephrine. Although concentrated solutions (2%) are commonly available from hospital pharmacies, more dilute solutions (0.25% and 0.5%) are equally as effective as 1–2% solutions. The diluted solutions cause less burning discomfort on injection and permit use of larger volumes without achieving toxic doses. In the surgical setting, cutaneous infiltration is more often performed with bupivacaine 0.25% or ropivacaine 0.2% because of the much longer duration of effect; maximum dosage of these long-acting amide anesthetics is 2-3 mg/kg and 3-4 mg/kg, respectively.

**Neuropathic pain** may respond well to the local application of a lidocaine topical patch (Lidoderm) for 12 hr/day (*Table 76.12*). Peripheral and central neuropathic pain also may respond to IV lidocaine infusions, which may be used in hospital settings for refractory pain, complex regional pain syndromes, and pain associated with malignancies or the therapy of malignancies, such as oral mucositis following bone marrow transplantation. In these patients, 1-2 mg/kg/hr should be administered, and the infusion titrated to achieve a blood lidocaine level in the 2-5 µg/mL range, with use of twice-daily therapeutic blood monitoring. *Table 76.13* outlines approaches to central neuropathic pain.

### Unconventional Medications in Pediatric Pain

*Unconventional analgesic medication* refers to a wide number of drugs developed for other indications but found to have analgesic properties. These drugs include some antidepressants, antiepileptic drugs, and neurotropic drugs.

The unconventional analgesics are generally used to manage neuropathic pain conditions, migraine disorders, fibromyalgia syndrome, and some forms of functional chronic abdominal pain syndromes. These agents also are used as components of multimodal analgesia in the management of surgical, somatic, and musculoskeletal pain. Fig. 76.4 presents a decision-making tree to help the physician select the appropriate analgesic category for various types of pain.
Although several unconventional analgesics are FDA approved for analgesic use, none is approved for use in youths with acute or chronic pain. Thus, these drugs should be used with caution, with a focus on mitigating pain to allow a child to participate effectively in therapies and return to normal activity as soon as possible. The use of psychotropic medications should be guided by the principles applied to pharmacologic treatment of any symptom or disease. Target symptoms should be identified, and medication side effects monitored. To determine dosing regimens, the physician should consider the child's weight and the effects that the medical condition and other medications, such as psychotropic drugs, may have on the child's metabolism. When available, therapeutic blood level monitoring should be performed. Side effects should be addressed in detail with both parent and child, and specific instructions given for responding to possible adverse events. Directly addressing concerns about
addiction, dependence, and tolerance may be necessary to decrease treatment-related anxiety and improve medication adherence.

**Antidepressant Medications**

Antidepressants are useful in adults with chronic pain, including neuropathic pain, headaches, and rheumatoid arthritis, independent of their effects on depressive disorders. Antidepressants' analgesic mechanism of action is inhibition of norepinephrine reuptake in the CNS. In children, because clinical trials have been limited, the practitioner should use antidepressants cautiously to treat chronic pain or associated depressive or anxiety symptoms. The FDA has issued a “black box warning,” its strongest warning, to inform the public of a small but significant increase in suicidal thoughts and attempts in children and adolescents receiving antidepressants. A meta-analysis of studies involving children and adolescents receiving antidepressants indicated that no suicides had been completed. The pediatrician should address this issue with parents of patients being treated with antidepressants and should develop monitoring plans consistent with current FDA recommendations.

**Tricyclic antidepressants (TCAs)** have been studied most in children with chronic pain and found to be effective in pain relief for symptoms that include neuropathic pain, functional abdominal pain, and migraine. TCA efficacy may be based on inhibition of the neurochemical pathways involved in norepinephrine and serotonin reuptake and interference with other neurochemicals involved in the perception or neural conduction of pain. Because sedation is the most common side effect, TCAs are also effective in treating the sleep disorders that frequently accompany pediatric pain. Biotransformation of TCAs is extensive in healthy children. Typically, TCAs are administered only at bedtime. Alternatively, the patient can be started on a bedtime dose of a TCA, which may be able to then be titrated to a daily divided dose, with the larger dose given at bedtime. The reader should note that pain symptoms usually remit at lower doses than those recommended or required for the treatment of mood disorders. Most children and adolescents do not require more than 0.25-0.5 mg/kg of amitriptyline or nortriptyline once daily at bedtime.

Attention should also be paid to hepatic microsomal enzyme metabolism, because CYP2D6 inhibitors, such as cimetidine and quinidine, can increase levels of TCAs. Anticholinergic side effects, which are less common in children than adults, may remit over time. Constipation, orthostatic hypotension, and
dental caries from dry mouth should be addressed by emphasizing the importance of hydration and oral hygiene. Other side effects include weight gain, mild bone marrow suppression, and liver dysfunction. Some practitioners recommend monitoring complete blood count (CBC) and liver function values at baseline and periodically during therapy. TCA blood levels can be obtained as well, but therapeutic blood monitoring generally should occur individually, particularly if adherence, overdose, or sudden change in mental status is an issue.

All TCAs inhibit cardiac conduction pathways and prolong the QT interval. Sudden cardiac death has been reported in children taking TCAs, principally desipramine, probably related to QTc prolongation. There is no general agreement for monitoring the electrophysiologic effects of these drugs, but it is prudent to obtain a careful personal and family history focusing on cardiac arrhythmias, heart disease, and syncope before the initiation of treatment. If personal or family history is positive for any of these conditions, a baseline electrocardiogram (ECG) should be obtained, with care taken to ensure that the QTc is <445 msec. We recommend that if the dose of amitriptyline or nortriptyline is increased beyond 0.25-0.5 mg/kg/day, an ECG should be performed for each dosing increase. With TCAs, as with other antidepressants, physical dependence and a known discontinuation syndrome can occur. The discontinuation syndrome includes agitation, sleep disturbances, appetite changes, and GI symptoms. These medications should be tapered slowly to assist in distinguishing among symptoms that indicate rebound, withdrawal, or the need for continuing the medication.

Selective serotonin reuptake inhibitors (SSRIs) have minimal efficacy in the treatment of a variety of pain syndromes in adults. SSRIs are very useful when symptoms of depression or anxiety disorders are present and cannot be addressed adequately by nonpharmacologic means. Escitalopram (Lexapro), fluoxetine (Prozac), and sertraline (Zoloft) have been approved by the FDA for use in children and adolescents. SSRIs have a significantly milder side effect profile than TCAs (most side effects are transient), and they have no anticholinergic side effects. Chief side effects include GI symptoms, headaches, agitation, insomnia, sexual dysfunction, and anxiety. Rarely, hyponatremia, or the syndrome of inappropriate antidiuretic hormone secretion (SIADH), may occur. Interactions with other medications that have serotonergic effects (tramadol, trazodone, tryptophan, and triptan migraine medication) may also occur in theory. When these medications are used in combination, many sources
state there may be increased likelihood that a life-threatening serotonergic syndrome may occur, with associated symptoms of myoclonus, hyperreflexia, autonomic instability, muscle rigidity, and delirium (see Chapter 77). In fact, serotonin syndrome has never been reported in adults or children with triptans taken for headache disorder and SSRIs. There is also a discontinuation syndrome associated with shorter-acting SSRIs (e.g., paroxetine), which includes dizziness, lethargy, paresthesias, irritability, and vivid dreams. Dosages of medications should be tapered slowly over several weeks.

The selective serotonin-norepinephrine reuptake inhibitors (SNRIs) duloxetine and venlafaxine have demonstrated significant efficacy with chronic neuropathic and other pain syndromes because they inhibit both serotonin and norepinephrine reuptake, and they may directly block associated pain receptors as well. Venlafaxine has no pain indication labeling. Duloxetine is FDA approved for managing neuropathic pain (specifically, diabetic neuropathy) and fibromyalgia syndrome and for use in children as young as 7 yr. A significant advantage of SNRIs over TCAs when used for headache prophylaxis or neuropathic pain is that they have therapeutic effects on mood and anxiety at dosages effective for pain control.

Because both SSRIs and SNRIs have fewer anticholinergic side effects than TCAs, adherence to them is better than in psychiatric populations taking TCAs. Side effects of both types of drugs include GI symptoms, hyperhidrosis, dizziness, and agitation, but these effects generally wane over time. Hypertension and orthostatic hypotension may occur; in addition, the patient's blood pressure should be closely followed, and appropriate hydration should be stressed. Note that whereas appetite stimulation and weight gain are associated with all TCAs, duloxetine is often associated with weight loss, frequently a desirable side effect, especially in weight-conscious adolescent females.

All antidepressants, including the TCAs, SSRIs and SNRIs, are thought to have the potential to increase the risk of suicidal ideation and the risk of suicide in patients. The FDA states, “All pediatric patients being treated with antidepressants for any indication should be observed closely for clinical worsening, suicidality, and unusual changes in behavior, especially during the initial few months of a course of drug therapy, or at times of dose changes, either increases or decreases.” However, the FDA also notes, “Although there has been a long-standing concern that antidepressants may have a role in inducing worsening of depression and the emergence of suicidality in certain patients, a causal role for antidepressants in inducing such behaviors has not been
established. Nevertheless, patients being treated with antidepressants should be observed closely for clinical worsening and suicidality, especially at the beginning of a course of drug therapy, or at the time of dose changes, either increases or decreases.”

**Antiepileptic Drugs**

Anticonvulsants, such as gabapentin, carbamazepine, and valproic acid, are believed to relieve chronic pain by blocking sodium (valproate and the gabapentanoids) or calcium (carbamazepine and oxcarbazepine) channels at the cellular neuronal level, thereby suppressing spontaneous electrical activity and restoring the normal threshold to depolarization of hypersensitive nociceptive neurons, without affecting normal nerve conduction. These medications are particularly useful in patients with mood disorders who have neuropathic pain. In adults, the FDA has approved carbamazepine for trigeminal neuralgia, valproate for migraine prophylaxis, and pregabalin for neuropathic pain complicating diabetes, for zoster, and for management of fibromyalgia. Anticonvulsant medications generally have GI side effects in addition to sedation, anemia, ataxia, rash, and hepatotoxicity. Carbamazepine and oxcarbazepine are also associated with Stevens-Johnson syndrome.

Liver function and CBC should be monitored at the start of therapy and periodically with antiepileptic drugs (AEDs). Carbamazepine and valproic acid have narrow therapeutic windows and variability in therapeutic blood medication levels, as well as many drug-drug interactions, and may cause liver disease and renal impairment. Drug levels should be measured with each dose increase and periodically thereafter. Carbamazepine, in particular, causes autoinduction of hepatic microsomal enzymes, which can further complicate obtaining a therapeutic medication level. Female patients should have pregnancy testing before taking valproate, and those who are sexually active must be cautioned to use effective contraception, because neural tube defects are associated with carbamazepine.

Less toxic AEDs have supplanted the use of valproate and carbamazepine in patients with pain. These newer agents have their own, sometimes troubling, side effect profiles, but they are much less toxic than their predecessors and do not require monitoring of liver or bone marrow function or blood levels. Furthermore, they are also far less lethal in accidental or deliberate overdose. **Gabapentin**, the most widely prescribed AED for the management of pain
disorders, demonstrates efficacy in treating children with chronic pain, particularly neuropathic pain, and is playing an increasing role in the management of routine surgical pain. Gabapentin has proved effective in treating chronic headache disorders and many neuropathic pain syndromes, including complex regional pain syndromes, chemotherapy-induced neuropathy, postherpetic neuralgia, and diabetic neuropathy in both children and adults. This agent has a relatively benign side effect profile and no drug interactions. Side effects include somnolence, dizziness, and ataxia. Children occasionally demonstrate side effects not reported in adults, such as impulsive or oppositional behavior, agitation, and occasionally depression. These side effects do not seem to be dose related.

**Pregabalin** works by similar mechanisms as gabapentin but has a better side effect profile. Both gabapentin and pregabalin undergo virtually no hepatic metabolism, with no significant drug-drug interactions, a concern in patients with chronic pain, who frequently take multiple medications—for both the pain and the underlying medical condition associated with the pain. However, because both AEDs depend on renal function for clearance, doses must be adjusted in the presence of renal dysfunction.

**Topiramate** also demonstrates greater success than traditional anticonvulsants in treating trigeminal neuralgia in adults and in migraine prophylaxis. Topiramate therapy results more frequently in cognitive dysfunction and short-term memory loss than gabapentin or pregabalin, and these neurocognitive effects are particularly problematic for school-aged children. The pediatrician should also be aware that topiramate is associated with weight loss, whereas other anticonvulsants are typically associated with significant weight gain. This side effect is particularly valuable in weight-conscious adolescents, whereas in the anorexic cancer patient, a TCA would be preferable to induce appetite and weight gain.

**Benzodiazepines**

Children and adolescents with chronic pain may have comorbid psychological conditions, such as depressed mood, sleep disturbances, and anxiety disorders, including generalized anxiety disorder, separation anxiety, posttraumatic stress disorder (PTSD), and panic attacks. Pervasive developmental disorders are common in this population. Psychological factors affect a youth's ability to cope with a pain disorder. *A conditioned response* to pain may be to feel out of control
and increase anxiety and pain, and conversely, *anticipatory anxiety* related to pain will inhibit activities and recovery. Feelings of helplessness sensitize the child to increasing amounts of pain, leading the child to perseverate on pain, think catastrophically, and feel hopeless. Changes in children's normal routines, with a negative impact on participation in valued activities, may further promote hopelessness, resulting in increased pain experiences and development of a depressive disorder.

Benzodiazepines are anxiolytic medications that also have muscle relaxant effects. They are particularly appropriate in acute situations as valuable adjuncts to the management of pain in the hospital setting, because they inhibit painful muscle spasms in surgical patients, but more importantly because they suppress the anxiety that virtually every hospitalized child experiences, anxiety that interferes with restorative sleep and amplifies the child's perception of pain. Benzodiazepines are useful to calm children with anxiety and anticipatory anxiety about planned, painful procedures.

Because dependence, tolerance, and withdrawal may occur with prolonged use, benzodiazepines are generally not recommended for the routine management of *chronic pain*. Further, the risk of respiratory depression when benzodiazepines are combined with opioid therapy has contributed to the increasing number of opioid-related deaths in the United States since 2001. In concert with psychotherapy, however, benzodiazepines help control anxiety symptoms that amplify the perception of pain.

Infrequently, benzodiazepines may cause behavioral disinhibition, psychosis-like behaviors, or, in large doses, respiratory depression. When dosing these medications, the pediatrician should consider that many benzodiazepines are metabolized by the cytochrome P-450 microsomal enzyme system. This issue may be less significant with lorazepam and oxazepam, which undergo first-pass hepatic conjugation. Side effects common to benzodiazepines include sedation, ataxia, anemia, increased bronchial secretions, and depressed mood. If a benzodiazepine is administered for more than several consecutive days, the dosage should be slowly tapered over 2 or more weeks; if therapy is abruptly discontinued, autonomic instability, delirium, agitation, seizures, and profound insomnia may occur. The child psychiatric literature cites concerns that the use of benzodiazepines during hospitalization for serious disease (e.g., organ transplantation, prolonged intensive care unit [ICU] stay) might increase the risk for development of PTSD or increase PTSD symptomatology by reducing orientation used in coping with stress. Thus, other anxiolytics, such as atypical
Antipsychotics, are often recommended.

**Antipsychotics and Major Sedatives**

Low doses of antipsychotic medications are often used to address the more severe anxiety, agitation, and behavioral decompensation sometimes associated with severe pain. The use of these medications is controversial because associated adverse events may be severe and irreversible. Typical antipsychotics used in the past, including thioridazine (Mellaril), haloperidol (Haldol), and chlorpromazine (Thorazine), are associated with a decreased seizure threshold, dystonia, agranulocytosis, weight gain, cardiac conduction disturbances, tardive dyskinesia, orthostatic hypotension, hepatic dysfunction, and life-threatening laryngeal dystonia. These side effects are generally less severe with atypical antipsychotics. Because these effects may still occur, the pediatrician should obtain a baseline ECG, liver function values, and CBC analysis, and if possible obtain a child psychiatry consultation. If the pediatrician is using typical antipsychotics, an inventory of movement disturbances, such as the Abnormal Involuntary Movement Scale (AIMS) test, should be performed at baseline and at every follow-up visit, because movement disorders can worsen with abrupt withdrawal of medications or can become irreversible.

**Atypical antipsychotics** are generally associated with less severe side effect profiles, particularly dyskinesias and dystonias. Use of olanzapine (Zyprexa), which is particularly helpful with insomnia and severe anxiety, requires assessing and monitoring blood levels of glucose, cholesterol, and triglyceride; olanzapine's side effects may include diabetes, hypercholesterolemia, or significant weight gain. The anticholinergic side effects associated with quetiapine (Seroquel) warrant frequent monitoring of blood pressure. Risperidone at doses >6 mg may cause side effects similar to those of typical antipsychotics. Clozapine (Clozaril), which causes increased incidence of life-threatening agranulocytosis, should generally be avoided as a treatment for children and adolescents with chronic pain. Aripiprazole (Abilify) has been used for severe anxiety and/or for treatment-resistant depression. All antipsychotics are associated with the rare, but potentially lethal **neuroleptic malignant syndrome**, which includes severe autonomic instability, muscular rigidity, hyperthermia, catatonia, and altered mental status.

**Other Pain Control Medications**
Alpha-adrenergic receptor agonists such as clonidine are typically used as antihypertensive agents. However, they are often helpful as both anxiolytics and sleep-onset agents in the anxious hospitalized child. The α-agonists also have central effects on pain reduction. Clonidine can be given orally or transdermally, if the child's blood pressure permits. In the ICU, IV dexmedetomidine, an α-agonist sedating agent, can be used for the anxious, medically unstable child. Weaning off the dexmedetomidine can often be accomplished with a transition to clonidine. Propranolol is a β-blocking agent typically used for the child with autonomic instability and for thalamic storm. There are reports that a β-blocker can enhance depression in a child who already has a major depressive disorder, and discussion with a child psychiatrist can be helpful in decisions about using propranolol if needed. Both clonidine and propranolol have been found useful for the agitated child with ASD. Another α-agonist, guanfacine, is more likely to be used during the day for the child with ASD because it is less sedating than clonidine. Despite research on the impact of clonidine on chronic pain, no data are available to determine if guanfacine is as effective in reducing pain. Lastly, ketamine, a blocker of N-methyl-D-aspartate (NMDA) receptors, has been used for intractable pain in hospitalized children and in outpatients with severe sickle cell disease–related chronic pain, as well as others in palliative care for whom opioids are not sufficient to reduce pain. Since ketamine can have central hallucinatory effects, such children should be monitored closely.

Nonpharmacologic Treatment of Pain

Numerous psychological and physical treatments for relieving pain, fear, and anxiety as well as enhancing functioning have excellent safety profiles and proven effectiveness and should always be considered for incorporation into pediatric pain treatment (Fig. 76.5). In acute and procedural pain, nonpharmacologic strategies have long been used to help reduce distress in children undergoing medical procedures and surgery. Many of these methods aim to help children shift attention from pain and alter pain perception (e.g., distraction, hypnosis, imagery). Similarly, in the treatment of chronic pain, several strategies, often falling under the umbrella category of cognitive-behavioral therapies (CBTs), have been shown to reduce pain and improve functioning and quality of life. CBT was developed with the goal of modifying social/environmental and behavioral factors that may exacerbate the child's experience of pain and pain-related disability. Several decades of research is
available on CBTs for pediatric chronic pain. Meta-analyses of randomized controlled trials (RCTs) of CBT interventions have found large positive effects of psychological intervention on reductions in pain and/or its deleterious effects in children with headache, abdominal pain, and fibromyalgia, with relative or comparative effectiveness of different interventions examined in areas such as headache and abdominal pain in children. Biofeedback and relaxation therapies have been found to have superior effects to pharmacologic treatments in reducing headache pain in children and adolescents. Similarly, for recurrent abdominal pain, positive effects for CBT were found relative to attention-control conditions and pharmaceutical, botanical, and dietary interventions (which had very weak evidence). Positive results have even resulted from very brief (3 sessions) and remotely delivered (telephone or internet) therapies, with outcomes lasting as long as 12 mo after intervention.

When deciding how to incorporate nonpharmacologic techniques to treat pain, the practitioner should (1) conduct a thorough assessment of individual, social, and environmental factors that may be contributing to the patient's pain and functioning limitations; (2) based on this assessment, decide whether nonpharmacologic techniques alone may be sufficient as a beginning to treatment, or if these treatments should be integrated with appropriate analgesics; (3) give children (and family members) developmentally and situationally appropriate information as to the rationale for treatment selection, and what to expect, given the child's medical condition, procedures, and treatments; (4) include patients and their families in decision making to ensure an appropriate treatment choice and to optimize adherence to treatment
protocols; and (5) above all, develop a communication plan among the different care providers, typically with the pediatrician as the case manager, so that the messages to the child and parent are consistent and the modes of therapy are organized into an integrative team approach. Finally, it is important to recognize that in addition to pain, other psychological disorders (e.g., anxiety disorders, major depression) may impact the presenting pain complaint and may need to be identified and addressed as part of, or separate from, the pain management plan. Individual psychotherapy or psychiatric intervention may be warranted to adequately treat a comorbid disorder.

CBT strategies refer to a range of techniques that teach children (and their caregivers) how to manage pain by learning new ways to think about the pain and how to change behaviors associated with the pain. Strategies focusing on cognitions are typically aimed at enhancing parents' and children's confidence and self-efficacy to handle pain and decrease fear of pain. In addition, pain coping skills may shift the child's attentional focus away from pain and painful stimuli.

The goals of those strategies focusing on behavior change are to modify (1) contingencies in the child's environment, such as teaching parents how to respond to pain behaviors in ways that encourage wellness, rather than illness behaviors; (2) the ways parents model reactions to pain or discomfort; (3) child and parent coping techniques when psychosocial distress or problems in social relations exist; and (4) the child's behavioral reactions to situations, such as relaxation and exposure to previously avoided activities. Common examples of these strategies are discussed next. Whereas comprehensive CBTs are typically conducted by trained mental health specialists over several sessions, some basic CBT strategies can be briefly and easily introduced by practitioners into most medical settings. If more in-depth CBT treatment is needed, a referral to a qualified mental health specialist with CBT skills would be warranted.

Parent and family education and/or psychotherapy, particularly within cognitive-behavioral family approaches, is one treatment modality through which these goals are accomplished, and thus has been shown to be effective for treating chronic pain. Parents can learn to cope with their own distress and to understand pain mechanisms and appropriate treatment of pain. Key components include teaching parents to alter family patterns that may inadvertently exacerbate pain through developing behavior plans. Parents are taught to create plans for the child to manage the child's own symptoms and increase independent functioning. Often, adult caregivers (e.g., parents, teachers) need
only guidance on developing a behavioral incentive plan to help the child return to school, gradually increase attendance, and receive tutoring, after a prolonged, pain-related absence. **Suggested sample brief strategy:** Ask caregivers how they react to the child's pain complaints; assess whether they encourage wellness activities or give attention and “rewards” primarily when the child says he or she does not feel well; and suggest that caregivers respond to the child in ways that encourage wellness both when complaining and not complaining.

**Relaxation training** is often employed to promote muscle relaxation and reduction of anxiety, which often accompanies and increases pain. Relaxation training, along with distraction and biofeedback, are treatments often included in CBT, but also are discussed in the literature without mention of CBT.

**Controlled breathing** and **progressive muscle relaxation** are commonly used relaxation techniques taught to preschool-age and older children. **Suggested sample brief strategy:** Ask the child (or instruct the caregiver to do so) to practice the following and use if pain is coming on: focus on the breath, and pretend to be blowing up a big balloon, while pursing the lips and exhaling slowly. This is one way to help induce controlled breathing.

**Distraction** can be used to help a child of any age shift attention away from pain and onto other activities. Common attention sustainers in the environment include bubbles, music, video games, television, the telephone, conversation, school, and play. Asking children to tell stories, asking parents to read to the child, and even mutual storytelling can be helpful distracters. Being involved with social, school, physical, or other activities helps the child in chronic pain to regain function. **Suggested sample brief strategy:** Encourage the child (or instruct the caregiver to do so) to shift attention away from the pain by continuing to engage in other activities and/or think of something else.

**Biofeedback** involves controlled breathing, relaxation, or hypnotic techniques with a mechanical device that provides visual or auditory feedback to the child when the desired action is approximated. Common targets of actions include muscle tension, peripheral skin temperature through peripheral vasodilation, and anal control through rectal muscle contraction and relaxation. Biofeedback also enhances the child's sense of mastery and control, especially for the child who needs more “proof” of change than that generated through hypnotherapy alone.

**Hypnotherapy** has also been used in the treatment of chronic pain in children, although the evidence for its effectiveness has not been as extensively studied as CBT. Hypnotherapy helps a child focus on an imaginative experience that is comforting, safe, fun, or intriguing. Hypnotherapy captures the child's
attention, alters his or her sensory experiences, reduces distress, reframes pain experiences, creates time distortions, helps the child dissociate from the pain, and enhances feelings of mastery and self-control. Children with chronic pain can use metaphor, for example, imagining they have overcome something feared because of pain in real life. As the child increases mastery of imagined experiences, the enhanced sense of control can be used during actual pain rehabilitation. Hypnotherapy is best for children of school age or older.

Nonpharmacologic treatments of pain may also be applied to other treatment needs. A child who learns relaxation to reduce distress from lumbar punctures in cancer treatment may also apply this skill to other stressful medical and nonmedical situations, such as stressors caused by school.

Yoga is intended to achieve balance in mind, body, and spirit. Therapeutic yoga can be helpful in treating chronic pain; improving mood, energy, and sleep; and reducing anxiety. Yoga involves a series of asanas (body poses) oriented to the specific medical condition or symptoms. Some forms of yoga use poses within a movement flow and format. Iyengar yoga is unique in its use of props, such as blankets, bolsters, blocks, and belts, to support the body while the child assumes more healing poses. Yoga promotes a sense of energy, relaxation, strength, balance, and flexibility and, over time, enhances a sense of mastery and control. Within a yoga practice, the child may learn certain types of breathing (pranayama) for added benefit. With a focus on body postures or in types of flow yoga, the child learns mindfulness or being present and in the moment. By focusing on body and breath, the child can develop strategies to avoid ruminating about the past or worrying about the future.

Mindfulness meditation involves a focus on the present, “in-the-moment” experience using a variety of strategies. Many studies in adults report the value of meditation for chronic pain states as well as for anxiety and depression. These strategies help children learn how to be mindful and in the present, with enhanced parasympathetic control. Many mindfulness smartphone applications are geared to children of different ages, as well as books for parents on how to help their children achieve a mindful state to enhance relaxation (see Susan Kaiser-Greenland's book). Although there are different schools of mindfulness, such as Vipassana (insight-oriented meditation often using a focus on the breath) and transcendental meditation (in which the child learns the use of a silent mantra to facilitate acquiring a deeper inner calmness), the goal is to help the child learn strategies that enhance self-competence in reducing stress and enhancing a state of well-being.
Massage therapy involves the therapist's touching and applying varied degrees of pressure on the child's muscles. Massage is very useful for children with chronic pain and especially helpful for those with myofascial pain. There are several types of massage, including craniosacral therapy. For young children, it can be helpful to have parents learn and perform brief massage on their children before bedtime. Massage therapy likely will not be helpful to or tolerated by the child with sensory sensitivity and sensory aversion.

Physical therapy can be especially useful for children with chronic, musculoskeletal pain and for those deconditioned from inactivity. Exercise appears specifically to benefit muscle functioning, circulation, and posture, also improving body image, body mechanics, sleep, and mood. The physical therapist and the child can develop a graded exercise plan for enhancing the child's overall function and for the child to continue at home. Recent research indicates that physical therapy affects central neurobiologic mechanisms that enhance “top-down” pain control.

Acupuncture involves the placement of needles at specific acupuncture points along a meridian, or energy field, after the acupuncturist has made a diagnosis of excess or deficiency energy in that meridian as the primary cause of the pain. Acupuncture is a feasible, popular part of a pain management plan for children with chronic pain. Acupuncture alleviates chronic nausea, fatigue, and several chronic pain states, including migraine and chronic daily headaches, abdominal pain, and myofascial pain. Acupuncture also has efficacy in adults with myofascial pain, primary dysmenorrhea, sickle cell crisis pain, and sore throat pain. The acupuncturist must relate well to children so that the experience is not traumatic, because added stress would undo the benefits gained.

Transcutaneous electrical nerve stimulation (TENS) is the use of a battery-operated tool worn on the body to send electrical impulses into the body at certain frequencies set by the machine. TENS is believed to be safe and can be tried for many forms of localized pain. Children often find TENS helpful and effective.

Music therapy and art therapy can be especially helpful for young and nonverbal children who would otherwise have trouble with traditional talk psychotherapies. Also, many creative children can more easily express fears and negative emotions through creative expression and, with the therapist’s help, learn about themselves in the process. There is also increasing research on the impact of art and music therapy on altering central neural circuits that maintain and enhance pain.
Dance, movement, and pet therapies, and aromatherapy have also been used and may be helpful, but these have not been as well studied in children for pain control as have other complementary therapies. Often, clinical experience helps guide the pediatrician in the benefits of these therapies with individual patients. For example, pet therapy is gaining favor in hospitals and in stress reduction for sick children. Pets often can become self-regulators for the child with ASD, although the neurobiologic mechanisms are not yet understood.

**Invasive Interventions for Treating Pain**

Interventional neuraxial and peripheral nerve blocks provide intraoperative anesthesia, postoperative analgesia (see Chapter 74), and treatment of acute pain (e.g., long-bone fracture, acute pancreatitis) and contribute to the management of chronic pain such as headache, abdominal pain, complex regional pain syndrome (CRPS), and cancer pain. Interventional procedures are often used in the treatment of nonmalignant chronic pain in children in some centers and are described here so that the pediatrician will understand the different types of procedures available to children but rarely described in pediatric texts. Interventional procedures may be useful in some children who have specific types of chronic pain, but their use in children (as widely practiced in adult pain clinics) generally is not recommended because the pediatric research is insufficient. Therefore the data are largely extrapolated from the adult population. In children with CRPS receiving multiple focal blocks at an adult pain center, the first block may work “wonders,” but the pain-free intervals between blocks may become shorter, until the blocks are no longer effective, and the CRPS pain spreads, including to the sites of the blocks. This does not mean that no block should be recommend in children, but that blocks should be used judiciously and in conjunction with other biopsychosocial treatments.

**Regional anesthesia** provides several benefits. As an alternative to or in augmentation of opioid-based pain control, regional anesthesia minimizes opioid requirements and therefore opioid side effects, such as nausea, vomiting, somnolence, respiratory depression, pruritus, constipation, and physical dependence. It generally provides better-quality pain relief than systemic medication because it interrupts nociceptive pathways and more profoundly inhibits endocrine stress responses. Regional anesthesia also results in earlier ambulation in recovering surgical patients, helps prevent atelectasis in the patient with chest pain, and usually results in earlier discharge from the hospital.
Theoretically, the interruption of nociceptive pathways in the periphery by regional anesthetics will prevent, or reverse, the process of amplification of pain signals induced by nociception (e.g., CNS wind-up, glial cell activation). For postoperative pain, effective regional anesthesia reduces the risks of acute pain evolving to chronic pain. Regional anesthesia is considered safe and effective if performed by trained staff with the proper instruments and equipment. Most frequently, nerve blocks are performed by an anesthesiologist or pain management physician; a few are easily performed by a nonanesthesiologist with appropriate training.

**Head and Neck Blocks**

Primary pain syndromes of the head, such as trigeminal neuralgia, are distinctly unusual in the pediatric population, and few surgical procedures in the head and neck are amenable to regional anesthesia. Pain following tonsillectomies is not amenable to nerve blockade, and neurosurgical incisional pain is usually mitigated by local infiltration of local anesthetic into the wound margins by the surgeon. Headache disorders, very common in the pediatric age-group, often respond well to regional anesthesia of the greater occipital nerve (2nd cervical, C2), which provides sensation to much of the cranial structures, from the upper cervical region, the occiput to the apex of the head, or even to the hairline. The greater occipital nerve can be blocked medial to the occipital artery, which can usually be identified at the occipital ridge midway between the occipital prominence and the mastoid process by palpation, Doppler sound amplification, or visually by high-frequency ultrasound. The short-term and especially long-lasting effects of nerve blocks for chronic headaches in children have not been documented by research. Studies are needed to determine which children with which types of headaches will benefit most from occipital nerve blocks.

**Upper-Extremity Blocks**

The brachial plexus block controls pain of the upper extremity. This block also protects the extremity from movement, reduces arterial spasm, and blocks sympathetic tone of the upper extremity. The brachial plexus, responsible for cutaneous and motor innervation of the upper extremity, is an arrangement of nerve fibers originating from spinal nerves C5 through 1st thoracic (T1), extending from the neck into the axilla, arm, and hand. The brachial plexus
innervates the entire upper limb, except for the trapezius muscle and an area of skin near the axilla. If pain is located proximal to the elbow, the brachial plexus may be blocked above the clavicle (roots and trunks); if the pain is located distal to the elbow, the brachial plexus may be blocked at the axilla (cords and nerves). The block may be given as a single injection with a long-acting anesthetic (bupivacaine or ropivacaine, sometimes augmented with clonidine or dexamethasone to prolong block duration and intensity) to provide up to 12 hr of analgesia, or by a percutaneous catheter attached to a pump that can provide continuous analgesia over days or even weeks.

**Trunk and Abdominal Visceral Blocks**

Trunk blocks provide somatic and visceral analgesia and anesthesia for pain or surgery of the thorax and abdominal area. Sympathetic, motor, and sensory blockade may be obtained. These blocks are often used in combination to provide optimal relief. Intercostal and paravertebral blocks may be beneficial in patients for whom a thoracic epidural injection or catheter is contraindicated (e.g., patient with coagulopathy). Respiratory function is maintained, and the side effects of opioid therapy are eliminated.

The intercostal, paravertebral, rectus sheath, and transverse abdominal plane blocks are most useful for pediatric chest and somatic abdominal pain. The celiac plexus and splanchnic nerve block is most useful for abdominal visceral pain, such as caused by malignancy or pancreatitis. These blocks are best performed by an experienced anesthesiologist, pain physician, or interventional radiologist using ultrasound or CT imaging guidance.

The **intercostal block** is used to block the intercostal nerves, the anterior rami of the thoracic nerves from T1 to T11. These nerves lie inferior to each rib, between the inner and innermost intercostal muscles with their corresponding vein and artery, where they can be blocked, generally posterior to the posterior axillary line. Ultrasound imaging of the intercostal nerves helps avoid injury to intercostal vessels or insertion of the needle through the pleura, which may result in pneumothorax.

The **paravertebral block**, an alternative to intercostal nerve block or epidural analgesia, is useful for pain associated with thoracotomy or with unilateral abdominal surgery, such as nephrectomy or splenectomy. Essentially this block results in multiple intercostal blocks with a single injection. The thoracic paravertebral space, lateral to the vertebral column, contains the sympathetic
chain, rami communicantes, dorsal and ventral roots of the spinal nerves, and dorsal root ganglion. Because it is a continuous space, local anesthetic injection will provide sensory, motor, and sympathetic blockade to several dermatomes. The paravertebral block may be performed as a single injection or, for a very prolonged effect, as a continuous infusion over several days or weeks via a catheter. This block is best performed by an anesthesiologist or interventional pain physician under ultrasound guidance.

**Iliinguinal and iliohypogastric nerve blocks** are indicated with surgery for inguinal hernia repair, hydrocele, or orchiopexy repair, as well as for chronic pain subsequent to these procedures. The 1st lumbar (L1) nerve divides into the iliohypogastric and ilioinguinal nerves, which emerge from the lateral border of the psoas major muscle. The iliohypogastric nerve supplies the suprapubic area as it pierces the transversus abdominis muscle and runs deep to the internal oblique muscle. The ilioinguinal nerve supplies the upper medial thigh and superior inguinal region as it also pierces the transversus abdominis muscle and runs across the inguinal canal. Ultrasound guidance has made this nerve block almost always successful.

The **celiac plexus block** is indicated for surgery or pain of the pancreas and upper abdominal viscera. The celiac plexus, located on each side of the L1 vertebral body, contains 1-5 ganglia. The aorta lies posterior, the pancreas anterior, and the inferior vena cava lateral to these nerves. The celiac plexus receives sympathetic fibers from the greater, lesser, and least splanchnic nerves, as well as from parasympathetic fibers from the vagus nerve. Autonomic fibers from the liver, gallbladder, pancreas, stomach, spleen, kidneys, intestines, and adrenal glands originate from the celiac plexus. This block is best performed with CT guidance to provide direct visualization of the appropriate landmarks, avoid vascular and visceral structures, and confirm correct needle placement. The close proximity of structures such as the aorta and vena cava make this a technical procedure best performed by an anesthesiologist, interventional pain physician, or interventional radiologist.

**Lower-Extremity Blocks**

**Lumbar plexus and sciatic nerve blocks** provide pain control for painful conditions or surgical procedures of the lower extremities, with the benefit of providing analgesia to only one extremity while preserving motor and sensory function of the other. The lumbosacral plexus is an arrangement of nerve fibers originating from spinal nerves L2-L4 and S1-S3. The lumbar plexus arises from
L2-L4 and forms the lateral femoral cutaneous, femoral, and obturator nerves. These nerves supply the muscles and sensation of the upper leg, with a sensory branch of the femoral nerve (saphenous nerve) extending below the knee to innervate the medial aspect of the foreleg, ankle, and foot. The sacral plexus arises from L4-S3 and divides into the major branches of the sciatic, tibial, and common peroneal nerves. These nerves in turn supply the posterior thigh, lower leg, and foot. Unlike the brachial plexus block, blockade of the entire lower extremity requires >1 injection because the lumbosacral sheath is not accessible. Separate injections are necessary for the posterior (sciatic) and anterior (lumbar plexus) branches, and the injections can be performed at any of several levels during the course of the nerve, as is clinically expedient. The lumbar plexus can be blocked in the back, resulting in analgesia of the femoral, lateral femoral cutaneous, and obturator nerves. Alternatively, any of these 3 nerves can be individually anesthetized, depending on the location of the pain. Similarly, the sciatic nerve can be anesthetized proximally as it emerges from the pelvis or more distally in the posterior thigh, or its major branches (tibial and peroneal nerves) can be individually anesthetized. These nerve blocks are generally best performed by an anesthesiologist, pain physician, or radiologist.

**Sympathetic Blocks**

Sympathetic blocks were once thought to be useful in the diagnosis and treatment of sympathetically mediated pain, CRPS, and other neuropathic pain conditions, but more recently, large meta-analyses have shown their utility to be minimal. The peripheral sympathetic trunk is formed by the branches of the thoracic and lumbar spinal segments, and it extends from the base of the skull to the coccyx. The sympathetic chain, which consists of separate ganglia containing nerves and autonomic fibers with separate plexuses, can be differentially blocked. These separate plexuses include the stellate ganglion in the lower neck and upper thorax, the celiac plexus in the abdomen, the 2nd lumbar plexus for the lower extremities, and the ganglion impar for the pelvis. When blocks of these plexuses are performed, sympathectomy is obtained without attendant motor or sensory anesthesia.

The **stellate ganglion block** is indicated for pain in the face or upper extremity as well as for CRPS, phantom limb pain, amputation stump pain, or circulatory insufficiency of the upper extremities. The stellate ganglion arises from spinal nerves C7-T1 and lies anterior to the 1st rib. It contains ganglionic
fibers to the head and upper extremities. Structures in close proximity include the subclavian and vertebral arteries anteriorly, the recurrent laryngeal nerve, and the phrenic nerve. Chassaignac tubercle, the transverse process of the C6 vertebral body superior to the stellate ganglion, is a useful and easily palpable landmark for the block, but radiographic or ultrasound imaging is used more often than surface anatomy and palpation.

The lumbar sympathetic block addresses pain in the lower extremity, CRPS, phantom limb pain, amputation stump pain, and pain from circulatory insufficiency. The lumbar sympathetic chain contains ganglionic fibers to the pelvis and lower extremities. It lies along the anterolateral surface of the lumbar vertebral bodies and is most often injected between the L2 and L4 vertebral bodies.

The analgesia produced by peripheral sympathetic blocks usually outlives the duration of the local anesthetic, often persisting for weeks or indefinitely. If analgesia is transient, the blocks may be performed with catheter insertion for continuous local anesthesia of the sympathetic chain over days or weeks. Because precise, radiographically guided placement of the needle and/or catheter is required for safety and success, sympathetic blocks are generally best performed by an anesthesiologist, interventional pain physician, or interventional radiologist.

Epidural Anesthesia (Thoracic, Lumbar, and Caudal)

Epidural anesthesia and analgesia are indicated for pain below the clavicles, management of regional pain syndromes, cancer pain unresponsive to systemic opioids, and pain limited by opioid side effects.

The 3 layers of the spinal meninges—dura mater (outer), arachnoid mater (middle), and pia mater (inner)—envelop the spinal neural tissue. The subarachnoid space contains cerebrospinal fluid between the arachnoid mater and pia mater. The epidural space extends from the foramen magnum to the sacral hiatus and contains fat, lymphatics, blood vessels, and the spinal nerves as they leave the spinal cord. The epidural space separates the dura mater from the periosteum of the surrounding vertebral bodies. In children the fat in the epidural space is not as dense as in adults, predisposing to greater spread of the local anesthetic from the site of injection.

Epidural local anesthetics block both sensory and sympathetic fibers, and if
the local anesthetic is of sufficient concentration, they also block motor fibers. Mild hypotension may occur, although it is unusual in children <8 yr. Epidural local anesthetics high in the thoracic spine may also anesthetize the sympathetic nerves to the heart (the cardiac accelerator fibers), producing bradycardia. In addition to using local anesthetics, it is routine to use opioids and α-agonists as adjunctive medications in the epidural space. Clonidine and opioids have been well studied and shown not to be neurotoxic. Other drugs (neostigmine, ketamine, diazepam) also are analgesic in the epidural space, but neurotoxicity studies have not established their safety. These agents have their primary site of action in the spinal cord, to which they diffuse from their epidural depot. Side effects of epidural opioid administration include delayed respiratory depression, particularly when hydrophilic opioids such as morphine are used. The risk of this effect requires that children receiving epidural opioids by intermittent injection or continuous infusion be monitored by continuous pulse oximetry and nursing observation, particularly during the 1st 24 hr of therapy or after significant dose escalations. Respiratory depression occurring after the 1st 24 hr of epidural opioid administration is distinctly unusual.

Epidural clonidine (an α₂-agonist with μ-opioid analgesic properties) is associated with minimal risk and side effects. Although product labeling indicates use only in children with severe cancer pain, clonidine is frequently used for routine postoperative pain as well as pain syndromes such as CRPS. Mild sedation is the most common side effect of epidural clonidine, and it is not associated with respiratory depression.

Because performing epidural blockade is technical and may result in spinal cord injury, it is best done by an anesthesiologist or pain physician skilled in the technique. Caution is advised in the use of epidural anesthesia/analgesia for CRPS in children because no published RCTs have shown these procedures superior to a combination of less invasive physical and psychological therapy with or without neuropathic pain-focused medications.

**Intrathecal Analgesia**

Intrathecal catheters infused with opioids, clonidine, ziconotide (derived from a marine neurotoxin produced by the cone snail), and local anesthetics are occasionally applicable in pediatric patients with intractable pain from cancer or other conditions. Typically, intrathecal catheters are attached to an implanted
electronic pump containing a drug reservoir sufficient for several months of dosing. The technique is technical and best performed by an experienced pain management physician.

Nerve Ablation and Destruction

In some cases, pain remains refractory despite maximal reliance on oral and IV medications and nerve blockade. In these patients, temporary (pulsed radiofrequency ablation) or permanent (neurolytic) destruction of one or more nerves may be performed. The techniques should be carefully weighed against the consideration of permanent nerve destruction in a growing child with decades of life ahead. On the other hand, when pain is severe in life-limiting disease processes, the long-term considerations are less concerning, and these techniques should be discussed with a skilled pain management specialist.

Considerations for Special Pediatric Populations

Pain Perception and Effects of Pain on Newborns and Infants

Pain has a number of sources in the newborn period, including acute pain (diagnostic and therapeutic procedures, minor surgery, monitoring), continuous pain (pain from thermal/chemical burns, postsurgical and inflammatory pain), and chronic or disease-related pain (repeated heelsticks, indwelling catheters, necrotizing enterocolitis, nerve injury, chronic conditions, thrombophlebitis). The most common sources of pain in healthy infants are acute procedures, such as heel lances, surgical procedures, and in boys, circumcision.

Many procedures are performed for premature infants in the neonatal intensive care unit (NICU). In the 1st wk of life, approximately 94% of preterm infants <28 wk gestational age are mechanically ventilated. Other procedures are heelsticks (most common) and airway suctioning. Few of these procedures are preceded by any type of analgesia. Repeated handling and acute pain episodes sensitize the neonate to increased reactivity and stress responses to subsequent procedures. Typical stress responses include increases in heart rate, respiratory rate, blood pressure, and intracranial pressure. Cardiac vagal tone,
transcutaneous oxygen saturation, carbon dioxide levels, and peripheral blood flow are decreased. Autonomic signs include changes in skin color, vomiting, gagging, hiccupping, diaphoresis, dilated pupils, and palmar and forehead sweating.

Untreated pain in the newborn has serious short- and long-term consequences. There has been a shift in most NICUs to more liberal use of opioids. Nonetheless, morphine, the traditional gold standard of analgesia for acute pain, may not be effective and may have adverse long-term consequences. No differences have been found in the incidence of severe intraventricular hemorrhage or in the mortality rate when infants receiving morphine are compared with the placebo group, and there are no changes in assessed pain from tracheal suctioning in ventilated infants receiving morphine compared with those receiving a placebo infusion. Morphine may not alleviate acute pain in ventilated preterm neonates, although there are few data on the effects of morphine and fentanyl in nonventilated newborns. The lack of opioid effects for acute pain in neonates may result from immaturity of opioid receptors; acute pain may cause the uncoupling of µ-opioid receptors in the forebrain. Repetitive acute pain may create central neural changes in the newborn that may have long-term consequences for later pain vulnerability, cognitive effects, and opioid tolerance. Most neonatologists use opioids in painful situations. Sucrose and pacifiers are also being used in the NICU. The effects of sucrose (sweet taste) are believed to be opioid mediated because they are reversed with naloxone; stress and pain relief are integrated through the endogenous opioid system. Sucrose, with or without a pacifier, may be effective for acute pain and stress control. Other nonpharmacologic strategies for stress and pain control include infant care by an individual primary nurse, tactile-kinesthetic stimuli (massage), “kangaroo care,” and soothing sensorial saturation.

**Children With Cancer Pain**

The World Health Organization (WHO) proposed an analgesic therapy model for cancer pain known as the analgesic ladder (Table 76.14). Designed to guide therapy in the Third World, this ladder consists of a hierarchy of oral pharmacologic interventions intended to treat pain of increasing magnitude. The hierarchy ignores modalities such as the use of nonconventional analgesics and interventional pain procedures, which are within the capability of physicians to prescribe in developed countries. Nevertheless, because oral medications are
simple and efficacious, especially for home use, the ladder presents a framework for rationally using them before applying other drugs and techniques of drug administration.

Table 76.14

World Health Organization Analgesic Ladder for Cancer Pain

<table>
<thead>
<tr>
<th>Step</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>Step 1</td>
<td>Patients who present with mild to moderate pain should be treated with a nonopioid.</td>
</tr>
<tr>
<td>Step 2</td>
<td>Patients who present with moderate to severe pain or for whom the step 1 regimen fails should be treated with an oral opioid for moderate pain combined with a nonopioid analgesic.</td>
</tr>
<tr>
<td>Step 3</td>
<td>Patients who present with very severe pain or for whom the step 2 regimen fails should be treated with an opioid used for severe pain, with or without a nonopioid analgesic.</td>
</tr>
</tbody>
</table>

Oral medications are the first line of analgesic treatment. Because NSAIDs affect platelet adhesiveness, they are typically not used. Opioid therapy is the preferred approach for moderate or severe pain. Nonopioid analgesics are used for mild pain, a weak opioid is added for moderate pain, and strong opioids are administered for more severe pain. Adjuvant analgesics can be added, and side effects and comorbid symptoms are actively managed. Determining the type and sources of the pain will help develop an effective analgesic plan. Certain treatments, such as the chemotherapeutic agent vincristine, are associated with neuropathic pain. Such pain might require anticonvulsants or TCAs. Organ-stretching pain from tumor growth within an organ might require strong opioids and/or radiation therapy if the tumor is radiosensitive. Organ obstruction, such as
intestinal obstruction, should be diagnosed to relieve or bypass the obstruction.

It is important to consider both pharmacologic and nonpharmacologic strategies (e.g., CBT, family/parent support) to treat pain in children with cancer.

**Children With Pain Associated With Advanced Disease**

Patients with advanced diseases, including cancer, acquired immunodeficiency syndrome (AIDS), neurodegenerative disorders, and cystic fibrosis, need palliative care approaches that focus on optimal quality of life. Nonpharmacologic and pharmacologic management of pain and other distressing symptoms is a key component. *Palliative care* should be offered to all children with serious diseases, whether or not the diseases are potentially curable or long life expectancy is predicted. Examples include young children diagnosed with acute lymphoblastic leukemia (>90% posttreatment life expectancy) and children undergoing organ transplantation. Palliative care in pediatrics connotes treatment that focuses on symptom reduction, quality of life, and good family and clinical team communication. It is not only for patients in hospice care or those at the end of life. Differences in the progression of underlying illness, associated distressing symptoms, and common emotional responses in these conditions should shape individual treatment plans. For end-of-life care, >90% of children and adolescents with cancer can be made comfortable by standard escalation of opioids according to the WHO protocol. A small subgroup (5%) has enormous opioid dose escalation to >100 times the standard morphine or other opiate infusion rate. Most of these patients have spread of solid tumors to the spinal cord, roots, or plexus, and signs of neuropathic pain are evident. **Methadone** given orally is often used in palliative care, not only end-of-life care, because of its long half-life and its targets at both opioid and NMDA receptors.

The type of pain experienced by the patient (neuropathic, myofascial) should determine the need for adjunctive agents. Complementary measures, such as massage, hypnotherapy, and spiritual care, must also be offered in palliative care. Although the oral route of opioid administration should be encouraged, especially to facilitate care at home if possible, some children are unable to take oral opioids. Transdermal and sublingual routes, as well as IV infusion with PCA, are likely next choices. Small, portable infusion pumps are convenient for home use. If venous access is limited, a useful alternative is to administer opioids (especially morphine or hydromorphone, but not methadone or
meperidine) through continuous SC infusion, with or without a bolus option. A small (e.g., 22-gauge) cannula is placed under the skin and secured on the thorax, abdomen, or thigh. Sites may be changed every 3-7 days, as needed. As noted, alternative routes for opioids include the transdermal and oral transmucosal routes. These latter routes are preferred over IV and SC drug delivery when the patient is being treated at home.

**Chronic and Recurrent Pain Syndromes**

*Chronic pain* is defined as recurrent or persistent pain lasting longer than the normal tissue healing time, 3-6 mo. Children may experience pain related to injury (e.g., burns) or to a chronic or underlying disease process (e.g., cancer, arthritis), or pain can also be the chronic condition itself (e.g., CRPS, fibromyalgia, functional abdominal pain) (see Chapter 147). During childhood, abdominal, musculoskeletal, and headache pain are the most frequently occurring conditions. However, definitions of chronic pain do not take into account standard criteria for assessing particular pain symptoms or for evaluating the intensity or impact of pain, and therefore includes individuals with varying symptoms and experiences. Consequently, in epidemiologic surveys, prevalence estimates vary widely. Overall prevalence rates for different childhood pains range from 4–88%. For example, an average of 13.5–31.8% of adolescents in a community sample reported having weekly abdominal, headache, or musculoskeletal pains. Most epidemiologic studies report prevalence and do not report the *severity* or impact of the pain. Research indicates that only a subset of children and adolescents with chronic pain (approximately 5%) experience moderate to severe disability, and this likely better represents the estimated population for whom help is needed to treat pain and associated problems.

**Neuropathic Pain Syndromes**

Neuropathic pain is caused by abnormal excitability in the peripheral or central nervous system that may persist after an injury heals or inflammation subsides. The pain, which can be acute or chronic, is typically described as burning or stabbing and may be associated with cutaneous hypersensitivity (allodynia), distortion of sensation (dysesthesia), and amplification of noxious sensations (hyperalgesia and hyperpathia). Neuropathic pain conditions may be responsible
for >35% of referrals to chronic pain clinics, conditions that typically include posttraumatic and postsurgical peripheral nerve injuries, phantom pain after amputation, pain after spinal cord injury, and pain caused by metabolic neuropathies. Patients with neuropathic pain typically respond poorly to opioids. Evidence supports the efficacy of antidepressants (nortriptyline, amitriptyline, venlafaxine, duloxetine) and anticonvulsants (gabapentin, pregabalin, oxcarbazepine) for treatment of neuropathic pain (see Tables 76.12 and 76.13).

**Complex regional pain syndrome**, formerly known as “reflex sympathetic dystrophy” (RSD), is well described in the pediatric population. **CRPS type 1** is a syndrome of neuropathic pain that typically follows an antecedent and usually minor injury or surgery to an extremity without identifiable nerve injury. It is often seen in oncology patients as a complication of their malignancy, IV infiltrations in the periphery, or surgery. The syndrome of CRPS type 1 includes severe spontaneous neuropathic pain, hyperpathia, hyperalgesia, severe cutaneous allodynia to touch and cold, changes in blood flow (typically extremity cyanosis), and increased sweating. In more advanced cases, symptoms include dystrophic changes of the hair, nails, and skin, immobility of the extremity (dystonia), and muscle atrophy. In the most advanced cases, symptoms include ankylosis of the joints of the extremity. Specific causal factors in CRPS type 1 in both children and adults remain elusive, although coincidental events may be noted. **CRPS type 2**, formerly referred to as “causalgia,” is less common and describes a very similar constellation of symptoms but is associated with a known nerve injury. CRPS type 2 pain may be restricted to the distribution of the injured nerve or too much of the involved limb in a stocking-glove distribution, whereas CRPS type 1 is generally seen in a stocking-glove distribution and by definition is not limited to a peripheral nerve or dermatomal distribution of signs and symptoms.

Treatment of CRPS in children has been extrapolated from that in adults, with some evidence for efficacy of physical therapy, CBT, nerve blocks, antidepressants, AEDs, and other related drugs. All experts in pediatric pain management agree on the value of aggressive physical therapy. Some centers provide aggressive therapy without the use of pharmacologic agents or interventional nerve blocks. Unfortunately, recurrent episodes of CRPS may be seen in up to 50% of patients, particularly adolescent females. Physical therapy can be extraordinarily painful for children to endure; it is tolerated only by the most stoic and motivated patients. If children have difficulty enduring the pain, there is a well-established role for pharmacologic agents with or without
peripheral or central neuraxial nerve blocks to render the affected limb sufficiently analgesic so that physical therapy can be tolerated. Pharmacologic interventions include the use of AEDs such as gabapentin and/or TCAs such as amitriptyline (see Fig. 76.4). Although there is clear evidence of a peripheral inflammatory component of CRPS, with release of cytokines and other inflammatory mediators from the peripheral nervous system in the affected limb, the use of antiinflammatory agents has been disappointing. Common nerve block techniques include IV regional anesthetics, epidural analgesia, and peripheral nerve blocks. In extreme and refractory cases, more invasive strategies have been reported, including surgical sympathectomy and spinal cord stimulation.

Although an array of treatments has some benefit, the mainstay of treatment remains physical therapy emphasizing desensitization, strengthening, and functional improvement. Additionally, pharmacologic agents and psychological and complementary therapies are important components of a treatment plan. Invasive techniques, although not curative, can be helpful if they permit the performance of frequent and aggressive physical therapy that cannot be carried out otherwise. A good biopsychosocial evaluation will help determine the orientation of the treatment components. There are insufficient data to indicate the superior value of interventional blocks, such as epidural anesthesia, in children with CRPS over physical and psychological interventions, with or without pharmacologic support.

**Myofascial Pain Disorders and Fibromyalgia**

Myofascial pain disorders are associated with tender points in the affected muscles as well as with muscle spasms (tight muscles). Treatment is targeted at relaxing the affected muscles through physical therapy, Iyengar yoga, massage, and acupuncture. Rarely are pharmacologic muscle relaxants helpful other than for creating tiredness at night for sleep. Dry needling or injections of local anesthetic into the tender points has been advocated, but the data do not support this as a standard treatment. Similarly, although botulinum toxin injections may be used, no data support this practice in children. Often, poor body postures, repetitive use of a body part not accustomed to that movement, or carrying heavy backpacks initiates pain. When it becomes widespread with multiple tender points, the diagnosis may be made of juvenile fibromyalgia, which may or may not continue to subsequently become adult fibromyalgia. Likely there are different subtypes of widespread pain syndromes, and physical therapy is a key
component of treatment. Psychological interventions may play an important role to assist the child in resuming normal activities and to manage any psychological comorbidities. Any pain rehabilitation plan should enhance return to full function. Because there is a high incidence of chronic pain in parents of children presenting with a chronic pain condition, especially fibromyalgia, attention to parent and family factors is important. Parent training may entail teaching the parent to model more appropriate pain coping behaviors and to recognize the child's independent attempts to manage pain and function adaptively. Parents may also need referrals to obtain appropriate pain management for their own pain condition.

Pregabalin and duloxetine are FDA approved for management of fibromyalgia in adults, but no clinical studies have confirmed their effectiveness in children and adolescents. One recent large study in adolescents with fibromyalgia found that CBT and physical therapy were superior to typical pharmacologic agents used in adults.

**Erythromelalgia**

Erythromelalgia in children is generally primary, whereas in adults it may be either primary or secondary to malignancy or other hematologic disorders, such as polycythemia vera. Patients with erythromelalgia exhibit red, warm, hyperperfused distal limbs. The disorder is usually bilateral and may involve either or both the hands and feet. Patients perceive burning pain and typically seek relief by immersing the affected extremities in ice water, sometimes so often and for so long so that skin pathology results. **Primary erythromelalgia** is caused by a genetic mutation (autosomal dominant) in the gene for the NaV1.7 neuronal sodium channel on peripheral C nociceptive fibers, resulting in their spontaneous depolarization, and thus continuous burning pain. The most common mutation identified is in the SCN9A gene, although there are several mutations that affect the NaV1.7 channel. Interestingly, another mutation in the NaV1.7 channel results in a rare but devastating genetic condition, the congenital indifference to pain.

It is easy to distinguish erythromelalgia (or related syndromes) from CRPS. The limb afflicted with CRPS is typically cold and cyanotic, the disease is typically unilateral, and children with CRPS have cold allodynia, making immersion in cold water exquisitely painful. In erythromelalgia, ice water immersion is analgesic, the condition is bilateral and symmetric, and it is
associated with hyperperfusion of the distal extremity. The evaluation of hyperperfused limbs with burning pain should include genetic testing for Fabry disease and screening for hematologic malignancies, with diagnosis of primary erythromelalgia being one of exclusion. At present, few clinical laboratories are Clinical Laboratory Improvement Amendments (CLIA) certified to perform the DNA analysis required to identify the common NaV1.7 mutations.

The definitive treatment of Fabry disease includes enzyme replacement as disease-modifying treatment and administration of neuropathic pain medications such as gabapentin, although the success of antineuropathic pain drugs in small-fiber neuropathies has not been impressive. The treatment of erythromelalgia is much more problematic. Antineuropathic pain medications (AEDs, TCAs) are typically prescribed but rarely helpful (see Fig. 76.4). Although one might predict that sodium channel–blocking AEDs might be effective in this sodium channelopathy, oxcarbazepine has not proved to be a particularly effective modality. The pain responds well to regional anesthetic nerve blocks, but it returns immediately when the effects of the nerve block resolve. In contrast, in other neuropathic syndromes, the analgesia usually (and inexplicably) persists well after the resolution of the pharmacologic nerve block. Aspirin and even nitroprusside infusions have been anecdotally reported to be of benefit with secondary erythromelalgia, but have not been reported to be helpful in children with primary erythromelalgia. Case reports in adults and clinical experience in children suggest that periodic treatment with high-dose capsaicin cream is effective in alleviating the burning pain and disability of erythromelalgia. Capsaicin (essence of chili pepper) cream is a vanilloid receptor (TRPV1) agonist that depletes small-fiber peripheral nerve endings of the neurotransmitter substance P, an important neurotransmitter in the generation and transmission of nociceptive impulses. Once depleted, these nerve endings are no longer capable of generating spontaneous pain until the receptors regenerate, a process that takes many months.

Other Chronic Pain Conditions in Children

A variety of genetic and other medical/surgical conditions are often associated with chronic pain. Examples include Fabry disease, Chiari/syringomyelia, epidermolysis bullosa, juvenile idiopathic arthritis, porphyria, mitochondrial disorders, degenerative neurologic diseases, cerebral palsy, ASD, intestinal pseudoobstruction, inflammatory bowel disease, chronic migraine/daily
headaches, and irritable bowel disease. In many cases, treating the underlying disease, such as enzyme replacement in Fabry disease and in other lysosomal disorders, will reduce what otherwise might be progression of symptoms, but may not totally reduce pain and suffering, and other modalities will be needed. Finally, pain that persists and is not well treated can lead to central sensitization and widespread pain, such as seen in children with one pain source who develop fibromyalgia.

Managing Complex Chronic Pain Problems

Some patients with chronic pain have a prolonged course of evaluation in attempts to find what is expected as the singular “cause” of the pain and thus also undergo many failed treatments (see Chapter 147). Parents worry that the doctors have not yet discovered the cause that may be serious and life threatening, and children often feel not believed, that they are faking their pain, or are “crazy.” There may be no identifiable or diagnosable condition, and families may seek opinions from multiple treatment facilities in an attempt to find help for their suffering child. For some children, what may have begun as an acute injury or infectious event may result in a chronic pain syndrome, with changes in the neurobiology of the pain-signaling system.

In the context of disabling chronic pain, it is very important for the pediatrician to avoid overmedication because this can exacerbate associated disability, maintain an open mind and reassess the diagnosis if the clinical presentation changes, and understand and communicate to the family that pain has a biologic basis (likely related to neural signaling and neurotransmitter dysregulation), and that the pain is naturally distressing to the child and family. All patients and families should receive a simple explanation of pain physiology that helps them understand the importance of (1) functional rehabilitation to normalize pain signaling, (2) the low risk of causing further injury with systematic increases in normal functioning, and (3) the likely failure of treatment if pain is managed as if it were acute. Because it is counterintuitive for most people to move a part of the body that hurts, many patients with chronic pain have atrophy or contractures of a painful extremity from disuse. Associated increases in worry and anxiety may exacerbate pain and leave the body even more vulnerable to further illness, injury, and disability. Pain can have a
significant impact on many areas of normal functioning and routines for children, and school absenteeism and related consequences of missed schooling are often significant problems. Appropriate assessment and evaluation of the child with chronic pain and the family is the critical 1st step necessary in developing a treatment plan. For example, a high–academically functioning child might have an acute injury that leads to chronic pain and significant school absenteeism. While many downstream contributors to pain and disability maintenance can accumulate the more school that is missed, often previously unrecognized focal learning disabilities may become the increasing trigger for a downhill cascade of pain, disability, and school absenteeism. Even for the child with outstanding grades, it may be helpful to learn about the amount of time spent on each subject. As certain subjects become more complicated, such as math, the child with a previously unrecognized math learning disability may be spending hours on math homework each night, even with good grades in math. In this case the acute illness or injury becomes the “final straw” that breaks down the child's coping and turns the acute pain into a chronic problem.

**Interdisciplinary pediatric pain programs** have become the standard of care for treating complex chronic pain problems in youth. Although available in many parts of the United States, Canada, Europe, Australia, and New Zealand, the overall number of programs is still small. Therefore, many children and adolescents with chronic pain will be unable to receive specialized pain treatment in their local communities. In recognition of the severity and complexity of pain and disability for some children, different settings and treatment delivery models for providing pain care have been explored. One option is inpatient and day hospital treatment programs, which often address barriers to access to outpatient treatment and coordination of care. In addition, these programs provide an intensive treatment option for children who do not make adequate progress in outpatient treatment or who are severely disabled by pain. Early programs developed in the 1990s focused on CRPS treatment through intensive inpatient rehabilitation and exercise-based programs. Later programs expanded to other clinical populations and broadened the treatment focus to incorporate a range of rehabilitation and psychological therapies delivered both individually and in groups. The typical length of inpatient admissions for children with chronic pain in such programs is 3-4 wk, and emerging evidence suggests benefit from these programs. A major problem that limits such care for children with complex chronic disabling pain is the long waiting list for entry into these still relatively few programs, as well as obtaining
insurance approval. Additional more widespread models of care are needed.

Another intervention delivery option is remote management, referring to pain interventions utilized outside the clinic/hospital setting to reach children in their homes or communities. Interventions are typically delivered using some form of technology, such as the internet, or may rely on other media, such as telephone counseling or written self-help materials. Typically, remote management of pain includes monitoring, counseling, and delivery of behavioral and CBT interventions. Internet interventions have received the most research attention to date, with published examples of several different pediatric chronic pain conditions with promising findings for pain reduction. Telemedicine, while in widespread use clinically for many pediatric health conditions, has not yet been formally evaluated in pediatric pain. Within any community, the pediatrician will need to locate appropriate referral sources for patients with complex chronic pain. However, while psychological interventions can be delivered through these telemedicine strategies, the pediatrician is still relied on to obtain the needed biopsychosocial history, complete a thorough physical examination, and provide the pharmacologic management as needed. The pediatrician also communicates with the family to help the child and family understand the pain and how the different pharmacologic and nonpharmacologic treatments will enhance function and alter the long-term neural processes underlying pain.

Poisoning is the leading cause of injury-related death in the United States, surpassing that from motor vehicle crashes. Most these deaths are unintentional (i.e., not suicide). In adolescents, poisoning is the 3rd leading cause of injury-related death. Of the >2 million human poisoning exposures reported annually to the National Poison Data Systems (NPDS) of the American Association of Poison Control Centers (AAPCC), approximately 50% occur in children <6 yr old, with the highest number of exposures occurring in 1 and 2 yr olds. Almost all these exposures are unintentional and reflect the propensity for young children to put virtually anything in their mouth. Fortunately, children <6 yr old account for <2% of all poisoning fatalities reported to NPDS.

More than 90% of toxic exposures in children occur in the home, and most involve a single substance. Ingestion accounts for the majority of exposures, with a minority occurring by the dermal, inhalational, and ophthalmic routes. Approximately 40% of cases involve nondrug substances, such as cosmetics, personal care items, cleaning solutions, plants, and foreign bodies. Pharmaceutical preparations account for the remainder of exposures, and analgesics, topical preparations, vitamins, and antihistamines are the most commonly reported categories.

The majority of poisoning exposures in children <6 yr old can be managed without direct medical intervention beyond a call to the regional poison control center (PCC). This is because the product involved is not inherently toxic or the quantity of the material is not sufficient to produce clinically relevant toxic effects. However, a number of substances can be highly toxic to toddlers in small doses (Table 77.1). In 2015, carbon monoxide (CO), batteries, and analgesics (mainly opioids) were the leading causes of poison-related fatalities in young children (<6 yr). In addition, stimulants/street drugs, cardiovascular (CV) drugs,
and aliphatic hydrocarbons were significant causes of mortality.

* "Small dose" typically implies 1 or 2 pills or 5 mL.

† Lipid-soluble β-blockers (e.g., propranolol) are more toxic than water-soluble β-blockers (e.g., atenolol).

CNS, Central nervous system.

Poison prevention education should be an integral part of all well-child visits, starting at the 6 mo visit. Counseling parents and other caregivers about potential poisoning risks, poison-proofing a child's environment, and actions in the event of an ingestion diminishes the likelihood of serious morbidity or mortality. Poison prevention education materials are available from the American Academy of Pediatrics (AAP) and regional PCCs. Through a U.S. network of PCCs, anyone at any time can contact a regional poison center by calling the toll-free number 1-800-222-1222. Parents should be encouraged to share this number with grandparents, relatives, babysitters, and any other caregivers.

Product safety measures, poison prevention education, early recognition of exposures, and around-the-clock access to regionally based PCCs all contribute
to the favorable exposure outcomes in young children. Poisoning exposures in children 6-12 yr are much less common, involving only approximately 10% of all reported pediatric exposures. A 2nd peak in pediatric exposures occurs in adolescence. Exposures in the adolescent age-group are primarily intentional (suicide or abuse or misuse of substances) and thus often result in more severe toxicity (see Chapter 140 ). Families should be informed and given anticipatory guidance that nonprescription and prescription medications, and even household products (e.g., inhalants), are common sources of adolescent exposures. Although adolescents (age 13-19 yr) account for only about 12% of exposures, they constituted a much larger proportion of deaths. Of the 90 poison-related pediatric deaths in 2015 reported to NPDS, 58 were adolescents (5% of all fatalities called in to poison centers). Pediatricians should be aware of the signs of drug abuse or suicidal ideation in adolescents and should aggressively intervene (see Chapter 40 ).

**Prevention**

Deaths caused by unintentional poisoning among younger children have decreased dramatically over the past 2 decades, particularly among children <5 yr old. In 1970, when the U.S. Poison Packaging Prevention Act was passed, 226 poisoning deaths of children <5 yr old occurred, compared with only 24 in 2015. Poisoning prevention demonstrates the effectiveness of passive strategies, including the use of child-resistant packaging and limited doses per container. Difficulty using child-resistant containers by adults is an important cause of poisoning in young children today. In 18.5% of households in which poisoning occurred in children <5 yr old, the child-resistant closure was replaced, and 65% of the packaging used did not work properly. Almost 20% of ingestions occur from drugs belonging to grandparents, who have difficulty using traditional child-resistant containers and often put their medications in pill organizers that are not childproof.

Even though there has been success in preventing poisoning in young children, there has been a remarkable rise in adolescent poison-related death over the past 20 years. This has mirrored the increasing rate of antidepressant prescriptions written by healthcare providers and the epidemic increase in opioid-related fatalities.
Approach to the Poisoned Patient

The initial approach to the patient with a witnessed or suspected poisoning should be no different than that in any other sick child, starting with stabilization and rapid assessment of the airway, breathing, circulation (pulse, blood pressure), and mental state, including Glasgow Coma Scale score and laryngeal reflexes (see Chapters 80 and 81). In any patient with altered mental status, a serum dextrose concentration should be obtained early, and naloxone administration should be considered. A targeted history and physical examination serves as the foundation for a thoughtful differential diagnosis, which can then be further refined through laboratory testing and other diagnostic studies.

History

Obtaining an accurate problem-oriented history is of paramount importance. Intentional poisonings (suicide attempts, drug abuse/misuse) are typically more severe than unintentional, exploratory ingestions. In patients without a witnessed exposure, historical features such as age of the child (toddler or adolescent), acute onset of symptoms without prodrome, multisystem organ dysfunction, or high levels of household stress should suggest a possible diagnosis of poisoning. In patients with a witnessed exposure, determining exactly what the child was exposed to and the circumstances surrounding the exposure is crucial to initiating directed therapy quickly. For household and workplace products, names (brand, generic, chemical) and specific ingredients, along with their concentrations, can often be obtained from the labels. PCC specialists can also help to identify possible ingredients and review the potential toxicities of each component. Poison center specialists can also help identify pills based on markings, shape, and color. If referred to the hospital for evaluation, parents should be instructed to bring the products, pills, and/or containers with them to assist with identifying and quantifying the exposure. If a child is found with an unknown pill, a list of all medications in the child’s environment, including medications that grandparents, parents, siblings, caregivers, or other visitors might have brought into the house, must be obtained. In the case of an unknown exposure, clarifying where the child was found (e.g., garage, kitchen, laundry room, bathroom, backyard, workplace) can help to generate a list of potential toxins.
Next, it is important to clarify the timing of the ingestion and to obtain some estimate of how much of the substance was ingested. It is better to overestimate the amount ingested to prepare for the worst-case scenario. Counting pills or measuring the remaining volume of a liquid ingested can sometimes be useful in generating estimates. For inhalational, ocular, or dermal exposures, the concentration of the agent and the length of contact time with the material should be determined, if possible.

**Symptoms**

Obtaining a description of symptoms experienced after ingestion, including their timing of onset relative to the time of ingestion and their progression, can generate a list of potential toxins and help anticipate the severity of the ingestion. Coupled with physical exam findings, reported symptoms assist practitioners in identifying **toxidromes**, or recognized poisoning syndromes, suggestive of toxicity from specific substances or classes of substances (Tables 77.2 to 77.4).

CNS, Central nervous system.

### Past Medical and Developmental History

Underlying diseases can make a child more susceptible to the effects of a toxin. Concurrent drug therapy can also increase toxicity because certain drugs may interact with the toxin. A history of psychiatric illness can make patients more prone to substance abuse, misuse, intentional ingestions, and polypharmacy complications. Pregnancy is a common precipitating factor in adolescent suicide attempts and can influence both evaluation of the patient and subsequent treatment. A developmental history is important to ensure that the exposure history provided is appropriate for the child's developmental stage (e.g., report of...
6 mo old picking up a large container of laundry detergent and drinking it should indicate urgent need for treatment, or indicate a severe condition, or “red flag”).

Social History
Understanding the child's social environment helps to identify potential sources of exposures (caregivers, visitors, grandparents, recent parties or social gatherings) and social circumstances (new baby, parent's illness, financial stress) that might have contributed to the ingestion (suicide or unintentional). Unfortunately, some poisonings occur in the setting of serious neglect or intentional abuse.

Physical Examination
A targeted physical examination is important to identifying the potential toxin and assessing the severity of the exposure. Initial efforts should be directed toward assessing and stabilizing the airway, breathing, circulation, and mental status. Once the airway is secure and the patient is stable from a cardiopulmonary standpoint, a more extensive physical exam can help to identify characteristic findings of specific toxins or classes of toxins.

In the poisoned patient, key features of the physical exam are vital signs, mental status, pupils (size, reactivity), nystagmus, skin, bowel sounds, and muscle tone. These findings might suggest a toxidrome, which can then guide the differential diagnosis and management.

Laboratory Evaluation
A basic chemistry panel (electrolytes, renal function, glucose) is necessary for all poisoned or potentially poisoned patients. Any patient with acidosis (low serum bicarbonate level on serum chemistry panel) must have an anion gap calculated because of the more specific differential diagnoses associated with an elevated anion gap metabolic acidosis (Table 77.5 ). Patients with a known overdose of acetaminophen should have liver transaminases (ALT, AST) assessed, as well as an international normalized ratio (INR). A serum creatinine kinase level is indicated on any patient with a prolonged “down time” to evaluate for rhabdomyolysis. Serum osmolality is only helpful as a surrogate marker for a toxic alcohol exposure if a serum concentration of the alcohol cannot be obtained in a reasonable time frame. A urine pregnancy test is mandatory for all
postpubertal female patients. Based on the clinical presentation and the presumed poison, additional lab tests may also be helpful. Acetaminophen is a widely available medication and a commonly detected co-ingestant with the potential for severe toxicity. There is an effective antidote to acetaminophen poisoning that is time dependent. Given that patients might initially be asymptomatic and might not report or be aware of acetaminophen ingestion, an acetaminophen level should be checked in all patients who present after an intentional exposure or ingestion.

**Table 77.5**

**Laboratory Clues in Toxicologic Diagnosis**

**Anion Gap Metabolic Acidosis (Mnemonic = Mudpiles Cat)**

- **M** ethanol, metformin
- **U** remia
- **D** iabetic ketoacidosis
- **P** ropylene glycol
- **I** soniazid, iron, massive ibuprofen
- **L**actic acidosis
- **E** thylene glycol
- **S** alicylates
- **C** ellular asphyxiants (cyanide, carbon monoxide, hydrogen sulfide)
- **A** lcoholic ketoacidosis
- **T** ylenol (clinical significance depends upon presence or absence of liver injury)

**Elevated Osmolar Gap**

- Alcohols: ethanol, isopropyl, methanol, ethylene glycol

**Hypoglycemia (Mnemonic = Hobbies)**

- **H** ypoglycemics, oral: sulfonylureas, meglitinides
- **O** ther: quinine, unripe ackee fruit
- **B** eta **B** lockers
Hyperglycemia

Salicylates (early)
Calcium channel blockers
Caffeine

Hypocalcemia

Ethylene glycol
Fluoride

Rhabdomyolysis

Neuroleptic malignant syndrome, serotonin syndrome
Statins
Mushrooms (*Tricholoma equestre*)
Any toxin causing prolonged immobilization (e.g., opioids, antipsychotics) or excessive muscle activity or seizures (e.g., sympathomimetics)

Radiopaque Substance on KUB (Mnemonic = Chipped)

CHloral hydrate, calcium carbonate
HEavy metals (lead, zinc, barium, arsenic, lithium, bismuth)
IRON
PHenothiazines
Ply-Doh, potassium chloride
ENTeric-coated pills
Dental amalgam, drug packets

KUB, Kidney-ureter-bladder radiograph.
For select intoxications (e.g., salicylates, some anticonvulsants, acetaminophen, iron, digoxin, methanol, ethanol, lithium, ethylene glycol, theophylline, CO, lead), quantitative blood concentrations are integral to confirming the diagnosis and formulating a treatment plan. However, for most exposures, quantitative measurement is not readily available and is not likely to alter management. All intoxicant levels must be interpreted in conjunction with the history. For example, a methanol level of 20 mg/dL 1 hr after ingestion may be nontoxic, whereas a similar level 24 hr after ingestion implies a significant poisoning. In general, patients with multiple or chronic exposures to a drug or other chemical will be more symptomatic at lower drug levels than those with a single exposure.

Both the rapid urine drug-of-abuse screens and the more comprehensive drug screens vary widely in their ability to detect toxins and generally add little information to the clinical assessment. This is particularly true if the agent is known and the patient's symptoms are consistent with that agent. If a drug screen is ordered, it is important to know that the components screened for, and the lower limits of detection, vary from laboratory to laboratory. In addition, the interpretation of most drug screens is hampered by many false-positive and false-negative results. Many opiate toxicology screens poorly detect hydrocodone, and do not detect the fully synthetic opioids at all (e.g., methadone, buprenorphine, fentanyl). Several common benzodiazepines may not be detected, as may not synthetic cannabinoids or “bath salts.” The amphetamine screen, on the other hand, is typically overly sensitive and often is triggered by prescription amphetamines and some over-the-counter cold preparations. As such, the urine drug-of-abuse screen is typically of limited utility for medical clearance, but may serve a useful function for psychiatrists in their evaluation of the adolescent patient. Besides its psychiatric usefulness, urine drug-of-abuse screens are potentially helpful in patients with altered mental status of unknown etiology, persistent unexplained tachycardia, and acute myocardial ischemia or stroke at a young age. These screens can also be useful in the assessment of a neglected or abused child. Consultation with a medical toxicologist can be helpful in interpreting drug screens and directing which specific drug levels or other lab analyses might aid in patient management.

In the case of a neglected or allegedly abused child, a positive toxicology screen can add substantial weight to a claim of abuse or neglect. In these cases and any case with medicolegal implications, any positive screen must be confirmed with gas chromatography/mass spectroscopy, which is considered the
gold standard measurement for legal purposes.

**Additional Diagnostic Testing**

An electrocardiogram (ECG) is a quick and noninvasive bedside test that can yield important clues to diagnosis and prognosis. Particular attention should be paid to the ECG intervals (Table 77.6). A widened QRS interval, putting the patient at risk for monomorphic ventricular tachycardia, suggests blockade of fast sodium channels. A widened QTc interval suggests effects at the potassium rectifier channels and portends a risk of torsades de pointes (polymorphic ventricular tachycardia).

Chest radiography may reveal signs of pneumonitis (e.g., hydrocarbon aspiration), noncardiogenic pulmonary edema (e.g., salicylate toxicity), or a foreign body. Abdominal radiography is most helpful in screening for the presence of lead paint chips or other foreign bodies. It may detect a bezoar (concretion), demonstrate radiopaque tablets, or reveal drug packets in a “body packer.” Further diagnostic testing is based on the differential diagnosis and pattern of presentation.

**Principles of Management**

The principles of management of the poisoned patient are supportive care, decontamination, directed therapy (antidotes, ILE), and enhanced elimination. Few patients meet criteria for all these interventions, although clinicians should consider each option in every poisoned patient so as not to miss a potentially lifesaving intervention. Antidotes are available for relatively few poisons (Tables 77.7 and 77.8), thus emphasizing the importance of meticulous supportive care and close clinical monitoring.

Poison control center personnel are specifically trained to provide expertise in the management of poisoning exposures. Parents should be instructed to call the poison control center (1-800-222-1222) for any concerning exposure. PCC specialists can assist parents in assessing the potential toxicity and severity of the exposure. They can further determine which children can be safely monitored at home and which children should be referred to the emergency department for further evaluation and care. Although up to one third of calls to PCCs involve hospitalized patients, and 90% of all calls for exposures in children <6 yr old are managed at home. The AAPCC has generated consensus statements for out-of-hospital management of common ingestions (e.g., acetaminophen, iron, calcium channel blockers) that serve to guide poison center recommendations.

**Supportive Care**

Careful attention is paid first to the “ABCs” of airway, breathing, and circulation; there should be a low threshold to aggressively manage the airway of a poisoned patient because of the patient’s propensity to quickly become comatose. In fact, endotracheal intubation is often the only significant intervention needed in many poisoned patients. An important caveat is the tachypneic patient with a clear lung examination and normal oxygen saturation. This should alert the clinician to the likelihood that the patient is compensating for an acidemia. Paralyzing such a patient and underventilating might prove fatal. If intubation is absolutely necessary for airway protection or a tiring patient, a good rule of thumb is to match the ventilatory settings to the patient's preintubation minute ventilation.
Hypotensive patients often are not hypovolemic but are poisoned, and aggressive fluid resuscitation may lead to fluid overload. If hypotension persists after 1 or 2 standard boluses of crystalloid, infusion of a direct-acting vasopressor, such as norepinephrine or epinephrine, is preferred. Dysrhythmias are managed in the standard manner, except for those caused by agents that block fast sodium channels of the heart, for which boluses of sodium bicarbonate are given.

Seizures should primarily be managed with agents that potentiate the γ-aminobutyric acid (GABA) complex, such as benzodiazepines or barbiturates. The goal of supportive therapy is to support the patient's vital functions until the patient can eliminate the toxin. Patients with an elevated creatine phosphokinase (CPK) should be aggressively hydrated with crystalloid, with a goal urine output of 1-2 mL/kg/hr and close monitoring of CPK trend.

Decontamination

The majority of poisonings in children are from ingestion, although exposures can also occur by inhalational, dermal, and ocular routes. The goal of decontamination is to minimize absorption of the toxic substance. The specific method employed depends on the properties of the toxin itself and the route of exposure. Regardless of the decontamination method used, the efficacy of the intervention decreases with increasing time since exposure. Decontamination should not be routinely employed for every poisoned patient. Instead, careful decisions regarding the utility of decontamination should be made for each patient and should include consideration of the toxicity and pharmacologic properties of the exposure, route of the exposure, time since the exposure, and risks vs benefits of the decontamination method.

Dermal and ocular decontamination begins with removal of any contaminated clothing and particulate matter, followed by flushing of the affected area with tepid water or normal saline (NS). Treating clinicians should wear proper protective gear when performing irrigation. Flushing for a minimum of 10-20 min is recommended for most exposures, although some chemicals (e.g., alkaline corrosives) require much longer periods of flushing. Dermal decontamination, especially after exposure to adherent or lipophilic (e.g., organophosphates) agents, should include thorough cleansing with soap and water. Water should not be used for decontamination after exposure to highly reactive agents, such as elemental sodium, phosphorus, calcium oxide, and
titanium tetrachloride. After an inhalational exposure, decontamination involves moving the patient to fresh air and administering supplemental oxygen if indicated.

_Gastrointestinal (GI) decontamination strategies are most likely to be effective in the 1 or 2 hours after an acute ingestion_. GI absorption may be delayed after ingestion of agents that slow GI motility (anticholinergic medications, opioids), massive amounts of pills, sustained-release (SR) preparations, and agents that can form pharmacologic bezoars (e.g., enteric-coated salicylates). GI decontamination more than 2 hr after ingestion may be considered in patients who ingest toxic substances with these properties. However, even rapid institution of GI decontamination with activated charcoal will, at best, bind only approximately 30% of the ingested substance. GI decontamination should never supplant excellent supportive care and should not be employed in an unstable or persistently vomiting patient. Described methods of GI decontamination include induced emesis with ipecac, gastric lavage, cathartics, activated charcoal, and whole-bowel irrigation (WBI). _Of these, only activated charcoal and WBI are of potential benefit._

**Syrup of Ipecac**

Syrup of ipecac contains 2 emetic alkaloids that work in both the central nervous system (CNS) and locally in the GI tract to produce vomiting. Many studies have failed to document a significant clinical impact from the use of ipecac and have documented multiple adverse events from its use. The AAP, the American Academy of Clinical Toxicology (AACT), and the AAPCC have all published statements in favor of _abandoning the use of ipecac._

**Gastric Lavage**

Gastric lavage involves placing a large tube orally into the stomach to aspirate contents, followed by flushing with aliquots of fluid, usually water or NS. Although gastric lavage was used routinely for many years, objective data do not document or support clinically relevant efficacy. This is particularly true in children, in whom only small-bore tubes can be used. Lavage is time-consuming and painful and can induce bradycardia through a vagal response to tube placement. It can delay administration of more definitive treatment (activated charcoal) and under the best circumstances, only removes a fraction of gastric contents. _Thus, in most clinical scenarios, the use of gastric lavage is no longer_
**Single-Dose Activated Charcoal**

Activated charcoal is a potentially useful method of GI decontamination. Charcoal is “activated” by heating to extreme temperatures, creating an extensive network of pores that provides a very large adsorptive surface area that many (but not all) toxins will bind to, preventing absorption from the GI tract. Charged molecules (i.e., heavy metals, lithium, iron) and liquids do not bind well to activated charcoal (*Table 77.9*). *Charcoal is most likely to be effective when given within 1 hr of ingestion.* Administration should also be avoided after ingestion of a caustic substance, as it can impede subsequent endoscopic evaluation. A repeat dose of activated charcoal may be warranted in the cases of ingestion of an extended-release product or, more frequently, with a significant salicylate poisoning as a result of its delayed and erratic absorption pattern.

</table>

The dose of activated charcoal, with or without sorbitol, is 1 g/kg in children or 50-100 g in adolescents and adults. Before administering charcoal, one _must_ ensure that the patient's airway is intact or protected and that the patient has a benign abdominal examination. In the awake, uncooperative adolescent or child who refuses to drink the activated charcoal, there is little utility and potential morbidity associated with forcing activated charcoal down a nasogastric (NG) tube, and such practice should be avoided. In young children, practitioners can attempt to improve palatability by adding flavorings (chocolate or cherry syrup) or giving the mixture over ice cream. Approximately 20% of children vomit...
after receiving a dose of charcoal, emphasizing the importance of an intact airway and avoiding administration of charcoal after ingestion of substances that are particularly toxic when aspirated (e.g., hydrocarbons). If charcoal is given through a gastric tube in an intubated patient, placement of the tube should be carefully confirmed before activated charcoal is given. Instillation of charcoal directly into the lungs can have disastrous effects. Constipation is another common side effect of activated charcoal, and in rare cases, bowel perforation has been reported.

Cathartics (sorbitol, magnesium sulfate, magnesium citrate) have been used in conjunction with activated charcoal to prevent constipation and accelerate evacuation of the charcoal-toxin complex. There are no data demonstrating their value and numerous reports of adverse effects from cathartics, such as dehydration and electrolyte imbalance.

**Whole-Bowel Irrigation**

Whole-bowel irrigation (WBI) involves instilling large volumes (35 mL/kg/hr in children or 1-2 L/hr in adolescents) of a polyethylene glycol electrolyte solution (e.g., GoLYTELY) to “wash out” the entire GI tract. This technique may have some success for the ingestion of SR preparations, substances not well adsorbed by charcoal (e.g., lithium, iron), transdermal patches, foreign bodies, and drug packets. In children, WBI is most frequently administered to decontaminate the gut of a child whose abdominal radiograph demonstrates multiple lead paint chips. Careful attention should be paid to assessment of the airway and abdominal exam before initiating WBI. WBI should never be given to a patient with signs of obstruction or ileus or with a compromised airway. Given the rate of administration and volume needed to flush the system, WBI is typically administered by NG tube. WBI is continued until the rectal effluent is clear. If the WBI is for a child with ingested paint chips, the end-point will be clearing of the chips from the bowel based on repeat radiographs. Complications of WBI include vomiting, abdominal pain, and abdominal distention. Bezoar formation might respond to WBI but may also require endoscopy or surgery.

**Directed Therapy**

**Antidotal Therapy**

Antidotes are available for relatively few toxins (Tables 77.7 and 77.8), but
early and appropriate use of an antidote is a key element in managing the poisoned patient.

**Intralipid Emulsion Therapy**

Intralipid emulsion (ILE) therapy is a potentially lifesaving intervention. ILE therapy sequesters fat-soluble drugs, decreasing their impact at target organs. It also enhances cardiac function by supplying an alternative energy source to a depressed myocardium and acting on calcium channels in the heart, increasing myocardial calcium and thus cardiac function. Intralipid is most effective as a reversal agent for toxicity from inadvertent intravenous (IV) injection of bupivacaine. Using the same 20% Intralipid used for total parenteral nutrition (TPN), a bolus dose of 1.5 mL/kg is given over 3 min, followed by an infusion of 0.25 mL/kg/min until recovery or until a total of 10 mL/kg has been infused. Lipophilic drugs, those in which the logarithm of the coefficient describing the partition between 2 solvents (hydrophobic phase and hydrophilic phase) is >2, have the most potential to be bound by ILE. These include, but are not limited to, calcium channel blockers (verapamil, diltiazem), bupropion, and tricyclic antidepressants.

**Enhanced Elimination**

Enhancing elimination results in increased clearance of a poison that has already been absorbed. It is only useful for a few toxins and in these cases is a potentially lifesaving intervention. Methods of enhanced elimination include urinary alkalinization, hemodialysis, and multidose activated charcoal.

**Urinary Alkalinization**

Urinary alkalinization enhances the elimination of drugs that are weak acids by forming charged molecules, which then become trapped in the renal tubules. Charged molecules, being polar and hydrophilic, do not easily cross cellular membranes, thus they remain in the renal tubules and are excreted. Urinary alkalinization is accomplished by a continuous infusion of sodium bicarbonate–containing IV fluids, with a goal urine pH of 7.5-8. Alkalinization of the urine is most useful in managing salicylate and methotrexate toxicity. Complications of urinary alkalinization include electrolyte derangements (e.g., hypokalemia, hypocalcemia), fluid overload, and excessive serum alkalinization. Serum pH should be closely monitored and not exceed a pH >7.55. Patients typically
unable to tolerate the volumes required for alkanlization are those with heart failure, kidney failure, pulmonary edema, or cerebral edema.

**Hemodialysis**

Few drugs or toxins are removed by dialysis in amounts sufficient to justify the risks and difficulty of dialysis. Toxins amenable to dialysis have the following properties: low volume of distribution (<1 L/kg) with a high degree of water solubility, low molecular weight, and low degree of protein binding. Hemodialysis may be useful for toxicity from methanol, ethylene glycol, salicylates, theophylline, bromide, lithium, and valproic acid. Hemodialysis is also used to correct severe electrolyte disturbances and acid-base derangements resulting from the ingestion (e.g., severe metformin-associated lactic acidosis).

**Multidose Activated Charcoal**

Whereas single-dose activated charcoal is used as a method of decontamination, multidose activated charcoal (MDAC) can help to enhance the elimination of certain toxins. MDAC is typically given as 0.5 g/kg every 4-6 hr (for 4 doses). MDAC enhances elimination by 2 proposed mechanisms: interruption of enterohepatic recirculation and “GI dialysis.” The concept of GI dialysis involves using the intestinal mucosa as a dialysis membrane and pulling toxins from the bloodstream back into the intraluminal space, where they are adsorbed to the charcoal. The AACT/European Association of Poisons Centres and Clinical Toxicologists position statement recommends MDAC in managing significant ingestions of carbamazepine, dapsone, phenobarbital, quinine, and theophylline. As with single-dose activated charcoal, contraindications to use of MDAC include an unprotected airway and a concerning abdominal examination (e.g., ileus, distention, peritoneal signs). Thus the airway and abdominal exam should be assessed before each dose. A cathartic (e.g., sorbitol) may be given with the 1st dose, but it should not be used with subsequent doses because of the risk of dehydration and electrolyte derangements. Although MDAC reduces the serum level of an intoxicant quicker than without MDAC, it has not been shown to have a significant impact on outcome.

**Select Compounds in Pediatric Poisoning**
See other chapters for herbal medicines (Chapter 78), drugs of abuse (Chapter 140), and environmental health hazards (Chapters 735-741).

**Pharmaceuticals**

**Analgesics**

**Acetaminophen.**

Acetaminophen (APAP) is the most widely used analgesic and antipyretic in pediatrics, available in multiple formulations, strengths, and combinations. Consequently, APAP is commonly available in the home, where it can be unintentionally ingested by young children, taken in an intentional overdose by adolescents and adults, or inappropriately dosed in all ages. In the United States, APAP toxicity remains the most common cause of acute liver failure and is the leading cause of intentional poisoning death.

**Pathophysiology.**

APAP toxicity results from the formation of a highly reactive intermediate metabolite, \( N\)-acetyl-\( p\)-benzoquinone imine (NAPQI). In therapeutic use, only a small percentage of a dose (approximately 5%) is metabolized by the hepatic cytochrome P450 enzyme CYP2E1 to NAPQI, which is then immediately joined with glutathione to form a nontoxic mercapturic acid conjugate. In overdose, glutathione stores are overwhelmed, and free NAPQI is able to combine with hepatic macromolecules to produce hepatocellular necrosis. The single acute toxic dose of APAP is generally considered to be >200 mg/kg in children and >7.5-10 g in adolescents and adults. Repeated administration of APAP at supratherapeutic doses (>90 mg/kg/day for consecutive days) can lead to hepatic injury or failure in some children, especially in the setting of fever, dehydration, poor nutrition, and other conditions that serve to reduce glutathione stores.

Any child with a history of acute ingestion of >200 mg/kg (unusual in children <6 yr) or with an acute intentional ingestion of any amount should be referred to a healthcare facility for clinical assessment and measurement of a serum APAP level.

**Clinical and Laboratory Manifestations.**

Classically, 4 general stages of APAP toxicity have been described (Table 77.10). The initial signs are nonspecific (i.e., nausea and vomiting) and may not be
present. Thus the diagnosis of APAP toxicity cannot be based on clinical symptoms alone, but instead requires consideration of the combination of the patient's history, symptoms, and laboratory findings.

**Table 77.10**

**Classic Stages in Clinical Course of Acetaminophen Toxicity**

If a toxic ingestion is suspected, a serum APAP level should be measured 4 hr after the reported time of ingestion. For patients who present to medical care more than 4 hr after ingestion, a stat APAP level should be obtained. *APAP levels obtained <4 hr after ingestion, unless “nondetectable,” are difficult to interpret and cannot be used to estimate the potential for toxicity.* Other important baseline lab tests include hepatic transaminases, renal function tests, and coagulation parameters.

**Treatment.**

When considering the treatment of a patient poisoned or potentially poisoned with APAP, and after assessment of the ABCs, it is helpful to place the patient into one of the following four categories.

**1 Prophylactic.**

By definition, these patients have a normal aspartate transaminase (AST). If the APAP level is known and the ingestion is within 24 hr of the level being drawn, treatment decisions are based on where the level falls on the Rumack-Matthew nomogram (Fig. 77.1). Any patient with a serum APAP level in the possible or probable hepatotoxicity range per the nomogram should be treated with N-acetylcysteine (NAC). This nomogram is only intended for use in patients who present within 24 hr of a single acute APAP ingestion with a known time of ingestion. If treatment is recommended, they should receive NAC as either oral
Mucomyst or IV Acetadote for 24 or 21 hr, respectively. Repeat AST and APAP concentration drawn toward the end of that interval should be obtained. If the AST remains normal and the APAP becomes nondetectable, treatment may be discontinued. If the AST becomes elevated, the patient moves into the next category of treatment (injury). If APAP is still present, treatment should be continued until the level is nondetectable. In the case of a patient with a documented APAP level, normal AST, and an unknown time of ingestion, treatment should ensue until the level is nondetectable, with normal transaminases.

![Rumack-Matthew nomogram for acetaminophen poisoning](image)

**FIG. 77.1** Rumack-Matthew nomogram for acetaminophen poisoning, a semilogarithmic plot of plasma acetaminophen concentrations vs time. **Cautions for the use of this chart:** The time coordinates refer to time after ingestion; serum concentrations obtained before 4 hr are not interpretable; and the graph should be used only in relation to a single acute ingestion with a known time of ingestion. This nomogram is not useful for chronic exposures or unknown time of ingestion and should be used with caution in the setting of co-ingestants that slow gastrointestinal motility. The lower solid line is typically used in the United States to
The importance of instituting therapy with either IV or oral NAC no later than 8 hr from the time of ingestion cannot be overemphasized. No patient, regardless of the size of the ingestion, who receives NAC within 8 hr of overdose should die from liver failure. The longer from the 8 hr mark the initiation of therapy is delayed, the greater the risk of acute liver failure. Any patient presenting close to or beyond the 8 hr mark after an APAP overdose should be empirically started on NAC pending laboratory results.

2 Hepatic Injury.
These patients are exhibiting evidence of hepatocellular necrosis, manifested first as elevated liver transaminases (usually AST first, then alanine transaminase [ALT]), followed by a rise in the INR. Any patient in this category requires therapy with NAC (IV or oral). When to discontinue therapy in the clinically well patient remains controversial, but in general the transaminases and INR have peaked and fallen significantly “toward” normal (they do not need to be normal). Most patients' liver enzymes will peak 3 or 4 days after their ingestion.

3 Acute Liver Failure.
The King's College criteria are used to determine which patients should be referred for consideration of liver transplant. These criteria include acidemia (serum pH <7.3) after adequate fluid resuscitation, coagulopathy (INR >6), renal dysfunction (creatinine >3.4 mg/dL), and grade III or IV hepatic encephalopathy (see Chapter 391). A serum lactic acid >3 mmol/L (after IV fluids) adds to both sensitivity and specificity of the criteria to predict death without liver transplant. The degree of transaminase elevation does not factor in to this decision-making process.

4 Repeated Supratherapeutic Ingestion.
APAP is particularly prone to unintentional overdose through the ingestion of multiple medications containing the drug or simply because people assume it to be safe at any dose. Ingestion of amounts significantly greater than the recommended daily dose for several days or more puts one at risk for liver injury. Because the Rumack-Matthew nomogram is not helpful in this scenario, a conservative approach is taken. In the asymptomatic patient, if the AST is
normal and the APAP is <10 µg/mL, no therapy is indicated. A normal AST and an elevated APAP warrants NAC dosing for at least long enough for the drug to metabolize while the AST remains normal. An elevated AST puts the patient in the “hepatic injury” category previously described. A patient presenting with symptoms (i.e., right upper quadrant pain, vomiting, jaundice) should be empirically started on NAC pending lab results.

NAC is available in oral and IV forms, and both are considered equally efficacious (see Table 77.7 for the dosing regimens of the oral vs IV form). The IV form is used in patients with intractable vomiting, those with evidence of hepatic failure, and pregnant patients. Oral NAC has an unpleasant taste and smell and can be mixed in soft drink or fruit juice or given by NG tube to improve tolerability of the oral regimen. Administration of IV NAC (as a standard 3% solution to avoid administering excess free water, typically in 5% dextrose), especially the initial loading dose, is associated in some patients with the development of anaphylactoid reactions (non–immunoglobulin E mediated). These reactions are typically managed by stopping the infusion; treating with diphenhydramine, albuterol, and/or epinephrine as indicated; and restarting the infusion at a slower rate once symptoms have resolved. IV NAC is also associated with mild elevation in measured INR (range: 1.2-1.5) because of laboratory interference. IV dosing, however, delivers less medication to the liver compared with the oral regimen. As a result, many toxicologists now recommend higher doses of the IV formulation in patients with large overdoses. Transaminases, synthetic function, and renal function should be followed daily while the patient is being treated with NAC. Patients with worsening hepatic function or clinical status might benefit from more frequent lab monitoring. A patient-tailored approach is now the norm for when to stop NAC therapy, for deciding whom to refer for transplantation evaluation, and often for the dose of IV NAC in patients with either very high APAP levels or signs of injury. Consultation with the regional PCC and medical toxicologist can help streamline the care of these patients, ultimately shortening their length of stay with potentially improved outcomes.

**Salicylates.**

The incidence of salicylate poisoning in young children has declined dramatically since APAP and ibuprofen replaced aspirin as the most commonly used analgesics and antipyretics in pediatrics. However, salicylates remain widely available, not only in aspirin-containing products but also in antidiarrheal
medications, topical agents (e.g., keratolytics, sports creams), oil of wintergreen, and some herbal products. Oil of wintergreen contains 5 g of salicylate in 1 teaspoon (5 mL), meaning ingestion of very small volumes of this product has the potential to cause severe toxicity.

Pathophysiology.
Salicylates lead to toxicity by interacting with a wide array of physiologic processes, including direct stimulation of the respiratory center, uncoupling of oxidative phosphorylation, inhibition of the tricarboxylic acid cycle, and stimulation of glycolysis and gluconeogenesis. The acute toxic dose of salicylates is generally considered to be >150 mg/kg. More significant toxicity is seen after ingestions of >300 mg/kg, and severe, potentially fatal, toxicity is described after ingestions of >500 mg/kg.

Clinical and Laboratory Manifestations.
Salicylate ingestions are classified as acute or chronic, and acute toxicity is much more common in pediatric patients. Early signs of acute salicylism include nausea, vomiting, diaphoresis, and tinnitus. Moderate salicylate toxicity can manifest as tachypnea and hyperpnea, tachycardia, and altered mental status. The tachycardia largely results from marked insensible losses from vomiting, tachypnea, diaphoresis, and uncoupling of oxidative phosphorylation. Thus, careful attention should be paid to volume status and early volume resuscitation in the significantly poisoned patient. Signs of severe salicylate toxicity include mild hyperthermia, coma, and seizures. Chronic salicylism can have a more insidious presentation, and patients can show marked toxicity (e.g. altered mental status, noncardiogenic pulmonary edema, acidemia) at significantly lower salicylate levels than in acute toxicity.

Classically, laboratory values from a patient poisoned with salicylates reveal a primary respiratory alkalosis and a primary, elevated anion gap metabolic acidosis. Early in the course of acute salicylism, respiratory alkalosis dominates and the patient is alkalemic. As the respiratory stimulation diminishes, the patient will move toward acidemia. Hyperglycemia (early) and hypoglycemia (late) have been described. Abnormal coagulation studies and acute kidney injury may be seen but are not common.

Serial serum salicylate levels should be closely monitored (every 2-4 hr initially) until they are consistently downtrending. Salicylate absorption in overdose is unpredictable and erratic, especially with an enteric-coated product,
and levels can rapidly increase into the highly toxic range, even many hours after the ingestion. The Done nomogram is of poor value and should not be used. Serum and urine pH and electrolytes should be followed closely. An APAP level should be checked in any patient who intentionally overdoses on salicylates, because APAP is a common co-ingestant, and people often confuse or combine their nonprescription analgesic medications. Salicylate toxicity can cause a noncardiogenic pulmonary edema, especially in chronic overdose; consequently, a chest radiograph is recommended in any patient in respiratory distress.

Treatment.
For the patient who presents soon after an acute ingestion, initial treatment should include gastric decontamination with activated charcoal. Salicylate pills occasionally form bezoars, which should be suspected if serum salicylate concentrations continue to rise many hours after ingestion or are persistently elevated despite appropriate management. Gastric decontamination is typically not useful after chronic exposure.

Initial therapy focuses on aggressive volume resuscitation and prompt initiation of sodium bicarbonate therapy in the symptomatic patient, even before obtaining serum salicylate levels. Therapeutic salicylate levels are 10-20 mg/dL, and levels >25 or 30 mg/dL warrant treatment.

The primary mode of therapy for salicylate toxicity is **urinary alkalinization**. Urinary alkalinization enhances the elimination of salicylates by converting salicylate to its ionized form, “trapping” it in the renal tubules, thus enhancing elimination. In addition, maintaining an alkalemic serum pH decreases CNS penetration of salicylates because charged particles are less able to cross the blood-brain barrier. Alkalinization is achieved by administration of a sodium bicarbonate infusion at approximately 2 times maintenance fluid rates. **The goals of therapy include a urine pH of 7.5-8, a serum pH of 7.45-7.55, and decreasing serum salicylate levels.** In general, in the presence of an acidosis, an aspirin-poisoned patient's status can be directly related to the patient's serum pH: the lower the pH, the greater the relative amount of salicylate in the uncharged, nonpolar form and the greater the penetration of the blood-brain barrier by the drug. Careful attention should also be paid to serial potassium levels in any patient on a bicarbonate infusion, since potassium will be driven intracellularly and hypokalemia impairs alkalinization of the urine. For these reasons, potassium is often added to the bicarbonate drip. Repeat doses of charcoal may be beneficial because of the often delayed and erratic absorption of aspirin.
Parenteral glucose should be provided to any salicylate-poisoned patients with altered mental status because they may have CNS hypoglycemia (i.e., neuroglycopenia) not seen in a peripheral serum glucose test.

In patients with severe toxicity, hemodialysis may be required. Indications for dialysis include severe acid-base abnormalities (specifically severe acidosis and acidemia), a rising salicylate level (despite adequate decontamination and properly alkalized urine), pulmonary edema, cerebral edema, seizures, and renal failure. Serum salicylate concentrations alone are not a clear indicator of the need for dialysis and should always be interpreted along with the clinical status of the patient.

**Ibuprofen and Other Nonsteroidal Antiinflammatory Drugs (NSAIDs).**

Ibuprofen and other NSAIDs are often involved in unintentional and intentional overdoses because of their widespread availability and common use as analgesics and antipyretics. Fortunately, serious effects after acute NSAID overdose are rare because of their wide therapeutic index.

**Pathophysiolo**

NSAIDs inhibit prostaglandin synthesis by reversibly inhibiting the activity of cyclooxygenase (COX), the primary enzyme responsible for the biosynthesis of prostaglandins. In therapeutic use, side effects include GI irritation, reduced renal blood flow, and platelet dysfunction. To minimize these side effects, NSAID analogs have been developed that are more specific for the inducible form of COX (the COX-2 isoform) than the constitutive form, COX-1. However, overdose of the more selective COX-2 inhibitors (e.g., celecoxib [Celebrex]) is treated the same as overdose of nonspecific COX inhibitors (e.g., ibuprofen) because at higher doses, COX-2-selective agents lose their COX inhibitory selectivity.

Ibuprofen, the primary NSAID used in pediatrics, is well tolerated, even in overdose. In children, acute doses of <200 mg/kg rarely cause toxicity, but ingestions of >400 mg/kg can produce more serious effects, including altered mental status and metabolic acidosis.

**Clinical and Laboratory Manifestations.**

Symptoms usually develop within 4-6 hr of ingestion and resolve within 24 hr. If
toxicity does develop, it is typically manifested as nausea, vomiting, and abdominal pain. Although GI bleeding and ulcers have been described with chronic use, they are rare in the setting of acute ingestion. After massive ingestions, patients can develop marked CNS depression, anion gap metabolic acidosis, renal insufficiency, and (rarely) respiratory depression. Seizures have also been described, especially after overdose of mefenamic acid. Specific drug levels are not readily available, nor do they inform management decisions. Renal function studies, acid-base balance, complete blood count (CBC), and coagulation parameters should be monitored after very large ingestions. Co-ingestants, especially APAP, should be ruled out after any intentional ingestion.

**Treatment.**

Supportive care, including use of antiemetics and acid blockade as indicated, is the primary therapy for NSAID toxicity. Decontamination with activated charcoal should be considered if a patient presents within 1-2 hr of a potentially toxic ingestion. There is no specific antidote for this class of drugs. Given the high degree of protein binding and excretion pattern of NSAIDs, none of the modalities used to enhance elimination is particularly useful in managing these overdoses. Unlike in patients with salicylate toxicity, urinary alkalinization is not helpful for NSAID toxicity. Patients who develop significant clinical signs of toxicity should be admitted to the hospital for ongoing supportive care and monitoring. Patients who remain asymptomatic for 4-6 hr after ingestion may be considered medically cleared.

**Prescription Opioids.**

Opioids are a frequently abused class of medications in both IV and oral forms. The opioid epidemic gripping the United States and other countries is discussed in Chapter 140. Two specific oral opioids, buprenorphine and methadone, merit mention because of potential life-threatening toxicity in toddlers with ingestion of even 1 pill. Both agents are used in managing opioid dependence, although buprenorphine is the drug of choice. Methadone is also widely used in the treatment of chronic pain, meaning multiday prescriptions can be filled. Both drugs are readily available for illicit purchase and potential abuse. Both drugs are of great potential toxicity to a toddler, especially buprenorphine because of its long half-life and high potency.

**Pathophysiology.**
Methadone is a lipophilic synthetic opioid with potent agonist effects at µ-opioid receptors, leading to both its desired analgesic effects and undesired side effects, including sedation, respiratory depression, and impaired GI motility. Methadone is thought to cause QTc interval prolongation through interactions with the human ether-a-go-go–related gene (hERG)-encoded potassium rectifier channel. Its duration of effect for pain control averages only about 8 hr, whereas the dangerous side effects can occur up to 24 hr from the last dose and longer after overdose. Methadone has an average half-life >25 hr, which may be extended to >50 hr in overdose.

Suboxone is a combination of buprenorphine, a potent opioid with partial agonism at µ-opioid receptors and weak antagonism at κ-opioid receptors, and naloxone. Naloxone has poor oral bioavailability but is included in the formulation to discourage diversion for IV use, during which it can precipitate withdrawal. Suboxone is formulated for buccal or sublingual administration; consequently, toddlers can absorb significant amounts of drug even by sucking on a tablet. Buprenorphine has an average half-life of 37 hr.

Clinical and Laboratory Manifestations.
In children, methadone and buprenorphine ingestions can manifest with the classic opioid toxidrome of respiratory depression, sedation, and miosis. Signs of more severe toxicity can include bradycardia, hypotension, and hypothermia. Even in therapeutic use, methadone is associated with a prolonged QTc interval and risk of torsades de pointes. Accordingly, an ECG should be part of the initial evaluation after ingestion of methadone or any unknown opioid. Neither drug is detected on routine urine opiate screens, although some centers have added a separate urine methadone screen. Levels of both drugs can be measured, although this is rarely done clinically and is seldom helpful in the acute setting. An exception may be in the cases involving concerns about neglect or abuse, at which point urine for gas chromatography/mass spectroscopy, the legal gold standard, should be sent to confirm and document the presence of the drug.

Treatment.
Patients with significant respiratory depression or CNS depression should be treated with the opioid antidote naloxone (see Table 77.7). In pediatric patients who are not chronically taking opioids, the full reversal dose of 1-2 mg should be used. In contrast, opioid-dependent patients should be treated with smaller initial doses (0.04-0.4 mg), which can then be repeated as needed to achieve the
desired clinical response, avoiding abrupt induction of withdrawal. Because the half-life of methadone and buprenorphine is much longer than that of naloxone, patients can require multiple doses of naloxone. These patients may benefit from a continuous infusion of naloxone, typically started at two thirds of the reversal dose per hour and titrated to maintain an adequate respiratory rate and level of consciousness. Patients who have ingested methadone should be placed on a cardiac monitor and have serial ECGs to monitor for the development of a prolonged QTc interval. If a patient does develop a prolonged QTc, management includes close cardiac monitoring, repletion of electrolytes (potassium, calcium, and magnesium), and having a defibrillator readily available should the patient develop torsades de pointes.

Given the potential for clinically significant and prolonged toxicity, any toddler who has ingested methadone, even if asymptomatic, should be admitted to the hospital for at least 24 hr of monitoring. Some experts advocate a similar approach to management of buprenorphine ingestions, even in the asymptomatic patient. All such cases should be discussed with a PCC or medical toxicologist before determining disposition.

**Cardiovascular Medications**

**β-Adrenergic Receptor Blockers.**

β-Blockers competitively inhibit the action of catecholamines at the β-adrenergic receptor. Therapeutically, β-blockers are used for a variety of conditions, including hypertension, coronary artery disease, tachydysrhythmias, anxiety disorders, migraines, essential tremor, and hyperthyroidism. Because of its lipophilicity and blockade of fast sodium channels, propranolol is considered to be the most toxic member of the β-blocker class. Overdoses of water-soluble β-blockers (e.g., atenolol) are associated with milder symptoms.

**Pathophysiology.**

In overdose, β-blockers decrease chronotropy and inotropy in addition to slowing conduction through atrioventricular nodal tissue. Clinically, these effects are manifested as bradycardia, hypotension, and heart block. Patients with reactive airways disease can experience bronchospasm as a result of blockade of β₂-mediated bronchodilation. β₂-Blockers interfere with glycogenolysis and gluconeogenesis, which can sometimes lead to hypoglycemia, especially in
patients with poor glycogen stores (e.g., toddlers).

**Clinical and Laboratory Manifestations.**

Toxicity typically develops within 6 hr of ingestion, although it may be delayed after ingestion of sotalol or slow-release (SR) preparations. The most common features of severe poisoning are bradycardia and hypotension. Lipophilic agents, including propranolol, can enter the CNS and cause altered mental status, coma, and seizures. Overdose of β-blockers with membrane-stabilizing properties (e.g., propranolol) can cause QRS interval widening and ventricular dysrhythmias.

Evaluation after β-blocker overdose should include an ECG, frequent reassessments of hemodynamic status, and blood glucose. Serum levels of β-blockers are not readily available for routine clinical use and are not useful in management of the poisoned patient.

**Treatment.**

In addition to supportive care and GI decontamination as indicated, glucagon is theoretically the preferred antidote of choice for β-blocker toxicity (see Table 77.7). Glucagon stimulates adenyl cyclase and increases levels of cyclic adenosine monophosphate (cAMP) independent of the β-receptor. Glucagon is typically given as a bolus and, if this is effective, followed by a continuous infusion. In practice, glucagon is often only marginally effective, limited by its proemetic effects, especially at the high doses typically required. Other potentially useful interventions include calcium, vasopressors, and high-dose insulin. Seizures are managed with benzodiazepines, and QRS widening should be treated with sodium bicarbonate. Children who ingest 1 or 2 water-soluble β-blockers are unlikely to develop toxicity and can typically be discharged to home if they remain asymptomatic over a 6 hr observation period. Children who ingest SR products, highly lipid-soluble agents, and sotalol can require longer periods of observation before safe discharge. Any symptomatic child should be admitted for ongoing monitoring and directed therapy.

**Calcium Channel Blockers.**

Calcium channel blockers (CCBs) are used for a variety of therapeutic indications and have the potential to cause severe toxicity, even after exploratory ingestions. Specific agents include verapamil, diltiazem, and the dihydropyridines (e.g., amlodipine, nifedipine). Of these, diltiazem and verapamil are the most dangerous in overdose because of their higher
lipophilicity and direct cardiac suppressant effects.

**Pathophysiology.**

CCBs antagonize $L$-type calcium channels, inhibiting calcium influx into myocardial and vascular smooth muscle cells. Verapamil works primarily by slowing inotropy and chronotropy and has no effect on systemic vascular resistance (SVR). Diltiazem has effects both on the heart and the peripheral vasculature. The dihydropyridines exclusively diminish SVR. Verapamil and diltiazem can significantly diminish myocardial contractility and conduction, with diltiazem also lowering SVR. By contrast, dihydropyridines will decrease the SVR, leading to vasodilation and reflex tachycardia, although this receptor selectivity may be lost after a large overdose. Because the same $L$-type calcium channels blocked by CCBs are also on the pancreatic islet cells, any patient significantly poisoned with a CCB usually is hyperglycemic.

**Clinical and Laboratory Manifestations.**

The onset of symptoms typically is soon after ingestion, although it may be delayed with ingestions of SR products. Overdoses of CCBs lead to hypotension, accompanied by bradycardia, normal heart rate, or even tachycardia, depending on the agent. A common feature of CCB overdose is the patient exhibiting profound hypotension with preserved consciousness.

Initial evaluation should include an ECG, continuous and careful hemodynamic monitoring, and rapid measurement of serum glucose levels. Both the absolute degree of hyperglycemia and the percentage increase in serum glucose have been correlated with the severity of CCB toxicity in adults. The development of hyperglycemia can even precede the development of hemodynamic instability. Blood levels of CCBs are not readily available and are not useful in guiding therapy.

**Treatment.**

Once initial supportive care has been instituted, GI decontamination should begin with activated charcoal as appropriate. WBI may be beneficial in a stable patient after ingestion of an SR product. Calcium channel blockade in the smooth muscles of the GI tract can lead to greatly diminished motility; thus any form of GI decontamination should be undertaken with careful attention to serial abdominal tests.

Calcium salts, administered through a peripheral IV line as calcium gluconate
or a central line as calcium chloride, help to overcome blocked calcium channels. **High-dose insulin euglycemia therapy** is considered the antidote of choice for CCB toxicity. An initial bolus of 1 unit/kg of regular insulin is followed by an infusion at 0.5-1 unit/kg/hr (see Table 77.7 ). The main mechanism of high-dose insulin euglycemia is to improve the metabolic efficiency of a poisoned heart that is in need of carbohydrates for energy (instead of the usual free fatty acids), but has minimal circulating insulin. Blood glucose levels should be closely monitored, and supplemental glucose may be given to maintain euglycemia, although this is rarely necessary in the severely poisoned patient.

Additional therapies include judicious IV fluid boluses and vasopressors (often in very high doses). Cardiac pacing is rarely of value. Lipid emulsion therapy (discussed earlier) is a potentially lifesaving intervention, especially for patients poisoned with the more lipid-soluble CCBs, verapamil and diltiazem. In extreme cases an intraaortic balloon pump or extracorporeal membrane oxygenation (ECMO) are potential rescue devices. Given the potential for profound and sometimes delayed toxicity in toddlers after ingestion of 1 or 2 CCB tablets, hospital admission and 12-24 hr of monitoring for all of these patients is strongly recommended.

**Clonidine.**

Although originally intended for use as an antihypertensive, the number of clonidine prescriptions in the pediatric population has greatly increased because of its reported efficacy in the management of attention-deficit/hyperactivity disorder (ADHD), tic disorders, and other behavioral disorders. With this increased use has come a significant rise in pediatric ingestions and therapeutic misadventures. Clonidine is available in pill and transdermal patch forms.

**Pathophysiology.**

Clonidine, along with the closely related agent **guanfacine**, is a centrally acting α₂-adrenergic receptor agonist with a very narrow therapeutic index. Agonism at central α₂ receptors decreases sympathetic outflow, producing lethargy, bradycardia, hypotension, and apnea. Toxicity can develop after ingestion of only 1 pill or after sucking on or swallowing a discarded transdermal patch. Even a “used” transdermal patch might contain as much as one-third to one-half the original amount of drug.
Clinical and Laboratory Manifestations.

The most common clinical manifestations of clonidine toxicity are lethargy, miosis, and bradycardia. Hypotension, respiratory depression, and apnea may be seen in severe cases. Very early after ingestion, patients may be hypertensive in the setting of agonism at peripheral α-receptors and resulting vasoconstriction. Symptoms develop relatively soon after ingestion and typically resolve within 24 hr. Serum clonidine concentrations are not readily available and are of no clinical value in the acute setting. Although signs of clinical toxicity are common after clonidine overdose, death from clonidine alone is extremely unusual.

Treatment.

Given the potential for significant toxicity, most young children warrant referral to a healthcare facility for evaluation after unintentional ingestions of clonidine. Gastric decontamination is usually of minimal value because of the small quantities ingested and the rapid onset of serious symptoms. Aggressive supportive care is imperative and is the cornerstone of management. Naloxone, often in high doses, has shown variable efficacy in treating clonidine toxicity. Other potentially useful therapies include atropine, IV fluid boluses, and vasopressors. Symptomatic children should be admitted to the hospital for close cardiovascular and neurologic monitoring. Also, in a patient receiving chronic clonidine or guanfacine therapy, rapid discontinuation of the drug, or even missing 1 or 2 doses, could lead to potentially dangerous elevations in blood pressure.

Digoxin.

Digoxin is a cardiac glycoside extracted from the leaves of Digitalis lanata. Other natural sources of cardiac glycosides include Digitalis purpura (foxglove), Nerium oleander (oleander), Convallaria majalis (lily of the valley), Siberian ginseng, and the Bufo marinus toad. Therapeutically, digoxin is used in the management of heart failure and some supraventricular tachydysrhythmias. Acute overdose can occur in the setting of dosing errors (especially in younger children), unintentional or intentional medication ingestion, or exposure to plant material containing digitalis glycosides. Regarding exposure to such plants, toxicity is unusual unless the poison is concentrated in the form of a tea. Chronic toxicity can result from alteration of the digoxin dose, alteration in digoxin
clearance as a result of renal impairment, or drug interactions.

**Pathophysiology.**

Digoxin blocks the sodium-potassium adenosine triphosphatase (Na\textsuperscript{+}, K\textsuperscript{+} - ATPase) pump, leading to intracellular loss of K\textsuperscript{+} and gain of Na\textsuperscript{+} and calcium (Ca\textsuperscript{2+}). This resulting rise in Ca\textsuperscript{2+} available to the contractile myocardium improves inotropy. An increase in myocardial automaticity leads to subsequent atrial, nodal, and ventricular ectopy. Digoxin also affects nodal conduction, leading to a prolonged refractory period, decreased sinus node firing, and slowed conduction through the atrioventricular node. Impaired Na\textsuperscript{+}/K\textsuperscript{+} exchange results in dangerously high levels of serum K\textsuperscript{+}. Overall, digoxin overdose manifests as a combination of slowed or blocked conduction and increased ectopy.

**Clinical and Laboratory Manifestations.**

Nausea and vomiting are common initial symptoms of acute digoxin toxicity, manifesting within 6 hr of overdose. Cardiovascular manifestations include bradycardia, heart block, and a wide variety of dysrhythmias. CNS manifestations consist of lethargy, confusion, and weakness. Chronic toxicity is more insidious and may also manifest as altered mental status and visual disturbances (rare).

Initial assessment should include an ECG, serum digoxin level, serum potassium, and kidney function tests. The serum digoxin level should be assessed at least 6 hr after ingestion and carefully interpreted in the setting of clinical symptoms, because the digoxin level alone does not entirely reflect the severity of intoxication. In acute ingestions, serum potassium is an independent marker of morbidity and mortality, with levels >5.5 mEq/L predicting poor outcomes. In chronic toxicity, serum K\textsuperscript{+} concentration is less useful as a prognostic marker and may be altered from concomitant use of diuretics.

Digoxin has a very narrow therapeutic index. Therapeutic plasma digoxin concentrations are 0.5-2.0 ng/mL; a level >2 ng/mL is considered toxic and >6 ng/mL is considered potentially fatal (in chronic poisonings). As with all serum levels of intoxicants, one must be careful to interpret the number in the context of the scenario of the poisoning and the status of the patient. An acutely poisoned patient may have a very high serum level and minimal to no symptoms, whereas a patient with a chronic or acute on chronic poisoning will usually be sicker with a lower serum level.
Numerous drug interactions affect plasma digoxin concentrations. Medications known to increase serum digoxin concentrations include the macrolides, erythromycin and clarithromycin, spironolactone, verapamil, amiodarone, and itraconazole.

**Treatment.**

Initial treatment includes good general supportive care and gastric decontamination with activated charcoal if the ingestion was recent. An antidote for digoxin, digoxin-specific antibody fragments (Fab: Digibind or DigiFab) is available (see Table 77.7). Fab fragments bind free digoxin in both the intravascular and the interstitial spaces to form a pharmacologically inactive complex that is subsequently eliminated renally. Indications for Fab fragments include life-threatening dysrhythmias, K⁺ value >5-5.5 mEq/L, serum digoxin level >15 ng/mL at any time or >10 ng/mL 6 hr after ingestion, clinically significant hypotension or other CV instability, altered mental state, and renal failure. Atropine is potentially useful in managing symptomatic bradycardia. Although dogma states that patients on digoxin with severe hyperkalemia and QRS widening on the ECG should not receive calcium salts, this has not been supported in the literature. Once stabilized, consultation with a cardiologist is recommended in the management of patients receiving chronic digoxin therapy, because administration of Fab fragments can lead to recurrence of the patient's underlying dysrhythmias or dysfunction.

**Iron.**

Historically, iron was a common cause of childhood poisoning deaths. However, preventive measures such as childproof packaging have significantly decreased the rates of serious iron toxicity in young children. Iron-containing products remain widely available, with the most potentially toxic being adult iron preparations and prenatal vitamins. The severity of an exposure is related to the amount of elemental iron ingested. Ferrous sulfate contains 20% elemental iron, ferrous gluconate 12%, and ferrous fumarate 33%. Multivitamin preparations and children's vitamins rarely contain enough elemental iron to cause significant toxicity. Furthermore, nonionic forms of iron, carbonyl iron and iron polysaccharide also do not cause significant toxicity.

**Pathophysiology.**

Iron is directly corrosive to the GI mucosa, leading to hematemesis, melena,
ulceration, infarction, and potential perforation. Early iron-induced hypotension is caused by massive volume losses, increased permeability of capillary membranes, and vasodilation mediated by free iron. Iron accumulates in tissues, including the Kupffer cells of the liver and myocardial cells, leading to hepatotoxicity, coagulopathy, and cardiac dysfunction. Metabolic acidosis develops in the setting of hypotension, hypovolemia, and iron's direct interference with oxidative phosphorylation and the Krebs cycle. Pediatric patients who ingest >40 mg/kg of elemental iron should be referred to medical care for evaluation, although moderate to severe toxicity is typically seen with ingestions >60 mg/kg.

Clinical and Laboratory Manifestations.
Iron toxicity is described in 5 often-overlapping stages. The 1st stage, 30 min to 6 hr after ingestion, consists of profuse vomiting and diarrhea (often bloody), abdominal pain, and significant volume losses leading to potential hypovolemic shock. Patients who do not develop GI symptoms within 6 hr of ingestion are unlikely to develop serious toxicity. The 2nd stage, 6-24 hr after ingestion, is often referred to as the “quiescent phase” since the GI symptoms typically have resolved. However, careful clinical examination can reveal subtle signs of hypoperfusion, including tachycardia, pallor, and fatigue. During the 3rd stage, 12-36 hr after ingestion, patients develop multisystem organ failure, shock, hepatic and cardiac dysfunction, acute lung injury, and profound metabolic acidosis. Death usually occurs during the 3rd stage. The 4th stage (hepatic) results in fulminant liver failure and coagulopathy about 2-5 days after ingestion. The 5th stage, 4-6 wk after ingestion, is marked by formation of strictures and signs of GI obstruction.

Symptomatic patients and patients with a large exposure by history should have serum iron levels drawn 4-6 hr after ingestion. Serum iron concentrations of <500 µg/dL 4-8 hr after ingestion suggest a low risk of significant toxicity, whereas concentrations of >500 µg/dL indicate that significant toxicity is likely. Additional laboratory evaluation in the ill patient should include arterial or venous blood gas, CBC, serum glucose level, liver transaminases, and coagulation parameters. Careful attention should be paid to the patient's hemodynamic status. An abdominal radiograph might reveal the presence of iron tablets, although not all formulations of iron are radiopaque.

Treatment.
Close clinical monitoring, combined with aggressive supportive and symptomatic care, is essential to the management of iron poisoning. Activated charcoal does not adsorb iron, and WBI remains the decontamination strategy of choice. **Deferoxamine**, a specific chelator of iron, is the antidote for moderate to severe iron intoxication (see Table 77.7). Indications for deferoxamine treatment include a serum iron concentration >500 µg/dL or moderate to severe symptoms of toxicity (e.g., acidosis), regardless of serum iron concentration. Deferoxamine is preferably given by continuous IV infusion at 15 mg/kg/hr. Hypotension is a common side effect of deferoxamine infusion and is managed by slowing the rate of the infusion and administering fluids and vasopressors as needed. Prolonged deferoxamine infusion (>24 hr) has been associated with pulmonary toxicity (acute respiratory distress syndrome, ARDS) and *Yersinia* sepsis. The deferoxamine-iron complex can color the urine reddish (“vin rosé”), although the degree of this coloration should not guide therapy. Deferoxamine is typically continued until clinical symptoms and acidosis resolve. Consultation with a PCC or medical toxicologist can yield guidelines for discontinuing deferoxamine.

**Oral Hypoglycemics**

Oral medications used in the management of type 2 diabetes include sulfonylureas, biguanides (e.g., metformin), thiazolidinediones, and meglitinides. Of these, only the sulfonylureas and meglitinides have the potential to cause profound hypoglycemia in both diabetic and nondiabetic patients. These classes of medications are widely prescribed and thus readily available for both unintentional and intentional exposures. In toddlers, ingestion of a single sulfonylurea tablet can lead to significant toxicity.

**Pathophysiology.**

Sulfonylureas work primarily by enhancing endogenous insulin secretion. In binding to the sulfonylurea receptor, these drugs induce closure of K⁺ channels, leading to membrane depolarization, opening of Ca²⁺ channels, and stimulation of Ca²⁺-mediated insulin release. Even in therapeutic use, the duration of hypoglycemic action can last up to 24 hr.

**Clinical and Laboratory Manifestations.**

Hypoglycemia and symptoms associated with hypoglycemia are the primary
clinical manifestations of sulfonylurea toxicity. These signs and symptoms can include diaphoresis, tachycardia, lethargy, irritability, coma, seizures, and even focal neurologic findings. As with other hyperinsulinemic states, sulfonylurea overdoses are associated with a nonketotic hypoglycemia. In the majority of patients, hypoglycemia develops within 6 hr of ingestion but can be delayed up to 16-18 hr after ingestion. Toddlers are particularly susceptible to hypoglycemia during an overnight fast.

**Treatment.**

Patients with symptomatic hypoglycemia should be promptly treated with dextrose. In patients with mild symptoms, oral dextrose may be sufficient. However, patients with severe symptoms or profound hypoglycemia should be treated with a bolus of IV dextrose. Continuous dextrose infusions and repeated IV dextrose boluses should be avoided if possible, because this can stimulate further insulin release and lead to recurrent and prolonged hypoglycemia. Instead, the preferred antidote for persistent (i.e., requiring ≥2 doses of IV dextrose) sulfonylurea toxicity is octreotide (see Table 77.7). Octreotide is a somatostatin analog that inhibits insulin release. Octreotide is given intravenously (IV) or subcutaneously (SC), typically in doses of 1-2 µg/kg (50-100 µg in teens or adults) every 6-8 hr.

Given the potential for significant hypoglycemia, toddlers with witnessed or suspected sulfonylurea ingestions should be admitted to the hospital for serial glucose measurements for at least 12 hr, including an overnight fast. Patients of any age who develop hypoglycemia are also candidates for admission given the prolonged duration of hypoglycemic activity. Prophylactic IV dextrose infusions are not recommended because they can mask the symptoms of toxicity and stimulate further insulin secretion. Patients who require IV dextrose and/or octreotide should be monitored until they can demonstrate euglycemia for at least 8 hr off all therapy.

With the increasing numbers of adolescents with type 2 diabetes, pediatricians should be familiar with the toxic effects of metformin as well. Although metformin does not cause hypoglycemia, its association with lactic acidosis is well documented (metformin-associated lactic acidosis, MALA). This state typically arises after a large overdose in which the agent interferes with the liver's ability to clear lactic acid. Dangerously high serum lactate levels can result, leading to hemodynamic instability. Hemodialysis is usually the best option for patients with severe MALA.
Psychiatric Medications: Antidepressants

Selective serotonin reuptake inhibitors (SSRIs; e.g., fluoxetine, sertraline, paroxetine, citalopram) are the most commonly prescribed class of antidepressants. This trend largely results from their wide therapeutic index and more favorable side effect profile compared with older agents such as tricyclic antidepressants (TCAs; amitriptyline, clomipramine, desipramine, doxepin, nortriptyline, imipramine) and monoamine oxidase inhibitors (MAOIs). Other agents include the serotonin-norepinephrine reuptake inhibitors (SNRIs; e.g., venlafaxine) and atypical antidepressants (e.g., bupropion).

Tricyclic Antidepressants.

Although now prescribed less often for depression, TCAs remain in use for a variety of other conditions, including chronic pain syndromes, enuresis, ADHD, and obsessive-compulsive disorder. TCAs can cause significant toxicity in children, even with ingestion of 1 or 2 pills (10-20 mg/kg).

Pathophysiology.

TCAs achieve their desired antidepressant effects primarily through blockade of norepinephrine and serotonin reuptake. TCAs have complex interactions with other receptor types. Antagonism at muscarinic acetylcholine receptors leads to clinical features of the anticholinergic toxidrome. Antagonism at peripheral α-receptors leads to hypotension and syncope. Key to the toxicity of TCAs is their ability to block fast sodium channels, leading to impaired cardiac conduction and arrhythmias.

Clinical and Laboratory Manifestations.

Cardiovascular and CNS symptoms dominate the clinical presentation of TCA toxicity. Symptoms typically develop within 1-2 hr of ingestion, and serious toxicity usually manifests within 6 hr of ingestion. Patients can have an extremely rapid progression from mild symptoms to life-threatening dysrhythmias. Patients often develop features of the anticholinergic toxidrome, including delirium, mydriasis, dry mucous membranes, tachycardia, hyperthermia, urinary retention, and slow GI motility. CNS toxicity can include lethargy, coma, myoclonic jerks, and seizures. Sinus tachycardia is the most common cardiovascular manifestation of toxicity; however, patients can also develop widening of the QRS complex, premature ventricular contractions, and
ventricular dysrhythmias. Refractory hypotension is a poor prognostic indicator and is the most common cause of death in TCA overdose.

An ECG is a readily available bedside test that can help determine the diagnosis and prognosis of the TCA-poisoned patient (Fig. 77.2; see Table 77.6). A QRS duration >100 msec identifies patients who are at risk for seizures and cardiac arrhythmias. An R wave in lead aVR of ≥3 mm is also an independent predictor of toxicity. Both ECG parameters are superior to measured serum TCA concentrations for identifying patients at risk for serious toxicity, and obtaining levels is rarely helpful in management of the acutely ill patient.

![Electrocardiographic findings in tricyclic antidepressant toxicity. Note the tachycardia, widened QRS interval (144 msec), and prominent R wave in lead aVR. These findings are consistent with blockade of fast sodium channels.](image)

**FIG. 77.2**

Treatment.

Initial attention should be directed to supporting vital functions, including airway and ventilation as needed. Gastric decontamination can be accomplished with activated charcoal in appropriate patients. Treating clinicians should obtain an ECG as soon as possible and follow serial ECGs to monitor for progression of toxicity. The 4 primary effects described next are seen at the bedside.

**1 Altered Mental State.**

TCA-poisoned patients can become deeply comatose relatively quickly, so careful and prompt attention to the airway and placement of an endotracheal tube is of paramount importance. The airway should be secured before any GI decontamination efforts.
2 Widened QRS on ECG.
TCAs, as well as with other agents (e.g., diphenhydramine, cocaine), will block the fast Na\(^+\) channels on the myocardial cells, slowing the upstroke of the QRS complex. Because the effect on Na\(^+\) channels is greatest within the 1st 6 hr, frequent ECGs (i.e., every 20-30 min) during this period are important. As the QRS approaches 160 msec, the risk of the patient developing monomorphic ventricular tachycardia rises to 30%. Sodium, usually in the form of sodium bicarbonate, is the antidote of choice. *Indications for sodium bicarbonate include a QRS duration $\geq 110$ msec, ventricular dysrhythmias, and hypotension*. Multiple bolus doses of sodium bicarbonate, 1-2 mEq/kg each, may be needed to narrow the QRS to $<110$ msec. Some prefer then to place the patient on an infusion of sodium bicarbonate, but this may not be necessary if the QRS is carefully monitored after the initial doses and repeat bolus dosing is provided as needed during the 1st 6-12 hr. Hypertonic (3%) saline and/or lipid emulsion therapy may be beneficial in refractory cases.

3 Hypotension.
A direct-acting vasopressor such as norepinephrine or epinephrine is the agent of choice. Boluses of IV crystalloid fluids should be used with caution to prevent fluid overload.

4 Seizures.
Likely a result of the anticholinergic effects of TCAs, seizures are relatively common, typically brief, and should be treated with agents targeting the GABA-receptor complex in the brain. Benzodiazepines are the agent of choice. Asymptomatic children should receive appropriate decontamination and have continuous cardiac monitoring and serial ECGs for at least 6 hr after exposure. If any manifestations of toxicity develop, the child should be admitted to a monitored setting. Children who remain completely asymptomatic with normal serial ECGs may be candidates for discharge after that monitoring period.

Selective Serotonin Reuptake Inhibitors.
In overdose, SSRIs are considerably less toxic than TCAs. SSRIs are unlikely to cause significant toxicity in exploratory ingestions. Some data suggest that initiating SSRI therapy is associated with an increased risk of suicidal ideation and behavior (see Chapter 40 ).
Pathophysiology.
SSRIs selectively block the reuptake of serotonin in the CNS. In contrast to TCAs and atypical antidepressants, SSRIs do not directly interact with other receptor types.

Clinical and Laboratory Manifestations.
In overdose, the principal manifestations of toxicity are sedation and tachycardia. Cardiac conduction abnormalities (primarily QTc prolongation) and seizures have been described in significant overdoses, especially after ingestions of citalopram. An ECG should be part of the initial assessment after SSRI ingestion. Serum creatine kinase (CK) levels are almost always elevated in a patient with clinically significant serotonin syndrome. Although seen more often after therapeutic use or overdose of several serotonergic agents in combination, the serotonin syndrome has also been described in ingestion of SSRIs alone (Table 77.11). Clinically, serotonin syndrome describes a spectrum of altered mental status, autonomic instability, fever, and neuromuscular hyperactivity (hyperreflexia, tremors, clonus in lower extremities > upper extremities). One or all of these signs may be present to varying degrees.

## Treatment.

Initial management includes a careful assessment for signs and symptoms of serotonin syndrome and an ECG. Most patients simply require supportive care and observation until their mental status improves and tachycardia, if present, resolves. Management of serotonin syndrome is directed by the severity of symptoms; possible therapeutic interventions include benzodiazepines in mild cases and intubation, sedation, and paralysis in patients with severe manifestations (e.g., significant hyperthermia). Because agonism at the 5-HT$_{2A}$ serotonin receptor is thought to be primarily responsible for the development of serotonin syndrome, use of the 5-HT$_{2A}$ receptor antagonist cyproheptadine may also be helpful. Cyproheptadine is only available in an oral form.

### Atypical Antidepressants.

The atypical antidepressant class includes agents such as venlafaxine and duloxetine (SNRIs), bupropion (dopamine, norepinephrine, and some serotonin reuptake blockade), and trazodone (serotonin reuptake blockade and peripheral α-receptor antagonism). The variable receptor affinities of these agents lead to some distinctions in their clinical manifestations and management.

### Clinical and Laboratory Manifestations.

In overdose, **venlafaxine** and other SNRIs have been associated with cardiac conduction defects, including QRS and QTc prolongation, and seizures. **Bupropion** warrants special consideration because it is one of the most common etiologies of toxicant-induced seizures in the United States. After ingestion of SR or extended-release (ER) preparations, seizures can occur as late as 18-20 hr after ingestion. In addition, bupropion can cause tachycardia, agitation, and QRS and QTc prolongation. These cardiac effects are thought to result from a reduction in cardiac intracellular coupling caused by inhibition at gap junctions.
in the heart. Mortality results from not only status epilepticus but also the cardiac conduction disturbances causing ventricular tachycardia. Bupropion is of growing concern with the rising popularity of the drug, especially in the ER formulation. In addition to sedation and signs of serotonin excess, trazodone overdose may be associated with hypotension from blockade of peripheral α-receptors.

**Treatment.**

Management is directed to clinical signs and symptoms. QRS and QTc interval prolongation after bupropion poisoning is typically resistant to the standard treatments of sodium bicarbonate and magnesium. Seizures are often brief and self-limited but can be treated with benzodiazepines if necessary. A patient poisoned with bupropion who shows unstable hemodynamics with prolonged ECG intervals or persistent seizure activity should receive Intralipid emulsion therapy. Because of the potential for delayed seizures, asymptomatic patients who have ingested an SR preparation of bupropion should be admitted to a monitored setting for at least 20-24 hr. Trazodone-associated hypotension typically responds to fluids, though it can require vasopressors in extreme cases.

**Monoamine Oxidase Inhibitors.**

Although now rarely used therapeutically, MAOIs remain important agents given their potential for serious and delayed toxicity. Ingestions of only 1 or 2 pills (6 mg/kg) are associated with toxicity in children. Clinical manifestations initially include hypertension, hyperthermia, tachycardia, muscle rigidity, and seizures, followed up to 24 hr later by hemodynamic instability and CV collapse. *Any child who ingests a MAOI should be admitted to a monitored setting for at least 24 hr, regardless of symptoms.* Management includes blood pressure control, cooling and benzodiazepines for hyperthermia, serial monitoring of CK and renal function, and fluid and vasopressor therapy for hemodynamic instability.

**Psychiatric Medications: Antipsychotics**

Clinicians are increasingly prescribing antipsychotic medications in the pediatric population. Antipsychotics are usually classified as either typical or atypical. In general, typical agents are associated with more side effects and toxicity than the atypical agents.
Pathophysiology.

Typical or “traditional” antipsychotics (haloperidol, droperidol, thioridazine, chlorpromazine, fluphenazine) are characterized by their antagonism at D2 dopamine receptors. In therapeutic use, these agents are associated with extrapyramidal symptoms, tardive dyskinesia, and development of the neuroleptic malignant syndrome (NMS). The atypical agents (aripiprazole, clozapine, quetiapine, risperidone, ziprasidone) were developed with relatively less dopamine (D2-receptor) antagonism in the nigrostriatum in an effort to avoid these side effects and improve their efficacy in managing the “negative” symptoms of schizophrenia. Instead, these agents have complex and varied interactions with multiple receptor types, including α-receptors, serotonin receptors, muscarinic acetylcholine receptors, and histamine receptors.

Clinical and Laboratory Manifestations.

Typical antipsychotic toxicity usually includes sedation, tachycardia, and QTc prolongation. Patients can present with acute dystonia, akathisia, and NMS, although these are seen less frequently in acute overdoses than in therapeutic use. The phenothiazines (e.g., thioridazine) can cause widening of the QRS interval from blockade of fast sodium channels. Clinically, NMS can be difficult to distinguish from serotonin syndrome.

Although the presentation of atypical antipsychotic toxicity can vary based on the receptor affinities of the specific agent, sedation, tachycardia, and QTc prolongation are common. Peripheral α-receptor blockade (e.g., with quetiapine) is associated with hypotension. In therapeutic use, clozapine is associated with agranulocytosis.

Diagnostic testing should include an ECG. Patients with hyperthermia or muscle rigidity should have a serum CK level sent to monitor for possible rhabdomyolysis. Antipsychotic levels are not readily available and are not helpful in managing acute poisoning.

Management.

Initial management involves assessing and supporting vital functions. In some patients, CNS depression may be so profound as to require intubation for airway control. Acute dystonia is treated with diphenhydramine and benztropine. Management of NMS includes conscientious supportive care, IV fluids, cooling, benzodiazepines, and bromocriptine or dantrolene in severe cases. QTc
prolongation is managed with repletion of electrolytes (especially calcium, magnesium, and potassium), continuous cardiac monitoring, prevention of bradycardia (overdrive pacing, isoproterenol, atropine), and defibrillation if the patient develops torsades de pointes. Seizures typically are well controlled with benzodiazepines. Hypotension usually responds to boluses of IV fluids, although vasopressor therapy is necessary in some patients.

Household Products

Caustics

Caustics include acids and alkalis as well as a few common oxidizing agents (see Chapter 353). Strong acids and alkalis can produce severe injury even in small-volume ingestions.

Pathophysiology.

Alkalis produce a liquefaction necrosis, allowing further tissue penetration of the toxin and setting the stage for possible perforation. Acids produce a coagulative necrosis, which limits further tissue penetration, although perforation can still occur. The severity of the corrosive injury depends on the pH and concentration of the product as well as the length of contact time with the product. Agents with a pH of <2 or >12 are most likely to produce significant injury.

Clinical Manifestations.

Ingestion of caustic materials can produce injury to the oral mucosa, posterior pharynx, vocal cords, esophagus, and stomach. Patients can have significant esophageal injury even in the absence of visible oral burns. Symptoms include pain, drooling, vomiting, abdominal pain, and difficulty swallowing or refusal to swallow. Laryngeal injury can manifest as stridor and respiratory distress, necessitating intubation. In the most severe cases, patients can present in shock after perforation of a hollow viscus. Circumferential burns of the esophagus are likely to cause strictures when they heal, which can require repeated dilation or surgical correction and long-term follow-up for neoplastic changes in adulthood. Caustics on the skin or in the eye can cause significant tissue damage.

Treatment.
Initial treatment of caustic exposures includes thorough removal of the product from the skin or eye by flushing with water. *Emesis and lavage are contraindicated*. Activated charcoal should not be used because it does not bind these agents and can predispose the patient to vomiting and subsequent aspiration. Stridor or other signs of respiratory distress should alert the provider to the need for a thorough evaluation of the airway for potential intubation or surgical airway management. Endoscopy can be performed within 12-24 hr of ingestion for prognostic and diagnostic purposes in symptomatic patients or those with suspected injury on the basis of history and known characteristics of the ingested product. Endoscopy's role is purely diagnostic. Whether the risks of the procedure are justified is debatable. Expectant management with a period of nothing by mouth (NPO) and proton pump inhibitor therapy is likely appropriate for the majority of patients *without* airway burns or signs of mediastinitis or peritonitis. Endoscopy is contraindicated in such patients, who instead require immediate surgical consultation. Corticosteroids or prophylactic antibiotics are not beneficial.

**Pesticides**

**Cholinesterase-Inhibiting Insecticides.**

The most commonly used insecticides in agriculture are *organophosphates* and *carbamates*; both are inhibitors of cholinesterase enzymes: acetylcholinesterase (AChE), pseudocholinesterase, and erythrocyte AChE. Most pediatric poisonings occur as the result of unintentional exposure to insecticides in and around the home or farm. The chemical warfare weapons known as “nerve agents” are also organophosphate compounds with a similar mechanism of action but much greater potency.

**Pathophysiology.**

Organophosphates and carbamates produce toxicity by binding to and inhibiting AChE, preventing the degradation of acetylcholine (ACh) and resulting in its accumulation at nerve synapses. If left untreated, organophosphates form an irreversible bond to AChE, permanently inactivating the enzyme. This process, called *aging*, occurs over a variable time period depending on the characteristics of the specific organophosphate. A period of weeks to months is required to regenerate inactivated enzymes. In contrast, carbamates form a temporary bond to the enzymes, typically allowing reactivation of AChE within 24 hr.
Clinical and Laboratory Manifestations.

Clinical manifestations of organophosphate and carbamate toxicity relate to ACh accumulation at peripheral nicotinic and muscarinic synapses and in the CNS. Symptoms of carbamate toxicity are usually less severe than those seen with organophosphates. A commonly used mnemonic for the symptoms of cholinergic excess at muscarinic receptors is **DUMBBELS**: diarrhea/defecation, urination, miosis, bronchorrhea/bronchospasm, bradycardia, emesis, lacrimation, and salivation. Nicotinic signs and symptoms include muscle weakness, fasciculation, tremors, hypoventilation (diaphragm weakness), hypertension, tachycardia, and dysrhythmias. Severe manifestations include coma, seizures, shock, arrhythmias, and respiratory failure.

Diagnosis of poisoning is based primarily on history and physical exam findings. Red blood cell cholinesterase and pseudocholinesterase activity levels can be measured in the laboratory. These are only helpful when compared to the patient's known baseline. As such, these assessments are typically limited to farmworkers undergoing ongoing occupational surveillance.

Treatment.

Basic decontamination should be performed, including washing all exposed skin with soap and water and immediately removing all exposed clothing. Activated charcoal is unlikely to be of benefit because these are liquids that are rapidly absorbed. Basic supportive care should be provided, including fluid and electrolyte replacement, intubation, and ventilation if necessary. The use of succinylcholine for rapid sequence intubation should be avoided because the same cholinesterase enzymes that are poisoned metabolize this neuromuscular blocking agent, leading to prolonged paralysis.

Two antidotes are useful in treating cholinesterase inhibitor poisoning: atropine and pralidoxime (see Table 77.7). **Atropine**, which antagonizes the muscarinic ACh receptor, is useful for both organophosphate and carbamate intoxication. Often, large doses of atropine must be administered by intermittent bolus or continuous infusion to control symptoms. Atropine dosing is primarily targeted to drying the respiratory secretions. **Pralidoxime** breaks the bond between the organophosphate and the enzyme, reactivating AChE. Pralidoxime is only effective if it is used before the bond ages and becomes permanent. Pralidoxime is not necessary for carbamate poisonings because the bond between the insecticide and the enzyme degrades spontaneously.

Without treatment, symptoms of organophosphate poisoning can persist for
weeks, requiring continuous supportive care. Even with treatment, some patients develop a delayed polyneuropathy and a range of chronic neuropsychiatric symptoms.

**Pyrethrins and Pyrethroids.**

Pyrethrins are derived from the chrysanthemum flower and along with pyrethroids, synthetic derivatives, are the most commonly used pesticides in the home. Although >1,000 pyrethrins and pyrethroids exist, <20 are available in the United States, with permethrin being the most common. Exposure to these compounds occurs by inhalation, dermal absorption, or ingestion. Ingestion is the predominant route and typically occurs by eating contaminated foods. Permethrin is also a prescribed medication for the treatment of scabies and lice.

**Pathophysiology.**

Pyrethrins and pyrethroids prolong the open state of the voltage-gated Na\(^+\) channel conduction, which is the main mechanism resulting in its pesticide activity. Pyrethrins have minimal toxicity in mammals because of rapid metabolism, higher affinity for the insect Na\(^+\) channel, and decreased activity at higher temperatures seen in warm-blooded animals. Since pyrethroids were specifically manufactured to be more stable in the environment, they have a higher likelihood of toxicity.

**Clinical and Laboratory Manifestations.**

Pyrethrin exposures can lead to allergic reactions ranging from dermatitis to urticaria to anaphylaxis. Acute exposure can result in headache, nausea, dizziness, tremors, ataxia, choreoathetosis, loss of consciousness, and seizures. The severity of the symptoms depends on the magnitude of the exposure. Reports of acute lung injury have also occurred after pyrethroid exposures, although this is likely from the other components of the insecticide, such as surfactants and solvents. Paresthesias limited to the cutaneous exposure area can also occur following a dermal exposure. Chronic exposures have not been shown to result in any clinical manifestations. Although one can test for urinary pyrethroid metabolites, this is only useful for monitoring occupational exposure and has no role for the acute exposure.

**Treatment.**
Initial treatment should focus on decontamination, which involves removing all clothing and irrigation of exposed areas. Allergic reactions are treated the same as for antihistamines and corticosteroids. Systemic toxicity should be treated with excellent supportive care, using benzodiazepines for tremors and seizures.

**Hydrocarbons**

Hydrocarbons include a wide array of chemical substances found in thousands of commercial products. Specific characteristics of each product determine whether exposure will produce systemic toxicity, local toxicity, both, or neither. Nevertheless, aspiration of even small amounts of certain hydrocarbons can lead to serious, potentially life-threatening toxicity.

**Pathophysiology.**

The most important manifestation of hydrocarbon toxicity is aspiration pneumonitis through inactivation of the type II pneumocytes and resulting in surfactant deficiency (see Chapter 425). Aspiration usually occurs during coughing and gagging at the time of ingestion or vomiting after the attempted ingestion of an aliphatic hydrocarbon. The propensity of a hydrocarbon to cause aspiration pneumonitis is inversely proportional to its viscosity, and directly proportional to its volatility. Compounds with low viscosity and high volatility, such as mineral spirits, naphtha, kerosene, gasoline, and lamp oil, spread rapidly across surfaces and cover large areas of the lungs when aspirated. Only small quantities (<1 mL) of such chemicals need be aspirated to produce significant injury. Pneumonitis does not result from dermal absorption of hydrocarbons or from ingestion in the absence of aspiration. Gasoline and kerosene are poorly absorbed, but they often cause considerable irritation of the GI mucosa as they pass through the intestines.

Certain hydrocarbons have unique toxicities and can cause symptoms after ingestion, inhalation, or dermal exposures. Several chlorinated solvents, most notably carbon tetrachloride, can produce hepatic toxicity. Methylene chloride, found in some paint removers, is metabolized to carbon monoxide. Benzene is known to cause cancer, most often acute myelogenous leukemia, after long-term exposure. Nitrobenzene, aniline, and related compounds can produce methemoglobinemia. A number of volatile hydrocarbons, including toluene, propellants, refrigerants, and volatile nitrites, are frequently abused by inhalation. Some of these substances, principally the halogenated hydrocarbons (which contain a chlorine, bromine, or fluorine), can sensitize the myocardium to
the effects of endogenous catecholamines. This can result in dysrhythmias and “sudden sniffing death.” Chronic abuse of these agents can lead to cerebral atrophy, neuropsychologic changes, peripheral neuropathy, and kidney disease (see Chapter 140).

**Clinical and Laboratory Manifestations.**

Transient, mild CNS depression is common after hydrocarbon ingestion or inhalation. Aspiration is characterized by coughing, which usually is the 1st clinical finding. Chest radiographs may initially be normal, but they often show abnormalities within 6 hr of exposure in patients who have aspirated. Respiratory symptoms can remain mild or progress rapidly to acute respiratory distress syndrome (ARDS) and respiratory failure. Fever and leukocytosis are common accompanying signs in patients with pneumonitis and do not necessarily imply bacterial superinfection. Chest radiographs can remain abnormal long after the patient is clinically normal. Pneumatoceles can appear on the chest radiograph 2-3 wk after exposure.

After inhalational exposures to halogenated hydrocarbons, patients can present with ventricular dysrhythmias, often refractory to conventional management. Recurrent inhalation of the aromatic hydrocarbon toluene can lead to a type IV renal tubular acidosis.

**Treatment.**

*Emesis and lavage are contraindicated given the risk of aspiration.* Activated charcoal is not useful because it does not bind the common hydrocarbons and can also induce vomiting. If hydrocarbon-induced pneumonitis develops, respiratory treatment is supportive (see Chapter 425). Neither corticosteroids nor prophylactic antibiotics have shown any clear benefit. Standard mechanical ventilation, high-frequency ventilation, and extracorporeal membrane oxygenation (ECMO) have all been used to manage the respiratory failure and ARDS associated with severe hydrocarbon-induced pneumonitis.

Patients with dysrhythmias in the setting of halogenated hydrocarbon inhalation should be treated with β-blockers (usually esmolol) to block the effects of endogenous catecholamines on the sensitized myocardium.

**Toxic Alcohols**

*Methanol* is found in windshield washer fluids, deicers, paint removers, fuel additives, liquid fuel canisters, and industrial solvents. *Ethylene glycol* is found
in antifreeze. Unintentional ingestion is the most common exposure in children, and small-volume ingestions of concentrated products can theoretically cause toxicity. The pathophysiology, acid-base derangements, and treatment of both chemicals are similar, although they differ in their primary end-organ toxicity. In both cases the metabolites of the parent compounds are responsible for the serious clinical effects that can follow exposure.

**Isopropyl alcohol** (rubbing alcohol), found in hand sanitizers, causes intoxication similar to that associated with ethanol but can also cause a hemorrhagic gastritis and myocardial depression in massive ingestions. Unlike ethylene glycol and methanol, isopropyl alcohol is metabolized to a ketone and does not cause a metabolic acidosis. Management is similar to that of ethanol ingestions (see *Chapter 140*) and is not further discussed here.

**Methanol**

**Pathophysiology.**

Methanol is oxidized in the liver by alcohol dehydrogenase to formaldehyde, which is further oxidized to formic acid by aldehyde dehydrogenase. Toxicity is caused primarily by formic acid, which inhibits mitochondrial respiration.

**Clinical and Laboratory Manifestations.**

Drowsiness, mild inebriation, nausea, and vomiting develop early after methanol ingestion. The onset of serious effects, including profound metabolic acidosis and visual disturbances, is often delayed up to 12-24 hr as the parent methanol undergoes metabolism to its toxic metabolites. This metabolism is further slowed if ethanol has also been ingested, since the liver will preferentially metabolize ethanol. Visual disturbances include blurred or cloudy vision, constricted visual fields, decreased acuity, and the “feeling of being in a snowstorm” and appear only after acidosis is well established. These visual defects may be reversible if treated early, but untreated can lead to permanent blindness. On examination, dilated pupils, retinal edema, and optic disc hyperemia may be noted. Initially, patients have an elevated osmolar gap, then develop an anion gap metabolic acidosis as the parent compound is metabolized to formic acid.

In young children, determining if a significant exposure has occurred is usually difficult based on history. Methanol blood levels are available at some laboratories and should be sent after a concerning exposure. If methanol blood levels are not readily available, estimation of an osmolar gap may be used as a
surrogate marker, but a normal osmolar gap does not rule out ingestion of any alcohol. Serum osmolality is measured by the freezing-point depression method and compared with a calculated serum osmolarity.

**Treatment.**
Treatment is as discussed for ethylene glycol toxicity.

**Ethylene Glycol**

**Pathophysiology.**
Ethylene glycol is oxidized by alcohol dehydrogenase in the liver to glycolaldehyde, which is further converted to glycolic acid by aldehyde dehydrogenase. Glycolic acid is responsible for the metabolic acidosis and is further metabolized to glyoxylic and then to oxalic acid. Oxalic acid combines with serum and tissue calcium, forming calcium oxalate crystals that deposit throughout the body, especially in the renal parenchyma, leading to acute tubular necrosis.

**Clinical and Laboratory Manifestations.**
Early symptoms include nausea, vomiting, CNS depression, and inebriation. Delayed manifestations include an anion gap metabolic acidosis, hypocalcemia, and acute kidney injury. Even later, patients can develop cranial nerve palsies.

Both ethylene glycol and methanol can produce profound, life threatening metabolic acidosis and acidemia, with measured serum bicarbonates that may even be nondetectable. The onset of the acidosis is delayed up to 4-12 hr after ethylene glycol ingestion and may be delayed further with any concomitant ingestion of ethanol. Ethylene glycol blood concentrations are technically difficult to perform and are available only at some larger reference laboratories. In the absence of readily available ethylene glycol concentrations, calculation of the osmolar gap may be helpful as a surrogate marker.

Examination of the urine with a Wood lamp is neither sensitive nor specific for ethylene glycol ingestion. The earliest sign on a urinalysis of ethylene glycol poisoning is usually hematuria. Calcium oxalate crystals can be seen on urine microscopy but might not be evident early after exposure. Electrolytes (including calcium), acid-base status, kidney function, and ECG should be closely monitored in poisoned patients.
Treatment.

Because methanol and ethylene glycol are rapidly absorbed, gastric decontamination is generally not of value. The classic antidote for methanol and ethylene glycol poisoning was ethanol, a preferential substrate for alcohol dehydrogenase, thus preventing the metabolism of parent compounds to toxic metabolites. Fomepizole, a potent competitive inhibitor of alcohol dehydrogenase, has almost entirely replaced ethanol because of its ease of administration, lack of CNS and metabolic effects, and overall excellent patient tolerability profile (see Table 77.7). A serum concentration must be interpreted along with the time removed from exposure. A patient with a methanol level of 20 mg/dL 24 hr after exposure had a much larger dose than a patient with the same level only 1 hr after ingestion. Classic indications for fomepizole include ethylene glycol or methanol level >20 mg/dL (assuming no ethanol is present), history of potentially toxic ingestion (e.g., any intentional overdose), or history of ingestion with evidence of acidosis. There are few disadvantages to giving the initial dose of fomepizole to patients with a concerning history of ingestion or lab findings, and given the dosing schedule of fomepizole (every 12 hr), this strategy buys the clinician time to confirm or exclude the diagnosis before giving a 2nd dose. Adjunctive therapy includes folate (methanol toxicity), pyridoxine (ethylene glycol toxicity), and sodium bicarbonate infusion for both (if acidemic). If a child has had an unintentional exposure and the alcohol level cannot be obtained, a reasonable approach is to follow serum chemistries every 4 hr until 12 hr after the exposure. If the bicarbonate level on the chemistry panel does not fall in that period, a toxic exposure is unlikely (assuming no ethanol is present).

Hemodialysis effectively removes ethylene glycol, methanol, and their metabolites (except calcium oxalate) and corrects acid-base and electrolyte disturbances. Fomepizole should be given both before and immediately after dialysis. Indications for dialysis include a methanol level >50 mg/dL, acidosis, severe electrolyte disturbances, and renal failure. However, in the absence of acidosis and kidney failure, even massive ethylene glycol ingestions have been managed without dialysis. Methanol, however, because its elimination in the setting of alcohol dehydrogenase inhibition is prolonged, often warrants dialysis to remove the parent compound. Therapy (fomepizole and/or dialysis) should be continued until ethylene glycol and methanol levels are <20 mg/dL. While the visual effects from methanol poisoning are usually permanent, the kidney injury from ethylene glycol injury is not. Patients requiring hemodialysis after ethylene
glycol poisoning will almost always recover complete renal function within 2-6 wk. Consultation with a PCC, medical toxicologist, and nephrologist may be helpful in managing toxic alcohol ingestions.

**Plants**

Exposure to plants, both inside the home and outside in backyards and fields, is one of the most common causes of unintentional poisoning in children. Fortunately, the majority of ingestions of plant parts (leaves, seeds, flowers) result in either no toxicity or mild, self-limiting effects. However, ingestion of certain plants can lead to serious toxicity (Table 77.12).

AV, Atrioventricular; CNS, central nervous system; CV, cardiovascular; ECG, electrocardiogram; Fab, fragment, antigen binding; GI, gastrointestinal.

The potential toxicity of a particular plant is highly variable, depending on the part of the plant involved (flowers are generally less toxic than the root or seed), the time of year, growing conditions, and the route of exposure. Assessment of the potential severity after an exposure is also complicated by the difficulty in properly identifying the plant. Many plants are known by several common names, which can vary among communities. Poison control centers have access to professionals who can assist in properly identifying plants. They also are well versed in the common poisonous plants in their service area and the seasons when they are more abundant. For these reasons, consultation with the local PCC may be very helpful in the management of these ingestions.

For potentially toxic plant ingestions, consider decontamination with activated charcoal in patients who present within 1-2 hr of ingestion; otherwise, treatment is primarily supportive and based on symptoms. The most common manifestation of toxicity after plant ingestion is GI upset, which can be managed with antiemetics and fluid and electrolyte support. Table 77.12 outlines management strategies for a few specific toxicities.
Toxic Gases

Carbon Monoxide

Although many industrial and naturally occurring gases pose a health risk by inhalation, the most common gas involved in pediatric exposures is carbon monoxide. CO is a colorless, odorless gas produced during the combustion of any carbon-containing fuel; the less efficient the combustion, the greater the amount of CO produced. Wood-burning stoves, kerosene heaters, old furnaces, hot-water heaters, closed-space fires, and automobiles are a few of the potential sources of CO.

Pathophysiology.

CO binds to hemoglobin with an affinity >200 times that of oxygen, forming carboxyhemoglobin (HbCO). In doing so, CO displaces oxygen and creates a conformational change in hemoglobin that impairs the delivery of oxygen to the tissues, leading to tissue hypoxia. HbCO levels are not well correlated with clinical signs of toxicity, likely because CO interacts with multiple proteins in addition to hemoglobin. CO binds to cytochrome oxidase, disrupting cellular respiration. CO displaces nitric oxide (NO) from proteins, allowing NO to bind with free radicals to form the toxic metabolite peroxynitrite, leading to lipid peroxidation and cellular damage. NO is also a potent vasodilator, in part responsible for clinical symptoms such as headache, syncope, and hypotension.

Clinical and Laboratory Manifestations.

Early symptoms are nonspecific and include headache, malaise, nausea, and vomiting. These symptoms are often misdiagnosed as indicating flu or food poisoning. At higher exposure levels, patients can develop mental status changes, confusion, ataxia, syncope, tachycardia, and tachypnea. Severe poisoning is manifested by coma, seizures, myocardial ischemia, acidosis, cardiovascular collapse, and potentially death. Physical examination should focus on the cardiovascular and neurologic systems because these are the most detrimentally effected by CO. Emergency department evaluation should include arterial or venous blood gas analysis with HbCO determined by CO-oximetry, CK level in severely poisoned patients, pregnancy test, and ECG in any patient with cardiac symptoms.
**Treatment.**

Prevention of CO poisoning is paramount and should involve educational initiatives and the use of home CO detectors. Treatment of CO poisoning focuses on the administration of 100% oxygen to enhance elimination of CO. In ambient air the average half-life of HbCO is 4-6 hr. This is dramatically reduced to 60-90 min by providing 100% oxygen at normal atmospheric pressures by non-rebreather face mask. Severely poisoned patients might benefit from **hyperbaric oxygen (HBO)**, which decreases the half-life of HbCO to 20-30 min and is thought also to decrease the risk of delayed neurologic sequelae. Although the clinical benefits and referral guidelines for HBO therapy remain controversial, frequently cited indications include syncope, coma, seizure, altered mental status, acute coronary syndrome, HbCO level >25%, abnormal cerebellar examination, and pregnancy. Consultation with a PCC, medical toxicologist, or HBO facility can assist clinicians in determining which patients could benefit from HBO therapy. Sequelae of CO poisoning include persistent and delayed cognitive and cerebellar effects. HBO advocates believe that the risk of such sequelae is minimized through the delivery of 100% oxygen at 3 atm of pressure. Patients typically receive oxygen, by non-rebreather mask or hyperbaric chamber, for 6-24 hr.

**Hydrogen Cyanide**

**Pathophysiology.**

Cyanide inhibits cytochrome-c oxidase, part of the electron transport chain, interrupting cellular respiration and leading to profound tissue hypoxia. Patients may be exposed to hydrogen cyanide (HCN) gas in the workplace (manufacturing of synthetic fibers, nitriles, and plastics) or by smoke inhalation in a closed-space fire.

**Clinical and Laboratory Manifestations.**

Onset of symptoms is rapid after a significant exposure. Clinical manifestations of toxicity include headache, agitation/confusion, sudden loss of consciousness, tachycardia, cardiac dysrhythmias, and metabolic acidosis. Cyanide levels can be measured in whole blood but are not readily available at most institutions. A severe lactic acidosis (lactate >10 mmol/L) in fire victims suggests cyanide toxicity. Impaired oxygen extraction by tissues is implied by elevated mixed-
venous oxyhemoglobin saturation, another laboratory finding suggesting cyanide toxicity.

Treatment.
Treatment includes removal from the source of exposure, rapid administration of high concentrations of oxygen, and antidotal therapy. The cyanide antidote kit (no longer manufactured) includes nitrites (amyl nitrite and sodium nitrite) used to produce methemoglobin, which then reacts with cyanide to form cyanomethemoglobin. The 3rd part of the kit is sodium thiosulfate, given to hasten the metabolism of cyanomethemoglobin to hemoglobin and the less toxic thiocyanate. In patients for whom induction of methemoglobinemia could produce more risk than benefit, the sodium thiosulfate component of the kit may be given alone.

The U.S. Food and Drug Administration (FDA) has approved hydroxocobalamin for use in known or suspected cyanide poisoning (see Table 77.7). This antidote reacts with cyanide to form the nontoxic cyanocobalamin (vitamin B₁₂), which is then excreted in urine. Side effects of hydroxocobalamin include red discoloration of the skin and urine, transient hypertension, and interference with colorimetric lab assays. Hydroxocobalamin has an overall safety profile that appears superior to that of the cyanide antidote kit and thus is the preferred antidote for cyanide poisoning.

Miscellaneous Toxic Agents Found in the Home
Nicotine-Containing Products
Nicotine poisoning has become increasingly common with the recent advent of vaporizer (“vaping”) and e-cigarette devices. Although there are many nicotine-containing products (patches, gums, snuff, chewing tobacco, sprays, lozenges), tobacco cigarettes remain the main source of exposure. Prescription medications (varenicline and cytisine) are available that are partial nicotine receptor agonists. For children, some of the most concerning exposures are from the bottles of liquid nicotine used to refill vaping and e-cigarette devices. These bottles typically do not have childproof caps and contain a large amount of concentrated nicotine.

Pathophysiology.
Nicotine acts on nicotinic ACh receptors in the nervous system, neuromuscular
junctions, and adrenal medulla, stimulating neurotransmitter release. Nicotine's effects on the dopaminergic reward pathway play a significant role in its addictive properties. The effects of nicotine are dose dependent; at lower doses it primarily acts on the brain, causing stimulation. At higher doses, nicotine overstimulates receptors, leading to inhibition and resulting in neuromuscular and nervous system blockade.

Clinical and Laboratory Manifestations.
Clinical effects of nicotine also depend on the dose. At low doses typically achieved through smoking, nicotine results in cognitive and mood enhancement, increased energy, and appetite suppression. At higher doses, significant toxicity follows a biphasic pattern, where cholinergic stimulation symptoms predominate and are later followed by inhibition. The first signs of nicotine poisoning are nausea, vomiting, diarrhea, and often muscle fasciculations. Tachycardia and hypertension occur initially, although in severe poisoning these progress to bradycardia, hypotension, coma, and respiratory muscle failure, which typically leads to death if not treated. Serum and urinary levels of nicotine and its metabolite cotinine can be obtained, but these rarely are available in real time and therefore have little effect on diagnosis and management.

Treatment.
Treatment of nicotine poisoning focuses on maximizing symptomatic and supportive care. Aggressive airway management should be the priority, especially in severe poisonings, because death usually occurs from respiratory muscle paralysis. IV fluids with escalation to vasopressors should be used for hypotension. Seizures should be managed with benzodiazepines, barbiturates, or propofol.

Single-Use Detergent Sacs
Commonly known as laundry “pods” for clothing, these products resemble candy to many children. When bitten into, a relatively large dose of concentrated detergent is expelled under pressure onto the posterior pharynx and vocal cords. This can lead to stridor and other signs of respiratory distress. Occasionally, and for unknown reasons, these children may also develop altered mental status. Supportive care with attention to any airway and breathing issues is warranted. Admission to the hospital is often indicated. Importantly, these are not considered caustic ingestions; the pH of these products is in the neutral zone. As
such, upper GI endoscopy is rarely indicated. Curiously, laundry detergent drank from a bottle is rarely of significant concern.

**Electric Dishwasher Detergent**

Especially when in the form of crystals, these products are highly alkaline (pH >13), and exposure by ingestion can cause significant burns to the vocal cords and GI tract. Admission for expectant management or upper GI endoscopy is usually indicated.

**Magnets**

Most foreign body ingestions pass through the GI tract once known to have passed into the stomach. However, ingestion of ≥2 magnets (unless very weak refrigerator-style magnets) cause concern for bowel obstruction and perforation. Admission for attempted retrieval by endoscopy or clearance by WBI should be considered.

**Batteries**

Any disk or button-style battery lodged in the esophagus or airway should be considered a true emergency warranting immediate referral to an endoscopist for removal. These batteries can cause necrosis of the tissues in which they are lodged by continued electrical discharge and leaking of their contents (the former is likely the primary method of injury). Mucosal contact for even 2 hr might induce necrosis. Once past the lower esophageal sphincter, button or even larger batteries (e.g., AA, AAA) can usually be allowed to pass through the GI tract with close follow-up.

CHAPTER 78

Complementary Therapies and Integrative Medicine

Paula M. Gardiner, Caitlin M. Neri

**Integrative medicine** focuses on promoting physical, mental, emotional, spiritual, social, and educational well-being in the context of a medical home in a healthy family and community. The foundations of integrative medicine are health-promoting practices such as optimal nutrition and dietary supplements to prevent deficiencies, avoidance of addictive substances (e.g., nicotine, illicit drugs), physical activity, adequate sleep, a healthy environment, and supportive social relationships. Evidence-based **complementary therapies** such as dietary supplements, massage, chiropractic, other forms of bodywork, yoga, meditation practices, hypnosis, guided imagery, biofeedback, and acupuncture may also be used. Although prayer and healing rituals are sometimes included under the rubric of complementary and integrative therapies, they are not covered in this chapter.

Not including multivitamins and mineral supplements such as iron and calcium, an estimated 10–40% of healthy children and >50% of children with chronic conditions use integrative medicine in the United States. The prevalence could be even higher because these treatments usually occur without disclosure to the children's primary care physician. Common therapies include dietary supplements, deep breathing, guided imagery, mediation, biofeedback, hypnosis, yoga, acupuncture, massage, and aromatherapy.

Use of complementary therapies is most common among youth with chronic, incurable, or recurrent conditions such as cancer, depression and other mental health conditions, asthma, autism, headaches, abdominal pain, and other chronic painful conditions. Children's hospitals and pediatric subspecialty programs are increasingly offering integrative medicine strategies alongside traditional medicine, as part of the care of children in both inpatient and outpatient settings.
In a 2014 survey the American Pain Society identified 48 pediatric chronic pain clinics, with most offering some type of integrative medicine or behavioral health strategies with conventional medicine. For example, integrative therapies are increasingly being used in pediatric chronic pain clinics to treat functional bowel disorders. Recent reviews include supplements (e.g., ginger, peppermint oil) and mind-body techniques (e.g., hypnotherapy, biofeedback, acupuncture/acupressure) with traditional medical management for these common pediatric conditions.

**Dietary Supplements**

Under the 1994 U.S. Dietary Supplement Health and Education Act, a dietary supplement is a product taken by mouth that contains a dietary ingredient intended to supplement the diet. These may include vitamins, minerals, herbs or other botanicals, amino acids, and substances such as enzymes, organ tissues, glands, and metabolites. Dietary supplements are the most frequently used complementary therapies for children and adolescents (Table 78.1). Some uses are common and recommended, such as vitamin D supplements for breastfed infants and probiotics to prevent antibiotic-associated diarrhea, whereas other uses are more controversial, such as using herbal products to treat otitis media.

ADHD, Attention-deficit/hyperactivity disorder.

In the United States, dietary supplements do not undergo the same stringent evaluation and postmarketing surveillance as prescription medications. Although they may not claim to prevent or treat specific medical conditions, product labels may make *structure-function* claims. For example, a label may claim that a product “promotes a healthy immune system,” but it may not claim to cure the common cold.

According to the 2012 National Health Interview Survey, 5% of U.S. children used non-vitamin/mineral dietary supplements. (e.g., fish oil, melatonin, prebiotics, probiotics) Use of dietary supplements is most common among children whose families have higher income and education and whose parents use supplements, among older children, and among those with chronic conditions.

Despite this widespread use, many patients and their parents who use dietary supplements do not talk with their physician about their use. Several guidelines have called for more complete dietary supplement history taking by healthcare professionals. The Joint Commission recommends that clinicians routinely ask patients about their use of dietary supplements and include this information as part of the medication reconciliation process.

**Dietary Supplement Safety**

Dietary supplements may have safety issues in children, but toxicity is much less common with nonprescription dietary supplements than with prescription medications (*Table 78.2*). Toxicity depends on dose, use of other therapies, and the child's underlying medical condition. Current use of a dietary supplement (e.g., ephedra for weight loss) may not reflect its traditional use (e.g., ephedra as a component of a traditional Chinese medicine tea in small doses to improve allergic or respiratory symptoms). Moreover, herbs that are apparently safe for
most adults may be more hazardous in specific conditions (e.g., newborns, patients with impaired renal or hepatic function), under special circumstances (e.g., after organ transplantation or other surgery), or when combined with prescription medications. Some natural products are toxic in and of themselves. Even when a product is safe when used correctly, it can cause mild or severe toxicity when used incorrectly. For example, although peppermint is a commonly used and usually benign gastrointestinal spasmolytic included in after-dinner mints, it can exacerbate gastroesophageal reflux.

Although there are good manufacturing practices for dietary supplements in the United States, dietary supplement labels might not accurately reflect the contents or concentrations of ingredients. Because of natural variability, variations of 10-1,000-fold have been reported for several popular herbs, even across lots produced by the same manufacturer. Herbal products may be contaminated with pesticides, microbial agents or products, or the wrong herb misidentified during harvesting. Products from developing countries (e.g., Ayurvedic products from South Asia) might contain toxic levels of mercury,
cadmium, arsenic, or lead, either from unintentional contamination during
manufacturing or from intentional additions by producers who believe that these
metals have therapeutic value. Approximately 30–40% of Asian patent
medicines include potent pharmaceuticals, such as analgesics, antibiotics,
hypoglycemic agents, or corticosteroids; typically the labels for these products
are not written in English and do not note the inclusion of pharmaceutical agents.
Even conventional mineral supplements, such as calcium, have been
contaminated with lead or had significant problems with product variability.

Many families use supplements concurrently with medications, posing
hazards of interactions (Table 78.3). Using the same principles of drug-drug
interactions can help determine if a supplement-drug interaction is a concern.
For example, St. John's wort induces CYP3A4 activity of the cytochrome P450
enzyme system and thus can enhance elimination of most drugs that use this
pathway, including digoxin, cyclosporine, protease inhibitors, oral
contraceptives, and numerous antibiotics, leading to subtherapeutic serum levels.

Dietary Supplement Efficacy

Evidence about the effectiveness of dietary supplements to prevent or treat pediatric problems is mixed, depending on the product used and condition treated. Some herbal products may be helpful adjunctive treatments for common childhood problems; some herbs have proved helpful for colic (fennel and the combination of chamomile, fennel, vervain, licorice, and balm mint), nausea (ginger), irritable bowel syndrome (peppermint), and diarrhea (probiotics).

Massage and Chiropractic

Massage is usually provided at home by parents and in clinical settings by professional massage therapists, physical therapists, and nurses. Infant massage is routinely provided in many neonatal intensive care units to promote growth and development in preterm infants. Massage also has been demonstrated to be beneficial for pediatric patients with asthma, insomnia, colic, cystic fibrosis, or juvenile arthritis and patients undergoing cancer therapy. Massage therapy is generally safe. Professional massage practice is regulated by state government and may be in the form of a license, registration, or certification. More than 40 states license massage therapists, with licensure being the strictest form of regulation, making it illegal for any nonlicensed professional to practice massage therapy.

Chiropractic healthcare deals with the diagnosis, treatment, and prevention of disorders of the neuromusculoskeletal system and their effects on general health. Currently, >60,000 chiropractors have licensure in the United States, with licensure in all 50 states. Most medical insurance companies cover chiropractic funding. Children and families seek chiropractic care for common childhood conditions such as asthma, infantile colic, nocturnal enuresis, constipation, and headache. A recent consensus update on chiropractic care in children overall found limited support in a small number of high-quality studies for effectiveness of chiropractic care for such common childhood conditions. With respect to safety, the evidence is also limited; however, published cases of serious adverse events in infants and children receiving chiropractic care are rare. If children and families are seeking chiropractic care, it is appropriately done in collaboration with the child's pediatric primary care provider to ensure patient safety.
Mind-Body Therapies

Mind-body therapies such as slow, deep breathing, meditation, guided imagery, biofeedback, hypnosis, tai chi, and yoga are also frequently used complementary therapies in pediatrics. These practices can be learned informally through books, YouTube videos, compact discs, digital video discs, smartphone apps, or classes, as well as in therapeutic sessions with health professionals, such as psychologists and social workers (Table 78.4). Substantial research suggests that such practices can aid in reducing anxiety, insomnia, and stress-related conditions, including migraine headaches and functional abdominal pain. These therapies can also help patients struggling with chronic pain.

Acupuncture

Modern acupuncture incorporates treatment traditions from China, Japan, Korea, France, and other countries. In the United States, acupuncturists are licensed to practice in 45 states. Acupuncture can be delivered to pediatric patients in hospital and clinic settings to treat a variety of ailments. Acupuncture is particularly useful for children experiencing pain, and acupuncture services are offered alongside conventional medicine and psychology by >50% of North American academic pediatric chronic pain programs. The technique that has undergone most scientific study involves penetrating the skin with thin, solid, metallic needles manipulated by hand or by electrical stimulation. Variants
include rubbing (shiatsu ), heat (moxibustion ), lasers, magnets, pressure (acupressure ), or electrical currents.

Although pediatric patients may be averse to needles, when approached in a developmentally appropriate way by an acupuncturist trained in pediatrics, children are often amenable to acupuncture and report that it is helpful. Acupuncture can offer significant benefits in the treatment of recurrent headache, anxiety, back and other types of pain, depression, abdominal pain, and nausea. As with any needle therapy, infections and bleeding are rare but can occur, and more serious complications, such as pneumothorax, occur in <1 in 30,000 treatments.

**Cannabis**

Because marijuana has been legalized in many states for both recreational (adult) use and medical use, caregivers and families have inquired about the potential health benefits of cannabis for both children and adults. At this time, no pediatric studies support any health benefit of cannabis for children. Furthermore, significant safety concerns remain, since detrimental effects of marijuana on the developing brain have been documented.

It is important to note that in some children with severe refractory epilepsy, oral cannabidiol, a nonpsychoactive component in marijuana, has provided improvement in seizure control. On a case-by-case basis, this is a reasonable consideration for families facing this rare and difficult challenge, and additional research is required in this area, especially since the purity and regulation of marijuana and its commercially available component products are variable. Most of the recent pediatric literature on cannabis describes an increase in accidental ingestions in young children, presumably in association with the increase in products now available for adult use; this is an additional safety risk for pediatricians to consider.

- Chapter 93 Cold Injuries
The overwhelming majority of the 27 million children who present annually for emergency care in the United States are seen at community hospital emergency departments (EDs). Visits to children's hospital EDs account for just 10% of initial emergency care encounters. This distribution suggests that the greatest opportunity to optimize care for acutely ill or injured pediatric patients, on a population basis, occurs broadly as part of a systems-based approach to emergency services, an approach that incorporates the unique needs of children at every level. Conceptually, emergency medical services for children are characterized by an integrated, continuum-of-care model (Fig. 79.1). The model is designed such that patient care flows seamlessly from the primary care medical home through transport and on to hospital-based definitive care. It includes the following 5 principal domains of activity:
FIG. 79.1  The emergency medical services for children (EMSC) continuum of care. Seriously ill and injured children interface with a large number of healthcare personnel as they move through the EMSC system.

1. Prevention, primary and secondary
2. Out-of-hospital care, both emergency response and prehospital transport
3. Hospital-based care: ED and inpatient, including critical care
4. Interfacility transport, as necessary, for definitive or pediatric medical and surgical subspecialty care (see Chapter 79.1)
5. Rehabilitation

The federal Emergency Medical Services for Children (EMSC) program of the Health Resources and Services Administration's Maternal and Child Health Bureau has stewarded improvements in the care of children in the context of the continuum-of-care model. The programmatic mission of the EMSC program is as follows:

- To ensure state-of-the-art emergency medical care for ill or injured children and adolescents of all ages.
- To ensure that pediatric services are well integrated
into an emergency medical services (EMS) system and backed by optimal resources.
◆ To ensure that the entire spectrum of emergency services—including primary prevention of illness and injury, acute care, and rehabilitation—is provided to infants, children, adolescents, and young adults.

Primary Care Physician and Office Preparedness

The primary care physician (PCP) has multiple important roles in the EMS system. Through anticipatory guidance, the PCP can help shape the attitudes, knowledge, and behaviors of parent and child, with the primary goal of preventing acute medical events, such as injury and status asthmaticus. The point-of-care initiation for many acute problems is often the PCP office. From the standpoint of personnel, equipment, training, and protocols, the PCP office setting must be adequately prepared to initially manage acute and emergency exacerbations of common pediatric conditions, such as respiratory distress and seizures. Furthermore, on rare occasion, the PCP office environment may be confronted with a child in clinical extremis who requires resuscitative intervention and stabilization. It is therefore incumbent on the PCP not only to ensure access to EMS, that is, 911 system activation, but also to ensure that there is adequate, on-site psychomotor skill preparation to deal with such an emergency. **Office preparedness** requires training and continuing education for staff members, protocols for emergency intervention, ready availability of appropriate resuscitation drugs and equipment, and knowledge of local EMS resources and ED capabilities. PCPs can also play a pivotal role in informing and advocating for pediatric emergency and disaster readiness in local EMS agencies, schools and childcare programs, and community hospitals; this is particularly important in rural communities.

Staff Training and Continuing Education

It is a reasonable expectation that all office staff, including receptionists and
medical assistants, be trained in cardiopulmonary resuscitation (CPR) with their certification maintained annually. Nurses and physicians should also have training in a systematic approach to pediatric resuscitation. Core knowledge may be obtained through standardized courses in advanced life support (ALS) offered by national medical associations and professional organizations. Frequent practice and timely recertification is important for knowledge retention and skill maintenance. Examples include the Pediatric Advanced Life Support (PALS) and Pediatric Emergency Assessment, Recognition and Stabilization (PEARS) courses sponsored by the American Heart Association (AHA), the Advanced Pediatric Life Support (APLS) course sponsored by the American Academy of Pediatrics (AAP) and American College of Emergency Physicians (ACEP), and the Emergency Nurses Pediatric Course (ENPC) sponsored by the Emergency Nurses Association (ENA).

**Protocols**

Standardized protocols for telephone triage of seriously ill or injured children are essential. When a child's clinical status is in question and prehospital care is available, ambulance transport in the care of trained personnel is always preferable to transport by other means (e.g., private vehicle). This obviates the potentially serious medical consequences of relying on unskilled and distraught parents without the ability to provide even basic life support (BLS) measures to an unstable child during transport to an ED. Practitioners can work with their local pediatric emergency care resource center (e.g., children's hospital, academic medical center, trauma center) to develop and maintain written protocols for office-based management of a range of conditions, including anaphylaxis, cardiopulmonary arrest, head trauma, ingestions, shock, status asthmaticus, status epilepticus, and upper airway obstruction. Regular practice using mock code scenarios improves office-based practitioner and office staff confidence and self-efficacy in managing these problems.

**Resuscitation Equipment**

Availability of necessary equipment is a vital part of an emergency response. Every physician's office should have essential resuscitation equipment and medications packaged in a pediatric resuscitation cart or kit (Table 79.1). This cart or kit should be checked on a regular basis and kept in an accessible location.
known to all office staff. Outdated medication, a laryngoscope with a failed light source, or an empty oxygen tank represents a potential catastrophe in a resuscitation scenario. Such an incident can be easily avoided if an equipment checklist and regular maintenance schedule are implemented. A pediatric kit that includes posters, laminated cards, or a color-coded length-based resuscitation tape specifying emergency drug doses and equipment size are invaluable in avoiding critical therapeutic errors during resuscitation.

</table>
To facilitate emergency response when a child needs rapid intervention in the office, all personnel should have designated roles. Organizing a “code team” within the office ensures that necessary equipment is made available to the physician in charge, that an appropriate medical record detailing all interventions and the child's response is generated, and that the 911 call for EMS response or a transport team is made in a timely fashion.

**Transport**

Once the child has been stabilized, a decision must be made on how best to transport a child to a facility capable of providing definitive care. If a child has required airway or cardiovascular support, has altered mental state or unstable vital signs, or has significant potential to deteriorate en route, it is not appropriate to send the child via privately owned vehicle, regardless of proximity to a hospital. Even when an ambulance is called, it is the PCP's responsibility to initiate essential life support measures and to attempt to stabilize the child before transport.

In metropolitan centers with numerous public and private ambulance agencies, the PCP must be knowledgeable about the level of service provided by each. The availability of BLS vs ALS services, the configuration of the transport team, and pediatric expertise vary greatly among agencies and across jurisdictions. BLS services provide basic support of airway, breathing, and circulation, whereas
ALS units are capable of providing resuscitation drugs and procedural interventions as well. Some communities may have only BLS services available, whereas others may have a 2-tiered system, providing both BLS and ALS. It may be appropriate to consider **medical air transport** when definitive or specialized care is not available within an immediate community or when ground transport times are prolonged. In that case, initial transport via ground to an appropriate helicopter landing zone or a local hospital for interval stabilization may be undertaken, pending arrival of the air transport team. Independent of whether a child is to be transported by air or ground, copies of the pertinent medical records and any imaging or laboratory studies should be sent with the patient, and a call made to the physicians at the receiving facility to alert them to the referral and any treatments administered. Such notification is not merely a courtesy; direct physician-to-physician communication is essential to ensure adequate transmission of patient care information, to allow mobilization of necessary resources in the ED, and to redirect the transport if the emergency physician believes that the child would be more optimally treated at a facility with specialized services.

**Pediatric Prehospital Care**

*Prehospital care* refers to emergency assistance rendered by trained emergency medical personnel before a child reaches a treating medical facility. The goals of prehospital care are to further minimize systemic insult or injury through a series of well-defined and appropriate interventions and to embrace principles that ensure patient safety. Most U.S. communities have a formalized EMS system; the organizational structure and nature of emergency medical response depend greatly on local demographics and population base. EMS may be provided by volunteers or career professionals working in a fire department–based or independent 3rd service response system. Key points to recognize in negotiation of the juncture between the community physician and the local EMS system include access to the system, provider capability, and destination determination.

**Access to the EMS System**

Virtually all Americans have access to the 911 telephone service that provides direct access to a dispatcher who coordinates police, fire, and EMS responses. Some communities have an enhanced telephone 911 system, in which the
location of the caller is automatically provided to the dispatcher, permitting emergency response even if the caller, such as a young child, cannot give an address. The extent of medical training for these dispatchers varies among communities, as do the protocols by which they assign an emergency response level (BLS vs ALS). In some smaller communities, no coordinated dispatch exists, and emergency medical calls are handled by the local law enforcement agency.

When activating the 911 system, the physician must make clear to the dispatcher the nature of the medical emergency and the condition of the child. In many communities, emergency medical dispatchers are trained to ask a series of questions per protocol that determines the appropriate level of provider to be sent.

**Provider Capability**

There are many levels of training for prehospital EMS providers, ranging from individuals capable of providing only first aid to those trained and licensed to provide ALS. All EMS personnel, whether basic emergency medical technicians (EMTs) or paramedics, receive some training in pediatric emergencies; however, pediatric cases constitute approximately 10% of all EMS transports.

First responders may be law enforcement officers or firefighters, who are dispatched to provide emergency medical assistance, or bystanders. Public safety personnel have a minimum of 40 hr of training in first aid and CPR. Their role is to provide rapid response and stabilization pending the arrival of more highly trained personnel. In some smaller communities, this may be the only prehospital emergency medical response available.

In the United States the bulk of emergency medical response is provided by EMTs, who may be volunteers or paid professionals. Basic EMTs may staff an ambulance after undergoing a training program of approximately 100 hr. They are licensed to provide BLS services but may receive further training in some jurisdictions to expand their scope of practice to include intravenous catheter placement and fluid administration, management of airway adjuncts, and use of an automated external defibrillator (AED).

Paramedics, or EMT-Ps, represent the highest level of EMT response, with medical training and supervised field experience of approximately 1,000 hr. Paramedic skills include advanced airway management, including endotracheal intubation; placement of peripheral, central, or intraosseous lines; intravenous
administration of drugs; administration of nebulized aerosols; needle thoracostomy; and cardioversion and defibrillation. These professionals provide ALS services, functioning out of an ambulance equipped as a mobile intensive care unit (ICU). In the joint policy statement Equipment for Ground Ambulances, the AAP, ACEP, American College of Surgeons Committee on Trauma, EMSC, ENA, National Association of EMS Physicians, and National Association of EMS Officials have published guideline standards for essential ambulance equipment, medications, and supplies necessary to provide BLS and ALS care across the age spectrum. This essential equipment list represents one of the reference standards that the federal EMSC program has adopted as a performance measure for state-level operational readiness to care for children in an EMS system.

Both basic EMTs and paramedics function under the delegated licensing authority of a supervisory EMS medical director. This physician oversight ofprehospital practice is broadly characterized under the umbrella term medical control. Direct, or online, medical control refers to medical direction either at the scene or in real time via voice or video transmission. Indirect, or offline, medical control refers to the administering of medical direction before and after the provision of care. Offline activities, such as provider education and training, protocol development, and medical leadership of quality assurance/quality improvement programs, represent areas in need of greater pediatric input. As a measure of the degree to which EMSC permanence is being established in state EMS systems, the federal EMSC program has required demonstration of participation in online and offline medical direction activities for pediatric patients and the presence of an EMSC advisory committee at the state level. These advisory bodies are well positioned to support EMS agencies in their pediatric readiness as well as provide a forum for the active engagement of pediatric care experts at a system level.

**Destination Determination**

The destination to which a pediatric patient is transported may be defined by parental preference, provider preference, or jurisdictional protocol, which is typically predicated on field assessment of anatomic and physiologic criteria and, in the case of trauma, mechanism of injury. In communities served by an organized trauma or regionalized EMS system that incorporates pediatric designation based on objectively verified hospital capabilities, seriously ill or
injured children may be triaged by protocol to the highest-level center reachable within a reasonable amount of time. The mantra is to deliver the child to the right care in the right time, even if it requires bypassing closer hospitals. An exception is the child in full cardiorespiratory arrest, for whom expeditious transport to the nearest facility is always warranted.

Regionalization in the context of EMS is defined as a geographically organized system of services that ensures access to care at a level appropriate to patient needs while maintaining efficient use of available resources. This system concept is especially germane in the care of children, given the relative scarcity of facilities capable of managing the full range and scope of pediatric conditions (Fig. 79.2). Regionalized systems of care coordinated with emergency medical dispatch, field triage, and EMS transport have demonstrated efficacy in improving outcomes for pediatric trauma patients, especially for younger children and for children with isolated head injury. Emerging evidence also suggests a similar benefit conferred to children in shock identified in the field who are preferentially transported to hospital EDs with documented pediatric ALS capability. The existence of statewide or regional standardized systems that formally recognize hospitals able to stabilize and/or manage pediatric medical emergencies is another federal EMSC performance measure against which operational capacity to provide optimal pediatric emergency care in the United States is currently being evaluated.

FIG. 79.2 Transport options within a coordinated, regionalized emergency medical
In communities that do not have a hospital with the equipment and personnel resources to provide definitive pediatric inpatient care, **interfacility transport** of a child to a regional center should be undertaken after initial stabilization (see Chapter 79.1).

### The Emergency Department

The ability of hospital EDs to respond to the emergency care of children varies and depends on a number of factors in addition to availability of equipment and supplies. Training, awareness, and experience of the staff as well as access to pediatricians and medical and surgical subspecialists also play a key role. The majority of children who require emergency care are evaluated in community hospitals by physicians, nurses, and other healthcare providers with variable degrees of pediatric training and experience. Although children account for approximately 25% of all ED visits, only a fraction of these encounters represent true emergencies. Because the volume of critical pediatric cases is low, emergency physicians and nurses working in lower-volume community hospital EDs often have limited opportunity to reinforce their knowledge and skills in the assessment of ill or injured children and in pediatric resuscitation. Indeed, 50% of U.S. hospital EDs provide care for <10 children per day. General pediatricians from the community or pediatric hospitalists may be consulted when a seriously ill or injured child presents to the ED, and they should have a structured approach to the initial evaluation and treatment of an unstable child of any age, regardless of the underlying diagnosis. Early recognition of life-threatening abnormalities in oxygenation, ventilation, perfusion, and central nervous system function and rapid intervention to correct those abnormalities are key to successful resuscitation and stabilization of the pediatric patient.

The **National Pediatric Readiness Project (NPRP)**, a 2013–2014 survey of pediatric readiness in U.S. EDs, found higher readiness levels (as measured by compliance with published guidelines) in larger-volume EDs and in hospitals with a physician and/or nurse pediatric emergency care coordinator. Further information about the NPRP, including data by state, may be found on the website of the EMSC Innovation and Improvement Center,
Baseline readiness standards must be met by all EDs that care for children, to ensure that children receive the best emergency care possible. Specific recommendations on equipment, supplies, and medications for the ED are listed and updates available on the AAP website. Table 79.2 lists sample policies, procedures, and protocols specifically addressing the needs of children in the ED.

Table 79.2

**Guidelines for Pediatric-Specific Policies, Procedures, and Protocols for the Emergency Department (ED)**

- Illness and injury triage
- Pediatric patient assessment and reassessment
- Documentation of pediatric vital signs, abnormal vital signs, and actions to be taken for abnormal vital signs
- Immunization assessment and management of the underimmunized patient
- Sedation and analgesia for procedures, including medical imaging
- Consent (including situations in which a parent is not immediately available)
- Social and mental health issues
- Physical or chemical restraint of patients
- Child maltreatment (physical and sexual abuse, sexual assault, and neglect) mandated reporting criteria, requirements, and processes
- Death of the child in the ED
- Do-not-resuscitate orders
- Family-centered care, including:
  1. Involving families in patient care decision-making and in medication safety processes.
  2. Family presence during all aspects of emergency care, including resuscitation.
  3. Education of the patient, family, and regular caregivers.
  4. Discharge planning and instruction.
  5. Bereavement counseling.
- Communication with patient's medical home or primary healthcare
Medical imaging policies that address age- or weight-appropriate dosing for children receiving studies that impart ionizing radiation, consistent with ALARA (as low as reasonably achievable) principles

All-hazard disaster preparedness plan that addresses the following pediatric issues:

a. Availability of medications, vaccines, equipment, and appropriately trained providers for children in disasters.
b. Pediatric surge capacity for both injured and noninjured children.
c. Decontamination, isolation, and quarantine of families and children of all ages.
d. A plan that minimizes parent-child separation and includes system tracking of pediatric patients, allowing for the timely reunification of separated children with their families.
e. Access to specific medical and mental health therapies, as well as social services, for children in the event of a disaster.
f. Disaster drills, which should include a pediatric mass casualty incident at least every 2 yr.
g. Care of children with special healthcare needs.
h. A plan that includes evacuation of pediatric units and pediatric specialty units.

The way the family supports the child during a crisis, and consequently how the family is supported in the ED when caring for the child, are critical to patient recovery, family satisfaction, and mitigation of behavioral and mental health impact. Commitment to patient- and family-centered care in the ED ensures that the patient and family experience guides the practice of culturally sensitive care and promotes patient dignity, comfort, and autonomy. In the ED setting, particular issues, such as family presence, deserve specific attention. Surveys of
parents have indicated that most want to be with their child during invasive procedures and even during resuscitation. Allowing their presence has been shown to reduce parental and patient anxiety and does not interfere with procedure performance. Patient- and family-centered care practices are also strongly associated with improved care quality and patient safety.

Disaster Preparedness

Throughout a catastrophic event, natural or human-made, several unique factors place children at disproportionate, increased risk. During an average workday, an estimated 69 million U.S. children are separated from their families, in schools and childcare centers, where mass casualty events can easily occur. This separation adds the additional challenge of safe and timely reunification of children with family during or after an incident. Furthermore, in the event of a biologic, chemical, or radionuclear attack, unique anatomic, developmental, and physiologic features make children especially vulnerable to absorption, ingestion, or inhalation of toxic agents and related morbidity and mortality.

Similar to day-to-day emergency readiness for ill and injured children, pediatric disaster preparedness requires advance considerations of the unique vulnerabilities and needs of children within planning, and exercises, at local, state, regional and even national levels. Pediatric planning considerations include training of first responders and other care providers, patient triage, decontamination, surge capacity and capability, medical countermeasures (medications, vaccines, equipment, supplies), evacuation, transport, sheltering, and family reunification. Planning for children should occur at all levels of the healthcare system, including the medical home, urgent care centers, EMS, acute care hospitals, pediatric tertiary hospitals, alternate care facilities, and rehabilitation services. While the NPRP noted meaningful progress in day-to-day emergency readiness, no improvement was found in disaster preparations, with less than half of U.S. hospitals having a disaster plan addressing the needs of children. Beyond acute medical treatment needs, pediatric planning must also consider the typically broad mental and behavioral health impact disasters have on children and families. Pediatric plans must also be in place for locations where children congregate, such as schools and childcare.

At the local, state, or regional level, healthcare coalitions have been identified as an optimal forum for disaster planning; core participants should include local or state public health departments, emergency management authorities, EMS
agencies, and hospitals. Many other key stakeholder groups should be involved in coalition planning, such as healthcare professional organizations. To ensure that the needs of children are effectively considered, it has been recommended that disaster planning at all levels include pediatric subject matter experts. Pediatricians are an obvious source for this expertise and are also uniquely positioned to educate families about emergency readiness, particularly families with special needs children. The presence of an intact medical home during a public health emergency, and after a disaster has occurred, will contribute enormously toward response, recovery, and community resiliency. Lastly, community practice and healthcare system readiness and resiliency begin with personal readiness planning engaged by healthcare providers and support staff.

The AAP’s Children and Disasters website* contains toolkits, checklists and other resources pertinent to pediatric readiness within the community, schools, the medical home, and hospitals; educational materials are also available for families. Reliable information and excellent disaster readiness resources may also located on the websites of the EMSC Innovation and Improvement Center (https://emscimprovement.center), U.S. Centers for Disease Control and Prevention (https://emergency.cdc.gov), U.S. Department of Health and Human Services (https://www.phe.gov/preparedness/Pages/default.aspx), and U.S. Federal Emergency Management Agency (https://www.fema.gov).

79.1

Interfacility Transport of the Seriously Ill or Injured Pediatric Patient

Corina Noje, Bruce L. Klein

Keywords
Patients often seek treatment at facilities that lack sufficient expertise to treat their conditions, necessitating transfer to more appropriate specialty centers. This is especially pronounced in pediatrics. Emergency medical services (EMS) providers or parents usually take children to local emergency departments (EDs) first, where their conditions and physiologic stabilities are assessed. Although bringing a child directly to the local ED may be proper logistically, local EDs can be less than ideal for pediatric emergencies. Children account for 27% of all ED visits, but only 6% of EDs have all the necessary supplies for pediatric emergencies. Also, general EDs are less likely to have pediatric expertise or policies in place for the care of children. Outcomes for critically ill children treated in pediatric intensive care units (PICUs) are better than for those treated in adult ICUs. When pediatric critical care is required, transport to a regional PICU is indicated. In addition, often the type of subspecialty care needed (e.g., pediatric orthopedics) is available only at the pediatric center.

**Pediatric transport medicine** consists of the interfacility transfer of infants, children, and adolescents from community facilities to pediatric centers that can provide the needed level of expertise. Transport is performed by professionals proficient in pediatric transport using age-equipped ground, rotorcraft, or fixed-wing ambulances. Pediatric transport medicine is a multidisciplinary field comprising pediatric critical care and **pediatric emergency medicine** (PEM) physicians (and, sometimes for very young infants, neonatologists); nurses, respiratory therapists, and paramedics with advanced training for pediatric transport; and communications specialists. The goal is to deliver quality pediatric care to the region's children, while optimizing the use of regional resources. For the individual child, the aim is to stabilize and, when appropriate, begin treating as soon as possible—that is, at the local ED and during transport, well before arrival at the referral center.

Models for pediatric transport services vary depending on the needs and available resources in a geographic region, but all should have certain basic components: a network of community hospitals and regional pediatric centers; an established communications and dispatch system that easily facilitates
transfer to the pediatric center; ground and/or air ambulances; medical and nursing leadership from pediatric critical care or PEM (or neonatology); experienced pediatric medical control physicians (MCPs); a multidisciplinary team of pediatric transport professionals specially trained to provide the appropriate level of care required during transport; operational and clinical policies and procedures that guarantee safe, state-of-the-art, and timely pediatric critical care transport; and a database for quality and performance assessment.

**Communications and Dispatch Center**

Communications are one of the most vital components of a regional transport system. Treating a critically ill or injured child is generally an uncommon event for most community physicians. Therefore, they need to know whom, how, and when to call for assistance in the stabilization and transfer of a pediatric patient. The communications and dispatch center provides a single telephone number for such calls.

The communications and dispatch center coordinates communications among the outlying facility, receiving unit, MCP, transport team, and other consultants. This center may be part of a hospital unit (e.g., ED, PICU), self-contained in a single institution (e.g., Emergency Communications and Information Center), or based offsite as a freestanding center coordinating communications and dispatch for multiple transport programs.

Staffing varies depending on the type of center. On-duty nurses or physicians may receive calls at unit-based models with low volumes. In contrast, dedicated communications specialists usually staff self-contained or freestanding centers, which tend to be busier. The communications specialist has numerous responsibilities, including answering the referring physician's call promptly; documenting essential patient demographic information; arranging for immediate consultation with the MCP; dispatching the transport team to the referring facility expeditiously; updating the referring facility with any changes in the arrival time; and coordinating medical control and other necessary transport-related calls. The transport team must be equipped with a cellular telephone or radio for immediate contact with the receiving and referring facilities. Furthermore, with advances in technology and wireless communication systems, telemedicine—either interactive (synchronous) or store and forward (asynchronous)—is being used during pediatric transport; certain programs have incorporated it into their routine transport operations.
Medical Control Physician

The MCP is involved in the clinical care and safe transport of the patient from the time of referral through arrival at the receiving hospital unit. The MCP's oversight increases once the transport team arrives at the referring facility. The MCP should have expertise in pediatric critical care or PEM (or sometimes neonatology). Besides having the knowledge required to stabilize a critically ill or injured child, the MCP must be familiar with the transport environment; the transport team members’ resources and capabilities; the program's policies and procedures; and the region's geography, medical resources, and regulations regarding interhospital transport. The MCP must possess good interpersonal and communication skills and must be able to maintain collegiality with the referring hospital's staff during a potentially difficult and stressful situation.

Once a transport call is received, the MCP must be immediately available to confer with the referring physician. Although the MCP may have other responsibilities, these transport responsibilities take priority in order to avoid undue delays when transferring a critically ill child. Often the MCP recommends further testing or therapeutic interventions that can be delivered by the referring hospital before the transport team arrives. The MCP may seek additional guidance from other specialists, as necessary. Because the child's condition may change rapidly, the MCP must remain ready to give additional advice. All conversations and recommendations regarding the care of the patient should be documented. Some centers record these conversations.

After discussion with the referring physician—and when warranted, with the transport staff—the MCP determines the best team composition and vehicle for transport. The MCP usually does not accompany the team but remains available, by phone or radio (and sometimes through telemedicine), to supervise care.

Transport Team

Transport team composition varies among programs—and sometimes within an individual program. The team's composition is based on a variety of factors, including the child's age; the severity of the illness or injury; the distance to the referring facility; the transport vehicle used; the team members’ advanced practice scope and abilities; the referrer's (reasonable or unreasonable) insistence that a physician be present; the program's historical professional makeup; and the region's staffing regulations. Team members are generally physicians, nurse
practitioners, nurses, respiratory therapists, and paramedics who have expertise in pediatric critical care, PEM, or neonatology (in some cases), as well as advanced education and training in those cognitive and procedural areas important for pediatric critical care transport. There is a lower incidence of transport-related morbidity for critically ill and injured children transported by pediatric specialty teams than for those transported by generalist teams. Nevertheless, in-transit critical events occur in almost 1 in 8 pediatric critical care transports.

Various scoring systems have been developed to predict the need for a physician during transport. It seems that a team member's training, experience, and skill in treating critically ill patients are more important considerations than that team member's professional degree. Team members must understand basic pediatric pathophysiology and collectively must be able to assess and monitor a critically ill or injured child; manage the airway and provide respiratory support; obtain vascular access; perform point-of-care testing; and administer medications typically used in pediatric critical care transport. They must be familiar with the physiologic alterations as well as practical difficulties of the transport environment and, importantly, must be comfortable working in an out-of-hospital setting. Physicians are less often deployed on transport teams in part because of the advanced training that other healthcare professionals on the transport team receive.

The transport team should have a designated team leader who, in addition to the team leader's many other responsibilities, interacts with the MCP during the transport. Once the team arrives at the referring facility, the team should reassess the child's condition, review all of the pertinent diagnostic studies and therapies, and discuss the situation with the referring staff and parents. If the patient's condition has changed significantly, the team leader may need to contact the MCP for additional advice. Otherwise, the team leader should generally notify the MCP before starting to bring the child to the receiving facility. Any care delivered by the team during transport should be documented, and copies of all medical records—including laboratory data, radiographs, and scans—should accompany the child to the pediatric center. The receiving unit must be updated prior to arrival so it can finalize preparations for the patient.

**Ground vs Air Ambulance**

Transport vehicle options include ground, rotorcraft, and fixed-wing
ambulances. Vehicle selection depends on the child's emergency needs; transport team's capabilities; any out-of-ordinary staffing or equipment requirements (e.g., for extracorporeal membrane oxygenation, inhaled nitric oxide or heliox); referring facility's abilities; distance; terrain; traffic patterns; ground or air ambulance availability; helicopter landing pad or airport access; weather conditions; and expense.

The transport vehicle must be equipped with electrical power, oxygen, and suction and must have sufficient space for the equipment and supplies that the team brings along—stretcher or isolette, monitor, ventilator, oxygen tank(s), medication pack(s), infusion pumps, and more. Compared with helicopters, ambulances are more spacious and able to carry more weight, so they can accommodate larger teams and more equipment. Another advantage of ground ambulance transport is the ability to stop en route if the patient's condition deteriorates; this may facilitate the performance of certain interventions, such as intubation.

An airplane may be able to fly to an area when distance (>150 miles), altitude, or weather precludes helicopter use. However, the use of an airplane necessitates several ambulance transfers, with their attendant delays and potential complications. There also are delays when the plane must fly from a remote base to the program's jurisdiction.

**Transport Physiology**

When possible, the transport team tries to provide the same care during transport as the patient would receive in the specialty center. This can be difficult, however, because of limitations in personnel, equipment, and space, as well as other environmental challenges.

The team and child are subjected to variable intensities of background noise and vibration while traveling in the vehicle cabin. **Noise** can impair the team's ability to auscultate breath sounds and heart sounds or accurately measure the blood pressure manually—another reason for monitoring vital signs mechanically and relying on other assessment modalities, such as the level of mentation, skin color, and capillary refill. For rotor transports in particular, the crew and patient should wear helmets or headphones (or another wearable noise attenuator, such as MiniMuffs, Natus Medical, San Carlos, CA) to mitigate noise. **Motion** and **vibration** are additional transport hazards and can lead to increased metabolic rate, shortness of breath, and fatigue in the patient, as well
as motion sickness in the patient and staff.

On fixed-wing or certain rotary-wing transports, the patient may suffer adverse physiologic effects from **altitude**. With increasing altitude, the barometric (atmospheric) pressure decreases and gas expands to occupy a greater volume due to decreased pressure exerted on it. Therefore, as barometric pressure drops with altitude, the partial pressures of inspired oxygen (PiO_2) and, consequently, arterial oxygen (Pao_2) decrease, as does the arterial oxygen-hemoglobin saturation (Spo_2). For example, at 8,000 feet—an elevation at which unpressurized airplanes may fly, as well as the effective cabin altitude for many pressurized airplanes flying at 35,000 to 40,000 feet—the barometric pressure, PiO_2, Pao_2, and Spo_2 fall to 565 mm Hg, 118 mm Hg, 61 mm Hg, an 93%, respectively. In comparison, the barometric pressure, PiO_2, Pao_2, and Spo_2 are 760 mm Hg, 159 mm Hg, 95 mm Hg, and 100% at sea level. Although healthy individuals usually tolerate these changes well, patients with respiratory insufficiency, pulmonary hypertension, significant blood loss, or shock may decompensate and should receive supplemental oxygen and/or have the cabin pressured at sea level.

Gases expand 10–15% at the few-thousand feet where helicopters typically fly, and approximately 30% at 8,000 feet. Gases within the body itself also expand as the altitude increases. The degree of gas expansion must be considered during transport via air of any patient with a pneumocephalus, pneumothorax, bowel obstruction, or another condition involving entrapped gas. Before transport, a pneumothorax should be decompressed and a nasogastric tube inserted for ileus.

## Safety

Safety is of paramount importance and mandates constant vigilance by everyone involved. Accident rates for pediatric air and ground transport are estimated at approximately 1 in 1,000 transports. The team should routinely attend pilot briefs, as well as perform safety inspections of the vehicles and equipment, aided by checklists. When in doubt, the MCP should solicit input from the staff about whether to transport via air or ground ambulance or to employ lights and sirens, decisions that cannot be taken lightly. The pilot's or driver's judgment as to the safety of proceeding during inclement weather or with a mechanical problem must not be overruled.
Organizations such as the Federal Aviation Administration (FAA) and the National Transportation Safety Board (NTSB), play a role in ensuring safe interfacility transport. The Commission on Accreditation of Medical Transport Systems (CAMTS) is an independent, peer-review organization established in 1990 in response to the number of air medical accidents in the 1980s. CAMTS, through voluntary participation, audits and accredits fixed-wing, rotary-wing, and ground interfacility medical transport services.

**Family-Centered Care**

Family-centered care represents a philosophy that respects the important role that family members play in a child's care. It recognizes family members and healthcare providers as partners in caring for the child. Family presence during transport is beneficial because it provides support to children in stressful situations and assists healthcare providers in delivering care to patients with complex and chronic medical problems.

As care is transitioned from the referring hospital, it is the transport team's responsibility to maintain family-centered care. The team meets with family members to explain the transport process, help obtain consent, and discuss anticipated management. When possible, the transport team should attempt to accommodate a family member's presence onboard. However, the family member and child may need to be separated when the child is critically ill and rapid transport is essential, or in case of space or weight limitations in the air or ground ambulance. In these situations, it is important that family members have a clear understanding of how the child will be cared for during the separation.

**Referring Hospital Responsibilities**

Transfer of a child to another facility requires written documentation by the referring physician of the need and reasons for transfer, including a statement that the risks and benefits, as well as any alternatives, have been discussed with the parents. Informed consent should be obtained from the parent/legal guardian before transfer.

Federal law under the Emergency Medical Treatment and Active Labor Act (EMTALA), part of the Consolidated Omnibus Budget Reconciliation Act (COBRA), imposes specific requirements that a patient presenting to an ED be
given a medical screening examination without regard to ability to pay. If on examination an emergency medical condition is found, the hospital is required to stabilize the patient or to transfer the patient to another facility if unable to stabilize the patient or if requested by the patient. The primary requirement is that the referring physician must certify that the medical risks of transfer are outweighed by its potential benefits. The receiving hospital must agree to accept the patient if it has the space and staff to provide the necessary level of care. The transferring hospital is responsible for arranging for the transfer and ensuring that it is performed by qualified medical personnel with appropriate equipment. The transferring hospital must also send copies of the patient's medical records and test results, even those that become available after the transfer is complete.

Some referring hospitals have entered into transfer agreements with specialty centers to facilitate the smooth and safe transfer of pediatric patients. Having prepared forms for all the above purposes also aids in the transfer process.

Each hospital needs to review its facility's guidelines; if established guidelines do not exist, the Emergency Medical Services for Children National Resource Center in partnership with the Emergency Nurses Association and the Society of Trauma Nurses has developed the “Inter Facility Transfer Tool Kit for the Pediatric Patient” (www.pediatricreadiness.org). This tool kit includes the essentials for comprehensively and safely transferring the pediatric patient to the most appropriate level of care in a timely manner.

**Educational Outreach**

Besides safe and rapid transport, regional pediatric transport programs (and their specialty centers) have an obligation to provide educational opportunities to community healthcare providers so that these providers can acquire the necessary skills to evaluate and stabilize a critically ill or injured child until the transport team arrives. These learning activities may include transport case reviews; lectures on pediatric acute care topics; resuscitation and related programs such as the Pediatric Advanced Life Support (PALS) course, Advanced Pediatric Life Support (APLS) course, Pediatric Education for Prehospital Professionals (PEPP) course, and S.T.A.B.L.E. (sugar and safe care, temperature, airway, blood pressure, lab work, emotional support) program; and rotations through the specialty center's pediatric ED and PICU. These activities also help cement relationships with the referring facility's staff.

**Outcomes and Risk Adjustment of Pediatric Emergency Medical Services**

*Robert C. Tasker, Evaline A. Alessandrini*

**Keywords**

- calibration
- discrimination
- PRISA II
- PRISM
- RePEAT
- risk adjustment

Health services research has documented wide variation in the likelihood that patients receive quality, evidence-based healthcare, and this can negatively impact the health of children and youth (see Chapter 2). The complexities of delivering high-quality healthcare are magnified in the emergency department...
Patients are in crisis, EDs are often overcrowded, patient–physician relationships are based on brief interactions, and the varieties of complaints and diagnoses are immense. Practitioners want to know whether the system is working well, and whether local performance is good compared with a recognized benchmark or standard. Physicians can make their practice better only if they can make the appropriate measurements. However, no two places of practice are the same, so besides assessing raw outcomes (e.g., times, mortality, patient satisfaction), practitioners also need to make some adjustment for severity of illness, case mix, or risk of morbidity (e.g., one ED's practice and cases may differ significantly from a theoretical standard being used as a benchmark for “best practice”).

Outcome Measures in Emergency Medical Services for Children

Pediatric emergency medical systems must support the development of national standards for emergency care performance measurement. The Donabedian structure-process-outcome model has set the framework for most contemporary quality measurement and improvement activities. Structural elements provide indirect quality-of-care measures related to a physical setting and resources. Process indicators provide a measure of the quality of care and services by evaluating the method or process by which care is delivered, including both technical and interpersonal components. Outcome elements describe valued results related to lengthening life, relieving pain, reducing disabilities, and satisfying the consumer.

A true outcome-based approach describes observable measures such as mortality, risk of organ system failure, and disability. An alternative approach is a resource-based outcome measure with a definition related to the level of care required. Children who are more ill, in general, require more resources. Thus, resource use across groups of patients reflects relative severity of illness in the groups, provided clinicians have a similar approach to practice. Examples of resource-based outcomes include need for hospital admission (ED disposition), ED length-of-stay, costs, and diagnostic and therapeutic interventions performed in the ED. This approach, certainly provides a measurement of activity, but child healthcare providers do not really know whether the patient receiving the therapeutic interventions or resources actually needed them (i.e., data may also
reflect physician behavior or [lack of] experience). Therefore, some other assessment is needed that incorporates information on how sick the patient is, or their specific diagnosis.

Table 79.3 provides a list of outcome measures for pediatric ED care developed by Emergency Medical Services for Children Innovation and Improvement Center supported by the Health Resources and Services Administration of the U.S. Department of Health and Human Services.

Table 79.3
Stakeholder-Endorsed Outcome Measures for Pediatric Emergency Care

- Overall patient satisfaction with ED visit—nurses
- Overall patient satisfaction with ED visit—physicians
- Parent/caregiver understanding of ED discharge instructions
- ED length of stay for patients <18 yr of age
- Percentage of patients <18 yr of age left without being seen (LWBS)
- Effective pediatric procedural sedation
- Acute fracture patients with documented reduction in pain within 90 min of ED arrival
- Improvement in asthma severity score for patients with acute exacerbations
- ED revisit within 48 hr resulting in admission
- Medication error rates
- Global sentinel never events
- Unplanned return visit within 72 hr for the same/related asthma exacerbation
- Failure to achieve seizure control within 30 min of ED arrival
- Return visits within 48 hr resulting in admission for all urgent and emergency patients

Risk Adjustment

The purpose of measuring outcomes in the ED is to evaluate performance and therefore to offer EDs and other components of the healthcare system the
opportunity to make effective improvements over time, using a benchmark within and between units. When making comparisons over time, one must ensure that patient-related attributes (e.g., age, preexisting conditions associated with outcome of interest, severity of illness) has not changed; otherwise one may be looking at changes in demography and case mix rather than any change in performance. The approach is to make some form of risk adjustment to level the playing field, so that comparison of outcomes is as fair and meaningful as possible. Because children present to EDs with illnesses of varying acuity, severity is inextricably linked to outcomes. Severity typifies the concept of risk—the higher the severity, the higher the risk of a given outcome. Without risk adjustment, EDs with sicker patients may appear to have poorer outcomes.

In the population of children admitted to a pediatric intensive care unit (PICU), 2 models, the Pediatric Risk of Mortality (PRISM) and Pediatric Index of Mortality (PIM), have been developed and validated against the outcome of death during PICU admission and, in the case of PRISM IV, against functional outcome. These models or prediction algorithms, use a composite of a priori known high- or low-risk diagnoses, as well as acute physiology measurements taken around the time of presentation. In PRISM IV the data collection is from 2 hr before to 4 hr after admission, or the 1st 4 hr of care. The main concept is that deranged physiology reflects underlying severity of illness; the other features of the patient (e.g., age, diagnoses, postintervention status) modify the relationship between physiologic status and risk and enable accurate and reliable estimates of mortality and morbidity risks. Importantly, in the PRISM methodology, physiologic status is not conflated with therapies (e.g., mechanical ventilation) used at presentation (i.e., in the initial window for assessment). Historically, the measure used after the initial window of assessment with its laboratory and clinical evaluation was a period of intervention in the PICU, lasting a median of 2 days, and then discharge survival. However, the mortality rate in many U.S. PICUs is now <2.5%, and thus the need for algorithms that also include development of morbidity, now approximately 5%. The PRISM IV methodology has been validated using a trichotomous outcome (i.e., death, new morbidity, no new morbidity) at hospital discharge.

The previous approach is not well suited for the population presenting to the ED. Interventions may have already occurred in the prehospital setting, or physiology may have stabilized. Mortality rate is very low, and the other outcome measures may reflect what happens on the PICU or during hospital
ward care. A number of disease-specific acuity scoring systems are available for use in the ED population, predominantly for those involved in trauma (e.g., Injury Severity Score, Trauma Score, Pediatric Trauma Score).

**Risk Adjustment Tools in the ED**

In the ED the choice of a risk adjustment tool depends on the outcomes of interest. Two general risk adjustment tools have been developed specifically for PEM, the second-generation Pediatric Risk of Admission (PRISA II) score and the Revised Pediatric Emergency Assessment Tool (RePEAT).

**Pediatric Risk of Admission II**

PRISA II uses components of acute and chronic medical history and physiology to determine the probability of hospitalization. The outcome measure of interest is *mandatory hospital admission* (admissions utilizing therapies best delivered as an inpatient). Table 79.4 lists the patient-related attributes contributing to the PRISA II risk adjustment score. Analytic models, including the PRISA II score, have good *calibration* (how well the probabilities predicted from the model correlated with the observed outcomes in the population) and *discrimination* (the ability to categorize subjects correctly into the categories of interest) with respect to mandatory hospital admission. Construct validity of the PRISA score has been demonstrated by measuring rates of the secondary outcomes: mandatory admission, PICU admission, and mortality. As the probability of hospital admission rises, the proportion of patients with these increasing care requirements also increases. This finding supports the use of the PRISA II score as a measure of severity of illness. PRISA II has also been used to demonstrate racial/ethnic differences in severity-adjusted hospitalization rates. One study demonstrated that teaching hospitals had higher-than-expected severity-adjusted admission rates than nonteaching hospitals.

- Low bicarbonate and high potassium values

**Revised Pediatric Emergency Assessment Tool**

RePEAT uses a limited set of data collected at the time of ED triage to model severity of illness as reflected by the level of care provided in the ED, for example, routine assessment (clinical examination only ± nonprescription medicine) vs specific ED care (ED diagnostics and/or therapeutics) vs hospital admission. It is assumed that patients needing a higher level of care have a higher severity of illness. Table 79.5 lists the patient-related attributes contributing to the RePEAT risk adjustment score. Analytic models such as RePEAT have good calibration and discrimination with respect to predicting ED care and hospital admission. Furthermore, analytic models that compare costs and ED length of stay between EDs are improved by adjustment for severity of illness using the RePEAT score. RePEAT is a reasonable objective marker of severity of illness that could be used in the administrative process comparing outcomes between EDs.

**Table 79.5**

triage

The maturity of pediatric emergency medicine (PEM) in any given area depends on the healthcare priorities and resources of that geographic or physical setting. The places in which emergency care takes place range from the community (for those with no access to organized medical care) to state-of-the-art pediatric EDs in populated centers. The scope ranges from care of the individual patient to the management of populations of children involved in large-scale disasters. Barriers to quality care are different in each situation and in each part of the world, with the implication for the astute international PEM practitioner that solutions must be targeted to the local context of healthcare within a given environment.
Continuum-of-Care Model

This Emergency Medical Services for Children (EMSC) framework can also be applied to discussion of emergency care for children on a global level (see Chapter 79). With medical infrastructures that may not be consistent or well organized, or that have been weakened by civil strife, natural disasters, or economic loss, the focus of child health in the developing world has mostly been on prevention and acute care.

Prevention

**Infectious Diseases**

International child health has focused mainly on reducing preventable childhood illnesses, primarily through immunizations. Enormous advances have been realized in measles, neonatal tetanus, and polio reduction; wild-type smallpox was eradicated in 1978. Although there are advocates for providing primary care interventions (e.g., vaccinations) in the ED, the role of the PEM practitioner in this area of prevention has been limited.

**Injuries**

Injuries are a leading cause of childhood morbidity and mortality. Unintentional injuries constitute 90% of injury mortality to children 5-19 yr old and are the cause of 9% of the world's mortality (see Chapter 13). Intentional injuries, which remain underrecognized and underreported, make a smaller but significant contribution. Unintentional injuries cause more than 2,000 childhood deaths daily, or 950,000 annually worldwide. The burden of these deaths is borne disproportionately by children in middle- and lower-income countries, where >95% of all injury deaths occur. For each of these deaths, many more children are permanently disabled, and an even larger number are treated and released without permanent sequelae.

The World Health Organization (WHO) and United Nations Children's Fund (UNICEF) have outlined several proven injury prevention strategies, of which child health practitioners in the global community must be aware. The top 3 causes of injury mortality are traffic-related injuries, burns, and drowning. There are 7 specific effective strategies for reducing traffic-related injuries: a minimum drinking age, appropriate child restraints and seatbelts, helmets for motorcycle and bicycle riders, reduced vehicle speeds around schools and
residential areas, running lights on motorcycles, graduated licensing for drivers, and separation of different types of road users. There is insufficient evidence to demonstrate that school-based programs on drunk driving, increased pedestrian visibility, or designated driver programs are effective. Although these strategies have proved effective, the data are based on U.S. research and may not be generalizable to other countries. It may be difficult to reduce vehicle speeds around schools when there is insufficient infrastructure for street signs. Alternatively, lack of separation of car and bus traffic from bicyclists and pedestrians contributes to unsafe and dangerous road conditions. This is more of a problem in lower- and middle-income countries, where bicycles and motorized 2-wheel vehicles are used to carry children as well as goods, while the drivers negotiate among rapidly moving vehicles. With rising income, these countries have seen increases in both the number of cars and the number of 2-wheeled vehicles, with a corresponding increase in the number of related injuries.

For reducing drowning deaths, strategies that have proven effective focus on creating barriers between children and water hazards, such as covering wells, buckets, and other standing sources of water, and placing high fences around pools (see Chapter 91). Burns have been addressed by advocating for installation of smoke detectors and lowering the temperature of water from water heaters (see Chapter 92).

**Out-of-Hospital Care**

Out-of-hospital care comprises access to emergency services, prehospital care, and interfacility transport of patients. Morbidity and mortality arise from delayed or limited access to emergency care, lack of prehospital care, transport without proper monitoring or trained personnel, or delayed transport to a higher level of care. *Safe transport of seriously ill children* is a neglected global health issue. An emergency response system must address the following links in the patient's care: a communication system with prompt activation of EMS, the correct assessment and initial treatment of the patient, and the rapid transport to definitive care.

**Access to Care**

When a child is injured or ill, a parent or caretaker must be able to access help and activate EMS. Many countries worldwide have dedicated emergency numbers to rapidly dispatch medical, police, or fire services. The simple 112
emergency number has been adopted and is being phased in throughout the European Union (EU) member states, to access medical, fire, and police services, in addition to secondary regional emergency access numbers. The universal U.S. emergency number system 911 today covers the large majority of the country (98%) and has enhanced features of automatically linking the phone number to an address. However, there remain limitations to universal access resulting from absence of phones in some households, unclear addresses in rural areas, and insufficient reach of the emergency system.

In the majority of low- and middle-income countries, no such universal emergency numbers have been established, requiring access by direct dialing to an ambulance, if such private services exist. In most low- and middle-income countries, the family must bring the ill or injured child to the health facility for stabilization and treatment. For this to occur, families must overcome financial and geographic barriers, which can result in delayed presentation for care. This delay predictably increases the acuity of the illness or injury and associated complications and decreases the likelihood of full recovery and survival.

Prehospital Care

In regions with maturing EMS systems, there must be adequately trained personnel to stabilize and transport the child to a medical facility. The quality and level of training of such prehospital personnel vary tremendously among countries and within regions of the same country. In urban areas, there is a greater concentration of medical care and therefore a greater opportunity to have strong prehospital training. In most of Asia and sub-Saharan Africa, trained personnel are used primarily to transfer patients between health facilities, not from the initial site of illness or injury. In most high-income countries, medical services are dispatched to the patient.

In the French model, Service d'Aide Médicale Urgente (SAMU), a physician, often an emergency medicine specialist, will review calls for acuity and can dispatch a physician-led team by ambulance to go to the patient's home to assess, stabilize, and initiate treatment. This Franco-German system is used in other countries, including many in Latin America and Europe. There are no clear data on the cost-effectiveness and patient outcomes associated with delivery of patients to the nearest facility vs bringing hospital resources to the patient.

Around the world, the effort to establish standardized approaches to prehospital care exists primarily in the form of courses to educate EMS and hospital personnel in the emergency management of patients. For trauma care,
the WHO manuals *Prehospital Trauma Care Systems* and *Guidelines for Essential Trauma Care* both focus on guidelines for prehospital and trauma care systems that are affordable and sustainable. The AAP course Pediatric Education for Prehospital Professionals is a dynamic, modularized teaching tool designed to provide specific pediatric prehospital education that can be adapted to any EMS system. Table 79.6 describes additional prehospital resources.

**Table 79.6**

**Pediatric Emergency Care Resources**

### Prehospital

**Advanced Medical Life Support (AMLS)**
Newest course developed by the National Association of Emergency Medical Technicians (NAEMT) to provide more clinical teaching and reasoning around emergent medical problems. Course is open to physicians, nurses EMTs and paramedics.

[www.naemt.org/education/aml/aml.aspx](http://www.naemt.org/education/aml/aml.aspx)

**Prehospital Trauma Life Support**
Available in 33 countries, PHTLS is the leading continuing education program for prehospital emergency trauma care.

[www.phtls.org](http://www.phtls.org)

**International Trauma Life Support**
Training course for prehospital trauma care.

[www.itrauma.org](http://www.itrauma.org)

**Pediatric Education for Prehospital Professionals (PEPP)**
Curriculum designed specifically to teach prehospital professionals how to assess and manage ill or injured children.

[www.pepps.org](http://www.pepps.org)

### Hospital Care

**Pocket Book of Hospital Care for Children**
WHO publication providing guidelines for the management of common illnesses with limited resources; incorporates both the Emergency Triage Assessment and Treatment (ETAT) and Integrated Management of Childhood Illness (IMCI) guidelines.
AFEM Handbook of Acute and Emergency Care
Management strategies based on available resources. It leads providers through a rapid, systematic, and integrated approach to stabilization and resuscitation of patients stratified to 3 resource levels: where there are no available resources, where there are minimal resources, and where there are full resources.
Available for purchase online.

Where There Is No Doctor: A Village Health Handbook
Healthcare manual for health workers, clinicians, and others involved in primary healthcare delivery and health promotion programs around the world. Available for purchase or as a free download.
www.hesperian.org

International Federation for Emergency Medicine
2012 International Standards of Care for Children in Emergency Departments.

Humanitarian Emergencies

CHILDDisaster Network
Registry for those with education and experience in humanitarian emergencies to volunteer their time when needed in a disaster.

Organizations Involved in International PEM Activities
Although most middle- and high-income countries have a system of trained EMS workers, low-income countries lack this advanced tier of emergency care. In these countries, commercial drivers, volunteers, and willing bystanders provide the first line of care. Training a cadre of first responders can rely on existing networks of aid or can be drawn from specific populations, such as students, soldiers, or public servants. Training needs to emphasize basic lifesaving and limb-saving interventions, including how to stop bleeding and support breathing, access advanced care, and splint broken limbs. In Ghana, for example, taxi drivers participated in a first-aid course that relied heavily on demonstration and practice rather than knowledge transfer through didactic sessions. Taxi drivers were selected because they already provided much of the transport for injured patients, either voluntarily or for pay by the family. Two years after the course, external evaluators favorably rated the quality of their care compared with untrained drivers. In rural areas, such first responders become vital in providing emergency interventions when more definitive care is distant. Thus a system of trained first responders forms the foundation of an effective prehospital system.

**Methods of Transport**
In many low-income countries, there is no means of transport other than the family's motorized or other type of transport. Health centers may only have 1 vehicle for transport to a higher-level facility. This vehicle may also be used for outreach primary care services, such as offering immunizations and collecting drugs and equipment from a central supply location, and sometimes, improperly for personal reasons by local officials or politicians. In large cities, taxis and auto rickshaws are frequently used because they are rapidly available, well disseminated, and able to pass around traffic jams. Where organized prehospital systems exist, different types of vehicles are adapted for emergency transportation, from fully equipped ambulances to basic transport with trained personnel. The WHO recommends identifying transport vehicles in advance, choosing vehicles that can be repaired and maintained locally, and equipping the vehicles according to recognized standards. Therefore the provision of available and appropriately staffed and equipped transport vehicles is crucial to the realization of recommended emergency care plans.

**Hospital-Based Care**

Once a child has reached a medical facility for the care of an injury or illness, adequate emergency services must be available. In many countries the ED serves only as a triage area where patients are distinguished by their likely disease process and directed for admission to the corresponding unit within the hospital. Strengthening emergency services includes seeing the ED as a unit where definitive treatment can be provided to the ill and injured child. Critically ill children must receive not only prompt care but also correct care. Such expedience and accuracy are ensured by implementation of an effective triage system, moving the sickest patients to immediate care and standardizing the initial care of emergency conditions.

**Triage**

Children requiring emergency care frequently are not promptly recognized. Too often, children presenting to EDs are treated on a first-come first-served basis, in an approach that creates long waiting times for critically ill children, a contributor to unnecessary mortality. Medical facilities need to adopt an efficient and effective triage system to respond rapidly to the needs of patients and to assign the appropriate amount of resources. To this end, WHO has developed a course entitled *Emergency Triage Assessment and Treatment (ETAT)*. This
course teaches to triage patients on arrival as having emergency, priority, or nonurgent signs and to provide emergency treatment for life-threatening conditions. ETAT emphasizes the evaluation of a patient's **ABCD status** to identify emergency situations—the patency of the airway (A), the quality of breathing (B), the quality of circulation and presence of coma or convulsions (C), and the presence of severe dehydration (D).

One of the benefits of the ETAT guidelines is that they can be adapted to centers with limited resources and are applicable to areas with high morbidity and mortality from meningitis, dehydration, malaria, respiratory illness, and malnutrition. Another benefit is that the care algorithms are based on limited diagnostic studies, that is, hemoglobin measurement, blood smear for malaria, and bedside blood glucose testing. Widely accepted triage assessment guidelines are teachable to emergency care staff, and their adoption can provide better organization within a healthcare center. At the Queen Elizabeth Central Hospital in Blantyre, Malawi, for example, the institution of triage and rapid treatment in its emergency care center led to a 50% decrease in the mortality of children within 24 hr of presentation to the hospital, with a further 50% decrease as implementation and practice of triaging patients have continued.

Beyond triage, education on overall emergency center organization is a low-resource intervention that can obviate some of the obstacles to quality care delivery. Additionally, the arrangement of short-stay areas (hydration and infusion rooms) can lessen the burden on inpatient units.

**Pediatric-Specific Emergency Centers**

Anecdotally, most countries have developed at least 1 pediatric-capable center, usually as part of an academic medical center. The emergency services in these centers are variable, but certainly can be a starting point from which to build overall improvement in pediatric emergency care.

**Practitioners**

Throughout the world, nurses, paramedics, and nonspecialist physicians provide most of the care to acutely ill or injured children. The majority of sick children attend local clinics or district or central hospitals, where financial and human resources are not always matched to the potential acuity of presenting patient complaints. Nominal supervision is provided to staff attending these patients. Pediatric EDs located in tertiary hospitals are often staffed by training physicians
with little or no supervision from faculty, who themselves may have limited exposure to or training in PEM. General hospitals lack dedicated pediatric staff; guidelines as to which patients should be moved to a higher level of care are often not standardized and depend on local influences and/or cultural beliefs about health and illness.

**Clinical Guidelines**

The **Integrated Management of Childhood Illnesses (IMCI)** guidelines were developed by the WHO and UNICEF to provide assistance in the initial triage and management of the presenting signs and symptoms of the major killers of children <5 yr old in first-level health facilities (e.g., clinics, health centers, outpatient departments of hospitals). The flow charts within each chapter of the IMCI manuals allow easy accessibility to materials that can enhance education and outreach to less experienced health workers.

Evaluations in various countries of the implementation of IMCI guidelines have shown improvements in health worker performance and quality of care, as well as decreases in delay in treatment and mortality of the under-5 population. These guidelines also dramatically reduce the cost of healthcare. The WHO website provides all the necessary implementation tools, including course manuals and evaluation tools.

The International Federation of Emergency Medicine developed standards to improve emergency care globally. These standards are not just aimed at dedicated EDs, but at any setting where emergency care takes place, regardless of the providers or the resources available. At the same time, however, the existence of the standards allows sites to advocate for improved resources dedicated to expertise in the various aspects of providing quality emergency care for children. The standards address design of care spaces, child- and family-centered care, assessment of ill and injured children, staff training and competencies, quality and safety, and disaster response.

**Trauma**

Morbidity and mortality from trauma are among the most prevalent problems for children worldwide. Trauma care presents the challenge of sequential, often simple, interventions that must be performed in a timely manner to limit the severity of the outcome. However, with lack of specific training, signs and symptoms of pediatric trauma may go unrecognized or may be underappreciated.
Trauma courses such as Advanced Trauma Life Support (ATLS) are educational tools that can be disseminated to improve the quality of care at emergency centers worldwide. For low-resource settings, WHO has developed the Integrated Management for Emergency and Essential Surgical Care toolkit, which provides clear directions and reasoning for the initial care of injured patients. Not expressly addressed in the ATLS course is specific concern about child abuse as the cause of trauma. This is an area of pediatric care that many countries do not yet address comprehensively in their medical training, their law enforcement, or their judicial systems. The epidemiologic need for reliable trauma registries is great, as is the need to identify personnel with trauma management skill sets and dedicated trauma centers to serve as higher-level referral sites.

**Equipment**

Pediatric emergency equipment guidelines are available for a variety of settings where acutely ill and injured children would present. Although these equipment guidelines may represent minimum supplies to treat the widest variety of pediatric emergencies, the roles of substitution and improvisation often provide for equivalent function of recommended supplies.

**Inpatient Services**

After the initial stabilization, children requiring ongoing care are admitted to the hospital. The quality of inpatient services varies greatly depending on institutional and provider experience, comfort with pediatric conditions, and the resources available to treat them. WHO has produced the *Pocket Book of Hospital Care for Children*, which is based on IMCI guidelines and focuses on inpatient management of high-morbidity/high-mortality illnesses common in developing countries.

**Humanitarian Disasters**

Children are a vulnerable population who experience disproportionate suffering during humanitarian emergencies, either natural (earthquakes, tsunamis, hurricanes, floods, droughts) or manmade (armed conflicts, terrorist attacks). The under-5 population is especially susceptible to infectious diseases, malnutrition, and trauma following disasters. The *Rainbow Center for Global*
Child Health at the Case Western Reserve University School of Medicine offers a training course, Management of Humanitarian Emergencies: Focus on Children and Families, to educate and train health professionals, relief workers, and policymakers to recognize and address the unique needs of children affected by manmade and natural disasters worldwide. AAP also maintains a CHILD disaster Network, which acts as an electronic database of child health professionals with education and experience in humanitarian emergencies. Nongovernmental organizations can access the database to solicit practitioners to aid in disaster response.

The WHO Manual for the Health Care of Children in Humanitarian Emergencies is based on IMCI guidelines and addresses the emergency care of children in disaster situations where hospital facilities and resources are not immediately available. It goes beyond the IMCI guidelines by discussing initial assessment and management of trauma, burns, and poisonings. Preexisting IMCI guidelines assumed a functioning health system that facilitated the referral of children, which may not be available in all emergency situations. This manual also includes the initial management of severe conditions, such as injuries, burns, neonatal illness, and psychosocial problems, which are considered high priority in acute care settings.

Exchange and Dissemination of Information

The WHO established the HINARI (Health InterNetwork Access to Research Initiative) program to allow free or reduced-cost access to more than 6,200 journal publications. This internet access is made available to the 108 countries with gross national income per capita <$3,500. For middle-income countries not meeting the financial eligibility, internet access continues to be a barrier, and resources may be limited to out-of-date textbooks and journals.

Another valuable tool is the website pemdatabase.org . This nonproprietary site was started as an online resource for PEM practitioners. It contains links to PEM abstracts and articles, evidence-based reviews, pediatric resuscitation websites, and relevant journals, as well as PEM conferences and professional organizations.

Identifying the acutely ill child in the ambulatory setting is a challenge. Children presenting to pediatricians’ offices, urgent care practices, and emergency departments (EDs) may have a range of illnesses from simple viral infections to life-threatening emergencies. Although most children in this setting will have a benign course of illness, it is incumbent on the pediatric practitioner to quickly and accurately discern which children are likely to deteriorate from potentially serious or life-threatening disease. When assessing an acutely ill child, practitioners must remember that the early signs of severe illness may be subtle.

**Assessment of Vital Signs**

Assessment of vital signs is critical in all pediatric visits for acute illness, including temperature, heart rate, respiratory rate, and blood pressure. Normal vital signs vary with age. Although there have been increasing efforts to build evidence-based vital sign cutoffs for different age-groups, most institutions use nonempirically derived cutoffs such as those in Pediatric Advanced Life Support (PALS). **Tachycardia** is common in children presenting for acute care and can result from benign (fever, pain, dehydration) to life-threatening (septic shock, hemorrhage) conditions. An abnormal heart rate should prompt a full history and physical examination, as described later, and careful *reassessment* (often multiple times) after the presumed cause is identified and treated. The vast majority of children will improve after initiation of simple interventions such as antipyretics or analgesia. Tachycardia that persists after fever, pain, and dehydration have been treated *must* be evaluated further, particularly if the child appears ill or has deficit in perfusion or altered mental state.

**Tachypnea** is also common and has many causes, including fever, respiratory
conditions (bronchiolitis, asthma, pneumonia), cardiac disease (e.g., heart failure), and metabolic acidosis (shock, poisoning, diabetic ketoacidosis). Similar to tachycardia, tachypnea often resolves with antipyretics in febrile children, and should be reassessed to ensure resolution once fever has been managed. In cases where bronchiolitis and asthma have been ruled out, persistent tachypnea and fever can be a sign of pneumonia, even in the absence of focal lung findings on examination. Consider evaluation for metabolic acidosis in cases of significant tachypnea without apparent pulmonary or cardiac causes. Apnea is a sign of respiratory failure and should be treated emergently with bag-valve-mask ventilation and immediate ED evaluation.

**Hypotension** is rare in children, and when present, it is a sign of critical illness. Children with hypotension should be evaluated in an ED. Hypotension is evidence of decompensated circulatory shock and can result from severe dehydration, sepsis, hemorrhage, neurogenic spinal shock, or cardiogenic shock.

Pulse oximetry (oxygen-hemoglobin saturation, \( \text{SpO}_2 \)) should be assessed in children with respiratory or cardiac illness/compromise and also in children with underlying abnormalities of oxygenation. Healthy children have \( \text{SpO}_2 \) >95%. The practitioner should consider evaluating for any underlying respiratory or cardiac causes in children with \( \text{SpO}_2 <93–95\)%. For children with underlying abnormalities, the child's baseline \( \text{SpO}_2 \) should be assessed and alterations from that baseline should be investigated further.

The combination of bradycardia, hypertension, and altered breathing known as **Cushing triad** can be a sign of life-threatening increased intracranial pressure (ICP) and should be evaluated in an ED. Anisocoria and a 6th cranial nerve palsy are other signs of increased ICP. **Toxidromes** should also be considered in children with abnormal combinations of vital signs (see Chapter 77).

**History**

A thorough history is paramount to identifying patients whose condition will require prompt intervention. Obtaining an accurate history from young patients is challenging, particularly with preverbal or very anxious children who are unable or unwilling to localize the source of their discomfort. In such instances, parents or caretakers often provide the most important information, and their perceptions of the child's course of illness must be carefully considered. Pediatricians should be guided by the patient's chief complaint to ask open-
ended questions that help distinguish between benign and potentially life-threatening disease entities. The most common complaints leading to acute care visits among children include fever, headache and altered mental status, trauma, abdominal pain and vomiting, respiratory distress, and chest pain. Table 80.1 describes signs and symptoms that should prompt immediate transfer to an ED or, if already in the ED, initiation of rapid intervention.

Adapted from Farah MM, Tay Y, Lavelle J. A general approach to ill and injured children. In Shaw KN, Bachur RG, editors: Fleischer and Ludwig's textbook of pediatric emergency medicine,
Fever is the most common reason for a sick-child visit. Most cases of fever are the result of self-limited viral infection. However, pediatricians need to be aware of the age-dependent potential for serious bacterial infections, such as urinary tract infection (UTI), sepsis, meningitis, pneumonia, acute abdominal infection, and osteoarticular infection.

During the 1st 2 mo of life, the neonate is at risk for sepsis caused by pathogens that are uncommon in older children. These organisms include group B streptococcus, Escherichia coli, Listeria monocytogenes, and herpes simplex virus (HSV). In neonates, the history must include untreated maternal obstetric information and the patient's birth history. Risk factors for sepsis include untreated maternal group B streptococcus colonization, prematurity, chorioamnionitis, and prolonged rupture of membranes. If there is a maternal history of sexually transmitted infections (STIs) during the pregnancy, the differential diagnosis must be expanded to include those pathogens. Septic infants can present with lethargy, poor feeding, grunting respirations, and cool or mottled extremities, in addition to fever (or hypothermia). Febrile infants in the 1st 1-2 mo of life should be evaluated broadly for infection, including sampling blood, urine, and cerebrospinal fluid (CSF).

When the infant matures beyond 2 mo of age and receives their 1st set of vaccinations, serious bacterial infections become less common. Evaluation to rule out serious infection is an important part of treating the febrile older child. Children with fever should have a full set of vital signs, history, and physical examination to ensure that critical illness is absent and to identify any focal source. Red flags for septic shock include hypotension, poor perfusion, altered mental status, or the presence of purpuric or erythrodermic rash. Red flags for meningitis include severe headache, meningismus, and altered mental state. The presence of any of these signs should prompt emergency evaluation in the ED or rapid treatment if the patient is already in the ED.

Additional focal findings to consider include evaluation for acute otitis media, pharyngitis, pneumonia, abdominal infections (bacterial enteritis, appendicitis), skin and soft tissue infections, septic arthritis, and osteomyelitis. Occult UTI should be considered if 3 of the following risk factors are present: age <1 yr, fever >39°C, fever >48 hr, and no focal source of fever. Pneumonia should be considered in the presence of tachypnea, hypoxia, or focal findings on chest examination. Bacteremia is rare in the post–pneumococcal and Haemophilus influenzae vaccine era but should be considered if staphylococcal infection or
Meningococcemia is suspected, as well as in unvaccinated children or children with signs of septic shock. In addition to infection, inflammatory conditions to consider include juvenile idiopathic arthritis and Kawasaki disease. The diagnosis of Kawasaki disease should be considered if the patient meets the diagnostic criteria for this illness although some patients may have an atypical or incomplete presentation (see Chapter 191).

For patients presenting in an altered mental state, the pediatrician should inquire about any symptoms, such as fever or headache. Screening questions should explore feeding changes, medications in the household, ill contacts, and the possibility of trauma. Parents will often describe a febrile child as lethargic, but further questioning will reveal a tired-appearing child who interacts appropriately when no longer febrile. The child who appears ill only when febrile must be differentiated from the lethargic patient who presents with suspected sepsis or meningitis, and from the child whose altered behavior is secondary to an intracranial emergency or seizure. Infants with meningitis, sepsis, or cardiac defects may have a history of irritability, being inconsolable, poor feeders, grunting breathing, seizures, poor urine output, and/or color changes such as pallor, mottling, or cyanosis. Patients with poisoning or inborn error of metabolism can also present with lethargy, poor feeding, unusual odors, seizures, and vomiting. Nonaccidental trauma should always be considered in a lethargic infant, particularly in the absence of additional signs or symptoms. In infants and young toddlers, rapidly growing head circumference or bulging anterior fontanel may signal increased ICP. Older children may present with altered mental state as a result of meningitis/encephalitis, trauma, or ingestions. School-age children and adolescents with meningitis may have a history of fever and neck pain; other associated symptoms may include rash, headache, photophobia, or vomiting. Children with ingestions can present with other abnormal neurologic symptoms, such as ataxia, slurred speech, and seizures, or with characteristic constellations of vital sign changes and other physical findings consistent with certain toxidromes.

In patients with headache, ask questions about the chronicity of the headache and any accompanying symptoms. Headaches that occur on arising in the morning, are worse when lying flat, or are accompanied by vomiting are concerning for increased ICP. Similarly, headache accompanied by focal neurologic deficit should be referred to an ED for urgent head imaging. While migraine headaches in teenagers are similar in presentation to those in adults (unilateral, throbbing, accompanied by an aura), pediatric practitioners should be
aware that migraines in prepubertal children may have a nonclassic presentation and may be bilateral and not accompanied by aura, photophobia, or phonophobia.

Parents may interpret a variety of symptoms as respiratory distress, and care must be taken to distinguish normal and benign respiratory patterns from true respiratory distress. Tachypnea secondary to fever is a common source of parental anxiety, and parents of newborn infants are sometimes alarmed by the presence of periodic breathing. Parents should be questioned about their child's other symptoms, such as fever, limitation of neck movement, drooling, choking, and the presence of stridor or wheezing. A history of apnea or cyanosis warrants further investigation. Practitioners should also remember that tachypnea in a child without evidence of true respiratory distress may be evidence of compensation for shock or metabolic acidosis, both of which will require rapid treatment. Although wheezing is often secondary to bronchospasm, it can also be caused by cardiac disease or congenital airway anomalies such as vascular rings. Parents may interpret true stridor as noisy breathing or wheezing. Stridor is most frequently caused by upper airway obstruction such as croup. However, anatomic abnormalities such as laryngeal webs, laryngomalacia, subglottic stenosis, and paralyzed vocal cords also cause stridor. Toddlers who present with breathing difficulty after a coughing or choking episode should be evaluated for foreign body aspiration. In these cases, practitioners must ask about the possibility of button-battery ingestion, as this constitutes a true medical emergency that warrants immediate endoscopic removal or transfer to a facility that can perform the procedure. In toxic-appearing children with stridor, the pediatrician should consider epiglottitis, bacterial tracheitis, or a rapidly expanding retropharyngeal abscess. The incidence of epiglottitis has greatly declined with the advent of the *H. influenzae* type b (Hib) vaccine, but it remains a possibility in the unimmunized or partially immunized patient. Children with retropharyngeal abscesses may also present with drooling and limitation of neck movement (especially hyperextension) after a recent upper respiratory infection or penetrating mouth injury.

**Abdominal pain** is a very common complaint in the ambulatory setting and can herald either acute intraabdominal or pelvic pathology, or it can be a subtler sign of systemic illness. Both relatively benign (e.g., streptococcal infection, UTI, pneumonia) and severe abdominal (e.g., appendicitis) or systemic (e.g., diabetic ketoacidosis) illness can present with abdominal pain, and questions to the patient and parent should include whether there is an extraabdominal source
of discomfort. Questions should include details about pain onset and location; presence of accompanying symptoms, such as fever, abdominal distention; and changes in feeding, urination, and stooling patterns. Care should be taken to elicit a history of peritonitis or obstruction, including worsening pain with abrupt movements and persistent or bilious vomiting.

In neonates, a tender abdomen with or without bilious emesis should raise concern for the presence of a small bowel obstruction (volvulus). These infants appear ill and may have a history of decreased stooling. Pediatricians should be wary of neonates with abdominal tenderness and bloody stools, because 10% of cases of necrotizing enterocolitis occur in term infants. Infants with milk protein intolerance can also present with bloody stools, but these infants appear well and do not have abdominal tenderness. In older patients the differential diagnosis for emergency causes of abdominal pain expands to include intussusception and appendicitis. Patients with intussusception present in a variety of ways, ranging from colicky abdominal pain but otherwise well between episodes to being lethargic or in shock. The diagnosis of appendicitis in the child younger than 3 yr is extremely difficult because children in this age-group cannot localize pain well. In adolescent females with abdominal pain, practitioners must obtain a menstrual and sexual history, because acute lower abdominal pain may be caused by adnexal pathology, including ovarian torsion or ectopic pregnancy.

For patients with vomiting, pediatricians should ask if they have experienced bilious or blood-stained emesis, abdominal distention or constipation, weight changes, and diarrhea or bloody stools. An infant with bilious emesis and abdominal distention may have intestinal obstruction (as with midgut volvulus or Hirschsprung disease), whereas an infant who appears immediately hungry after nonbilious projectile vomiting may have pyloric stenosis. In an older child, vomiting may be caused by peritonitis or obstruction, as well as by systemic illnesses, including diabetic ketoacidosis, ingestion, or trauma. Patients with headache and vomiting raise the concern for increased ICP and should be questioned about neurologic changes, meningismus, and fever.

Practitioners should also obtain a thorough account of the child's past medical history. It is important to be aware of any underlying chronic problems that might predispose the child to recurring infections or a serious acute illness. Children with sickle cell anemia, indwelling central venous access devices, or immune compromise are at increased risk for bacteremia and sepsis. Similarly, children with prior surgery, including ventriculoperitoneal shunt placement or intraabdominal procedures, can develop complications from their previous
surgeries.

**Physical Examination**

Observation is important when evaluating the acutely ill child. Most observational data that the pediatrician gathers should focus on assessing the child's response to stimuli. Does the child awaken easily? Does the child smile and interact with the parent, or with the examiner? Evaluating these responses requires knowledge of normal child development and an understanding of the manner in which normal responses are elicited, depending on the child's age.

During the physical examination, the pediatric practitioner seeks evidence of illness. The portions of the exam that require the child to be most cooperative are completed first. Initially, it is best to seat the child on the parent's lap; the older child may be seated on the examination table. It is also important to assess the child's willingness to move, as well as ease of movement. It is reassuring to see the child moving about on the parent's lap with ease and without discomfort. *Vital signs are often overlooked but are invaluable in assessing ill children.* The presence of tachycardia out of proportion to fever and the presence of tachypnea and blood pressure abnormalities raise the suspicion for more serious illness. The respiratory evaluation includes determining respiratory rate, noting the presence or absence of hypoxia by $\text{SpO}_2$, and noting any evidence of inspiratory stridor, expiratory wheezing, grunting, coughing, or increased work of breathing (e.g., retractions, nasal flaring, accessory muscle use). The skin should be carefully examined for rashes. Frequently, viral infections cause an exanthem, and many of these eruptions are diagnostic, such as the reticulated rash and slapped-cheek appearance of parvovirus infections and the stereotypical appearance of hand-foot-and-mouth disease caused by coxsackieviruses, as well as measles, chickenpox, and roseola. The skin examination may also yield evidence of more serious infections, including petechiae and purpura associated with bacteremia and erythroderma associated with a toxin-producing systemic infection. Cutaneous perfusion should be assessed by warmth and capillary refill time. The extremities may then be evaluated not only for ease of movement but also for the presence of swelling, warmth, tenderness, or alterations in perfusion. Such abnormalities may indicate focal infections (e.g., cellulitis, bone/joint infection) or vascular changes (e.g., arterial or venous thromboembolus).

When an infant is seated and is least perturbed, the examiner should assess the
anterior fontanel to determine whether it is depressed, flat, or bulging. While the child is calm and cooperative, the eyes should be examined to identify features that might indicate an infectious or neurologic process. Often, viral infections result in watery discharge or redness of the bulbar conjunctivae. Bacterial infection, if superficial, results in purulent drainage; if the infection is more deep-seated, tenderness, swelling, and redness of the tissues surrounding the eye may be present, as well as proptosis, altered visual acuity, and impaired extraocular movement. Abnormalities in pupillary response or extraocular movements may also be indicators of cranial nerve abnormalities and if new, are indications for head imaging.

During this initial portion of the physical examination, when the child is most comfortable (and therefore most likely to be quiet), the heart and lungs are auscultated. It is important to assess the adequacy of air entry into the lungs, the equality of breath sounds, and any evidence of adventitial breath sounds, especially wheezes, rales, or rhonchi. The coarse sound of air moving through a congested nasal passage is frequently transmitted to the lungs. The examiner can become attuned to these coarse sounds by placing the stethoscope near the child's nose and then compensating for this sound as the chest is auscultated. The cardiac examination is next; findings such as pericardial friction rubs, loud murmurs, and distant heart sounds may indicate cardiac inflammation or infection. In the neonate, murmurs may herald congenital heart disease, especially in the presence of cyanosis, unequal extremity pulses, or a differential in upper- vs lower-extremity blood pressures. A complete cardiac exam should also look for displacement of the PMI (point of maximal impulse) and the presence of jugular venous distention or facial plethora.

The components of the physical examination that are more bothersome to the child are completed last. This is best done with the patient on the examination table. Initially, the neck is examined to assess for areas of swelling, redness, or tenderness, as may be seen in cervical adenitis. Resistance to neck movement should prompt evaluation for signs of meningeal irritation or retropharyngeal abscess. During examination of the abdomen, the diaper, if present, is removed. The abdomen is inspected for distention. Auscultation is performed to assess adequacy of bowel sounds, followed by palpation. Every attempt should be made to quiet a fussing child during this part of the exam; if this is not possible, practitioners should note that increased crying as the abdomen is palpated may indicate tenderness, especially if this finding is focally reproducible. In addition to focal tenderness, palpation may elicit involuntary guarding or rebound
tenderness (including tenderness to percussion); these findings indicate peritoneal irritation, as seen in appendicitis. During palpation of the abdomen, practitioners should look for signs of hepatomegaly or splenomegaly. When palpating the bottom-most edge of the liver or spleen, examiners should begin in the pelvis and work upward toward the ribs, because severe organomegaly can be missed if the examiner begins palpatating in the mid-abdomen. The **inguinal area and genitals** are then examined. One should assess the inguinal area for hernias. Care should be taken to examine the testicles of boys with abdominal pain; testicular trauma, testicular torsion, and epididymitis all may present with abdominal discomfort. A unilateral swollen or painful testicle with an absent cremasteric reflex on the affected side is concerning for testicular torsion and should be referred for emergent ultrasound and urologic consultation. After the genital exam, the child is then placed in the prone position, and abnormalities of the **back** are sought. The spine and costovertebral angle areas are percussed to elicit any tenderness; such findings may be indicative of vertebral osteomyelitis or diskitis and pyelonephritis, respectively.

Examining the **ears and throat** completes the physical examination. These are usually the most bothersome parts of the examination for the child, and parents frequently can be helpful in minimizing head movement. During the oropharyngeal examination, it is important to document the presence of enanthemas; these may be seen in many infectious processes, such as stomatitis caused by herpes or enteroviruses. This portion of the examination is also important in documenting inflammation or exudates on the tonsils, which may indicate viral or bacterial infection. Findings such as trismus or unilateral tonsillar swelling are concerning for peritonsillar abscess and for infections in the para- and retropharyngeal spaces; such cases should be referred for specialist ear, nose, and throat evaluation and imaging of the neck.

*Repeating portions of the assessment may be indicated.* If the child cried continuously during the initial clinical evaluation, the examiner may not be certain whether the crying was caused by the high fever, stranger anxiety, or pain, or is indicative of a serious or localizing illness. Constant crying also makes portions of the physical examination, such as auscultation of the chest, more difficult. Before a repeat assessment is performed, efforts to make the child as comfortable as possible are indicated. In young infants, **persistent irritability**, even when the examiner is absent from the room, is concerning for meningitis, encephalitis, or other causes of meningeal irritation (e.g., intracranial injury from nonaccidental trauma). When faced with a truly inconsolable infant, practitioners
should have a low threshold to obtain head imaging and/or perform lumbar puncture, as the clinical scenario dictates.

**Management**

Most patients who present to the pediatrician's office with an acute illness will not require acute stabilization. However, the pediatrician needs to be prepared to evaluate and begin resuscitation for the seriously ill or unstable child. Outpatient pediatric offices and urgent care facilities should be stocked with appropriate equipment necessary to stabilize an acutely ill child. Maintenance of that equipment and ongoing training of the office staff in its use is required, and every effort should be made to ensure that pediatric clinicians are PALS certified (see Chapter 81).

The evaluation of the potentially unstable child must begin with assessment of the ABCs—airway, breathing, and circulation. When assessing the airway, chest rise should be evaluated and evidence of increased work of breathing sought. The examiner should ensure that the trachea is midline and should listen carefully for evidence of air exchange at the level of the extrathoracic airway. If the airway is patent and no signs of obstruction are present, the patient is allowed to assume a position of comfort. If the child shows signs of airway obstruction, repositioning of the head with the chin-lift maneuver may alleviate the obstruction. An oral or nasal airway may be necessary in patients in whom airway patency cannot be maintained. These devices are not well tolerated in conscious patients because they may induce gagging or vomiting; instead, they are most often used to facilitate effective bag-valve-mask ventilation in semiconscious or unconscious children. Once airway patency has been established, the adequacy of breathing should be evaluated. Slow respiratory rates or cyanosis may signal impending respiratory failure. If the airway is patent but the child's respiratory effort is inadequate, positive pressure ventilation via bag-valve-mask support should be initiated. Oxygen should be administered to all seriously ill or hypoxic children via nasal cannula or face mask. Auscultation of the lung fields should assess for air entry, symmetry of breath sounds, and presence of adventitious breath sounds such as crackles or wheezes. Bronchodilator therapy can be initiated to alleviate bronchospasm. Racemic epinephrine is indicated for stridor at rest in a patient with croup. Once airway and breathing have been addressed, circulation must be evaluated. Symptoms of shock include tachycardia, cool extremities, delayed capillary refill time, mottled
or pale skin, and effortless tachypnea. In children, hypotension is a late finding in shock and indicates that significant decompensation has already taken place. Vascular access is necessary for volume resuscitation in patients with impaired circulation, and an intrasosseous line should be considered early if there is any difficulty in obtaining vascular access for a patient requiring resuscitation. Each time an intervention is performed, the clinician should reassess the patient to determine whether interventions have been successful and whether additional care is needed.

**Disposition**

The majority of children evaluated in the office or urgent care setting for an acute illness can be managed as an outpatient. These patients should have a reassuring physical examination, stable vital signs, and an adequate follow-up plan before being sent home. A mildly dehydrated patient can be discharged home for a trial of oral rehydration. Patients with respiratory illness who exhibit signs of mild respiratory distress may be monitored at home, with a repeat examination scheduled the next day. Depending on the child's condition, the comfort of the parents, and the relationship of the family with the physician, telephone follow-up may be all that is necessary. When no specific diagnosis has been established at the first outpatient visit, a follow-up examination may yield the diagnosis and can provide reassurance for both the caregiver and the practitioner that a child's severity of illness has not progressed.

However, if it is deemed that the child needs a higher level of care, it is the pediatrician's responsibility to decide what method of transfer is appropriate. Physicians may be reluctant to call for help because of a misperception that emergency 911 services should be activated only for ongoing resuscitation. Emergency medical services (EMS) transport should be initiated for any child who is physiologically unstable (e.g., with severe respiratory distress, hypoxia, signs of shock, or altered mental state). If the family's ability to comply promptly with recommendation for ED evaluation is in question, this patient also should be transported by EMS. Some physicians and families may defer calling EMS because of the perception that a parent can reach the hospital faster by private motor vehicle. Although rapidity of transport should be considered, the need for further interventions during transport and the risk of clinical decompensation are other important factors in the decision to activate EMS. Ultimately, the legal responsibility for choosing an appropriate level of transport for a patient lies
with the referring physician, until responsibility of care is officially transferred to another medical provider.

Injuries are the leading cause of death in American children and young adults and account for more childhood deaths than all other causes combined (see Chapter 13). Rapid, effective bystander cardiopulmonary resuscitation (CPR) for children is associated with survival rates as high as 70%, with good neurologic outcome. However, bystander CPR is still provided for <50% of children who experience cardiac arrest outside medical settings. This failing has led to long-term survival rates of <40%, often with a poor neurologic outcome.

**Approach to the Emergency Evaluation of a Child**

The first response to a pediatric emergency of any cause is a systematic, rapid general assessment of the scene and the child to identify immediate threats to the child, care providers, or others. If an emergency is identified, the emergency response system (emergency medical services, EMS) should be activated immediately. Care providers should then proceed through primary, secondary, and tertiary assessments as allowed by the child's condition, safety of the scene, and resources available. This standardized approach provides organization to what might otherwise be a confusing or chaotic situation and reinforces an organized thought process for care providers. If at any point in these assessments the caregiver identifies a life-threatening problem, the assessment is halted and lifesaving interventions are initiated. Further assessment and intervention should be delayed until other caregivers arrive or the condition is successfully treated or stabilized.
General Assessment

On arrival at the scene of a compromised child, a caregiver's first task is a quick survey of the scene itself. Is the rescuer or child in imminent danger because of circumstances at the scene (e.g., fire, high-voltage electricity)? If so, can the child be safely extricated to a safe location for assessment and treatment? Can the child be safely moved with the appropriate precautions (i.e., cervical spine protection), if indicated? A rescuer is expected to proceed only if these important safety conditions have been met.

Once the caregiver and patient's safety has been ensured, the caregiver performs a rapid visual survey of the child, assessing the child's general appearance and cardiopulmonary function. This action should be only a few seconds and include assessment of (1) general appearance, determining color, tone, alertness, and responsiveness; (2) adequacy of breathing, distinguishing between normal, comfortable respirations and respiratory distress or apnea; and (3) adequacy of circulation, identifying cyanosis, pallor, or mottling. A child found unresponsive from an unwitnessed collapse should be approached with a gentle touch and the verbal question, “Are you OK?” If there is no response, the caregiver should immediately shout for help and send someone to activate the emergency response system and locate an automated external defibrillator (AED). Figs. 81.1 and 81.2 present basic life support (BLS) pediatric cardiac arrest algorithms for 1 rescuer and 2 or more rescuers, respectively. The provider should then determine whether the child is breathing and, if not, provide 2 rescue breaths. If the child is breathing adequately, the circulation is quickly assessed. Any child with heart rate <60 beats/min or without a pulse requires immediate CPR. If the caregiver witnesses the sudden collapse of a child, the caregiver should have a higher suspicion for a sudden cardiac event. In this case, rapid deployment of an AED is crucial. Any interruptions in care of the child to activate EMS and locate the nearest AED should be very brief. If >1 caregiver is present, someone should always remain with the child and provide initial care or stabilization (see Fig. 81.2).
Once the emergency response system has been activated and the child is determined not to need CPR, the caregiver should proceed with a primary assessment that includes a brief, **hands-on assessment** of cardiopulmonary and neurologic function and stability. This assessment includes a limited physical examination, evaluation of vital signs, and measurement of pulse oximetry if available. The American Heart Association, in its Pediatric Advanced Life Support (PALS) curriculum, supports the structured format of **airway, breathing, circulation, disability, exposure (ABCDE)**. The goal of the primary assessment is to obtain a focused, systems-based assessment of the child’s injuries or abnormalities, so that resuscitative efforts can be directed to these areas; if the caregiver identifies a life-threatening abnormality, further evaluation is postponed until appropriate corrective action has been taken.

The exam and vital sign data can be interpreted only if the caregiver has a thorough understanding of normal values. In pediatrics, normal respiratory rate, heart rate, and blood pressure have age-specific norms (**Table 81.1**). These ranges can be difficult to remember, especially if used infrequently. However, several standard principals apply: (1) a child’s respiratory rate should not be >60 breaths/min for a sustained period; (2) normal heart rate is 2-3 times normal respiratory rate for age; and (3) a simple guide for pediatric blood pressure is that the lower limit of systolic blood pressure should be ≥60 mm Hg for neonates; ≥70 mm Hg for 1 mo-1 yr olds; ≥70 mm Hg + (2 × age) for 1-10 yr olds; and ≥90 mm Hg for any child older than 10 yr.

* In sleep, infant heart rates may drop significantly lower, but if perfusion is maintained, no intervention is required.

† A blood pressure cuff should cover approximately two thirds of the arm; too small a cuff yields
spuriously high pressure readings, and too large a cuff yields spuriously low pressure readings. Values are systolic/diastolic.

‡ Many premature infants require mechanical ventilatory support, making their spontaneous respiratory rate less relevant.

Airway and Breathing

The most common precipitating event for cardiac instability in infants and children is respiratory insufficiency. Therefore, rapid assessment of respiratory failure and immediate restoration of adequate ventilation and oxygenation remain the first priority in the resuscitation of a child. Using a systematic approach, the caregiver should first assess whether the child's airway is patent and maintainable. A healthy, patent airway is unobstructed, allowing normal respiration without noise or effort. A maintainable airway is one that is either already patent or can be made patent with a simple maneuver. To assess airway patency, the provider should look for breathing movements in the child's chest and abdomen, listen for breath sounds, and feel the movement of air at the child's mouth and nose. Abnormal breathing sounds (e.g., snoring or stridor), increased work of breathing, and apnea are all findings potentially consistent with airway obstruction. If there is evidence of airway obstruction, maneuvers to relieve the obstruction should be instituted before the caregiver proceeds to evaluate the child's breathing.

Assessment of breathing includes evaluation of the child's respiratory rate, respiratory effort, abnormal sounds, and pulse oximetry. Normal breathing appears comfortable, is quiet, and occurs at an age-appropriate rate. Abnormal respiratory rates include apnea and rates that are either too slow (bradypnea) or too fast (tachypnea). Bradypnea and irregular respiratory patterns require urgent attention because they are often signs of impending respiratory failure and/or apnea. Signs of increased respiratory effort include nasal flaring, grunting, chest or neck muscle retractions, head bobbing, and seesaw respirations. Hemoglobin oxygen desaturation, as measured by pulse oximetry, often accompanies parenchymal lung disease apnea or airway obstruction. However, providers should keep in mind that adequate perfusion is required to produce a reliable oxygen saturation ($S_O^2$) measurement. A child with low $S_O^2$ is a child in distress. Central cyanosis is a sign of severe hypoxia and indicates an emergent need for oxygen supplementation and respiratory support.

Circulation
Cardiovascular function is assessed by evaluation of skin color and temperature, heart rate, heart rhythm, pulses, capillary refill time, and blood pressure. In nonhospital settings, much of the important information can be obtained without measuring the blood pressure; lack of blood pressure data should not prevent the provider for determining adequacy of circulation or implementing a lifesaving response. Mottling, pallor, delayed capillary refill, cyanosis, poor pulses, and cool extremities are all signs of diminished perfusion and compromised cardiac output. **Tachycardia** is the earliest and most reliable sign of shock but is itself fairly nonspecific and should be correlated with other components of the exam, such as weakness, threadiness, and absence of pulses. An age-specific approach to pulse assessment will yield best results.

**Disability**

In the setting of a pediatric emergency, *disability* refers to a child's neurologic function in terms of the level of consciousness and cortical function. Standard evaluation of a child's neurologic condition can be done quickly with an assessment of pupillary response to light (if one is available) and use of either of the standard scores used in pediatrics: the Alert, Verbal, Pain, Unresponsive (AVPU) Pediatric Response Scale and the Glasgow Coma Scale (GCS). The causes of decreased level of consciousness in children are numerous and include conditions as diverse as respiratory failure with hypoxia or hypercarbia, hypoglycemia, poisonings or drug overdose, trauma, seizures, infection, and shock. **Most often, an ill or injured child has an altered level of consciousness because of respiratory compromise, circulatory compromise, or both.** Any child with a depressed level of consciousness should be immediately assessed for abnormalities in cardiorespiratory status.

**Alert, Verbal, Pain, Unresponsive Pediatric Response Scale.**

The AVPU scoring system is used to determine a child's level of consciousness and cerebral cortex function ([Table 81.2](#)). Unlike the GCS, the AVPU scale is not developmentally dependent—a child does not have to understand spoken language or follow commands, merely respond to a stimulus. The child is scored according to the amount of stimulus required to obtain a response, from *alert* (no stimulus, the child is already awake and interactive) to *unresponsive* (child does not respond to any stimulus).

Glasgow Coma Scale.

Although it has not been systematically validated as a prognostic scoring system for infants and young children as it has in adults, GCS is frequently used in the assessment of pediatric patients with an altered level of consciousness. The GCS is the most widely used method of evaluating a child's neurologic function and has 3 components. Individual scores for eye opening, verbal response, and motor response are added together, with a maximum of 15 points (Table 81.3). Patients with a GCS score ≤8 require aggressive management, generally including stabilization of the airway and breathing with endotracheal intubation and mechanical ventilation, respectively, and if indicated, placement of an intracranial pressure monitoring device. The Full Outline of Unresponsiveness (FOUR) score is another useful assessment and monitoring tool (see Table 85.1).

Patients with a GCS score ≤8 require aggressive management, generally including stabilization of the airway and breathing with endotracheal intubation and mechanical ventilation, respectively, and if indicated, placement of an intracranial pressure monitoring device. The Full Outline of Unresponsiveness (FOUR) score is another useful assessment and monitoring tool (see Table 85.1).
Exposure

Exposure is the final component of the pediatric primary assessment. This component of the exam is reached only after the child's airway, breathing, and circulation have been assessed and determined to be stable or have been stabilized through simple interventions. In this setting, exposure stands for the dual responsibility of the provider to both expose the child to assess for previously unidentified injuries and consider prolonged exposure in a cold environment as a possible cause of hypothermia and cardiopulmonary instability. The provider should undress the child (as is feasible and reasonable) to perform a focused physical exam, assessing for burns, bruising, bleeding, joint laxity, and fractures. If possible, the provider should assess the child's temperature. All maneuvers should be performed with careful maintenance of cervical spine precautions.

Secondary Assessment

For healthcare providers in community or outpatient settings, transfer of care of a child to emergency or hospital personnel may occur before a full secondary assessment is possible. However, before the child is removed from the scene and separated from witnesses or family, a brief history should be obtained for medical providers at the accepting facility. The components of a secondary assessment include a focused history and focused physical examination.

The history should be targeted to information that could explain cardiorespiratory or neurologic dysfunction and should take the form of a SAMPLE history: signs/symptoms, allergies, medications, past medical history, timing of last meal, and events leading to this situation. Medical personnel not engaged in resuscitative efforts can be dispatched to elicit history from witnesses or relatives. The physical examination during the secondary assessment is a thorough head-to-toe exam, although the severity of the child's

illness or injury could necessitate curtailing portions of the exam or postponing nonessential elements until a later time.

**Tertiary Assessment**

The tertiary assessment occurs in a hospital setting, where ancillary laboratory and radiographic assessments contribute to a thorough understanding of the child's condition. A basic blood chemistry profile, complete blood count, liver function tests, coagulation studies, and arterial blood gas analyses give fairly broad (but somewhat nonspecific) estimates of renal function, acid-base balance, cardiorespiratory function, and presence or absence of shock. Chest radiographs can be useful to evaluate both the heart and lungs, although more detailed estimates of heart function and cardiac output can be made with **echocardiography**. Arterial and central venous catheters can be placed to monitor arterial and central venous pressure.

**Recognition and Treatment of Respiratory Distress and Failure**

The goals of initial management of respiratory distress or failure are to rapidly stabilize the child's airway and breathing and to identify the cause of the problem so that further therapeutic efforts can be appropriately directed.

**Airway Obstruction**

Children <5 yr old are particularly susceptible to foreign body aspiration and choking. Liquids are the most common cause of choking in infants, whereas small objects and food (e.g., grapes, nuts, hot dogs, candy) are the most common source of foreign bodies in the airways of toddlers and older children. A history consistent with foreign body aspiration is considered diagnostic. Any child in the proper setting with the sudden onset of choking, stridor, or wheezing has foreign body aspiration until proven otherwise.

Airway obstruction is treated with a sequential approach, starting with the head-tilt/chin-lift maneuver to open and support the airway, followed by inspection for a foreign body, and finger-sweep clearance or suctioning if one is visualized (Fig. 81.3). **Blind suctioning or finger sweeps of the mouth are not recommended.** A nasopharyngeal airway or oropharyngeal airway can be
inserted for airway support, if indicated. A conscious child suspected of having a partial foreign body obstruction should be permitted to cough spontaneously until coughing is no longer effective, respiratory distress and stridor increase, or the child becomes unconscious.

If the child becomes unconscious, the child should be gently placed on the ground, supine. The provider should then open the airway with the head-tilt/chin-lift maneuver and attempt mouth-to-mouth ventilation (Figs. 81.4 and 81.5). If ventilation is unsuccessful, the airway is repositioned and ventilation attempted again. If there is still no chest rise, attempts to remove a foreign body are indicated. In an infant <1 yr old, a combination of 5 back blows and 5 chest thrusts is administered (Fig. 81.6). After each cycle of back blows and chest thrusts, the child's mouth should be visually inspected for the presence of the foreign body. If identified within finger's reach, it should be removed with a
gentle finger sweep. If no foreign body is visual, ventilation is again attempted. If this is unsuccessful, the head is repositioned and ventilation attempted again. If there is still no chest rise, the series of back blows and chest thrusts is repeated.

FIG. 81.4 Rescue breathing in an infant. The rescuer’s mouth covers the infant’s nose and mouth, creating a seal. One hand performs the head-tilt while the other hand lifts the infant’s jaw. Avoid head-tilt if the infant has sustained head or neck trauma. (From Guidelines for cardiopulmonary resuscitation and emergency cardiac care. Emergency Cardiac Care Committee and Subcommittees, American Heart Association. Part V. Pediatric basic life support, JAMA 268:2251–2261, 1992.)
FIG. 81.5  Rescue breathing in a child. The rescuer’s mouth covers the child’s mouth, creating a mouth-to-mouth seal. One hand maintains the head-tilt; the thumb and forefinger of the same hand are used to pinch the child’s nose. (From Guidelines for cardiopulmonary resuscitation and emergency cardiac care. Emergency Cardiac Care Committee and Subcommittees, American Heart Association. Part V. Pediatric basic life support, JAMA 268:2251–2261, 1992.)
For a conscious child >1 yr old, providers should give a series of 5 abdominal thrusts (Heimlich maneuver) with the child standing or sitting (Fig. 81.7); this should occur with the child lying down if unconscious (Fig. 81.8). After the abdominal thrusts, the airway is examined for a foreign body, which should be removed if visualized. If no foreign body is seen, the head is repositioned and ventilation attempted. If unsuccessful, the head is repositioned and ventilation attempted again. If these efforts are unsuccessful, the Heimlich sequence is repeated.
FIG. 81.7  Abdominal thrusts with the victim standing or sitting (conscious). (From Guidelines for cardiopulmonary resuscitation and emergency cardiac care. Emergency Cardiac Care Committee and Subcommittees, American Heart Association. Part V. Pediatric basic life support, JAMA 268:2251–2261, 1992.)
Airway Narrowing

Airway obstruction can also be caused by airway narrowing, in both the upper and lower airways. *Upper airway obstruction* refers to narrowing of the extrathoracic portion of the airway, including the oropharynx, larynx, and trachea. In the upper airways, narrowing is most often caused by airway edema (e.g., croup or anaphylaxis). Lower airway disease affects all intrathoracic airways, notably the bronchi and bronchioles. In the lower airways, bronchiolitis and acute asthma exacerbations are the major contributors to intrathoracic airway obstruction in children, causing airway narrowing through a combination of airway swelling, mucus production, and circumferential smooth muscle constriction of smaller airways.

Airway support for these processes is dictated by both the underlying condition and the clinical severity of the problem. In cases of mild upper airway obstruction, the child has minimally elevated work of breathing (evidenced by tachypnea and few to mild retractions). Stridor, if present at all, should be
audible with only coughing or activity. Children with these findings can be supported with supplemental oxygen as needed. In cases with moderate obstruction, in which the child has a higher work of breathing and more pronounced stridor, nebulized racemic epinephrine and oral or intravenous (IV) dexamethasone can be added. Heliox (combined helium-oxygen therapy) administration may also be considered. Children with severe upper airway obstruction have marked intercostal retractions, prominent stridor, and decreased air entry on auscultation of the lung fields. Most children with significant airway obstruction are also hypoxic, and many appear dyspneic and agitated. A child in severe distress needs to be closely observed because the signs of impending respiratory failure may be initially confused with improvement. Stridor becomes quieter and intercostal retractions less prominent when a child's respiratory effort begins to diminish. The child in respiratory failure can be distinguished from one who is improving by evidence of poor air movement on auscultation and lethargy or decreased level of consciousness from hypercarbia, hypoxia, or both. When anaphylaxis is suspected as the cause for upper airway edema, providers should administer an intramuscular (IM) or IV dose of epinephrine as needed (see Chapter 174). No matter the cause, any child in impending respiratory failure should be prepared for endotracheal intubation and respiratory support. Prompt notification of providers trained in airway management is essential.

In cases of lower airway obstruction, therapies are targeted to both relieving the obstruction and reducing the child's work of breathing. Inhaled bronchodilators, such as albuterol, augmented by oral or IV corticosteroids, remain the mainstay of therapy in settings of mild to moderate acute distress caused by lower airway obstruction (e.g., asthma). Children with more significant obstruction appear dyspneic, with tachypnea, retractions, and easily audible wheezing. In these cases, the addition of an anticholinergic agent, such as nebulized ipratropium bromide, or a smooth muscle relaxant, such as magnesium sulfate, may provide further relief, although the evidence for these measures remains controversial (see Chapter 169). Supplemental oxygen and IV fluid hydration can also be useful adjuncts. As in cases of upper airway obstruction, impending respiratory failure in children with lower airway obstruction can be insidious. When diagnosed early in a school-age child who is cooperative, respiratory failure can be averted through judicious use of noninvasive support, including heated, high-flow nasal cannula (HFNC) therapy, continuous positive airway pressure (CPAP), bilevel positive airway pressure (BiPAP), or heliox therapy. Endotracheal intubation should be performed only by
skilled providers, preferably in a hospital setting, because there is a high risk of cardiorespiratory compromise in patients with lower airway obstruction during the procedure.

**Parenchymal Lung Disease**

Parenchymal lung disease includes a heterogeneous list of conditions, such as pneumonia, acute respiratory distress syndrome (ARDS), pneumonitis, bronchiolitis, bronchopulmonary dysplasia, cystic fibrosis, and pulmonary edema. The commonalities of these conditions are their effects on the small airways and alveoli, including inflammation and exudation leading to consolidation of lung tissue, decreased gas exchange, and increased work of breathing. Clinical management of these conditions includes specific treatment as indicated (e.g., antibiotics for bacterial pneumonia) and supportive care in the form of supplemental oxygen, noninvasive respiratory support (with HFNC, CPAP, or BiPAP), or invasive mechanical ventilation.

**Advanced Airway Management Techniques**

**Bag-Valve-Mask Positive Pressure Ventilation**

Rescue breathing with a bag-valve-mask apparatus can be as effective as endotracheal intubation and safer when the provider is inexperienced with intubation. Bag-valve-mask ventilation itself requires training to ensure that the provider is competent to select the correct mask size, open the child's airway, form a tight seal between the mask and the child's face, deliver effective ventilation, and assess the effectiveness of the ventilation. An appropriately sized mask is one that fits over the child's mouth and nose but does not extend below the chin or over the eyes (Fig. 81.9). An adequate seal is best achieved through a combination “C-E” grip on the mask, in which the thumb and index finger form the letter “C” on top of the mask, pressing the mask downward onto the child's face, and the remaining 3 fingers form an “E” grip under the child's mandible, holding the jaw forward and extending the head up toward the mask. Using this method, the care provider can secure the mask to the child's face with one hand and use the other hand to compress the ventilation bag (Fig. 81.10).
FIG. 81.10 “C-E” grip to secure bag-valve-mask to a child's face with appropriate seal.

The provider may have to move the head and neck through a range of positions to find the one that best maintains airway patency and allows maximal ventilation. In infants and young children, optimal ventilation is often provided when the child's head is in the neutral sniffing position without hyperextension of the head (Fig. 81.11). Poor chest rise and persistently low So₂ values indicate inadequate ventilation. In this setting the care provider should recheck the mask's seal on the child's face, reposition the child's head, and consider suctioning the airway, if indicated. If these maneuvers do not restore ventilation, the provider should consider noninvasive or invasive respiratory support (i.e., endotracheal intubation) as clinically indicated.
Endotracheal Intubation

A child generally requires intubation when at least one of these conditions exists: (1) the child is unable to maintain airway patency or protect the airway against aspiration (as occurs in settings of neurologic compromise); (2) the child is failing to maintain adequate oxygenation; (3) the child is failing to control blood carbon dioxide levels and maintain safe acid-base balance; (4) sedation and/or paralysis is required for a procedure; and (5) care providers anticipate a deteriorating course that will eventually lead to any of the first 4 conditions. It should be noted that in centers experienced in noninvasive respiratory support, a trial of HFNC, CPAP, and/or BiPAP may be indicated based on the specific clinical scenario.

There are few absolute contraindications to tracheal intubation, but experts generally agree that in settings of known complete airway obstruction, endotracheal intubation should be avoided, and emergency cricothyroidotomy performed instead. Another important consideration is to ensure that caregivers provide appropriate cervical spine (C-spine) protection during the intubation procedure when neck or spinal cord injury is suspected.

The most important phase of the intubation procedure is the preprocedural preparation, when the provider ensures all the equipment and staff needed for safe intubation are present and functioning. An easy pneumonic for this is SOAP MM: suction (Yankauer suction catheter attached to wall suction); oxygen (both preoxygenation of the patient and devices needed to deliver oxygen, such as a bag-valve-mask); airway (appropriately sized endotracheal tube and laryngoscope); people (all those needed during and immediately after the
procedure, including respiratory therapists and nurses); monitor ($\text{SO}_2$, heart rate, blood pressure, capnography); and medications (sedation and often neuromuscular blockade to allow the provider(s) to control the airway). A simple formula for selecting the appropriately sized endotracheal tube (ETT) is:

$$\text{Uncuffed ETT size (in mm)} = \left(\frac{\text{age in years}}{4}\right) + 4$$

Cuffed ETTs should generally be 0.5 mm smaller. Providers should always have a range of ETTs available given the heterogeneity of patients and airway size.

Analgesia is recommended to reduce metabolic stress, discomfort, and anxiety during intubation. Pretreatment with a sedative, an analgesic, and possibly a muscle relaxant is recommended unless the situation is emergent (i.e., apnea, asystole, unresponsiveness) and the administration of drugs would cause an unacceptable delay.

Because many intubations in critically ill children are emergency procedures, caregivers should be prepared for rapid sequence intubation (RSI) (Fig. 81.12 and Table 81.4). The goals of RSI are to induce anesthesia and paralysis and to complete intubation quickly. This approach minimizes elevations of intracranial pressure and blood pressure that may accompany intubation in awake or lightly sedated patients. Because the stomach generally cannot be emptied before RSI, the Sellick maneuver (downward pressure on the cricoid cartilage to compress the esophagus against the vertebral column) should be used to prevent aspiration of gastric contents.
**Table 81.4**

ETT, Endotracheal tube; ICP, intracranial pressure.

Once the patient is intubated, proper ETT placement should be assessed by auscultation of breath sounds, evidence of symmetric chest rise, and analysis of exhaled carbon dioxide (CO₂) by a colorimetric device placed within the respiratory tubing near the ETT or a device that directly measures CO₂ elimination (capnogram or capnograph). Chest radiography is necessary to
Recognition and Management of Shock

In simple terms, shock occurs when oxygen and nutrient delivery to the tissues is inadequate to meet metabolic demands (see Chapter 88). The definition of shock does not include hypotension, and it is important for care providers to understand that shock does not begin when blood pressure drops; it merely worsens and becomes more difficult (refractory) to treat once blood pressure is abnormal.

Early compensated shock, whereby oxygen delivery is mostly preserved through compensatory mechanisms, is defined by the presence of normal blood pressure. When compensatory mechanisms fail, the shock progresses to decompensated shock, as defined by hypotension and organ dysfunction. In irreversible shock, organ failure progresses and death ensues.

Shock is also often described according to the underlying pathophysiology, which dictates the appropriate therapeutic response. Hypovolemic shock is the most common type of shock in children worldwide, usually related to fluid losses from severe diarrhea. Hemorrhage is a cause of hypovolemic shock after trauma or intestinal hemorrhage. When hypovolemia occurs because of third spacing of intravascular fluids into the extravascular compartment, the shock is described as distributive shock. The most common causes of distributive shock are sepsis, anaphylaxis, and burn injuries, in which release of inflammatory cytokines causes massive capillary leak of fluid and proteins, leading to low oncotic pressure and intravascular volume. In settings of profound myocardial dysfunction, a child has tissue hypoperfusion from cardiogenic shock. The most common causes of cardiogenic shock are myocarditis, cardiomyopathy, and congenital heart disease, generally in the postoperative setting. Obstructive shock occurs when cardiac output is lowered by obstruction of blood flow to the body, as occurs when a ductus arteriosus closes in a child with ductus-dependent systemic blood flow, pericardial tamponade, tension pneumothorax, or massive pulmonary embolism.

The evaluation of a child in shock should proceed as described in the preceding sections on primary, secondary, and tertiary assessments. If the child presents in a hospital setting, providers should generally place a central venous line to provide secure venous access and an arterial line to permit continuous blood pressure monitoring and a more thorough laboratory assessment of organ
systems, including studies of renal and liver function, acid-base balance and presence of lactic acidosis, hypoxemia and/or hypercapnia, and evidence of coagulopathy or disseminated intravascular coagulation. Chest radiography and echocardiography may also be useful. Respiratory and cardiovascular support should be provided as clinically indicated.

The treatment of shock focuses on the modifiable determinants of oxygen delivery while reducing the imbalance between oxygen supply and demand. A multipronged approach is recommended consisting of optimizing the arterial oxygen content of the blood, improving the volume and distribution of cardiac output, correcting metabolic derangements, and reducing oxygen demand. Blood oxygen content is maximized when hemoglobin values are normal and 100% of available hemoglobin is saturated with oxygen. Transfusion may be considered in the presence of hemorrhagic or distributive shock, in which crystalloid volume resuscitation has led to hemodilution and anemia. Appropriate $S_o_2$ may be achieved by simple maneuvers, such as oxygen administration by nasal cannula or face mask; supportive measures (e.g., HFNC, CPAP, BiPAP) or invasive mechanical ventilation may be necessary. Therapies to increase cardiac output should be selected on the basis of the underlying pathophysiology. For hypovolemic and distributive shock, aggressive volume resuscitation, guided by arterial and central venous pressures, is the mainstay of therapy. In obstructive shock, relief of the obstruction is critical. The ductus arteriosus can often be reopened with prostaglandin administration and tamponade physiology relieved with appropriate drainage.

**Recognition of Bradyarrhythmias and Tachyarrhythmias**

In the advanced life support (ALS) setting, arrhythmias are most usefully classified according to the observed heart rate (i.e., slow or fast) and its effect on perfusion (i.e., adequate or poor). If, in the primary survey, a caregiver finds a child with an abnormal heart rate plus poor perfusion and/or altered mental status, the rhythm is inadequate no matter its rate. In those settings the child is diagnosed with shock, and further evaluation is generally halted until appropriate resuscitation has been initiated.
Bradyarrhythmias

By definition, a child is bradycardic when the heart rate is slower than the normal range for age (see Table 81.1). Sinus bradycardia can be a harmless incidental finding in an otherwise healthy person and not usually associated with cardiac compromise. A relative bradycardia occurs when the heart rate is too slow for a child's activity level or metabolic needs. A clinically significant bradycardia occurs when the heart rate is slow and there are signs of systemic hypoperfusion (i.e., pallor, altered mental status, hypotension, acidosis). Symptomatic bradycardia occurs most often in the setting of hypoxia but can also be caused by hypoglycemia, hypocalcemia, other electrolyte abnormalities, hypothermia, heart block, and intracranial hypertension. Bradyarrhythmias are often the most common prearrest rhythms in young children.

Initial management of symptomatic bradycardia includes support or opening of the airway and confirming or establishing adequate $\text{SO}_2$ and ventilation (Fig. 81.13). After breathing has been secured, the child should be reassessed for continued bradycardia and poor perfusion. If cardiac compromise was solely the result of respiratory insufficiency, support of the child's airway and breathing may have been sufficient to restore normal hemodynamics. If respiratory support does not correct the perfusion abnormalities, further care is based on the quality of perfusion and degree of bradycardia. A heart rate $< 60$ beats/min with poor perfusion is an indication to begin chest compressions. If the bradycardia persists, vascular access should be obtained; resuscitative epinephrine should be administered, and it should be repeated every 3-5 min for persistent symptomatic bradycardia. If increased vagal tone (e.g., in the setting of head injury with increased intracranial pressure) or primary atrioventricular block is suspected, atropine can also be given. For cases of refractory bradycardia, cardiac pacing should be considered. During the resuscitation of a child with bradycardia, providers should assess and treat factors known to cause bradycardia, referred to collectively as the 6 Hs—hypoxia, hypovolemia, hydrogen ions (acidosis), hypokalemia or hyperkalemia, hypoglycemia, and hypothermia—and 5 Ts—toxins, tamponade, tension pneumothorax, thrombosis (in either the pulmonary or cardiac circulations), and trauma (causing hypovolemia, intracranial hypertension, cardiac compromise or tamponade) (Table 81.5).
Pediatric Bradycardia
With a Pulse and Poor Perfusion

Identify and treat underlying cause
- Maintain patent airway; assist breathing as necessary
- Oxygen
- Cardiac monitor to identify rhythm; monitor blood pressure and oximetry
- IO/IV access
- 12-Lead ECG if available; don’t delay therapy

Cardiopulmonary compromise continues?

No

CPR if HR <60/min with poor perfusion despite oxygenation and ventilation

Yes

Bradycardia persists?

No

Support ABCs
- Give oxygen
- Observe
- Consider expert consultation

Cardiopulmonary Compromise
- Hypotension
- Acutely altered mental status
- Signs of shock

Doses/Details
Epinephrine IO/IV Dose:
- 0.01 mg/kg (0.1 mL/kg of 1:10,000 concentration).
- Repeat every 3-5 minutes.
- If IO/IV access not available but endotracheal (ET) tube in place, may give ET dose:
- 0.1 mg/kg (0.1 mL/kg of 1:1,000).

Atropine IO/IV Dose:
- 0.02 mg/kg. May repeat once. Minimum dose 0.1 mg and maximum single dose 0.5 mg.

Yes

- Epinephrine for increased vagal tone or primary AV block
- Consider transthoracic pacing/transvenous pacing
- Treat underlying causes

If pulseless arrest develops, go to Cardiac Arrest Algorithm*

## Tachyarrhythmias

Tachyarrhythmias represent a wide variety of rhythm disturbances of atrial and ventricular origin (see Chapter 462). Sinus tachycardia is a normal physiologic response to the body's need for increased cardiac output or oxygen delivery, as occurs with fever, exercise, or stress. It can also occur in more pathologic states, such as hypovolemia, anemia, pain, anxiety, and metabolic stress. Tachyarrhythmias that do not originate in the sinus node are often categorized as narrow complex rhythms (i.e., originating in the atrium, such as atrial flutter or supraventricular tachycardia, SVT) and wide complex rhythms (i.e., rhythms of ventricular origin, such as ventricular tachycardia).

The initial management of tachycardia includes confirmation that the child has an adequate airway and life-sustaining breathing and circulation (Fig. 81.14). For children with persistent symptoms, further treatment is based on whether the QRS complex of the electrocardiogram (ECG) is narrow (≤0.09 sec) or wide (>0.09 sec). For narrow complex tachycardia, providers must distinguish between sinus tachycardia and SVT. In sinus tachycardia, (a) the history and onset are consistent with a known cause of tachycardia, such as fever or dehydration, and (b) P waves are consistently present, are of normal morphology,
and occur at a rate that varies somewhat. In supraventricular tachycardia, (a) onset is often abrupt without prodrome, and (b) P waves are absent or polymorphic, and when present, their rate is often fairly steady at or above 220 beats/min. For children with SVT and good perfusion, vagal maneuvers can be attempted. When SVT is associated with poor perfusion, providers should rapidly move to convert the child's heart rhythm back to sinus rhythm. If the child already has IV access, adenosine can be given via IV access with rapid push. Adenosine has an extremely short half-life, so a proximal IV line is best, and the adenosine should be set up with a 3-way stopcock so it can be given and immediately flushed into the circulation. If the child does not have IV access, or adenosine does not successfully convert the heart rhythm back to sinus rhythm, then synchronized cardioversion, using 0.5-1.0 joule (J)/kg, should be performed. In cases of wide complex tachycardia, providers should generally move immediately to cardioversion and increase the dose to 2 J/kg if 1 J/kg is not effective. As with cases of bradycardia, providers should review the 6 Hs and 5 Ts to identify factors that might be contributing to the tachycardia (see Table 81.5).
**FIG. 81.14** Pediatric advanced life support tachycardia algorithm. AV, Atioventricular (conductor); ECG, electrocardiogram; HR, heart rate; IO/IV, intraosseous/intravenous.

Recognition and Management of Cardiac Arrest

Cardiac arrest occurs when the heart fails as an effective pump and blood flow ceases. Outwardly, the patient in cardiac arrest presents as unresponsive and apneic with no palpable pulse. Internally, the cessation of nutrient flow causes progressive tissue ischemia and organ dysfunction. If not rapidly reversed, cardiac arrest leads to progressive deterioration in brain, heart, and other organ function, such that resuscitation and recovery are no longer possible.

Pediatric cardiac arrest is rarely caused by a sudden coronary event or arrhythmia. Instead, cardiac arrest in children is most often the end result of progressive organ and tissue ischemia, caused by tissue hypoxia, acidosis, and nutrient depletion at the end stages of respiratory deterioration, shock, or heart failure. Therefore, the most important treatment of cardiac arrest is anticipation and prevention. Intervening when a child manifests respiratory distress or early stages of shock can prevent deterioration to full arrest.

When sudden cardiac arrest does occur, it is often associated with an arrhythmia, specifically ventricular fibrillation (VF) or pulseless ventricular tachycardia (VT). In sudden events such as these, the key to successful resuscitation is early recognition of the arrhythmia and prompt treatment with high-quality CPR and defibrillation.

The principle behind high-quality CPR is that adequate chest compressions—those that circulate blood around the body with a good pulse pressure—are the most important component of CPR. The caregiver providing chest compressions should push hard, push fast, allow for complete chest recoil, and minimize interruptions. Ideally, chest compressions should be interrupted only for a rhythm check or delivery of a defibrillating shock. Providers should refer to the most recent American Heart Association (AHA) guidelines for pediatric BLS and ALS (eccguidelines.heart.org).

Cardiac arrest is recognized from general and primary survey findings consistent with a pale or cyanotic child who is unresponsive, apneic, and pulseless. Even experienced providers have a relatively high error rate when asked to determine presence or absence of pulse in a child. Therefore, any child found unresponsive and apneic can be presumed to be in cardiac arrest, and a rescuer should respond accordingly. A lone rescuer for an unwitnessed pediatric cardiac arrest in an outpatient setting should treat the arrest as
asphyxial in nature, immediately initiate CPR, and activate the emergency response system via a mobile phone (if available). If a mobile phone is not immediately available, the rescuer should perform initial rescue breaths and 2 min of chest compressions and ventilations before leaving the child to activate the emergency response system. For an in-hospital arrest, the provider should call for help and have a team member activate the emergency response system while beginning CPR. A lone rescuer in an outpatient setting who witnesses a child's sudden collapse should treat the arrest as a primary arrhythmia, should immediately activate the EMS system, and obtain an AED. On returning to the child, the rescuer should confirm pulselessness, turn on the AED, place the leads on the child's chest, and follow the defibrillator's voice commands.

The initial step in CPR for a child of any age is to restore ventilation and oxygenation as quickly as possible. On confirmation of unresponsiveness, apnea, and/or pulselessness, resuscitation should follow current AHA Basic Life Support (BLS), (or Advanced Cardiac Life Support, ACLS) guidelines, as appropriate (eccguidelines.heart.org).

If a person is pulseless, chest compressions should be initiated. Chest compressions in infants <1 yr old may be performed by placing 2 thumbs on the midsternum with the hands encircling the thorax or by placing 2 fingers over the midsternum and compressing (Figs. 81.15 and 81.16). For children >1 yr old, the care provider should perform chest compressions over the lower half of the sternum with the heel of 1 hand, or with 2 hands as used for adult resuscitation (Fig. 81.17). In all cases, care should be taken to avoid compression of the xiphoid and the ribs. When feasible, a cardiac resuscitation board should be placed under the child's back to maximize the efficiency of compressions. CPR and rescue breathing should be performed based on current AHA BLS/ACLS guidelines.
FIG. 81.15  Cardiac compressions. Top, The infant is supine on the palm of the rescuer’s hand. Bottom, Performing CPR while carrying an infant or small child. Note that the head is kept level with the torso. (From Guidelines for cardiopulmonary resuscitation and emergency cardiac care. Emergency Cardiac Care Committee and Subcommittees, American Heart Association. Part V. Pediatric basic life support, JAMA 268:2251–2261, 1992.)
**FIG. 81.16** Thumb method of chest compressions. A, Infant receiving chest compressions with thumb 1 fingerbreadth below the nipple line and hands encircling chest. B, Hand position for chest encirclement technique for external chest compressions in neonates. Thumbs are side by side over the lower third of the sternum. In the small newborn, thumbs may need to be superimposed (inset). Gloves should be worn during resuscitation. (From Fleisher GR, Ludwig S, editors: Textbook of pediatric emergency medicine, Philadelphia, 2010, Wolters Kluwer/Lippincott Williams & Wilkins Health, Fig 2.2.)

**FIG. 81.17** Locating the hand position for chest compression in a child. Note that the rescuer’s other hand is used to maintain the head position to facilitate ventilation. (From Guidelines for cardiopulmonary resuscitation and emergency cardiac care. Emergency Cardiac Care Committee and Subcommittees, American Heart Association. Part V. Pediatric basic life support, JAMA 268:2251–2261, 1992.)

The goal of CPR is to reestablish spontaneous circulation at a level that is
compatible with survival. If resuscitative efforts do not succeed in reestablishing life-sustaining breathing and circulation, the medical team must decide whether continued efforts are warranted or whether the resuscitation should be stopped. If EMS care is en route, bringing the potential for further escalation in care, such as endotracheal intubation, vascular access, and medications, CPR should be continued as long as possible or deemed reasonable by the rescuers.

In the in-hospital setting, the ECG should dictate further resuscitative efforts. For children without a pulse and in asystole or electromechanical dissociation (pulseless electrical activity, PEA), providers should continue rescue breathing and CPR, obtain vascular access, and administer emergency IV epinephrine (Fig. 81.18). For continued asystole or PEA, epinephrine can be repeated every 3-5 min. Patient history, physical exam findings, and laboratory evaluation should be used to elicit correctable causes of arrest (e.g., 6 Hs, 5 Ts; see Table 81.5). CPR should be continued after epinephrine administration, to circulate the drug through the body. After 5 cycles of CPR, providers should reassess the child for the presence of a pulse or a change in the ECG rhythm that would necessitate a different response.
Pediatric Cardiac Arrest

**Shout for Help/Activate Emergency Response**

1. Start CPR
   - Give oxygen
   - Attach monitor/defibrillator

2. Rhythm shockable?
   - Yes

       - Yes
       - Shock
         - CPR 2 min
         - Epinephrine every 3-5 min
         - Consider advanced airway
       - CPR 2 min
       - Amiodarone
       - Treat reversible causes

   - No
     - VF/VT
     - Asystole/PEA
     - Doses/Details
       - CPR Quality
         - Push hard (1/3 of anterior-posterior diameter of chest) and fast (at least 100/min) and allow complete chest recoil
         - Minimize interruptions in compressions
         - Avoid excessive ventilation
         - Rotate compressor every 2 minutes
         - If no advanced airway, 15:2 compression-ventilation ratio. If advanced airway, 8-10 breaths per minute with continuous chest compressions
       - Shock Energy for Defibrillation
         - First shock 2 J/kg, second shock 4 J/kg, subsequent shocks ≥ 4 J/kg, maximum 10 J/kg or adult dose
       - Drug Therapy
         - Epinephrine (IV) Dose: 0.01 mg/kg (0.1 mL/kg of 1:10,000 concentration). Repeat every 3-5 minutes.
         - If no IV access, may give endotracheal dose: 0.1 mg/kg (0.1 mL/kg of 1:1000 concentration).
         - Amiodarone (IV) Dose: 5 mg/kg bolus during cardiac arrest may repeat up to 2 times for refractory VF/pulseless VT.
       - Advanced Airway
         - Endotracheal intubation or supraglottic advanced airway
         - Wavelong capnography or capnometry to confirm and monitor ET tube placement.
         - Once advanced airway in place give 1 breath every 6-8 seconds (8-10 breaths per minute)
       - Return of Spontaneous Circulation (ROSC)
         - Pulse and blood pressure
         - Spontaneous arterial pressure waves with intra-arterial monitoring
       - Reversible Causes
         - Hypovolemia
         - Hypoxia
         - Hyperkalemia
         - Acidosis
         - Hyperglycemia
         - Hypothermia
         - Tension pneumothorax
         - Tamponade cardiac
         - Toxins
         - Thrombosis, pulmonary
         - Thrombosis, coronary

3. Asystole/PEA
   - 10 or 11
   - Organized rhythm → check pulse
   - Pulse present (ROSC) → post-cardiac arrest care

Go to 5 or 7
For those children with pulseless VT or VF, emergency defibrillation is indicated (Fig. 81.18). Providers should apply the pads to the child's bare chest and back and follow the verbal instructions given by the AED. For younger children, a defibrillator (if available) set to the dose of 2 J/kg should be used. Ideally, the AED used in a child ≤8 yr of age should be equipped with an attenuated adult dose or should be designed for children; if neither device is available, a standard adult AED should be used. CPR should be immediately restarted after defibrillation. Emergency dose epinephrine can also be administered with another 5 cycles of CPR to ensure its circulation throughout the child's body. If the ECG rhythm continues to show VF or VT, defibrillation can be alternated with epinephrine. For refractory VF or VT, an IV antiarrhythmic, such as lidocaine or amiodarone, can be given (Tables 81.6 and 81.7). Some adult studies have suggested that a combination of epinephrine, vasopressin, and methylprednisolone improves intact survival after CPR.

* Alternative formula for calculating an infusion: Infusion rate (mL/hr) = [weight (kg) × dose (µg/kg/min) × 60 (min/hr)]/concentration µg/mL. |
Traditionally, continuing CPR >20 min in children with in-hospital cardiac arrest has been considered futile. With current practice for CPR, survival for in-hospital cardiac arrest is approximately 40% for CPR duration <15 min, compared with approximately 12% for CPR lasting >35 min. Survivors had a favorable neurologic outcome in 70% with a CPR duration <15 min, compared with 60% for those requiring resuscitation for >35 min.

**Vascular Access**

**Venous Access**

Veins suitable for cannulation are numerous, but there is considerable anatomic variation from patient to patient. In the upper extremities, the *median antecubital vein*, located in the antecubital fossa, is often the largest and easiest to access (Fig. 81.19). Many veins on the dorsum of the hand are also suitable for cannulation because they are often large and easily located, and their cannulation is generally well tolerated. The *cephalic vein* is usually cannulated at the wrist, along the forearm, or at the elbow. The *median vein* of the forearm is also suitable as it lies along a flat surface of the forearm. In the lower extremity, the *great saphenous vein*, located just anterior to the medial malleolus, is accessible in most patients. The dorsum of the foot usually has a large vein in the midline, passing across the ankle joint, but catheters are difficult to maintain in this vein because dorsiflexion tends to dislodge them. A 2nd large vein on the lateral side of the foot, running in the horizontal plane, usually 1-2 cm dorsal to the lower margin of the foot, is preferable (Fig. 81.20). The most notable scalp veins are the *superficial temporal* (just anterior to the ear) and *posterior auricular* (just behind the ear).
Deeper and larger central veins can provide more reliable, larger-bore access
for medications, nutritive solutions, and blood sampling than peripheral venous lines. They may be reached by percutaneous cannulation or surgical exposure. In infants and young children, the femoral vein is often the easiest to access and cannulate, but the internal jugular and subclavian veins may also be used (Figs. 81.21 and 81.22). Because of its proximity to the median nerve, the brachial vein is not often recommended for cannulation.

**FIG. 81.21** Femoral vein approach. Remember the mnemonic NAVEIL for nerve, artery, vein, empty space, and lymphatics. (From Putigna F, Solenberger R: Central venous access. [http://emedicine.medscape.com/article/940865-overview](http://emedicine.medscape.com/article/940865-overview).)
### Intraosseous Access

Intraosseous (IO) needles (for intramedullary venous plexus access) are special rigid, large-bore needles. IO cannulation is recommended for patients in whom IV access proves difficult or unattainable, even in older children. If venous access is not available within approximately 1 min in a child with cardiopulmonary arrest, an IO needle should be placed in the anterior proximal tibia (with care taken to avoid traversing the epiphyseal plate). The needle should penetrate the anterior layer of compact bone, and its tip is advanced into the spongy interior of the bone (Fig. 81.23). Commercially available IO kits frequently include drills that obviate the complications of needle placement associated with manual placement. All medications, blood products, and fluids may be administered through the IO route, including medications required for emergency resuscitation. Complications are uncommon but may include osteomyelitis with prolonged infusions and tibial fracture.
If IV and IO routes are unavailable in an intubated patient, medication can be given through the ETT (epinephrine, atropine, naloxone, vasopressin).

**Arterial Access**

Arterial access is indicated when care providers need frequent blood sampling, particularly to assess adequacy of oxygenation, ventilation, or acid-base balance, and/or continuous blood pressure monitoring. The radial artery, the most commonly cannulated artery, lies on the lateral side of the anterior wrist, just medial to the styloid process of the radius (Fig. 81.24). The ulnar artery, just lateral to the tendon of the flexor carpi ulnaris, is used less often because of its proximity to the ulnar nerve. Useful sites in the lower extremity, particularly in neonates and infants, are the dorsalis pedis artery, on the dorsum of the foot between the tendons of the tibialis anterior and the extensor hallucis longus, and the posterior tibial artery, posterior to the medial malleolus. Arterial catheters require special care for insertion and subsequent management.
Thoracentesis is the placement of a needle or catheter into the pleural space to evacuate fluid, blood, or air. Most insertions are performed in one of the intercostal spaces between the 4th and 9th ribs in the plane of the midaxillary line. After appropriate systemic and local anesthesia/sedation is performed as clinically indicated, a skin incision is made, and dissection through the chest wall is accomplished in layers with use of blunt dissection techniques. The needle (and later the chest tube) that enters the pleural space should penetrate the intercostal space by passing over the superior edge of the lower rib, because there are larger vessels along the inferior edge of the rib. Ideally, the chest tube should lie anterior in the pleural space for air accumulation and posterior for fluid accumulation. A radiograph must be obtained to verify chest tube placement and evacuation of the pleural space.

Pericardiocentesis

When fluid, blood, or gas accumulates in the pericardial sac, the heart may become compressed and may be unable to fill/empty with normal volumes of blood, leading to diminished cardiac output. The cardinal signs of such a restrictive pericardial effusion are tachycardia, hypotension generally with a
narrowed pulse pressure, and decreased So\textsubscript{2}. Pericardiocentesis includes needle aspiration of the pericardial sac, often followed by the placement of a catheter for continuous drainage. As with thoracentesis, chest radiography should be done to confirm catheter location as well as evaluate for any complications, such as pneumothorax or hemothorax. Pericardiocentesis may be performed with echocardiography.

**Postresuscitation Care**

After successful resuscitation, close observation in an intensive care unit, where the child can receive ongoing multiorgan system assessments and support, is critical. Optimal postresuscitation care includes ongoing support of cardiovascular and respiratory system function as needed and the identification and treatment of other organ system dysfunction that may have contributed to (or resulted from) the child's cardiopulmonary instability. Good postresuscitation intensive care also includes supportive services for the child's parents, siblings, family, and friends.

Induced hypothermia (32-34°C [89.6-91.4°F] versus targeted temperature 36.8°C (98.2°F) (range, 36-37.5°C [96.8-99.5°F]) for about 48 hr) has not been shown to improve survival and neurologic function in pediatric survivors of CPR. However, hyperthermia must be avoided. Hypoxic-ischemic encephalopathy with subsequent development of seizures, intellectual impairment, and spasticity, is a serious and common complication of cardiac arrest. In addition, hyperglycemia and hypoglycemia should be avoided.

Postresuscitation management generally has 2 phases. First, the providers must assess the child's airway and breathing and support oxygenation and ventilation as indicated. If the child has ongoing respiratory failure and has been supported with bag-valve-mask ventilation until this time, the providers should now move forward with intubation. Once the child is intubated, mechanical ventilation must be established and respiratory assessments performed, such as chest radiography and arterial blood gas analysis. The child's circulatory system must also be assessed and supported as needed. Continuous arterial blood pressure monitoring can help the provider determine the need for, and response to, inotropic and chronotropic medications (see Table 81.7). Once the ABCs have been managed, providers can move on to full organ system assessments. A systematic approach should be used, with a full physical exam and laboratory
evaluation to reveal the child's respiratory, cardiovascular, neurologic, gastrointestinal, renal, and hematologic system function.

**Communication** with the patients’ family is an essential element of postresuscitation care. The family should be thoroughly briefed on the elements of the resuscitation performed, the child's condition, and ongoing medical concerns, uncertainties, or issues by the most senior provider available. This provider should be available to answer the family's questions, clarify information, and provide comfort. Other support staff, including social workers and chaplains, should be contacted, as the family wishes, to provide additional support and comfort. For situations in which the resuscitation is ongoing and the child is not expected to survive, it is recommended that the provider make every effort possible to have the family present at the bedside, if they wish. Family presence during CPR or other emergency resuscitative efforts, even if the child dies, is associated with a more positive medical experience than if they are excluded. In situations where the child is critically ill but stable, the family should be brought to the bedside as soon as the healthcare team deems it safe and appropriate (see Chapter 7).

**Bibliography**

Acute Care of Multiple Trauma

Cindy Ganis Roskind, Howard I. Pryor II, Bruce L. Klein

Epidemiology

Injury is a leading cause of death and disability in children throughout the world (see Chapter 13). Deaths represent only a small fraction of the total trauma burden. Approximately 140,000 children were treated in U.S. trauma centers in 2016 for serious injury. Many survivors of trauma have permanent or temporary functional limitations. Motor vehicle–related injuries and falls rank among the top 15 causes of disability-adjusted life years in children worldwide.

Trauma is frequently classified according to the number of significantly injured body parts (≥1), the severity of injury (mild, moderate, or severe), and the mechanism of injury (blunt or penetrating). In childhood, blunt trauma predominates, accounting for the majority of injuries. In adolescence, penetrating trauma increases in frequency, accounting for approximately 15% of injuries, and penetrating trauma secondary to a firearm is associated with a high case fatality rate of 11%.

Regionalization and Trauma Teams

Mortality and morbidity rates have decreased in geographic regions with comprehensive, coordinated trauma systems. Treatment at designated trauma centers is associated with decreased mortality. At the scene of injury, paramedics should administer necessary advanced life support and perform triage (Fig. 82.1). It is usually preferable to bypass local hospitals and rapidly transport a seriously injured child directly to a pediatric trauma center (or a trauma center with pediatric commitment). Children have lower mortality rates, lower complication rates, and less operative interventions after severe blunt trauma
when they are treated in designated pediatric trauma centers or in hospitals with pediatric intensive care units.
Measure vital signs and level of consciousness

Step One

- Glasgow Coma Scale ≤13
- Systolic Blood Pressure (mmHg) <90
- Respiratory rate ≤10 or ≥29 breaths per minute
  (≥20 in infant aged <1 year), or need for ventilatory support

Assess anatomy of injury

No

Step Two

- All penetrating injuries to head, neck, torso, and extremities proximal to elbow or knee
- Chest wall instability or deformity (e.g., flail chest)
- Two or more proximal long-bone fractures
- Crushed, depressed, mangled, or pathologic extremity
- Amputation proximal to wrist or ankle
- Pelvic fractures
- Open or depressed skull fracture
- Paralysis

Assess mechanism of injury and evidence of high-energy impact

Yes

Step Three

- Falls
  - Adults: ≥20 feet (one story is equal to 10 feet)
  - Children: ≥10 feet or two or three times the height of the child
- High-risk auto crash
- Intoxication**, including (e.g., ≥12 inches occupant seat; ≥18 inches any seat)
- Ejection (partial or complete) from automobile
- Death in same passenger compartment
- Vehicle telemetry data consistent with a high risk of injury
- Auto vs. pedestrian/cyclist/thrower; run-over, or with significant (>20 mph) impact†††
- Motorcycle crash ≥20 mph

Assess special patient or system considerations

Yes

Step Four

- Older adults†††
  - Risk of many/many deaths increases after age 65 years
  - SEER ≥110 might represent shock after age 65 years
- Low impact mechanisms (e.g., ground-level falls) might result in severe injury
- Children
  - Should be triaged preferentially to pediatric capable trauma centers
- Anticoagulants and bleeding disorders
- Patients with head injury are at high risk for rapid deterioration
- Burns
  - Without other trauma mechanism: triage to burn facility**
- With trauma mechanism: triage to trauma center***
- Pregnancy >20 weeks
- EMS provider judgment

Transport according to protocol†††

When in doubt, transport to a trauma center

* The upper limit of respiratory rate in infants is >20 breaths per minute to maintain a higher level of over-diagnosis for infants.

† Trauma centers are designated Level I-IV. A Level I center has the greatest amount of resources and personnel for care of the injured patient and provides regional leadership in education, research, and prevention programs. A Level II facility offers similar resources to a Level I facility, possibly differing only in the continuous availability of certain subspecialties or sufficient prevention, education, and research activities for Level I designation. Level II facilities are not required to be resident of follow education centers. A Level III center is capable of assessment, resuscitation, and emergency surgery, with severely injured patients being transferred to a Level I or II facility. A Level IV trauma center is capable of providing 24-hour physician coverage, resuscitation, and stabilization to injured patients before transfer to a facility that provides a higher level of trauma care.

‡ Any injury noted in Step Two or mechanism identified in Step Three triggers a "yes" response.

§ Age <13 years.

** Intoxication refers to interior compartment intoxification, as opposed to intoxication which refers to exterior damage.

†† Includes pedestrians or bicyclists thrown or run over by a motor vehicle or those with estimated impact >20 mph with a motor vehicle.

‡‡‡ Local or regional protocols should be used to determine the most appropriate level of trauma center within the defined trauma system, need not be the highest-level trauma center.

††† Age ≥65 years.

** Patients with both burns and concomitant trauma for whom the burn injury poses the greatest risk for morbidity and mortality should be transferred to a burn center. If the burn trauma patient presents a greater immediate risk, the patient may be stabilized in a trauma center and then transferred to a burn center.

*** Patients who do not meet any of the triage criteria in Steps One through Four should be transported to the most appropriate medical facility as outlined in local EMS protocols.
FIG. 82.1 Guidelines for field triage of injured patients—United States, 2011. (From Guidelines for field triage of injured patients: recommendations of the National Expert Panel on Field Triage, MMWR 61:6, 2012.)

When the receiving emergency department (ED) is notified before the child's arrival, the trauma team should also be mobilized in advance. Each member has defined tasks. A senior surgeon (surgical coordinator) or, sometimes initially, an emergency physician leads the team. Team compositions vary somewhat from hospital to hospital; Fig. 82.2 shows the model used at The Johns Hopkins Hospital Bloomberg Children's Center (Baltimore, MD). Consultants, especially neurosurgeons and orthopedic surgeons, must be promptly available; and the operating room staff should be alerted.
Physiologic status, anatomic locations, and/or mechanism of injury are used for field triage as well as to determine whether to activate the trauma team. More importance should be placed on physiologic compromise and less on mechanism of injury. Scoring scales such as the Abbreviated Injury Scale (AIS), Injury Severity Score (ISS), Pediatric Trauma Score (Table 82.1), and Revised Trauma
Score use these parameters to predict patient outcome. The AIS and ISS are used together. First, the AIS is used numerically to score injuries—as 1 minor, 2 moderate, 3 serious, 4 severe, 5 critical, or 6 probably lethal—in each of 6 ISS body regions: head/neck, face, thorax, abdomen and pelvic contents, extremities and bony pelvis, and external. The ISS is the sum of the squares of the highest 3 AIS region scores.

* Children with a Pediatric Trauma Score ≤6 are at increased risk of mortality as well as morbidity.

BP, Blood pressure; CNS, central nervous system; LOC, loss of consciousness.

**Primary Survey**

During the primary survey, the physician quickly assesses and treats any life-threatening injuries. The principal causes of death shortly after trauma are airway obstruction, respiratory insufficiency, shock from hemorrhage, and central nervous system (CNS) injury. The primary survey addresses the ABCDEs: Airway, Breathing, Circulation, neurologic Deficit, and Exposure of the patient and control of the Environment.

**Airway/Cervical Spine**

Optimizing oxygenation and ventilation, while protecting the cervical spine (C-spine) from potential further injury, is of paramount importance. Initially, C-spine injury should be suspected in any child sustaining multiple, blunt trauma. Although C-spine injuries occur less often in children than adults, children are at
risk for such injuries because of their relatively large heads in proportion to the rest of their body, which augment flexion-extension forces, and weak neck muscles, which predispose them to ligament injuries. To prevent additional spinal injury, paramedics have traditionally been taught to immobilize the cervical (and thoracic and lumbar) spine in neutral position with a stiff collar, head blocks, tape or cloth placed across the forehead, torso, and thighs to restrain the child, and a rigid backboard.

Airway obstruction manifests as snoring, gurgling, hoarseness, stridor, and/or diminished breath sounds (even with apparently good respiratory effort). Children are more likely than adults to have airway obstruction because of their smaller oral and nasal cavities, proportionately larger tongues and more tonsillar and adenoidal tissue, higher and more anterior glottic opening, and narrower larynx and trachea. Obstruction is common in patients with severe head injuries, partly because of decreased muscle tone, which allows the tongue to fall posteriorly and occlude the airway. With trauma, obstruction can also result from fractures of the mandible or facial bones, secretions such as blood or vomit, crush injuries of the larynx or trachea, and foreign body aspiration.

*If it is necessary to open the airway, a jaw thrust without head tilt is recommended. This procedure minimizes cervical spine motion.* In an unconscious child, an oropharyngeal airway may be inserted to prevent posterior displacement of the mandibular tissues. A semiconscious child will gag with an oropharyngeal airway but may tolerate a nasopharyngeal airway. A nasopharyngeal airway is contraindicated when there is a possibility of cribriform plate fracture. If these maneuvers plus suctioning do not clear the airway, oral endotracheal intubation is indicated. When endotracheal intubation proves difficult, a laryngeal mask airway can be used as a temporary alternative. A laryngeal mask airway consists of a tube with an inflatable cuff that rests above the larynx and thus does not require placement of the tube into the trachea. Video-assisted laryngoscopy or the use of a bougie can also be helpful in the management of a difficult airway. Emergency cricothyrotomy is needed in <1% of trauma victims.

**Breathing**

The physician assesses breathing by counting the respiratory rate; visualizing chest wall motion for symmetry, expansion, and accessory muscle use; and auscultating breath sounds in both axillae. Continuous waveform capnography
monitoring should also be used as an adjunct; however, it is less reliable in patients with shock. In addition to looking visually for cyanosis, pulse oximetry is standard. If ventilation is inadequate, bag-valve-mask ventilation with 100% oxygen must be initiated immediately, followed by endotracheal intubation. End-expiratory carbon dioxide (CO$_2$) detectors or capnography help verify accurate tube placement.

Head trauma is the most common cause of respiratory insufficiency. An unconscious child with severe head injury may have a variety of breathing abnormalities, including Cheyne-Stokes respiration, slow irregular breaths, and apnea.

Although less common than a pulmonary contusion, tension pneumothorax and massive hemothorax are immediately life threatening (Tables 82.2 and 82.3). Tension pneumothorax occurs when air accumulates under pressure in the pleural space. The adjacent lung is compacted, the mediastinum is pushed toward the opposite hemithorax, and the heart, great vessels, and contralateral lung are compressed or kinked (see Chapter 439). Both ventilation and cardiac output are impaired. Characteristic findings include cyanosis, tachypnea, retractions, asymmetric chest rise, contralateral tracheal deviation, diminished breath sounds on the ipsilateral (more than contralateral) side, and signs of shock. Needle thoracentesis, followed by thoracostomy tube insertion, is diagnostic and lifesaving. Hemothorax results from injury to the intercostal vessels, lungs, heart, or great vessels. When ventilation is adequate, fluid resuscitation should begin before evacuation, because a large amount of blood may drain through the chest tube, resulting in shock.

Table 82.3  
Life-Threatening Chest Injuries

**Tension Pneumothorax**  

- One-way valve leak from the lung parenchyma or tracheobronchial tree  
- Lung collapse with mediastinal and tracheal shift to the side opposite the leak  
- Compromises venous return and decreases ventilation of the other lung  
- Clinically, manifests as respiratory distress, unilateral absence of breath sounds, tracheal deviation, distended neck veins, tympany to percussion of the involved side, and cyanosis  
- Relieve first with needle aspiration, then with chest tube drainage  

**Open Pneumothorax (Sucking Chest Wound)**  

- Effect on ventilation depends on size  

**Major Flail Chest**  

- Usually caused by blunt injury resulting in multiple rib fractures  
- Loss of bone stability of the thoracic cage  
- Major disruption of synchronous chest wall motion  
- Mechanical ventilation and positive end-expiratory pressure required  

**Massive Hemothorax**  

- Must be drained with a large-bore tube  
- Initiate drainage only with concurrent vascular volume replacement  

**Cardiac Tamponade**
Beck's triad:
1. Decreased or muffled heart sounds
2. Jugular venous distention
3. Hypotension (with narrow pulse pressure)
   Must be drained

Circulation

Signs of shock include tachycardia; weak pulse; delayed capillary refill; cool, mottled, pale skin; and altered mental state (see Chapter 88 ). The most common type of shock in trauma is hypovolemic shock caused by hemorrhage. Cardiac tamponade, which is a form of obstructive shock, may be suspected clinically or diagnosed by focused assessment with sonography in trauma (FAST) examination or echocardiography. Cardiac tamponade is best managed by thoracotomy or pericardial window, although pericardiocentesis may be necessary as a temporizing maneuver (see Table 82.3 ).

Early in shock, blood pressure remains normal because of compensatory increases in heart rate and peripheral vascular resistance (Table 82.4 ). Some individuals can lose up to 30% of blood volume before blood pressure declines. It is important to note that 25% of blood volume equals 20 mL/kg, which is only 200 mL in a 10 kg child. Losses >40% of blood volume cause severe hypotension that, if prolonged, may become irreversible. Direct pressure should be applied to control external hemorrhage. When direct pressure does not control hemorrhage, a tourniquet should be applied to a proximal pressure point. Blind clamping of bleeding vessels, which risks damaging adjacent structures, is not advisable.

</table>
Cannulating a larger vein, such as an antecubital vein, is usually the quickest way to achieve intravenous (IV) access. A short, large-bore catheter offers less resistance to flow, allowing for more rapid fluid administration. Ideally, a 2nd catheter should be placed within the first few minutes of resuscitation in a severely injured child. If IV access is not rapidly obtainable, an intraosseous (IO) needle should be inserted; all medications and fluids can be administered intraosseously. Other alternatives are central venous access using the Seldinger technique (e.g., in the femoral vein) and, rarely, surgical cutdown (e.g., in saphenous vein). Ultrasonography should be used to facilitate central venous catheter placement, if possible.

Traditionally, fluids are administered aggressively early in hemorrhagic shock to reverse and prevent further clinical deterioration. Isotonic crystalloid solution, such as lactated Ringer injection or normal saline (20 mL/kg), should be infused rapidly. When necessary, repeated crystalloid boluses may be given. Most children are stabilized with administration of crystalloid solution alone. However, if the patient remains in shock after boluses totaling 40-60 mL/kg of crystalloid, packed red blood cells should be transfused. Massive transfusion protocols (including fresh-frozen plasma) should be initiated early to prevent coagulopathy. When shock persists despite these measures, surgery to stop internal hemorrhage is usually indicated. Although literature is emerging regarding the benefits of permissive hypotension, hemostatic resuscitation, and damage control surgery for adult trauma patients, currently there are no pediatric data.

### Neurologic Deficit

Neurologic status is briefly assessed by determining the level of consciousness and evaluating pupil size and reactivity. The level of consciousness can be
classified using the mnemonic **AVPU**: Alert, responsive to Verbal commands, responsive to Painful stimuli, or Unresponsive.

At least 75% of pediatric blunt trauma deaths are accounted for by head injuries. Primary direct cerebral injury occurs within seconds of the event and is irreversible. Secondary injury is caused by subsequent anoxia or ischemia. *The goal is to minimize secondary injury by ensuring adequate oxygenation, ventilation, and perfusion, and maintaining normal cerebral perfusion pressure.*

A child with severe neurologic impairment—i.e., with a Glasgow Coma Scale (GCS; see Chapter 85 ) score of $\leq 8$—should undergo endotracheal intubation and supportive mechanical ventilation.

Signs of **increased intracranial pressure** (ICP), including progressive neurologic deterioration and evidence of transtentorial herniation, must be treated immediately (see Chapter 85 ). Hyperventilation lowers the arterial partial pressure of carbon dioxide ($\text{PaCO}_2$), resulting in cerebral vasoconstriction, reduced cerebral blood flow, and decreased ICP. Brief hyperventilation remains an immediate option for patients with acute increases in ICP. Prophylactic hyperventilation, or vigorous or prolonged hyperventilation, is not recommended, because the consequent vasoconstriction may excessively decrease cerebral perfusion and oxygenation. Mannitol lowers ICP and may improve survival. Because mannitol induces an osmotic diuresis, it can exacerbate hypovolemia and must be used cautiously. Hypertonic saline may be a more useful agent for control of increased ICP in patients with severe head injury. Neurosurgical consultation is mandatory. If signs of increased ICP persist, the neurosurgeon must decide whether to operate emergently.

**Exposure and Environmental Control**

*All clothing should be cut away to reveal any injuries.* Cutting is quickest and minimizes unnecessary patient movement. Children often arrive in the ED mildly hypothermic because of their higher body surface area-to-mass ratios. They can be warmed with use of radiant heat as well as heated blankets and IV fluids.

**Secondary Survey**

During the secondary survey, the physician completes a detailed, head-to-toe physical examination.
Head Trauma

A GCS or Pediatric GCS score (see Chapter 85) should be assigned to every child with significant head trauma. This scale assesses eye opening and motor and verbal responses. In the Pediatric GCS, the verbal score is modified for age. The GCS helps categorize neurologic disability, and serial measurements identify improvement or deterioration over time. Patients with low scores 6-24 hr after injuries have poorer prognosis.

In the ED, cranial CT scanning of the head without a contrast agent has become standard to determine the type of injury in patients with concerning findings. Diffuse cerebral injury with edema is a common and serious finding on CT scan in severely brain-injured children. Focal hemorrhagic lesions (e.g., epidural hematoma) that can be evacuated occur less often but may require immediate neurosurgical intervention (Fig. 82.3).

**FIG. 82.3** Epidural hematoma. CT head scan from 7 mo old girl who, according to the history provided, did not wake up for her nightly feeding and began vomiting in the morning. The mother's boyfriend reported that the infant had fallen from a chair the previous day. The CT scan shows a large epidural hematoma on the right and marked shift of the midline from right to left. The right lateral ventricle is compressed as a result of the mass effect, and the left lateral ventricle is slightly prominent. The infant underwent emergency surgical evacuation of the epidural hematoma and recovered uneventfully. (From O'Neill JA Jr: Principles of pediatric surgery, ed 2, St Louis, 2003, Mosby, p 191.)
Monitoring of ICP should be strongly considered for children with severe brain injury, particularly for those with a GCS score of ≤8 and abnormal head CT findings (see Chapter 85). One advantage of an intraventricular catheter over an intraparenchymal device is that cerebrospinal fluid can be drained to treat acute increases in ICP. Hypoxia, hypercarbia, hypotension, and hyperthermia must be aggressively managed to prevent secondary brain injury. Cerebral perfusion pressure (i.e., the difference between mean arterial blood pressure and mean ICP) should be maintained >40 mm Hg, at least (and an even higher minimum, >50 mm Hg, especially for older children).

A child with a severe brain injury must be treated aggressively in the ED because it is difficult to predict the long-term neurologic outcome.

**Cervical Spine Trauma**

Cervical spine injuries occur in <3% of children with blunt trauma—with the risk being substantially higher in those with GCS scores ≤8—but they are associated with significant mortality and morbidity. Bony injuries occur mainly from C1 to C4 in children younger than 8 yr. In older children, they occur equally in the upper and lower cervical spine. The mortality rate is significantly higher in patients with upper C-spine injuries. Spinal cord injury without radiographic abnormalities (SCIWORA) on plain films or CT may be present. Patients with SCIWORA have neurologic symptoms, and spinal cord abnormalities are nearly always noted on MRI. Approximately 30% of all patients with C-spine injuries have permanent neurologic deficits.

Evaluation begins with a detailed history and neurologic examination. Identifying the mechanism of injury helps in estimating the likelihood of a C-spine injury. Both the patient and the paramedic should be asked whether any neurologic symptoms or signs, such as weakness or abnormal sensation, were present before arrival in the ED. In a child with neurologic symptoms and normal findings on C-spine plain radiographs and CT scan, SCIWORA must be considered.

Whenever the history, physical examination, or mechanism of injury suggests a C-spine injury, radiographs should be obtained after initial resuscitation. The National Emergency X-Radiography Utilization Study (NEXUS) cervical spine rule helps identify low-risk patients who may not require radiographs (Table 82.5). The standard series of plain radiographs includes lateral, anteroposterior (AP), and odontoid views. Some centers use cervical spine CT as
the primary diagnostic tool, particularly in patients with abnormal GCS scores and/or significant injury mechanisms, recognizing that CT is more sensitive in detecting bony injury than plain radiographs. CT is also helpful if an odontoid fracture is suspected, because young children typically do not cooperate enough to obtain an open-mouth (odontoid) radiographic view. Use of cervical spine CT scan must be balanced with the knowledge that CT exposes thyroid tissue to 90-200 times the amount of radiation from plain films. MRI is indicated in a child with suspected SCIWORA and in the evaluation of children who remain obtunded.

Table 82.5
National Emergency X-Radiography Utilization Study (NEXUS) to Rule Out Cervical Spine Injury Following Blunt Trauma

| If none of the following is present, the patient is at very low risk for clinically significant cervical spine injury: |
| Midline cervical tenderness |
| Evidence of intoxication |
| Altered level of alertness |
| Focal neurologic deficit |
| Distracting painful injury |

Rapid diagnosis of spinal cord injury is essential. Initiating high-dose IV methylprednisolone within 8 hr of spinal cord injury has been reported to improve motor outcome, but this treatment has become controversial.

**Thoracic Trauma**
**Pulmonary contusions** occur frequently in young children with blunt chest trauma. A child's chest wall is relatively pliable; therefore, less force is absorbed by the rib cage, and more is transmitted to the lungs. Respiratory distress may be noted initially or may develop during the 1st 24 hr after injury.

**Rib fractures** result from significant external force. They are noted in patients with more severe injuries and are associated with a higher mortality rate. Flail chest, which is caused by multiple rib fractures, is rare in children. Table 82.6 lists indications for operative management in thoracic trauma. (See Table 82.2 for the differential diagnosis of immediately life-threatening cardiopulmonary injuries.)

Abdominal Trauma

Liver and spleen contusions, hematomas, and lacerations account for the majority of intraabdominal injuries from blunt trauma. The kidneys, pancreas, and duodenum are relatively spared because of their retroperitoneal location. Pancreatic and duodenal injuries are more common after a bicycle handlebar impact or a direct blow to the abdomen.

Although a thorough examination for intraabdominal injuries is essential, achieving it often proves difficult. Misleading findings can result from gastric distention after crying or in an uncooperative toddler. Calm reassurance, distraction, and gentle, persistent palpation help with the examination. Important findings include distention, bruises, and tenderness. Specific symptoms and signs give insight into the mechanism of injury and the potential for particular injuries. Pain in the left shoulder may signify splenic trauma. A lap belt mark across the abdomen raises concern for bowel or mesentery injury. The presence of certain other injuries, such as lumbar spinal fractures and femur fractures, increases the likelihood of intraabdominal injury.

An abdominal (and pelvic) CT scan with IV contrast medium enhancement rapidly identifies structural abnormalities and is the preferred study in a stable child. Negative abdominal CT scan has been shown to have a negative predictive value (NPV) of 99.6%. It has excellent sensitivity and specificity for splenic (Fig. 82.4), hepatic (Fig. 82.5), and renal injuries, but is less sensitive for diaphragmatic, pancreatic, or intestinal injuries. Small amounts of free fluid or air or a mesenteric hematoma may be the only sign of an intestinal injury. Administration of an oral contrast agent is not routinely recommended for all abdominal CT scans, but it sometimes aids in identifying an intestinal, especially a duodenal, injury.
FIG. 82.4  Splenic rupture. CT scan with intravenous and gastrointestinal contrast enhancement shows an isolated splenic rupture that resulted from blunt trauma. This injury responded to nonoperative management, as do most splenic injuries. (From O'Neill JA Jr: Principles of pediatric surgery, ed 2, St Louis, 2003, Mosby, p 166.)

FIG. 82.5  Liver injury. CT scan performed after severe blunt injury of the abdomen shows a bursting injury of the liver. The patient was stable, and no operative intervention was required. The decision to perform surgery should be based on the patient's physiologic stability. (From O'Neill JA Jr: Principles of pediatric surgery, ed 2, St Louis, 2003, Mosby, p 168.)

Although the FAST examination helps detect hemoperitoneum, the variably low sensitivity of this test in children suggests that it should not be used alone to
exclude intraabdominal injury in patients with a moderate to high pretest probability for injury. A positive FAST exam for hemoperitoneum requires further investigation. Serial FAST exams over time (by a skilled ultrasonographer) may be used to rule out injury in need of intervention. The FAST exam is most clinically useful in patients who have blunt trauma and are hemodynamically unstable or in patients who require operative intervention for nonabdominal injuries, because in these cases the performance of a CT scan may not be feasible.

Nonoperative treatment has become standard for hemodynamically stable children with splenic, hepatic, and renal injuries from blunt trauma. The majority of such children can be treated nonsurgically. In addition to avoiding perioperative complications, nonoperative treatment decreases the need for blood transfusions and shortens hospital stay. When laparotomy is indicated, splenic repair is preferable to splenectomy.

**Pelvic Trauma**

Pelvic fractures in children are much less common than in adults, occurring in approximately 4% of children with more severe blunt trauma. Pelvic fractures are typically caused by high forces (e.g., high-speed motor vehicle crashes or pedestrian impacts) and are often associated with intraabdominal and/or vascular injuries. The pelvis itself forms a ring, and high-force impacts can lead to disruption of this ring. When the ring is disrupted in >1 location, such as the symphysis pubis and the sacroiliac joint, the ring can become unstable and displaced, potentially injuring large pelvic vessels and leading to massive blood loss. Catheter-directed embolization to control bleeding, performed by an interventional radiologist, may be required.

The pelvis should be assessed for stability by means of compression-distraction maneuvers. If instability is noted, immediate external fixation with a pelvis-stabilizing device or a sheet should be applied and orthopedic consultation sought. A trauma patient with a potential pelvic fracture should receive an AP pelvic radiograph in the trauma bay, or a CT scan, if there is high suspicion of injury. Children without a high-risk clinical finding (i.e., GCS <14; abdominal pain or tenderness; pelvic tenderness, laceration, ecchymosis, or abrasion; gross hematuria or >20 red blood cells/high-power field on urinalysis; or femur fracture) or a high-risk mechanism of injury (i.e., unrestrained motor vehicle collision, motor vehicle collision with ejection, motor vehicle collision rollover,
auto vs pedestrian, or auto vs bicycle), however, are unlikely to have pelvic fractures.

**Lower Genitourinary Trauma**

The perineum should be inspected and the stability of the bones of the pelvis assessed. Urethral injuries are more common in males. Findings suggestive of urethral injury include scrotal or labial ecchymosis, blood at the urethral meatus, gross hematuria, and a superiorly positioned prostate on rectal examination (in an adolescent male). Certain pelvic fractures also increase the risk for potential genitourinary injury. Any of these findings is a contraindication to urethral catheter insertion and warrants consultation with a urologist. Retrograde urethrocystogram and CT scan of the pelvis and abdomen are used to determine the extent of injury.

**Extremity Trauma**

Thorough examination of the extremities is essential because extremity fractures are among the most frequently overlooked injuries in children with multiple trauma. All limbs should be inspected for deformity, swelling, and bruises; palpated for tenderness; and assessed for active and passive range of motion, sensory function, and perfusion.

Before radiographs are obtained, suspected fractures and dislocations should be immobilized and an analgesic administered. Splinting a femur fracture helps alleviate pain and may decrease blood loss. An orthopedic surgeon should be consulted immediately to evaluate children with compartment syndrome, neurovascular compromise, open fracture, or most traumatic amputations.

**Radiologic and Laboratory Evaluation**

Most authorities recommend ordering multiple laboratory tests (e.g., complete blood cell count, electrolytes, glucose, blood urea nitrogen, creatinine, liver function tests, amylase, lipase, lactate, blood gas, prothrombin and partial thromboplastin times, type and cross-match, urinalysis) and x-ray films (e.g., lateral C-spine, AP chest, AP pelvis) in the ED. One benefit of standardizing the evaluation of patients with major trauma is that fewer decisions need to be made on an individual basis, possibly expediting ED management. Some of these
studies have prognostic importance. A large base deficit is associated with a higher mortality rate, and elevated lactate values correlate with poor prognosis.

There are some limitations in standard tests. The lateral cervical spine radiograph can miss clinically significant injuries. Hemoglobin and hematocrit values provide baseline values in the ED, but they may not have yet equilibrated after a hemorrhage. Abnormal liver function test results or elevated serum amylase and lipase values may be noted in patients with significant abdominal trauma, but most patients with significant trauma to the abdomen already have clinical indications for CT scanning or surgery. The majority of previously healthy children have normal coagulation profiles; these may become abnormal after major head trauma. Although routine urinalysis or dipstick urine testing for blood has been recommended for children, other data suggest that this evaluation may be unnecessary in patients without gross hematuria, hypotension, or other associated abdominal injuries.

Clinical prediction rules that combine patient history with physical examination findings have been developed to identify those at low risk of injury for whom specific radiographic and laboratory studies may not be necessary. The NEXUS C-spine rule is a sensitive, easily applicable rule that was validated for adults and children, although there were fewer young patients studied (see Table 82.5). Several clinical prediction rules have been developed to identify children at low risk of traumatic brain injury (Table 82.7). Another clinical prediction rule has been developed to identify children at very low risk of clinically important intraabdominal injuries following blunt trauma (Table 82.8). Although this rule has an NPV of 99.9%, it needs to be externally validated before widespread implementation.

Children 2-18 yr old are at very low risk of clinically important traumatic brain injury if they have none of the following:
Severe mechanism of injury
History of LOC
History of vomiting
GCS ≤14 or other signs of altered mental status
Severe headache in the ED
Signs of basilar skull fracture

ED, Emergency department; GCS, Glasgow Coma Scale score; LOC, loss of consciousness.

Table 82.8
Prediction Rule for Identification of Children at Very Low Risk of Clinically Important Intraabdominal Injuries After Blunt Trauma

If none of the following is present, the patient is at very low risk for clinically significant intraabdominal injury:
- Glasgow Coma Scale score <14
- Vomiting
- Evidence of thoracic wall trauma
- Decreased breath sounds
- Evidence of abdominal wall trauma or seatbelt sign
- Abdominal pain
- Abdominal tenderness

Psychological and Social Support

Serious multisystem trauma may result in significant long-term psychological and social difficulties for the child and family, particularly when there is a major head injury. Like adults, children are at risk for depressive symptoms and posttraumatic stress disorder. Caregivers face persistent stress and have been noted to have more psychological symptoms. Psychological and social support, during the resuscitation period and afterward, is extremely important. Parents often prefer to be offered the choice to be present during resuscitations. A member of the resuscitation team should be made responsible for answering the family's questions and supporting them in the trauma room.

CHAPTER 83

Spinal Cord Injuries in Children

Mark R. Proctor

See also Chapter 729.

Compared with adults, spine and spinal cord injuries are rare in children, particularly young children, because of both anatomic differences and etiologies of injury. The main mechanisms of injury to the spine are motor vehicle crashes, falls, sports, and violence, which affect young children less often (see Chapter 82).

Several anatomic differences affect the pediatric spine. The head of a young child is larger relative to body mass than in adults, and the neck muscles are still underdeveloped, which places the fulcrum of movement higher in the spine. Therefore, children <9 yr old have a higher percentage of injuries in the upper cervical spine than older children and adults. The spine of a small child also is very mobile, with pliable bones and ligaments, so fractures of the spine are exceedingly rare. However, this increased mobility is not always a positive feature. Transfer of energy leading to spinal distortion may not affect the structural integrity of the bones and ligaments of the spine but can still lead to significant injuries of the spinal cord. This phenomenon of spinal cord injury without radiographic abnormalities (SCIWORA) is more common in children than adults. The term is relatively outdated, since almost all injuries are detectable by MRI, but is still clinically useful when referring to spinal cord injuries evaluated by plain radiographs or CT. There seem to be 2 distinct forms of SCIWORA. The infantile form involves severe injury of the cervical or thoracic spinal cord; these patients have a poor chance of complete recovery. In older children and adolescents, SCIWORA is more likely to be a less severe injury, with a high likelihood of complete recovery over time. The adolescent form, also called transient neurapraxia, is assumed to be a spinal cord concussion or mild contusion, as opposed to the severe spinal cord injury related
to the mobility of the spine in small children.

Although the mechanisms of spinal cord injury in children include birth trauma, falls, and child abuse, the major cause of morbidity and mortality across all ages remains motor vehicle injuries. Adolescents incur spinal cord injuries with epidemiology similar to that of adults, including significant male predominance and a high likelihood of fracture dislocations of the lower cervical spine or thoracolumbar region. In infants and children <5 yr old, fractures and mechanical disruption of spinal elements are more likely to occur in the upper cervical spine between the occiput and C3, for the reasons previously discussed.

**Clinical Manifestations**

One in 3 patients with significant trauma to the spine and spinal cord will have a concomitant severe head injury, which makes early diagnosis challenging. For these patients, clinical evaluation may be difficult. Patients with a potential spine injury need to be maintained in a protective environment, such as a collar, until the spine can be cleared by clinical and/or radiographic means. A careful neurologic examination is necessary for infants with suspected spinal cord injuries. Complete spinal cord injury will lead to spinal shock with early areflexia (see Chapter 729). Severe cervical spinal cord (C-spine) injuries will usually lead to paradoxical respiration in patients who are breathing spontaneously. Paradoxical respiration occurs when the diaphragm, which is innervated by the phrenic nerves with contributions from C3, C4, and C5, is functioning normally, but the intercostal musculature innervated by the thoracic spinal cord is paralyzed. In this situation, inspiration fails to expand of the chest wall but distends the abdomen. Other complications during the acute (2-48 hr) phase include autonomic dysfunction (brady- and tachyarrhythmias, orthostatic hypotension, hypertension), temperature instability, thromboembolism, dysphagia, and bowel/bladder dysfunction.

The mildest injury to the spinal cord is transient quadriparesis evident for seconds or minutes with complete recovery in 24 hr. This injury follows a concussion of the cord and is most frequently seen in adolescent athletes. If their imaging is normal, these children can generally return to normal activities after a period of rest from days to weeks, depending on the initial severity, similar to cerebral concussion management.

Significant spinal cord injury in the cervical region is characterized by: flaccid quadriparesis, loss of sphincter function, and a sensory level corresponding to
the level of injury. An injury at the high cervical level (C1-C2) can cause respiratory arrest and death in the absence of ventilatory support. Injuries in the thoracic region are generally the result of fracture dislocations. They may produce paraplegia when at T10 or above, or the conus medullaris syndrome if at the T12-L1 level. This includes a loss of urinary and rectal sphincter control, flaccid weakness, and sensory disturbances of the legs. A central cord lesion may result from contusion and hemorrhage in the center of the spinal cord. It typically involves the upper extremities to a greater degree than the legs, because the motor fibers to the cervical and thoracic region are more centrally located in the spinal cord. There are lower motor neuron signs in the upper extremities and upper motor neuron signs in the legs, bladder dysfunction, and loss of sensation caudal to the lesion. There may be considerable recovery, particularly in the lower extremities, although sequelae are common (see Chapter 729).

**Clearing the Cervical Spine in Children**

The management of children following major trauma is challenging. For older children, the clearance is similar to a lucid adult, and the NEXUS (National Emergency X-Radiography Utilization Study) criteria are appropriate (see Chapter 82, Table 82.5). Clearing the cervical spine in younger and uncooperative children involves similar issues as in adults with an altered level of consciousness. Small children generally have a difficult-to-assess physical examination, and it is difficult to determine if they have cervical pain. Plain radiography remains a mainstay for assessing the spine because it is easy to obtain. There has been increasing emphasis on MRI for evaluation of potential C-spine instability, but in small children MRI requires sedation and in most centers the presence of an anesthesiologist (Fig. 83.1). CT scan is another important study with high sensitivity and specificity, but the risk of radiation exposure must be considered.
FIG. 83.1  T2-weighted MRI performed the day after the accident showed cervical spinal cord swelling combined with high signal intensity (C1-C3) (arrow) and dislocation of C5-C6 (arrowhead). (From Inoue K, Kumada T, Fujii T, Kimura N: Progressive cervical spinal cord atrophy after a traffic accident, J Pediatr 180:287, 2017, Fig 1, p 287.)

**Treatment**

The cervical spine should be immobilized in the field by the emergency medical technicians. In cases of acute spinal cord injury, weak data suggest the acute infusion of a bolus of high-dose (30 mg/kg) methylprednisolone, followed by a 23 hr infusion (5.4 mg/kg/hr). The data for this treatment are controversial and have not been tested specifically in children; *many centers no longer use it routinely*. Maintenance of euvoolemia and normotension are very important, and vasopressors might be needed if the sympathetic nervous system has been compromised.

Surgical management of spinal injuries must be tailored to the patient's age but can be a crucial step in management. Any compression of the spinal cord must be surgically relieved to afford the best chance of a favorable outcome. In addition, spinal cord injury can be worsened by instability, so surgical stabilization can prevent further injury (Fig. 83.2). In general, younger children
have a higher healing capacity for bones and ligaments, and external immobilization might be considered for injuries that require surgery in older children and adults. However, some injuries are highly unstable and always require surgery. **Occipitocervical dislocation** is one such highly unstable injury, and early surgery with fusion from the occiput to C2 or C3 should be performed, even in very young children. Fixation of the subaxial spine must be tailored to the size of the pedicles and other osseous structures of the developing axial skeleton.

**FIG. 83.2** A 15 yr old hockey player suffered acute paraplegia after his head struck the boards during a hockey game. A, CT scan shows compression fractures of C4 and C5. B, MRI shows severe spinal cord contusion. C, Because of the need to decompress the spinal cord and stabilize the spine, anterior and posterior surgery was performed. No meaningful recovery was obtained.

## Prevention

The most important aspect of the care of spinal cord injuries in children is injury prevention. Use of appropriate child restraints in automobiles is the most important precaution. In older children and adolescents, rules against “spear tackling” in American football and the *Feet First, First Time* aimed at adolescents diving into swimming pools and natural water areas are important ways to help prevent severe cervical spinal cord injuries. Safe driving practices, such as using safety belts, avoiding distracted driving, and following the speed limit, can have substantial beneficial effects on injury rates.

Lacerations and Cuts

Lacerations are tears of the skin caused by blunt or shearing forces. A cut (or a stab), in contrast, is an injury inflicted by a sharp object. Although distinguishing between the two can be important for forensic purposes, their evaluation and management are similar. In this chapter, lacerations include cuts and stabs.

Epidemiology

More than half of the 12 million wounds treated annually in U.S. emergency departments (EDs) are lacerations. Approximately 30% occur in children younger than 18 yr. Approximately 2% of pediatric office visits are related to wound management.

Evaluation

The history should include the mechanism of injury, the amount of force, and the time the injury occurred. The mechanism helps determine whether there may be foreign material in the wound, which would increase the risk for infection. Particularly in children, it is essential to determine whether the injury was inflicted intentionally. If nonaccidental trauma is suspected, child protective services should be notified. The type of force causing the laceration also influences the risk of infection, because a significant crush injury is more likely to become infected than a shearing one. Blunt injury, such as bumping the
head, is a common cause of lacerations in children and is less likely to become infected. Theoretically, the amount of bacteria in the wound should increase exponentially with the time from injury to repair; however, the length of time that results in a clinically significant increase in wound infection is unclear. Older wounds may require delayed primary closure or healing by secondary intention. The patient or parent should be asked about any special host factors that may predispose to infection or impede healing, such as diabetes, malnutrition, obesity, and corticosteroid therapy, as well as immunization status, with particular attention to tetanus administration.

On examination, the clinician should note the size and depth of the wound, as well as any associated vascular, neurologic, tendon, or other tissue injury. The laceration's location also is important with regard to both the risk for infection and the cosmetic outcome. Compared with lacerations in adults, those in children occur more often on the face and scalp and less often on the upper extremities. Because the face and scalp are more vascular, wounds located there are less likely to become infected. Lacerations overlying joints are more likely to develop wider scars as a result of tension during healing.

**Treatment**

The goals of treatment are to establish hemostasis, minimize the risk of infection, restore skin and underlying tissue integrity, and produce the most functionally and cosmetically acceptable result possible. Complications of wounds, including infection, hypertrophic scar formation, and functional limitation occur in approximately 8% of children.

Any significant bleeding must be controlled, usually with external pressure, before a thorough evaluation of the wound can occur. If there is a skin flap, it should be returned to its original position before application of pressure. Infrequently, a tourniquet may need to be applied if bleeding cannot be controlled with direct pressure. Clothing over the injury should be removed to minimize wound contamination. Jewelry encircling an injured extremity should be removed to prevent the jewelry from forming a constricting band when the extremity swells.

It is best to administer a local anesthetic early, before exploration and more meticulous cleansing of the wound. This anesthetic can be applied topically (e.g., lidocaine, epinephrine, and tetracaine gel) or infiltrated locally or as a regional nerve block (e.g., lidocaine or bupivacaine), depending on the location
of the laceration and the complexity of the repair. Buffering the acidic lidocaine with sodium bicarbonate can reduce pain during injection. Sometimes, nonpharmacologic or additional pharmacologic methods of analgesia and anxiolysis are required for a young, frightened, or uncooperative child. The wound should be examined under proper light to enable identification of foreign bodies or damage to vessels, nerves, or tendons.

Many lacerations, especially heavily contaminated ones, benefit from **irrigation**, with either water or sterile saline, to reduce the risk of infection. It is important to recognize that many traumatic lacerations treated in the ED, or office, are only minimally contaminated, containing <10^2 bacterial colonies. In fact, in one of the few human studies on irrigation, irrigation did not decrease the infection rate of **minimally** contaminated scalp or facial lacerations in patients who presented to an ED within 6 hr of injury. Higher-pressure irrigation may actually increase tissue damage, making the wound and adjacent tissue more susceptible to infection and delaying healing. These caveats notwithstanding, irrigation has benefits, although which technique to use—that is, which device, what size syringe, what size needle, which solution, how much volume, how much pressure—remains to be determined. These features may vary for different types of lacerations. In heavily contaminated wounds, the benefit of higher-pressure irrigation likely outweighs the harm of tissue damage. For heavily contaminated lacerations, a typical recommendation is to use a 35-65 mL syringe attached to a plastic splatter shield, or a 19-gauge needle if a splatter shield is unavailable, and to irrigate with approximately 100 mL of solution per centimeter of wound. Conversely, for relatively clean wounds, lower-pressure irrigation minimizes tissue damage, which may be more important for outcome than any decrease in bacterial clearance that may ensue. Debridement of devitalized tissue with higher-pressure irrigation, scrubbing, or surgical excision can also be necessary in certain cases, such as crush injuries.

Most lacerations seen in the pediatric ED or office should be closed primarily. Contraindications exist to primary closure (e.g., certain bite wounds; see Chapter 743). Although it is accepted that the time from injury to repair should be as brief as possible to minimize the risk of infection, there is no universally accepted guideline as to what length of time is too long for primary wound closure. Also, this length of time varies for different types of lacerations. A prudent recommendation is that higher-risk wounds should be closed within 6 hr at most after the injury but that some low-risk wounds (e.g., clean facial lacerations) may be closed as late as 12-24 hr.
Many lacerations can be closed with simple, interrupted, 4-0, 5-0, or 6-0, nonabsorbable sutures. For certain lacerations, absorbable sutures for external skin closure are not necessarily inferior to nonabsorbable sutures, and may provide cost and time savings, as well as avoiding having to remove them, an unpleasant procedure in a young child. For lacerations under tension, horizontal or vertical mattress sutures, which provide added strength and may evert the wound edges better, can be used instead. For lacerations in cosmetically significant areas, a running intradermal stitch may produce a less conspicuous, more aesthetic scar than simple or mattress skin sutures, which can leave unattractive track marks. Deeper lacerations may need repair with an absorbable dermal and/or fascial layer. Other complex lacerations, such as those involving the ear, eyelid, nose, lip, tongue, genitalia, or fingertip, sometimes require more advanced techniques as well as subspecialty consultation.

Staples, topical skin adhesives, and surgical tape are acceptable alternatives to sutures, depending on the laceration's location and the healthcare provider's preference. Staples are particularly useful for scalp lacerations, where the scar's appearance tends to be less important. Topical skin adhesives (octyl cyanoacrylates or butyl cyanoacrylates) are ideal for linear, relatively superficial lacerations with easily approximated edges that are not under tension. Adhesives are particularly useful for lacerations located in areas where suture track marks are especially undesirable, or in situations where resources are constrained.

Maintaining a warm, moist, wound environment following repair accelerates wound healing without increasing the risk of infection. A topical antimicrobial ointment (e.g., bacitracin or bacitracin, neomycin, and polymyxin B combination) and conventional gauze dressing provide such an environment and reduce the infection rate. Compared with conventional dressings, occlusive dressings (hydrocolloids, hydrogels, polyurethane films) may be better at accelerating healing, reducing infection, and decreasing pain but are more expensive. Occlusive dressings that adhere (hydrocolloids or polyurethane films) are impractical for lacerations with protruding sutures. If the laceration overlies or is near a joint, splinting helps limit mobility and can speed healing and minimize dehiscence.

For most routine lacerations that are repaired early and meticulously, prophylactic systemic antibiotics are unnecessary because they do not decrease the rate of infection. Antibiotic prophylaxis is or may be indicated for human and many animal bites, for open fractures and joints, and for grossly contaminated wounds, as well as for wounds in patients who are
immunosuppressed or have prosthetic devices. *Tetanus prophylaxis should be administered, if indicated*, according to U.S. Centers for Disease Control and Prevention guidelines (see Chapter 238).

### Abrasions

An **abrasion** is a scrape to the epidermis, and sometimes the dermis, that is usually caused by friction of the skin against a rough surface. *Road rash* is a colloquial term for abrasions that result from friction of the skin against pavement. Motor vehicle collisions with pedestrians and cycling accidents are common causes of road rash in children. Road rash can be extensive, involving multiple areas on the body. These abrasions also can be deep, and they often contain embedded debris. A **rug burn** is an abrasion sustained by sliding across a carpet. Some abrasions display specific patterns and are called **imprint abrasions**. *Ligature marks* are a type of imprint abrasion caused by a rope or cord that has been tied around a part of the body and has rubbed against the skin. These injuries should alert the clinician to the likelihood of nonaccidental (including self-inflicted) trauma.

### Treatment

All abrasions should be cleansed thoroughly and any debris or foreign material removed. If debris is not removed, abnormal skin pigmentation, known as **posttraumatic tattooing**, can occur and can be difficult to treat. A nonadherent occlusive dressing or a topical antibiotic and conventional dressing should be applied. *Tetanus prophylaxis should be administered, if indicated* (see Chapter 238). Large and/or deep abrasions that have not healed in a few weeks require consultation with a plastic surgeon for more advanced care.

Neurocritical Care Principles

The brain has high metabolic demands, which are further increased during growth and development. Preservation of nutrient supply to the brain is the mainstay of care for children with evolving brain injuries. *Intracranial dynamics* describes the physics of the interactions of the contents—brain parenchyma, blood (arterial, venous, capillary), and cerebrospinal fluid (CSF)—within the cranium. Normally, brain parenchyma accounts for up to 85% of the contents of the cranial vault, and the remaining portion is divided between CSF and blood. The brain resides in a relatively rigid cranial vault, and cranial compliance decreases with age as the skull ossification centers gradually replace cartilage with bone. The *intracranial pressure* (ICP) is derived from the volume of its components and the bony compliance. The *perfusion pressure* of the brain (cerebral perfusion pressure, CPP) is equal to the pressure of blood entering the cranium (mean arterial pressure, MAP) minus the ICP, in most cases.

Increases in intracranial volume can result from swelling, masses, or increases in blood and CSF volumes. As these volumes increase, compensatory mechanisms decrease ICP by (1) decreasing CSF volume (CSF is displaced into the spinal canal or absorbed by arachnoid villi), (2) decreasing cerebral blood volume (venous blood return to the thorax is augmented), and/or (3) increasing cranial volume (sutures pathologically expand or bone is remodeled). Once compensatory mechanisms are exhausted (the increase in cranial volume is too large), small increases in volume lead to large increases in ICP, or intracranial hypertension (Fig. 85.1). As ICP continues to increase, brain ischemia can occur as CPP falls. Further increases in ICP can ultimately displace the brain.
downward into the foramen magnum—a process called **cerebral herniation**, which can become irreversible in minutes and may lead to severe disability or death; **Fig. 85.2** notes other sites of brain herniation.
FIG. 85.2  Different forms of brain herniation. 1, Cingulate. 2, Uncal. 3, Cerebellar tonsillar. 4, Upward cerebellar. 5, Transcalvarial. (From Fishman RA: Cerebrospinal fluid in diseases of the nervous system, Philadelphia, 1980, Saunders.)

Oxygen and glucose are required by brain cells for normal functioning, and these nutrients must be constantly supplied by cerebral blood flow (CBF). Normally, CBF is constant over a wide range of blood pressures (i.e., blood pressure autoregulation of CBF) via actions mainly within the cerebral arterioles. Cerebral arterioles are maximally dilated at lower blood pressures and maximally constricted at higher pressures so that CBF does not vary during normal fluctuations (Fig. 85.3). Above the upper limit of autoregulation, breakthrough dilation occurs, which if severe can produce hypertensive encephalopathy. Acid-base balance of the CSF, often reflected by acute changes in arterial partial pressure of carbon dioxide (Paco₂), body/brain temperature, glucose utilization, blood viscosity, and other vasoactive mediators (i.e., adenosine, nitric oxide), can also affect the cerebral vasculature.
FIG. 85.3  Schematic of the relationship between cerebral blood flow (CBF) and cerebral perfusion pressure (CPP). The diameter of a representative cerebral arteriole is also shown across the center of the y axis to facilitate understanding of the vascular response across CPP that underlies blood pressure autoregulation of CBF. CPP is generally defined as the mean arterial pressure (MAP) minus the intracranial pressure (ICP). At normal values for ICP, this generally represents MAP. Thus, normally, CBF is kept constant between the lower limit and upper limit of autoregulation; in normal adults, these values are approximately 50 mm Hg and 150 mm Hg, respectively. In children, the upper limit of autoregulation is likely proportionally lower than the adult value relative to normal MAP for age. However, according to the work of Vavilala et al. (2003), lower-limit values are surprisingly similar in infants and older children. Thus, infants and young children may have less reserve for adequate CPP.

Knowledge of these concepts is instrumental to preventing secondary brain injury. Increases in CSF pH that occur because of inadvertent hyperventilation (which decreases PaCO$_2$) can produce cerebral ischemia. Hyperthermia-mediated increases in cerebral metabolic demands may damage vulnerable brain regions after injury. Hypoglycemia can produce neuronal death when CBF fails to compensate. Prolonged seizures can lead to permanent injuries if hypoxemia occurs from loss of airway control.

Attention to detail and constant reassessment are paramount in managing children with critical neurologic insults. Among the most valuable tools for serial, objective assessment of neurologic condition is the Glasgow Coma Scale (GCS) (see Chapter 81, Table 81.3). Originally developed for use in comatose adults, the GCS is also valuable in pediatrics. Modifications to the GCS have been made for nonverbal children and are available for infants and toddlers. Serial assessments of the GCS score along with a focused neurologic examination are invaluable to detection of injuries before permanent damage occurs in the vulnerable brain. The full outline of unresponsiveness (FOUR) score is a modification of the GCS, with eye and motor response, but eliminates the verbal response and adds 2 functional assessments of the brainstem (pupil, corneal, and cough reflexes) and respiratory patterns (Table 85.1).
